field (near the building or in boreholes), can provide valuable insights into the structural response during an earthquake (Craifaleanu & Borcia, 2011; 2012; Craifaleanu, 2013; Craifaleanu, 2025; Dobre, 2006; Dobre et al., 2015).

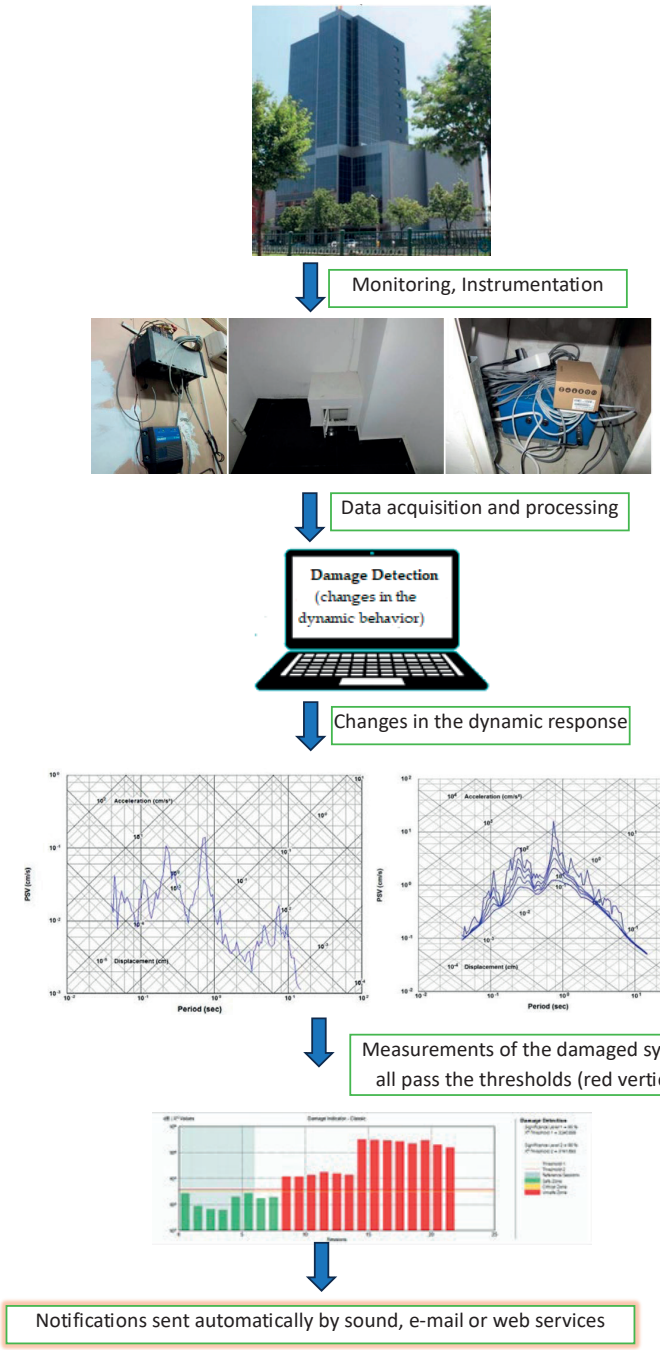

Figure 1. Implementing a remote access earthquake damage detection system within SHM for a high-rise building

The use of the finite element method in developing even simplified models of structural systems strengthens the connection between SHM and BIM by determining dynamic characteristics that evolve over time (Dragomir & Dobre, 2023). Another important factor to consider in this context is the seismic response of structures with active tuned mass dampers or any control dissipation system (Bratu et al., 2024; Paulet-Crainiceanu et al., 2024). However, the interpretation of long-term data collected from continuous monitoring SHM can be overwhelming due to the processing of an enormous amount of data. On the other hand, Building Information Modelling (BIM) tools provide storage and visualisation capabilities for digitally representing a 3D building, including lifecycle management information, with the possibility for a structural analysis and damage detection visualised in the model by assimilating the sensor data within the BIM model, that can aid the stakeholders and infrastructure owners in monitoring in real-time the state of any construction (An et al., 2015; Colucci et al., 2020; Hamdan & Scherer, 2018; Theiler et al., 2018; Singh & Sadhu, 2019; Castelli et al., 2023; Xu et al., 2023; Gragnaniello et al., 2024; Riggio & Nasir, 2024). BIM uses a static data source to assess the structure, and the sensor data can extend the application of BIM model from static to dynamic model to get the current performance of the structure (Chen et al., 2014). Within the framework established by SHM and BIM approaches, various theoretical, technical, syntactic, and semantic elements (connections between concepts and objects) aim to enhance reports generated after a major earthquake. The research directions involved in SHM with BIM and monitoring networks (seismic, but not only) show a strong correlation between key terms such as BIM, SHM, technology, damage detection, response, modal identification etc., as can be seen in Figure 2.

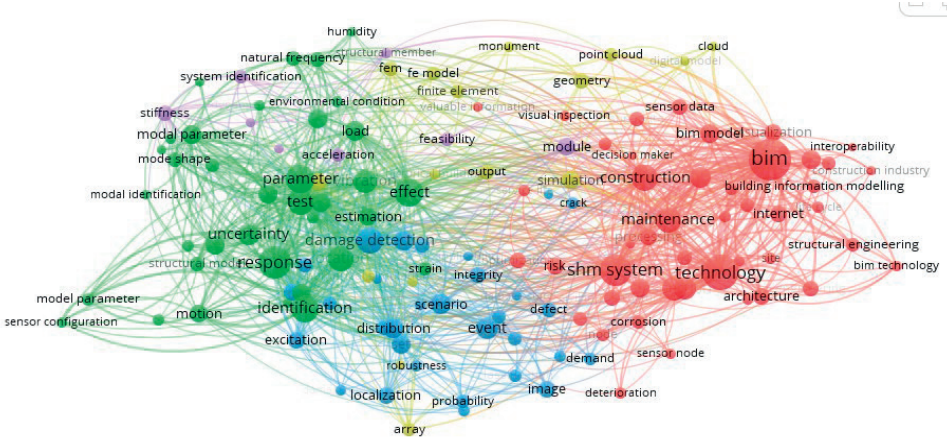

Figure 2. Frequency keywords clustering

MATERIALS AND METHODS

Elements of SHM and BIM as they relate to seismic monitoring

The integrated concept BIM-based SHM, i.e. to insert real-time data into the BIM model, is possible by standardizing the formats of the two approaches (formulate a standard data model to include and visualize SHM data directly to BIM models, including damage sensitive features in the object properties, data to sensor representations within the BIM model). Specific aspects of SHM and BIM are presented below, along with their technical compatibility - objectives, components, format standards, software, damage assessment.

a. Objectives:

- SHM: extracting information from structural response data collected by sensors attached to buildings;
- BIM: conventional building information (geometry, material, costs), communication,

feedback and user-input, sharing of asset data, damage visualization;

- SHM-BIM: modelling and integrating SHM-related algorithms into IFC-based Building Information Models (IFC monitoring-related information).

b. Components:

- SHM: sensors, data acquisition system, wired/wireless connection (data transmission), communication system, data processing and storage, data analysis, damage detection, data interpretation;
- BIM: physical geometry of the building, management of vast amounts of data associated with the building, Common Data Environment (CDE) platform (all project information is stored, managed and shared).

c. Format standards

- SHM: sensor-related information - Sensor Model Language (SensorML), Semantic Sensor Network (SSN) Ontology, Systems Modeling Language (SysML), Web Ontology Language (OWL);
- BIM: Proprietary file formats (RVT, NWD, DWG), Non-Proprietary file formats (Construction operation building information exchange (COBie); Industry Foundation Classes (IFC));
- SHM-BIM: IFC Monitor to describe SHM (semantic compositions of SHM systems, network topologies, and semantic relationships between components of SHM systems and components of structural systems to be monitored), Exporting Revit SHM model to IFC, Information delivery specification (IDS) based on specific Level of Information Need (LoIN).

d. Software:

Revit and Robot Structural Analysis, REVIT and MATLAB, Excel, Autodesk, Dynamo, GIS.

e. Damage assessment:

- SHM: without any particular physical model, only data-driven approaches, but analytical models (identify the characteristics of damage progress and predict the future state); physics-based approaches, with a physical damage model and with measured data (An et al., 2015);
- BIM: plug-in for BIM environments to study the preservation of any structural element (Fernández-Mora et al., 2025; Ionita & Stoian, 2024); BIM through the Revit add-ins able to store and manage real-time data (Chen et al., 2014), developed using Revit's NET API (Application Programming Interface);
- SHM-BIM: identify and visualize the damage status of the structural and non-structural elements following a seismic event, from direct measurements by sensors installed on the building; The information processed therefore it can be inserted into fragility curves relating the performance of the element as a function of an engineering demand parameter such as the absolute acceleration or the inter-story drift ratio; information imported into modelling software working on a BIM architecture through a specific code. The procedure provides both a clear and immediate visualization of the building's health status, and its real-time sharing in the cloud (Castelli et al., 2023).

Figure 3 shows the already multidimensional relationship based on all aspects presented above between SHM and BIM.

RESULTS AND DISCUSSIONS

How could the traditional database be upgraded?

The main objective of enhancing the relationship between Structural Health Monitoring (SHM) and Building Information Modeling (BIM) is to evaluate how a structure performs and to detect potential damage. This is accomplished by analyzing changes in its dynamic characteristics, which include natural frequencies, damping ratios, mode shapes, inter-story drift ratios, and the modal assurance criterion.

Keeping in mind the classic components of SHM (Figure 1) and the possible multidimensional relationship between SHM-BIM (Figure 3), for a correct upgrade of the existing database, with several buildings already instrumented and/or seismically monitored, it is necessary to initially evaluate the current situation of all data formats acquired in fields such as urban planning, cadastre, design, research, signal processing, or multidisciplinary ones.

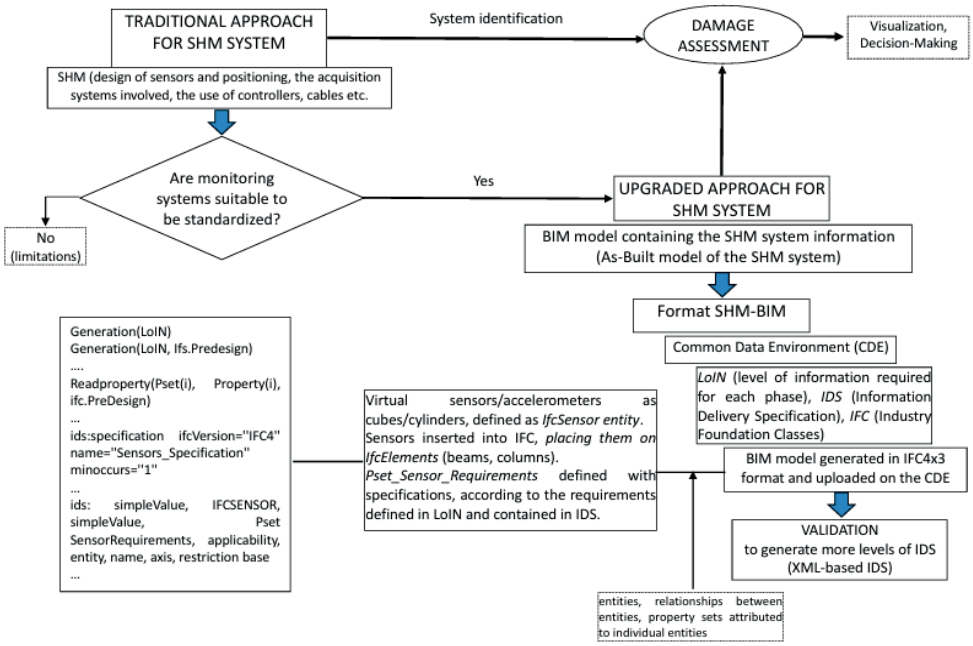

Figure 3. A multidimensional relationship SHM-BIM

The text describes the integration of Structural Health Monitoring (SHM) and Building Information Modelling (BIM) to enhance the management of building data. It emphasizes that providing accurate geospatial information and attributes about the condition of buildings is essential. By leveraging the strengths of both SHM and BIM, it is crucial to ensure compatibility of the data formats used, as this is a key factor in achieving effective real-time monitoring and modelling. Then, the compatibility of these formats with the corresponding structural software for linear and nonlinear static and dynamic analyses is considered. In the next stage, a data management system for storage, retrieval and sharing of extremely large measurement data sets constantly acquired from SHM systems and the creation of web interfaces are required. The options for a database are relational (MySQL)/non-relational (NoSQL), with adaptability, high traffic capacity and open-source.

An integrative concept for the digital analysis of seismic monitoring data is currently being developed at INCD URBAN-INCERC. This initiative aims to cover a large area of the national territory and its built environment, facilitating the rapid identification of the destructive potential of earthquakes. The effectiveness of this concept is evident in its ability to characterize seismic motion and evaluate the structural system of the monitored building. This includes real-time visualization, processing, and analysis of seismic recordings using SeisComP software, as well as the graphical representation of shake maps that incorporate attenuation laws. SeisComP has its own data storage and archiving system, compatible with SeedLink (an international standard in the field). Data archiving is done through SDS (SeisComP Data Structure), in which the archiving format is compatible with SeedLink. The seismic data storage structure follows pre-established hierarchical levels, adapted to specific needs. Certain essential BIM elements are currently absent, which limits the provision of crucial technical information related to buildings, utility networks, ground conditions, acoustic parameters, energy consumption, various costs, and solutions for data access, storage, archiving, data security, software updates, AI and machine learning integration, as well as backup and recovery tools. As part of an experimental program focused on seismic

monitoring of buildings, data is generated in a standardized format for several purposes. This includes finite element modelling, static and dynamic load testing, enhancement of existing structural health monitoring (SHM) systems, building information modelling (BIM), and supporting both national and international advancements in this field (Guide on the management and monitoring of information generated in the BIM system; EN ISO 19650).

CONCLUSIONS

The behaviour of structural systems of buildings under dynamic actions and the detection of damage shortly after their occurrence represent important technical aspects and are, to a certain extent, obtained rapidly through monitoring, non-destructive testing. The SHM-BIM approach offers a significant advantage by enabling the definition and modelling of the pre-earthquake structural system in a compatible digital format. This aligns with established regulations for structural analysis and allows for results to be presented in the same format. Additionally, it facilitates real-time damage assessment, utilizing fragility curves as indicators of probabilistic damage or real-time identification methods based on frequency analysis for damage detection. It is also beneficial to incorporate elements related to the architecture and acoustics of buildings and installations (Zaharia, 2010; Zaharia & Voloaca, 2023), or integrating information from requirements of 3D-printing applications for the field of constructions, current technologies, the advantages of 3D printed buildings/houses with seismic/ambient vibration monitoring possibilities (Vitalie et al., 2020).

The conceptual methods and data gathered through seismic monitoring are essential for a database directly associated with seismic vulnerability. The development of scientific and experimental databases for building stock is an emerging approach in current global research and serves as a fundamental component of the Romanian National Strategy for Seismic Risk Reduction. Digital building information models enable real-time updates and enhance coordination among intervention teams after significant earthquakes.

Abstract

This study investigates how different stand structures influence vulnerability to windthrows, using the vertical differentiation index as an analytical tool. Measurements were conducted in three forest districts containing stands with varying structures: even-aged, relatively even-aged, relatively uneven-aged, and uneven-aged. Findings indicate that the vertical differentiation index has subunit values close to zero in even-aged stands and approaches one in uneven-aged stands. A significant inverse correlation was observed between this index and the percentage of wood affected by windthrows. These results underscore the importance of diversifying stand structures in Romanian forest management to mitigate ecological and economic losses.

Key words*: stand structure, windthrows, vertical differentiation index, correlation.*

INTRODUCTION

Due to ongoing climate change, forest stands' increasing vulnerability to extreme weather events, particularly windthrows, is a significant concern. Historically, pure even-aged spruce stands were considered highly susceptible, primarily due to shallow rooting systems (Barbu & Barbu, 1993). However, recent evidence suggests that stand structure and management practices also play a crucial role in determining susceptibility to windthrows (Gardiner & Quine, 2000).

The susceptibility of forest stands can be further increased by soil characteristics and land orography, significantly raising the likelihood and severity of these phenomena, particularly in areas where multiple contributing factors interact simultaneously (Negron-Juarez et al., 2023). Additionally, water retention from precipitation in the tree canopy and soil can amplify the impact of windthrows while also causing rapid fluctuations in stream flow over short periods in mountainous regions (Iovan et al., 2024). The vertical differentiation index serves as a valuable tool for assessing the vulnerability of forest stands to various disturbance factors. By providing insights into stand stability, it aids in the development of resilient forests capable of withstanding extreme climatic events in the future (Valinger & Fridman, 2011).

Windthrows, caused by strong winds, can be categorized based on their intensity and impact into endemic and catastrophic windthrows. Catastrophic windthrows result from extreme weather conditions, involving high-intensity winds that devastate large areas, often affecting thousands of cubic meters of wood. In contrast, endemic windthrows occur more frequently - almost annually - due to moderate-intensity winds and are influenced by a combination of site-specific, meteorological, and stand structure factors. Addressing endemic windthrows is a pressing challenge for forestry management, as their cumulative effects can disrupt forest ecosystems, degrade wood quality, and cause economic and ecological disturbances over time. Without proper intervention, these disturbances may ultimately lead to the fragmentation and deterioration of forest stands. Given the increasing frequency and intensity of windthrows, it is crucial to implement adaptive forestry strategies that enhance stand resilience and promote sustainable forest management (Popa, 2005).

The decline of natural forest structures, coupled with environmental degradation and the growing impact of climate change, has intensified extreme weather events, even in

forested areas that were previously considered stable 15-20 years ago - excluding pure spruce stands, which have historically been more vulnerable (Duduman, 2011). Large-scale windthrows were predominantly observed in artificially regenerated spruce stands, highlighting the structural weaknesses of such forests in the face of climatic stressors.

To address these challenges, rational forestry practices grounded in ecological principles must be prioritized.

Sustainable forestry should focus on conservation, protection, and the development of structurally diverse and resilient forest ecosystems that align with contemporary environmental realities (Ichim, 1990).

Over the past few decades, forest management has largely promoted uniform stand structures, minimizing horizontal and vertical differentiation. However, these homogeneous stands have exhibited declining self-protection capacity as they age, making them increasingly vulnerable to external stressors and complicating the implementation of effective management plans. In the forests of Trentino, Italy, researchers have identified key stand structure indices that serve as the foundation for modern management strategies, emphasizing the importance of diversified forest structures (Pastorella & Paletto, 2013).

The size and spatial distribution of trees within a stand significantly influences its overall complexity and ability to fulfill eco-protective functions. Greater structural diversity enhances forest stability and resilience, underscoring the need for management strategies that prioritize stand complexity and adaptability to environmental changes (Peck et al., 2014).

This study aims to analyze the relationship between vertical differentiation index values and windthrow vulnerability to inform sustainable forest management practices. To support this analysis, three locations encompassing various types of stand structures were examined. Data were collected and analyzed, vertical differentiation indices were determined, and the occurrence of disruptive phenomena was assessed probabilistically. The results section presents the findings, which served as the basis for formulating the conclusions.

MATERIALS AND METHODS

Study area

Field data were collected from three forest districts:

- U.P. II Valea Seaca, O.S. Gârda, D.S. Alba - this area consists of pure beech stands and mixed stands of beech, fir, and spruce, with little to no silvicultural interventions. These forests are characterized by complex natural structures that have adapted to the local site conditions. Field observations indicate that windthrows in these stands occur sporadically over small areas. Notably, the gaps created by these windthrows provide ideal conditions for natural regeneration, allowing the forest to recover and evolve without human intervention
- U.P.I Sâniob, O.S. Săcuieni, D.S. Bihor - this area consists of pure and mixed Quercus cerris stands, predominantly even-aged, with a few exceptions. While forestry measures have been consistently applied, the stands exhibit limited structural diversity both horizontally and vertically. According to the analyses conducted in this study, these structurally simplified stands are potentially more vulnerable to disturbance factors.
- U.P. VII Văratec, O.S. Sudrigiu D.S. Bihor - included stands affected by severe windthrows in 2017, characterized by high densities and instability due to insufficient silvicultural interventions (Crainic et al., 2024). Field observations indicate that stands with simplified horizontal and vertical structures are prone to both isolated and large-scale windthrows, which can occur frequently due to the combined influence of various disturbance factors. To enhance the resilience of these stands against such disturbances, future management strategies should focus on increasing structural diversity.

Data collection and analysis

In the analyzed stands, a minimum of 30 trees were measured, with their closest neighboring trees identified. For each measured tree, the heights of both the tallest and shortest trees within its group were recorded. The vertical differentiation index for each analyzed stand was determined using the equation provided by Ciubotaru & Păun (2014) and Keren et al. (2020):

$$DHn = \frac{1}{N} * \sum \left[\sum \frac{1}{n} \left(1 - \frac{Xijmin}{Xijmax} \right) \right]$$

where:

- DHn is vertical differentiation index;
- N - number of measured trees;
- n - number of neighboring trees;
- Xijmin - minimum tree height in the group;
- Xijmax - maximum tree height in the group.

The relationship between the vertical differentiation index and the percentage of volume affected by disturbance factors was analyzed. Special attention was given to stands with even-aged and relatively even-aged structures, as distinguishing between these two categories in the field can sometimes be challenging. Some stands contain areas that could be classified into either category, despite the management plan specifying only one structure type. For consistency, relatively uneven-aged and uneven-aged stands were analyzed separately using the same approach.

To estimate the risk of windthrows over the duration of the management plan with sufficient accuracy, a probabilistic model was developed, based on the approach proposed by Popa I. (2005). The probabilistic model utilized in this study is expressed as follows:

$$V_{dob} = p_{dec} \cdot pdv_{dec} \cdot V_{ha}$$

where:

- V_{dob} is probable decadal volume of windthrows (m^3/ha/decade);
- p_{dec} - decadal probability of occurrence of windthrows;
- pdv_{dec} - decadal intensity of the windthrows caused by the wind (% of the volume per hectare);
- V_{ha} -volume per hectare.

This model provides an estimation of windthrow risk by quantifying the probable volume of wood affected by wind over a ten-year period.

RESULTS AND DISCUSSIONS

The analysis of the four types of stand structures in relation to their stability against disturbance factors, assessed using the vertical differentiation index, provides valuable insights for both theoretical and practical forest management. Understanding these relationships allows for the development of strategies that minimize stand vulnerability to windthrows. The following section explores how different structural types influence the likelihood of windthrow occurrence.

Windthrows result in significant economic and ecological losses. From an economic perspective, they lead to wood depreciation, increased costs for evaluation and extraction, and difficulties in adhering to forest management plans. Ecologically, they can cause a partial or complete disruption of forest functions, with long-term effects that may take decades to fully manifest. While economic losses can be quantified relatively easily during timber assessment and harvesting, ecological impacts - such as biodiversity reduction, habitat disruption, and changes in microclimatic conditions - are more challenging to measure.

Statistical analyses reveal a strong and consistent correlation between windthrow probability and key stand parameters, including production class, average tree diameter, and height. However, the most influential factor appears to be standing age. Research conducted in the Suceava Forestry District indicates that the highest windthrow susceptibility occurs in stands aged between 60 and 80 years (Popa, 2005).

To estimate the volume of wood likely to be affected, an average value was calculated based on the minimum and maximum values within specific probability intervals. The classification of windthrow intensities is as follows:

- 20-40% probability (Table 1): windthrows at this level are generally low-intensity and occur sporadically across the landscape. These events, often classified as endemic windthrows, are particularly beneficial in uneven-aged and relatively uneven-aged stands, as they promote continuous natural regeneration.
- 40-60% probability (Table 1): windthrow intensity increases slightly, but the events remain localized and do not immediately threaten the overall stability of the stand. These can still be considered endemic windthrows, albeit with slightly higher intensities.
- 60-80% probability (Table 1): windthrows become more concentrated over large areas, indicating structural instability

within the stand. This level of impact highlights the need for urgent management interventions to reduce the volume of affected wood and prevent further stand degradation. Such stands require targeted silvicultural measures to restore their resilience and shift them into structural categories where windthrows remain isolated rather than widespread disturbances.

By integrating these findings into forest management planning, strategies can be refined to enhance stability, reduce economic losses, and ensure long-term ecological sustainability.

The probable volume of wood affected by windthrows follows an increasing trend as the probability class rises. Specifically:

- at the 20-40% probability level, the affected wood volume ranges between 8-10%.
- for the 40-60% probability level, this increases to 13-16%.
- at the 60-80% probability level, the percentage of affected wood reaches 18-22% (Table 1).

Table 1. Probably affected volume per hectare based on probability classes

Average volume per hectare (m^3)	Probability classes (%)		
	20-40%	40-60%	60-80%
	Probable volume affected per hectare (m^3)		
300	24	41	60
400	31	56	79
500	49	80	105
600	60	96	112
700	70	112	154

The similarity between the percentage of wood affected across different probability classes and the harvesting indices at the stand level suggests that regular and well-executed silvicultural interventions reduce the likelihood of windthrows. Field observations reinforce this conclusion, as it stands that systematic and properly executed management practices are significantly less affected by destabilizing factors compared to those with irregular or poorly implemented interventions.

Figure 1 illustrates the relationship between the percentage of wood affected by windthrows and the vertical differentiation index for even-aged and relatively even-aged stands. The data indicate that when the vertical differentiation index is low (0-0.1), windthrow damage is substantial, ranging from 60-80%. However, as vertical differentiation increases, the percentage of affected wood declines sharply. This trend is clearly demonstrated by the regression equation, which has a coefficient of determination (R^2) of 0.63, indicating a strong negative correlation.

For even-aged and relatively even-aged stands, improving vertical differentiation through consistent silvicultural practices can significantly enhance stand stability. The correlation coefficient of -0.55 further supports this relationship, highlighting the crucial role of structural diversity in mitigating windthrow susceptibility (Figure 1).

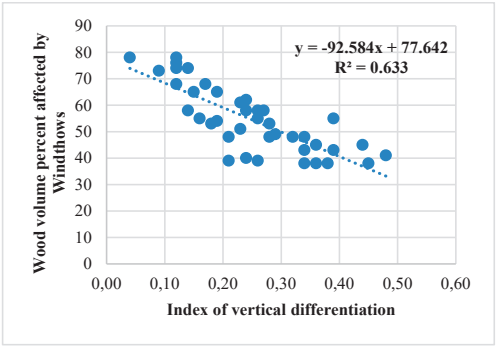

Figure 1. Wood volume percent affected by windthrows in correlation with vertical differentiation index in even-aged and relative even-aged stands

Figure 2 illustrates the relationship between the percentage of wood affected by windthrows and the vertical differentiation index for uneven-aged and relatively uneven-aged stands. The data indicate that these stands experience significantly lower windthrow impact compared to even-aged stands.

A clear downward trend in the regression equation confirms that as the vertical differentiation index increases, windthrow susceptibility decreases. However, in contrast to even-aged stands, the affected wood volume generally remains below 50%, with only a few exceptions.

The coefficient of determination (R^2 = 0.65) closely aligns with the findings for even-aged stands, reinforcing the consistency of this relationship.

For uneven-aged stands, stability can be further enhanced through silvicultural interventions where applicable. However, in cases where

management constraints prevent interventions, maintaining a high vertical differentiation index through continuous natural regeneration proves to be the most effective strategy for reducing windthrow susceptibility.

The correlation coefficient of -0.81 between the percentage of volume affected by windthrows and the vertical differentiation index further supports the strong inverse relationship between these variables, demonstrating that greater structural complexity significantly enhances stand resilience (Figure 2).

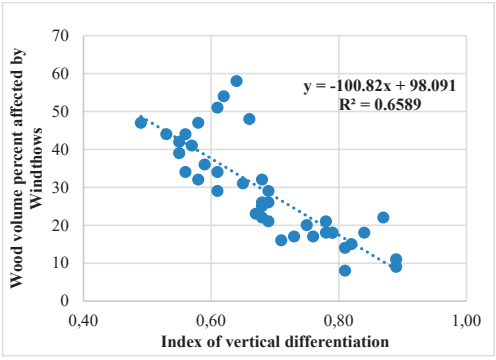

Figure 2. Wood volume percent affected by windthrows in correlation with vertical differentiation index in uneven-aged and relative uneven-aged stands

The percentage of wood likely to be affected by windthrows starts at approximately 10% for windthrow intensities in the 20-40% range. This percentage increases to around 15% for intensities between 40-60% and further rises to an average of 20% for windthrow intensities in the 60-80% range (Figure 3).

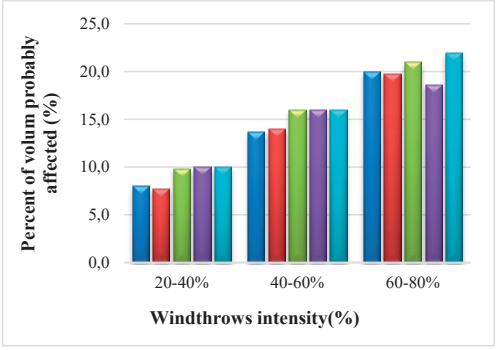

Figure 3. The percentage of volume probably affected in correlation with windthrows intensity

The vertical differentiation index serves as a reliable indicator of stand stability in the face of various disturbance factors. Higher index values, approaching 1, indicate structurally complex and resilient stands where only isolated windthrows occur, often benefiting natural regeneration. Conversely, index values close to zero suggest highly vulnerable stands, where the likelihood of extensive windthrows is significantly increased.

Windthrow probability is also influenced by site conditions, which can either amplify or mitigate the effects of these disturbances. Previous studies have identified three primary factors contributing to windthrows: stand structure, site conditions, and extreme weather events (Popa, 2005).

In the medium to long term, forestry practices must focus on developing uneven-aged stands with high structural diversity, ensuring greater stability against disturbances. The vertical differentiation index not only assesses stand resilience but also provides insights into long-term sustainability. Stands with higher differentiation indices demonstrate strong resistance to disturbances, whereas those with lower values remain highly susceptible (Dorog, 2021).

The impact of climate change is becoming increasingly evident in forests, with more frequent extreme events such as prolonged droughts, heavy rainfall over short periods, and large-scale windthrows affecting entire ecosystems. Findings from this study confirm that stands with both vertical and horizontal structural diversity are significantly less vulnerable to such disturbances. This reinforces the urgent need for Romanian forestry to prioritize diversified stand structures, ensuring they can perform multiple ecological functions effectively.

To address these evolving challenges, forestry regulations and technical norms must be revised to incorporate strategies that reduce damage and enhance stand resilience. The eco-protective role of forests should be evaluated not only in terms of their ecosystem functions but also their structural stability against extreme events.

Future silvicultural interventions must be adapted to align with the new realities brought by intensifying climatic events. In addition to achieving traditional management goals, these

interventions should prioritize enhancing stand complexity. Forestry operations should be conducted at low intensities (6-10%), with a maximum threshold of moderate intensities (10-16%), ensuring that no large gaps are created, as these can become weak points for future windthrows.

A localized approach is also essential-forest management strategies should be tailored to specific site conditions, considering regional variations and unique environmental challenges. Implementing adaptive solutions at the local level will be key to increasing stand stability and resilience to combined disturbance factors.

This study serves as a foundation for future research, focusing both on identifying factors that negatively impact forest stability and on developing effective, science-based solutions to mitigate the risks associated with climate-induced disturbances.

CONCLUSIONS

The vertical differentiation index serves as a key indicator of stand structure complexity and stability. In diversified stands (uneven-aged and relatively uneven-aged), the index exhibits subunit values, with figures approaching 1 reflecting a highly organized and resilient forest ecosystem. Conversely, in simplified stands (even-aged and relatively even-aged), the index also takes subunit values, but as it approaches zero, it signifies a simplified and structurally vulnerable forest ecosystem.

A strong negative correlation is observed between the vertical differentiation index and the percentage of wood volume affected by windthrows. In areas where windthrows have severely impacted more than 60% of the stand volume, the vertical differentiation index is typically low (0–0.2). In contrast, in areas experiencing localized or point windthrows, the index tends to be significantly higher (0.7–0.9).

Field observations confirm that stands most affected by disturbance factors are those with simplified structures. These stands, with only minor exceptions, are highly susceptible to windthrows, leading to the loss of significant wood volumes over time. To reduce the long-term risk of stand collapse, forest management should prioritize structural diversification as a preventative measure.

For diversified stands, it is recommended to maintain and further enhance structural complexity to mitigate risks. Notably, these stands experience localized windthrows, which are beneficial as they facilitate continuous natural regeneration and help sustain or even increase structural diversity over time.

In areas with low windthrow probability, the affected volumes remain minimal, aligning with the concept of point windthrows, which naturally support ongoing regeneration and structural maintenance.

In areas with moderate windthrow probability, a higher proportion of stands are affected, leading to progressive structural degradation and increased vulnerability.

In areas with high windthrow probability, the impact is often irreversible, requiring the complete extraction of affected wood, which disrupts the forest's ecological functions and jeopardizes long-term sustainability.

Both ecological and economic losses are significant in simplified stands, reinforcing the urgent need for structural diversification as a core forest management strategy. The structure of a stand directly influences its stability, and therefore, forest management must prioritize the promotion of diverse, resilient stand structures. Naturally regenerated stands demonstrate higher stability against disturbances compared to artificially regenerated stands, which often lack the necessary structural complexity.

To enhance the stability of artificially regenerated stands, it is recommended to use genetically selected planting material that aligns with both current and future stand stability requirements.

Moreover, an analysis of harvesting indices in various forestry interventions reveals that stands systematically managed through appropriate silvicultural practices are significantly less vulnerable to disturbances. In contrast, stands with above-normal density and high slenderness coefficients - where interventions are irregular or absent - are at a greater risk of windthrows.

Moving forward, Romanian forestry must adopt complex and adaptive management solutions aimed at diversifying stand structures to minimize ecological and economic damage while ensuring the long-term sustainability of forest ecosystems.

Abstract

The study analyzes the use of InSAR technology and validated data for risk management and natural disaster impact assessment, focusing on the subsidence in Bucharest, associated with underground works and activities, and earthquakes. The TerraSAR-X and TanDEM-X satellites provide crucial information for rapid mapping, spatial analysis, and thematic mapping, supporting effective responses to earthquakes, floods, and other hazards. The analysis identifies ground changes based on radar data using techniques such as Persistent Scatterers (PS) and Small Baseline Subset (SBAS). The study integrates decision analysis into the ILWIS software, using the multi-criteria method (SMCE) to assess vulnerabilities along the M5 Metro Line. The methodology involves structuring problems, evaluating alternatives, and prioritizing solutions, demonstrating the applicability of innovative tools in reducing urban risks. The results highlight the importance of advanced technologies in risk prevention and management, providing recommendations for reducing the impact of subsidence and improving urban planning. There is a clear need for integrated, rapid, and accurate approaches to respond to the more frequent and complex challenges in contemporary society based on validated data and modern technologies.

Key words*: remote sensing, interferometry, subsidence, risk management, urban planning.*

INTRODUCTION

With rapid population growth and urban expansion, urban risk management has become a global priority (Oprea et al., 2015; Sabău et al., 2023; Sanda et al., 2023). Bucharest, a city with an intense pace of development, faces major challenges related to subsidence, seismic vulnerability, and the impact of anthropogenic activities on soil and buildings. Previous studies have shown that Bucharest is one of the most vulnerable cities to earthquakes, with a historical rate of 2-3 major earthquakes per century (Armaș et al., 2017). Research conducted after the earthquake from 1977 highlighted the influence of the surface geological layer on seismic movements, and the damage reported to tall buildings is closely related to the subsurface sedimentology and the seismic amplification effects due to the Vrancea earthquakes (Radulian et al., 2007). More recently, to improve the understanding of seismic risks, a 3D geological model of the city was developed, based on hundreds of boreholes made for the metro and a digital terrain model (DEM), using GIS kriging interpolation, thus highlighting the Quaternary layers and the influence of hydrogeology on seismic micro-zonation (Bala et al., 2023).

The first decision-making analyses on urban vulnerability were conducted for the Historic Center of Bucharest by Gheorghe and Armaș (2015), identifying buildings that can serve as shelters in case of disaster.

In addition to seismic risk, subsidence is an aggravating factor of urban vulnerability and is caused by both natural phenomena and anthropogenic activities (Huang et al., 2016). New constructions, including taller buildings, deep foundations, expansion of the metro network, and aboveground transportation infrastructure, can have a significant impact on soil stability (Poncos et al., 2014). In this context, monitoring land surface deformations is one of the most reliable methods for assessing and managing geological hazards.

In Bucharest, using Sentinel-1 data and the PSI technique, a map of vertical displacements was produced for the period 2014-2018, identifying several subsidence areas, one of which contains a thick layer of debris from urban constructions, analyzed in detail in correlation with the local geological model and the urban hydrogeological system (Radutu et al., 2020).
Also, a combined *in situ* monitoring and remote sensing study investigated the effects of metro tunneling and groundwater pumping, demonstrating that interferometric remote sensing is a viable alternative to *in situ* measurements (Boukhemacha et al., 2021).
Long-term monitoring of urban subsidence and its correlation with metro infrastructure development and local hydrogeological characteristics are essential for risk prevention and optimization of urban planning (Bala et al., 2023). International studies have shown that subsidence is more pronounced in cities with intense economic activity and extensive urban infrastructure (Wang et al., 2024). Cities such as Mexico City and Istanbul have implemented effective risk reduction strategies, demonstrating that adopting proactive measures can significantly contribute to the protection of infrastructure and population (Glod-Lendvai, 2019). In this context, Bucharest must adapt its monitoring and prevention strategies to face the challenges related to subsidence and seismic risk in a continuously expanding urban environment.
The present study explores the use of InSAR (Interferometric Synthetic Aperture Radar) technology for monitoring and assessing urban subsidence, providing a solid scientific basis for the reliable management of urban planning and associated risk reduction.

MATERIALS AND METHODS

Subsidence monitoring was carried out using advanced Persistent Scatterers (PS) and Small Baseline Subset (SBAS) techniques, applied to a set of 24 TRS-X (downslope) and 27 TRS-X (upslope) scenes, covering the period 2011-2014. Analysis of radar data provided by the TerraSAR-X and TanDEM-X satellites provided a detailed picture of ground changes, and their correlation with field measurements allowed the identification of areas with the highest risk of instability.
An essential component of the study was the application of the Spatial Multi-Criteria Evaluation (SMCE) method in the ILWIS software, to classify vulnerable areas based on critical factors, such as geological composition, infrastructure density, and the impact of anthropogenic activities.
By using InSAR technology and advanced analysis methods, the study provides a detailed perspective on soil dynamics, contributing to a better understanding of geotechnical risks and the substantiation of decisions regarding sustainable urban development. The vulnerability of buildings was analyzed through an analytical method based on the correlation of information about buildings, obtained from the Digital Terrain Model (DTM) and the Digital Surface Model (DSM). In parallel, the vulnerability of the population was determined through the analytical method.
The validation of the results was achieved by correlating radar images provided by the TerraSAR-X and TanDEM-X satellites with field measurements. This integrated approach provided a detailed perspective on the evolution of subsidence and the risks associated with it, contributing to a better understanding of the phenomenon and the substantiation of decisions regarding urban infrastructure.
The decision-making analysis carried out for the M5 Metro line from Drumul Taberei was carried out using the multicriteria method, using a spatial decision-making assistance system through the SMCE (Spatial Multicriteria Evaluation) module of the ILWIS software. The study aimed to identify the most vulnerable sectors along the M5 Metro Line, considering the impact of subsidence caused by underground works, in the seismic context specific to the city of Bucharest.
The analyzed area includes a 400-meter-wide corridor, located along the M5 metro line (Figure 1). The route starts from the Dâmbovița meadow and crosses the Drumul Taberei neighborhood to the west, passing through a complex urban environment, with different types of constructions and varied geotechnical conditions.

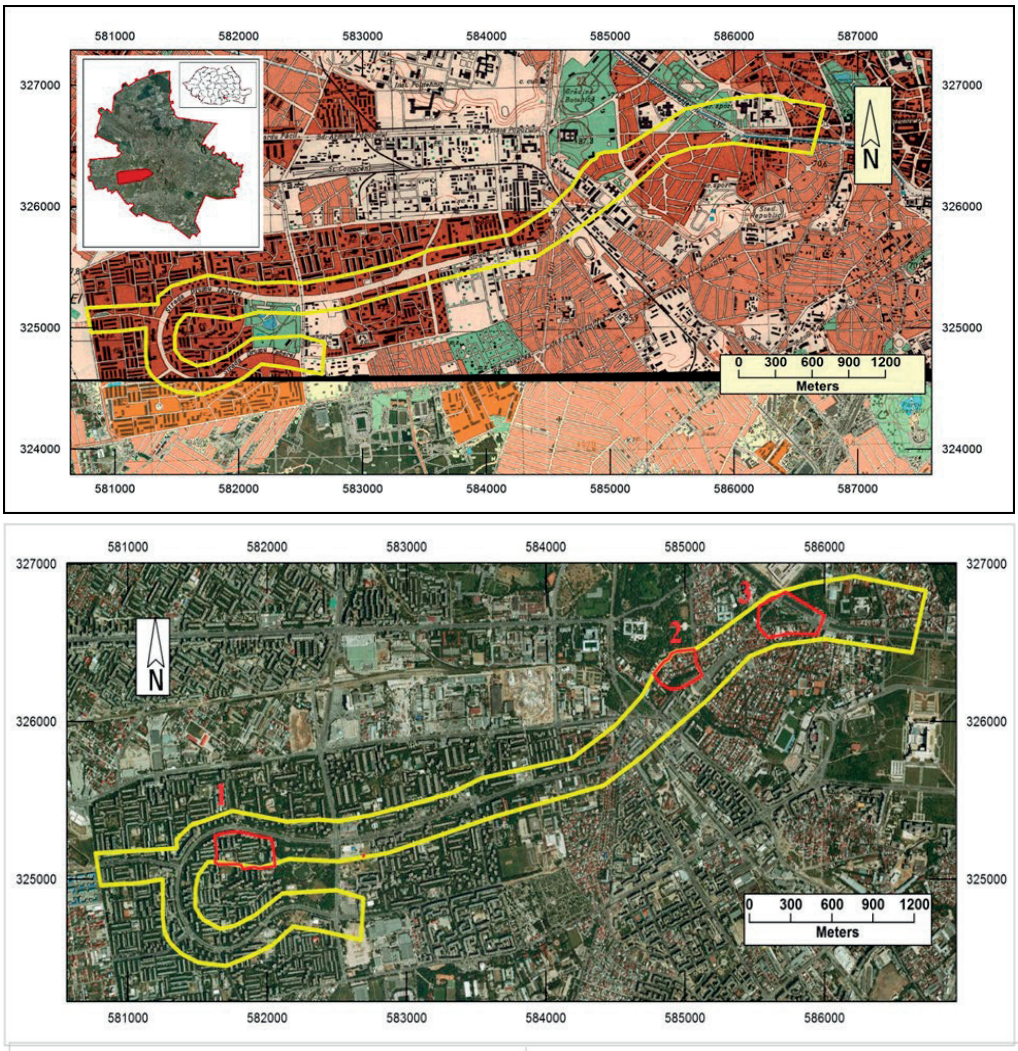

Figure 1. Study area in Bucharest, Romania

The incident at Eroilor station raised essential questions regarding the safety of buildings located above the metro tunnels.

The main concerns focused on their vulnerability in the event of an earthquake and on the influence that underground works may have on the stability of the buildings. Also, the trends of vertical movements captured by satellite interferometry were studied, to determine to what extent these phenomena are the result of anthropogenic interventions.

The analysis followed a clear methodology, structured in several stages. In the first phase, the problem was defined and organized by developing a decision tree using the ILWIS-SMCE module. In the next stage, relevant InSAR points were selected for the assessment of subsidence, using the PS (Persistent Scatterer) and SBAS (Small Baseline Subset) techniques (Figure 2). The obtained data were statistically analyzed to determine the speed of land movement over one year, highlighting the areas with the highest subsidence (Figure 3).

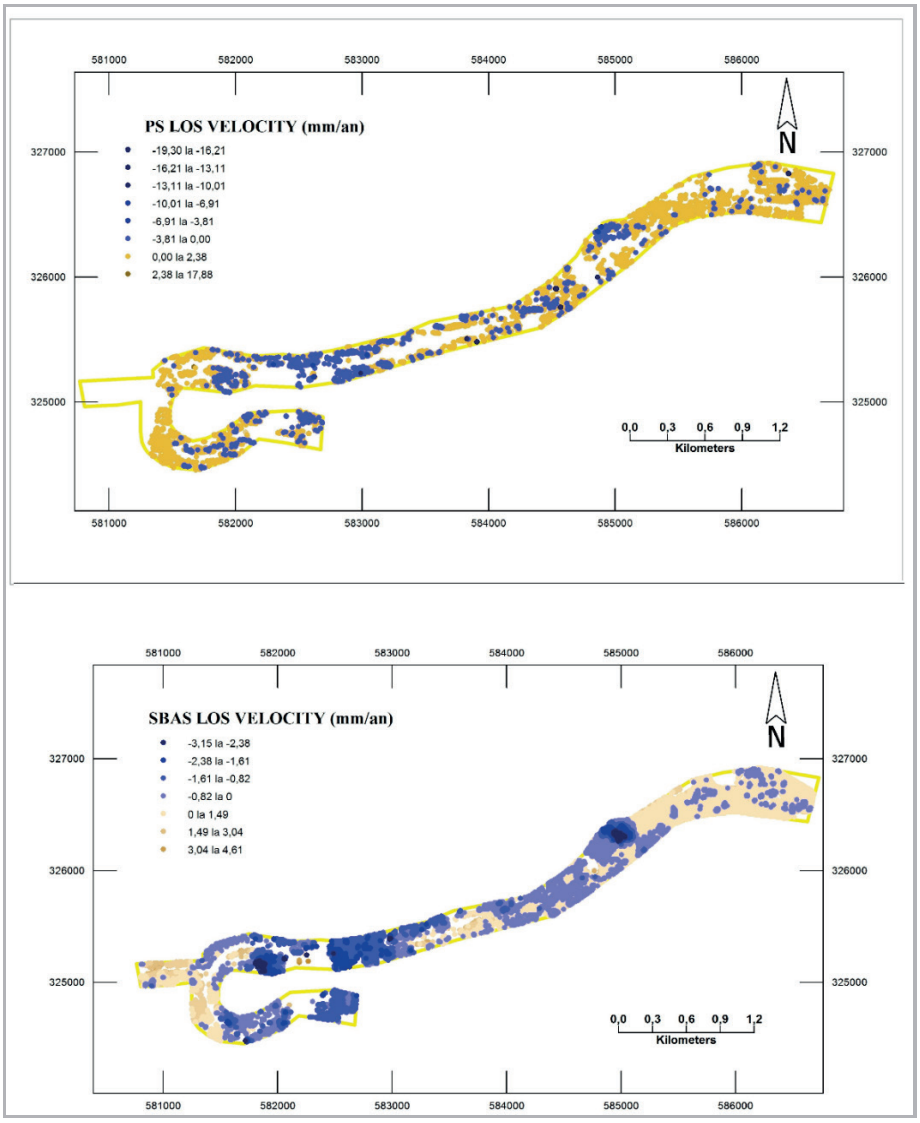

Figure 2. Deformation rates in the M5 metro line area

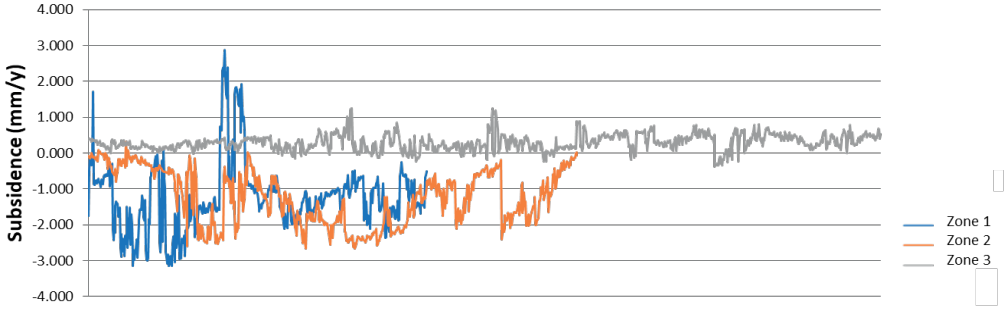

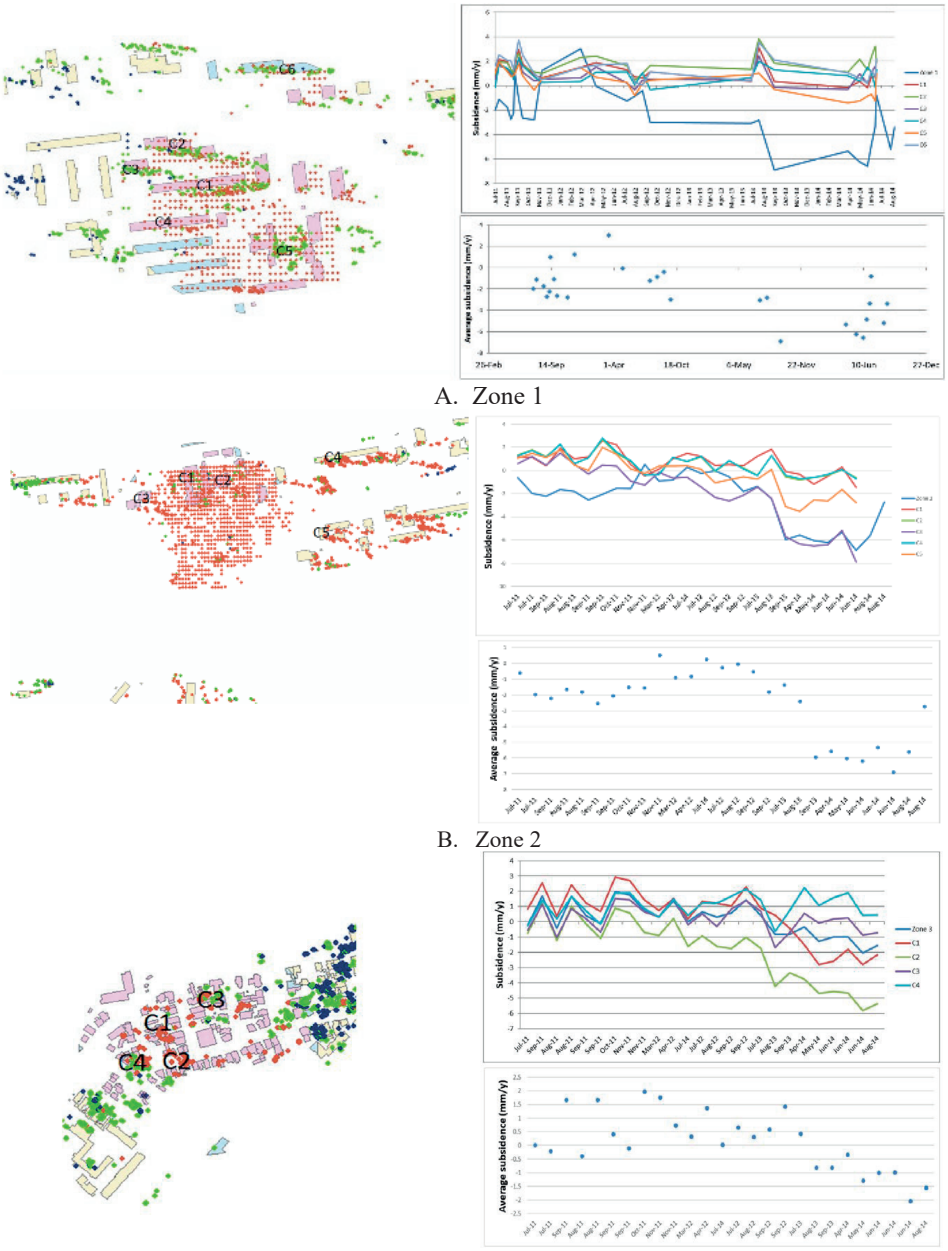

Figure 3. Vertical displacements from SBAS points in time

RESULTS AND DISCUSSIONS

The results showed that the most pronounced subsidence was found in two main areas, located in sectors where infrastructure works were carried out between 2011 and 2020. The Eroilor area was also identified as the most affected, given the major incident that occurred during the execution of the metro line (Figure 4).

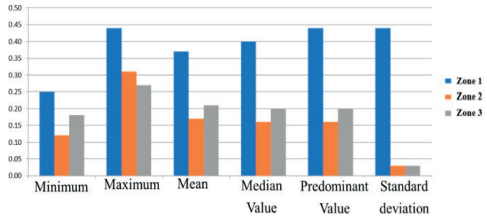
A. Zone 1

B. Zone 2

C. Zone 3

Figure 4. Estimation of subsidence at the level of buildings in all three zones between 2011 and 2014

To understand the impact of these phenomena on buildings, the InSAR analysis was extended to buildings in the most affected areas. The results indicated that, in general, most buildings are stable, and the observed subsidence movements did not exceed the critical threshold of 25 mm mentioned in the specialized literature. The highest values were recorded in the Eroilor area, where settlements reached a peak of 21 mm during the incident.



The study highlighted significant differences between the construction typologies in the three analyzed areas. The buildings in the first area are reinforced concrete structures, with a high height regime, built between 1977 and 1985 according to the construction norms of that period. In contrast, most buildings in areas two and three are masonry constructions, with rigid or flexible ceilings, built before the earthquakes of 1977 and even 1940, which makes them more vulnerable to seismic risks and subsidence phenomena.

For a correct assessment of vulnerability, the data were subjected to a normalization process. The interval procedure was used to highlight and differentiate even the smallest variations in the datasets. Regarding the seismic vulnerability of buildings, the maximum procedure was applied, thus avoiding any intervention that could alter the initial distribution of the data. Also, the distance from the RATB stations was considered an important factor, being evaluated in inverse proportion to the vulnerability of the area, with short distances being perceived as an advantage.

To rank the risk factors and calculate the specific scores, the SMCE module of ILWIS was used. After selecting the indicators, normalizing them, and defining the weights, the analysis led to the generation of vulnerability maps.

The final results indicated a variable vulnerability index depending on the area analyzed. The lowest values of this index, i.e., 0.12, were recorded in zone two, while zone one presented the highest level of vulnerability, with a maximum index of 0.44. The detailed analysis of each indicator and sub-objective confirmed that zone one is the most vulnerable of the entire investigated sector (Figure 5). By applying a rigorous multi-criteria assessment method, this decision-making analysis allowed the identification of the sectors with the highest degree of vulnerability and provided a solid basis for making informed decisions regarding the necessary protection and consolidation measures along the M5 Metro Line.

The results of the study showed that the vulnerability index varied between 0.12 and 0.44, with the highest values being recorded in the area delimited by Drumul Taberei (north), Târgu Neamț Street (east), Pașcani Alley (south), and Cetății Street (west). In this region, the analysis indicated a higher predisposition to soil instability and possible negative effects on buildings.

Zone	Minimum	Maximum	Mean	Median Value	Predominant Value	Standard deviation
Zone 1	0.25	0.44	0.37	0.40	0.44	0.44
Zone 2	0.12	0..31	0.17	0.16	0.16	0.03
Zone 3	0.18	0.27	0.21	0.20	0.20	0.03

Figure 5. Statistical analysis for the three studied areas

A consistent uplift pattern was identified in the interfluve area between the Dâmbovița and Colentina rivers, suggesting an active process of land deformation. In addition, subsidence phenomena were evident in the northwestern and southeastern outskirts of Bucharest, highlighting the need for prevention and intervention measures to reduce the risks associated with these areas.

CONCLUSIONS

The analysis of urban vulnerability and subsidence in Bucharest highlighted the need to implement advanced risk monitoring and management strategies. The use of modern technologies, such as InSAR, together with advanced analytical methods, provides a solid basis for informed decision-making, contributing to the protection of infrastructure and population against natural and anthropogenic hazards.

The application of these methods allows for an efficient management of urban risks, demonstrating that validated data can be used to reduce the impact of subsidence, optimize urban planning, and prevent disasters. By integrating advanced technologies, such as InSAR and multi-criteria analysis, it is possible to identify and classify vulnerable areas, providing support for evidence-based urban policies.

These conclusions confirm that an integrated approach, based on long-term state-of-the-art monitoring technologies, is an essential tool in securing the urban environment and adapting the city to geodynamic risks. Implementing proactive strategies can significantly contribute to reducing infrastructure vulnerability and creating a safer and more sustainable urban environment.

ACKNOWLEDGEMENTS

We thank Dr. Mihaela Gheorghe for the support in processing the InSAR data. The publishing of this research work received support from the Valahia University of Târgovişte research fund.

Abstract

Railway infrastructure is constantly undergoing processes of change and development, it is becoming an important means of transportation. At European level, railways are going through a period of transformations aimed at increasing the transportation capacity for both goods and passengers, as well as increasing travel speeds. Railway infrastructure is constantly exposed to the action of rainwater, groundwater or extreme weather events such as floods. The problem arises when the water is not quickly drained, it remains for a longer period in the embankments leading to wetting or even saturation of the ground. Soil saturation leads to a decrease in bearing capacity and contributes to soil degradation, compromising infrastructure stability. This paper presents advanced numerical modelling with MIKE11 software of real flood situations in the Nădab area, as well as to assess mitigation scenarios through works on railway infrastructure and land improvement

Key words*: flooding, hazard maps, MIKE11, railway infrastructure, soil saturation.*

INTRODUCTION

Floods are among the most frequent and destructive natural phenomena globally, with significant impacts on the environment, population, and critical infrastructure. In recent decades, Central and Eastern Europe have experienced an increase in both the frequency and intensity of flood events, a trend amplified by climate change. These climatic changes directly affect infrastructure vulnerability, particularly in the transport sector, such as railway networks.

Floods rank among the most widespread natural disasters and are third in terms of global impact. These disasters impact both the natural environment, where they take place, and the socio-economic sphere, causing loss of human lives, damage to transportation infrastructure, destruction of agricultural land, the spread of diseases, and interruptions in drinking water supply systems, among other consequences.

Climate change is one of the greatest challenges of the 21st century, having a significant impact on both natural and human systems. In particular, hydro-geomorphological risk events, such as floods, landslides, and erosion, have become more frequent and more intense as a result of climate changes. Floods, in particular, are complex events with significant impact at both global and regional levels, driven by a combination of natural and anthropogenic mechanisms. Their geographical distribution is influenced by climatic, topographic, and hydrological factors specific to each region. Modern risk assessments increasingly rely on geomatic tools and hydrological modeling to better predict and manage these events.

In Romania, the Crișul Alb River Basin, located in the western part of the country, is an area exposed to flood risks due to both geomorphological conditions and extreme weather events. In this context, railway infrastructure in the region is becoming increasingly vulnerable, frequently affected by flash floods and terrain erosion.

The Crișul Alb Basin (Figure 1) largely overlaps with Arad County, and in the southeastern part, with Hunedoara County; in the east, it extends slightly into Alba County, and in the north, it also partially overlaps with a small area of Bihor County.

The hydrographic basin features varied climate, influenced by differences in altitude and the shape of the terrain through which it flows. It covers several geographical units, such as the

Bihor Mountains, the Metaliferi Mountains, the Codru-Moma Mountains, the Zărand Mountains, and the associated hills and plains. The distribution of precipitation in the Crișul Alb Basin varies significantly from east to west (Figure 2).

The mountainous areas in the east are characterized by the highest amounts of precipitation, while in the western area, the amounts are lower. The diversity of soil types (Figure 3) reflects the geological, geomorphological, and climatic variability of the region. Fertile soils such as chernozems and alluvial soils predominate in the plains, while less fertile soils or those with special characteristics (such as lithosols and dystric cambisols) are found in the mountainous areas (NARW, 2024).

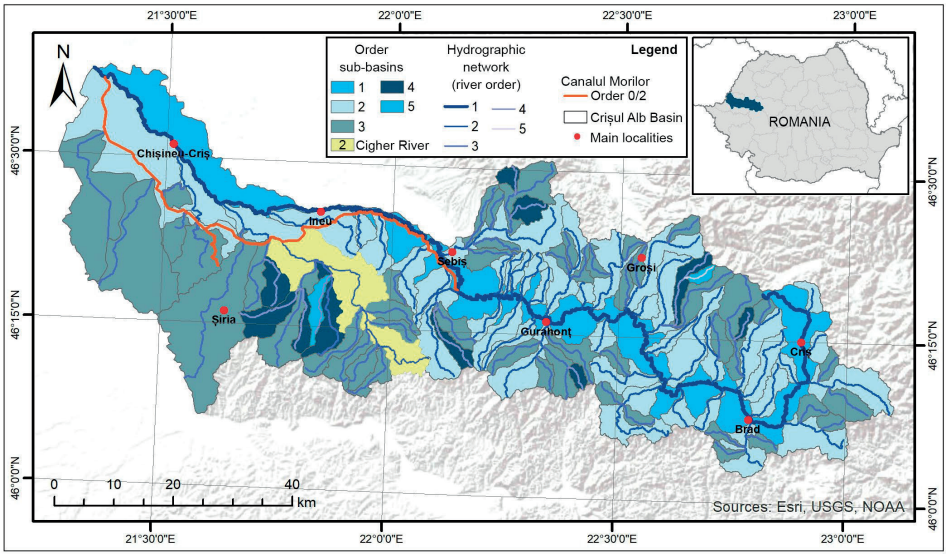

Figure 1. Overview map of the Crișul Alb River Basin, showing administrative boundaries and main hydrographic features

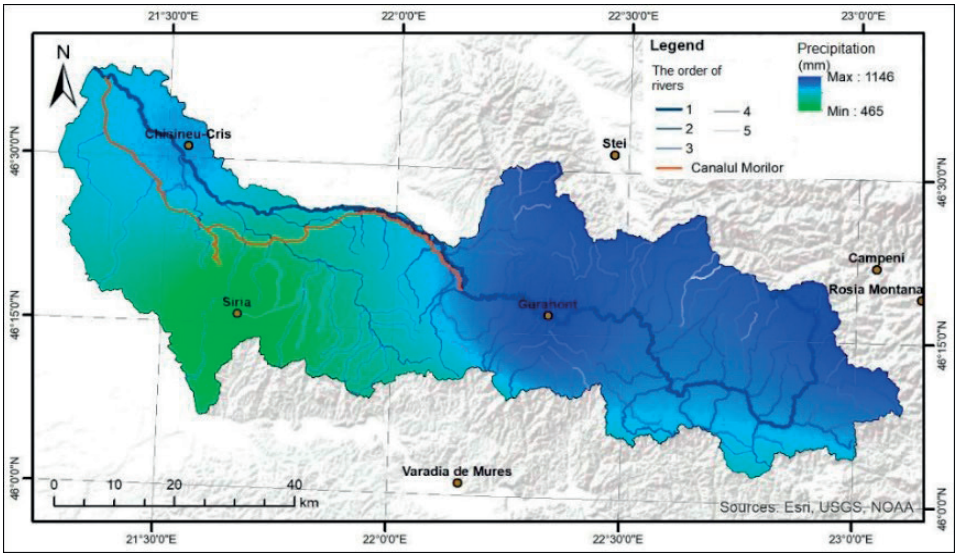

Figure 2. Annual precipitation distribution in the Crișul Alb Basin (mm/year), highlighting east-west variation

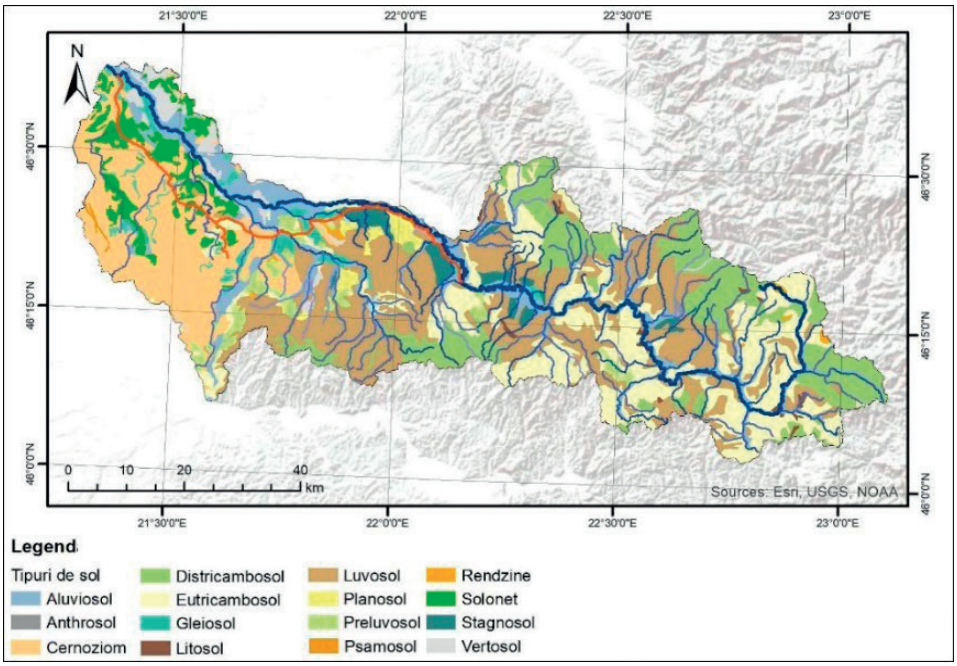

Figure 3. Spatial distribution of soil types in the study area, based on NARW classification

The Crișul Alb River originates in the Apuseni Mountains, in the northern area of the Bihor Mountains, at an altitude of approximately 1,250 meters. It flows through the counties of Hunedoara, Arad, and Bihor, covering a distance of about 234 km before discharging into the Tisza River on the territory of Hungary. In the Crișul Alb Basin, the hydrographic network is composed of 103 rivers, with a total length of 1,667 km.

The Crișuri hydrographic area has a complex system of hydraulic works for the quantitative management of water resources, containing several water diversion structures that transfer water volumes from one river course to another. To supply water for various uses (drinking water, irrigation, fish farming), as well as for collecting high waters from interfluves, 27 water intakes and diversions have been constructed.

The existing flood protection works in the Crișuri hydrographic area include river regulation, embankments, bank reinforcements, as well as permanent and temporary reservoirs or polders.

This study aims to assess the impact of floods on railway infrastructure using numerical modelling, with a case study focused on the locality of Nădab. The main objective is to gain understand hydraulic behaviour in critical flood-prone areas and to propose solutions to reduce risks to railway transport.

MATERIALS AND METHODS

The analyzed area is located in the western part of Romania, in the Crișul Alb River Basin, with a focus on the sector corresponding to the locality of Nădab. This region is characterized by a predominantly low-plain relief and the presence of critical infrastructure, including the Arad-Oradea railway line, which is vulnerable to recurrent flooding.

In the last two decades, Europe has experienced over 100 major floods, resulting in more than 700 casualties, displacing over half a million people, and causing damages exceeding 25 billion EUR.

The extreme hydrological phenomena occurring in recent decades, both globally and in Romania, highlight the fact that society is affected not only by slow floods, caused by rivers with medium and large catchment areas, but also, to the same extent, by fast floods, typical of small basins, generally less than 200-300 km^2. There is a

growing trend in the frequency of severe flash floods, which have caused significant material damage and, in many cases, loss of human lives (Biali et al., 2022).

Global practice has shown that the occurrence of floods cannot be avoided, but they can be managed their effects on the social, economic, environmental, and cultural heritage sectors can be reduced through a process involving complex analyses and targeted prevention and mitigation measures at the local, regional, and national levels, designed to contribute to reducing the risk associated with these phenomena (Hausler et al., 2020).

The National Flood Risk Management Strategy for the medium and long term encourages the construction of communication routes (roads, railways) with embankments reinforced to appropriate levels whitch serve as flood localization lines, and must include properly dimensioned bridges.

Additionally, it encourages the construction embankments for national roads and railways in such a way that they can serve as flood protection lines in areas identified with a high flood risk particularly where geographic conditions require such measures to be the only viable option for protecting settlements. These specific cases will be included in the River Basin Master Plan and, later, in the Flood Risk Management Plan, and will be carried out in accordance with the approved budgets.

The history of risk phenomena in the Crișul Alb basin highlights the need for proactive management of hydrographic resources and flood protection measures. Repeated flooding and landslide events underscore the region's vulnerability and the importance of risk prevention and management interventions.

Floods are natural phenomena, and of the 20 types of hazards considered natural disasters, they are ranked highest terms of geographic spread, number of events, and number of people affected.

In determining areas at risk of flooding, both river overflow floods (medium/large basins) and flash floods (small catchments) are considered.

Flash floods are floods that occur in a short period of time and are characterized by sudden increases in water levels and flow rates. The main characteristic of flash floods is that they have a maximum growth time of 4 to 6 hours, occurring in small catchment areas ranging from a few to several hundred km². The main cause of these flash floods is torrential rainfall, with exceptionally high intensities. However, there are also other physical and geographical factors that contribute to or trigger flash flood events, factors that will be detailed in the section dedicated to hazard analysis.

Historical flood events with significant impacts on health, the environment, cultural heritage, and economic activity were included in the assessment, including those that could occur in areas with hydraulic infrastructure, such as embanked zones. (Gabor et al., 2019).

To carry out hydraulic simulations and assess the potential impact of floods on railway infrastructure, the MIKE21 and MIKE FLOOD applications developed by DHI were used.

MIKE 11 is a software developed by DHI (Danish Hydraulic Institute) and is designed to perform one-dimensional hydraulic and hydrodynamic calculations, with integrated storage zones to represent networks of natural and engineered channels (Armas et al., 2016).

In essence, the calculation procedure is based on a numerical solution of the one-dimensional energy and mass conservation equations (the Barre-de-Saint-Venant system of equations). Energy losses are primarily evaluated through friction (Manning's equation) and contraction/expansion (via a dynamic head loss coefficient) (Marossy et al., 2016).

The hydraulic modeling of river sections identified as potentially flood-prone, using specialized software, consisted of one-dimensional (1D) and two-dimensional (2D) simulations of flow on the analyzed river courses. For 1D hydraulic modeling, the dependence of water level on flow rate was determined using the MIKE 11 (DHI) application, while for areas requiring more detailed analysis, the MIKE 21 (DHI) application was used. The 1D and 2D hydrodynamic modeling was applied with calibration and verification for significant historical floods (DHI, 2021).

MIKE21 allows for the two-dimensional modeling of surface runoff, which is useful for assessing the spatial extent of water in flood-prone areas.

MIKE FLOOD integrates 1D and 2D models, enabling complex analysis of the interaction

between watercourses and surrounding land, including transport infrastructure.

Flood hazard maps were obtained using the MIKE Flood (DHI) mathematical model, a model that allowed the coupling of 2D and 1D models into a single calculation system. These maps indicate, for different analyzed scenarios (Qp%), the extent of flooded areas and water depth.

The model was fed with data obtained from multiple sources:

- Topography: High-resolution digital terrain model (DTM) obtained using LiDAR technology;
- Hydrographic Network: Cross-sections and hydraulic parameters of the Crișul Alb River;
- Climatic and Hydrological Data: Historical records of precipitation and discharge, obtained from ANAR;
- Railway Infrastructure: Positioning and physical characteristics of the Nădab railway line, including embankment levels and existing flood defense works.

The railway infrastructure is constantly exposed to the action of water.

Types of water that affect railway infrastructure:

- Surface water comes from atmospheric precipitation that falls directly on the railway embankment or on the adjacent land (berms, slopes);
- Groundwater is found in aquifer layers located beneath the ground level;
- Extreme weather events: Floods result from flash floods, heavy rains, storms, or river flooding. Although the railway infrastructure is not designed within riverbeds, there are situations where high waters affect the embankments. The embankments serve as dikes against high waters, which leads to soil erosion and landslides, consequently damaging the railway infrastructure (Vara et al., 2024).

The problem arises when water is not quickly evacuated, remaining for a longer period of time in the embankments, which leads to the dampening or even saturation of the soil. (Kellermann et al., 2016). Dampening or saturation of the soil with water leads to a decrease in load-bearing capacity and soil degradation (Hausler et al., 2020). The MIKE11 program was used for numerical modeling. At the beginning, the existing situation of the Crișul Alb River was modeled. The model plan is shown in Figure 4.

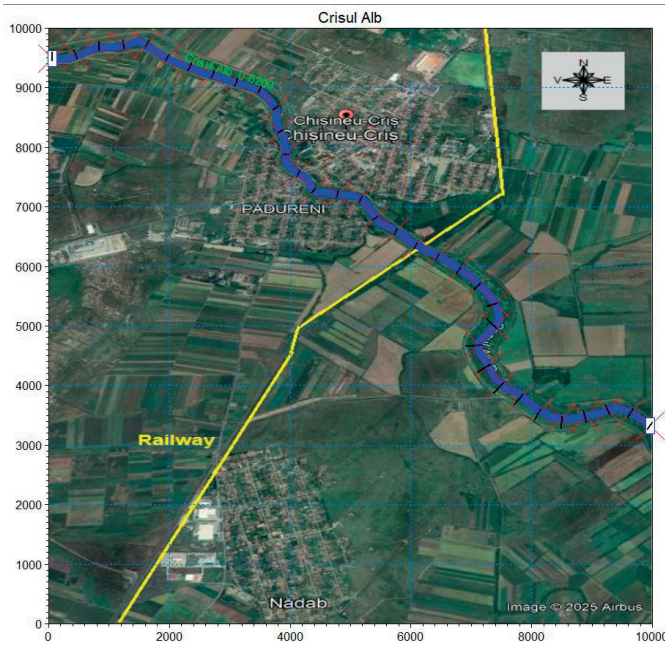

Figure 4. MIKE11 model plan view for the Crișul Alb River, showing simulation domain in the Nădab sector

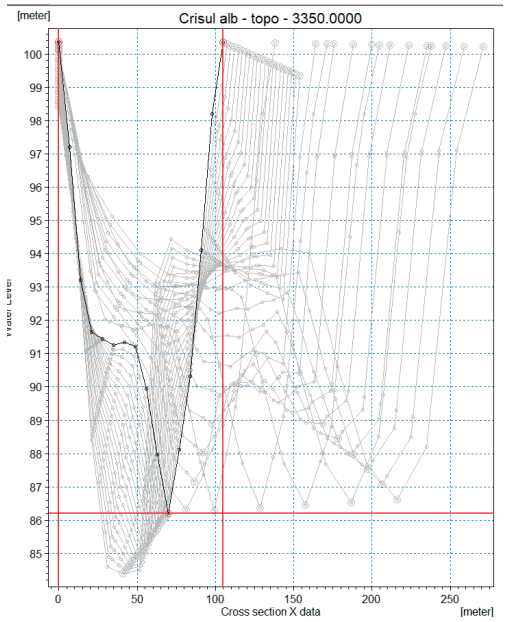

Figure 5. Topographic cross-sections of the canal used in MIKE11 hydraulic modeling

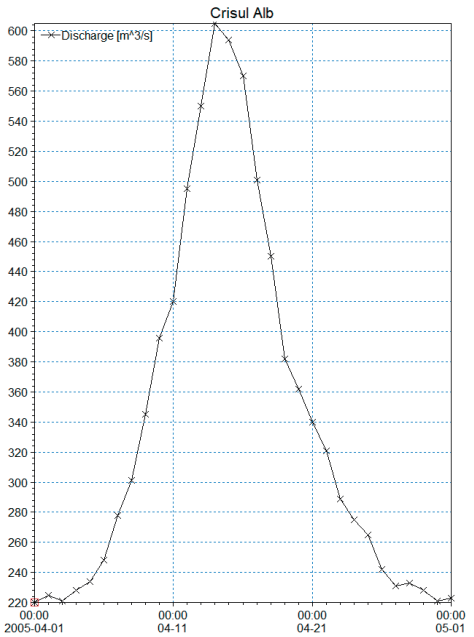

Figure 6. Inflow hydrograph (m³/s) used as upstream boundary condition for the 2005 flood event simulation

Cross-sections obtained from topographic surveys are shown in Figure 5.

Boundary conditions included an upstream flood hydrograph at chainage 0+000 and a downstream rating curve at chainage 8+200 (Damian et al., 2022).

The flow hydrograph is shown in Figure 6.

RESULTS AND DISCUSSIONS

The model was configured to simulate flood scenarios with different occurrence probabilities (1%, 2%, 10%). Hydraulic parameters, such as Manning's roughness and loss coefficients, were adapted based on local characteristics. Built-up areas and agricultural lands were treated differently to improve the accuracy of flow distribution.

The model was calibrated using data from historical events (the floods of 2000 and 2006) by adjusting hydraulic parameters the simulated values closely matched observed water extents and recorded levels. Validation was performed on a separate data set to ensure the robustness and applicability of the model for future scenarios.

The water levels from the initial results were compared with measured levels in several sections. Roughness coefficients were adjusted in specific sections until the simulated levels aligned with observed data.

By carrying out the MIKE11 program, a longitudinal profile of the canal was obtained showing water levels over the simulation period (Figure 7).

From Figures 7, it follows that for the hydrograph of the inflows introduced in 2005 on the Crisul Alb River, the maximum water transport capacity of the canal was exceeded, with the flood risk occurring for flows greater than those considered. Flood hazard maps generated with the MIKE Flood model show the spatial extent and depth of inundation under each flood scenario (Figure 8).

The results included detailed maps of the water extent and longitudinal profiles of the affected railway line, as well as estimates of water depth and flow velocity along sections of the railway line.

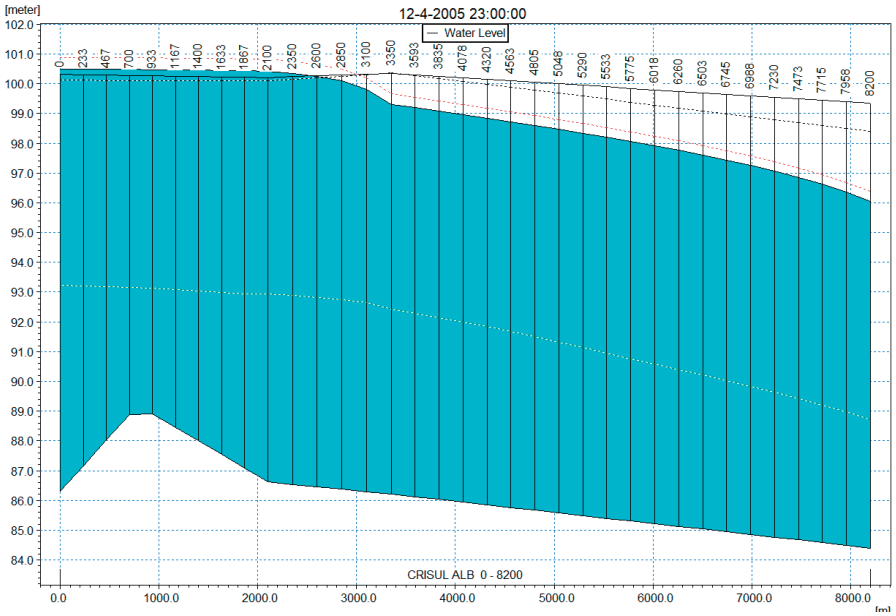

Figure 7. Longitudinal profile of the Crișul Alb Canal, showing simulated water levels during peak flow

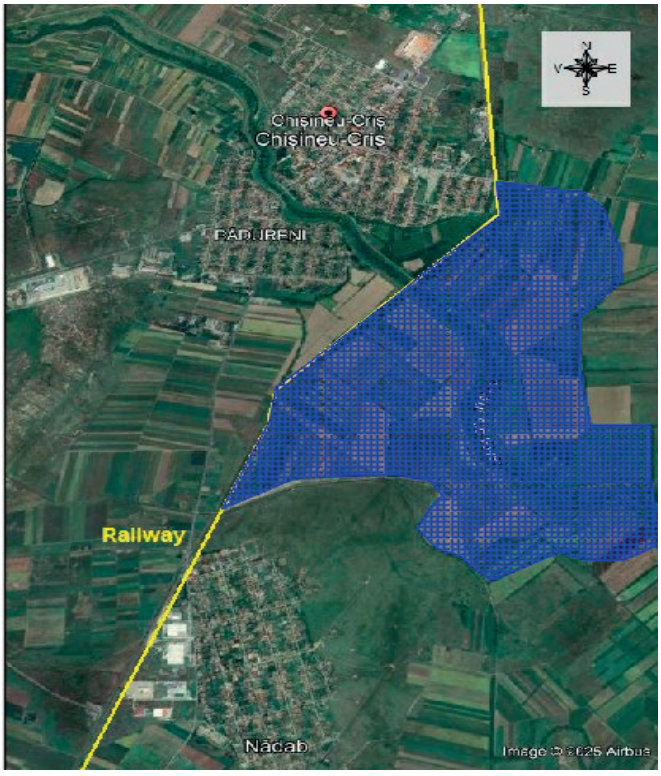

Figure 8. Flood hazard map of the Nădab area for the 1% probability scenario (Q100), showing extent and depth of inundation

In the specific context of the Nădab locality, the results suggest the need for additional protective measures, such as raising the railway embankments or constructing protective barriers to prevent flooding of the railway line during extreme events. Additionally, interventions to improve drainage systems in the area should be considered to reduce the risk of railway infrastructure blockage due to heavy precipitation.

On a broader scale, the results of this model help to improve understanding of the impact of flooding on critical infrastructure, especially in areas vulnerable to extreme weather events. This information may inform urban and infrastructure planning, considering climate change and the increased risks of flooding in the future. Furthermore, it can assist authorities in developing prevention strategies and rapid-response plans for natural disasters.

Comparisons with existing studies suggest that the vulnerability of railway infrastructure to flooding is a well-documented issue, especially in regions with low-lying terrain and nearby watercourses. While previous research has indicated similar protective measures (e.g., raising embankments and improving drainage systems), the current study highlights the specificity of the Nădab area, with its unique topographic and hydrological characteristics.

Among the limitations of the study are the simplified assumptions of the hydraulic model and the limited availability of historical flood data, which could have improved the model's calibration. In the future, it would be useful to expand studies to include long-term flood scenarios, considering climate forecasts and potential changes in the region's hydrological regime. Additionally, innovative solutions, such as green infrastructure (e.g., water retention zones), could be explored to enhance the flood resilience of railway infrastructure.

CONCLUSIONS

The study showed that the Nădab railway sector is vulnerable to flooding, especially in low-probability scenarios (1%), where water levels can exceed the capacity of the embankments. The results of the hydraulic simulations indicate significant water extent along the railway line during flood conditions, which poses a major risk infrastructure stability and operational safety.

The railway infrastructure in the Nădab area is vulnerable to recurring floods, particularly under he influence of climate change, which is expected to increase both the frequency and intensity of extreme weather events.

The greatest threat is the overload of local drainage capacity and subsequent flooding of the railway corridor, which can lead to major disruptions in train circulation and material damage.

Hydraulic modeling and hazard maps provide a clear picture of flood risks and help identify critical areas that require protective measures. These tools are essential for assessing potential impacts and supporting well-informed infrastructure protection strategies, particularly in flood risk planning and management.

Protective actions such as embankment elevation and the installation of barriers should be urgently considered to prevent flooding of the railway. Moreover, authorities are encouraged to prioritize drainage system upgrades and to invest in long-term infrastructure resilience strategies in light of future flood risk escalation.

Looking ahead, it is important to continue monitoring flood risks and improving hydraulic models by incorporating reliable climate projections.

Additionally, innovative green infrastructure solutions, such as water retention areas and the use of permeable materials, should be explored to enhance the resilience of railway infrastructure and help mitigate the effects of a changing climate.

The growing recognition of climate-related risks has brought the issue of water-related impacts on railway infrastructure to the forefront of discussions at the European level.

Abstract

Romania faces challenges related to climate change, such as rising temperatures, floods, and droughts, while urban areas struggle with air and water pollution. The growing public awareness of sustainability and environmental protection creates a favorable context for the large-scale implementation of such infrastructure across the country. This research provides a detailed classification of green and blue infrastructure types, highlighting their diversity and the specific functions each fulfills in improving urban life. Green and blue areas are essential for improving urban life quality and protecting the environment. The growing significance of green and blue infrastructure is reflected in Romania's urban laws and policies, highlighting a shift towards sustainable development and city resilience. However, implementing this is difficult due to the lack of a single legal definition, causing inconsistent use and confusion. Additionally, there is no cohesive national strategy, and legal frameworks addressing different aspects are uncoordinated. Local authorities also need clearer guidelines and better methods for planning, designing, and managing these infrastructures effectively.

Key words*: climate change, environmental quality, sustainability.*

INTRODUCTION

Currently, over half of the global population (55%) resides in urban areas, and this percentage is projected to rise in the coming years (United Nations, 2019). Cities are increasingly confronting various risks, with escalating heat stress driven by rising temperatures being one of the most pressing challenges (Sari Kovats & Hajat, 2007). As urban areas grow, the heat island effect amplifies heat stress, reducing quality of life and increasing heat-related mortality, particularly among vulnerable groups like the elderly, children, and those with health conditions (Oleson et al., 2015; Argüeso et al., 2015). These factors make it necessary for cities to implement effective adaptation strategies to mitigate the health risks associated with extreme heat, including nature-based solutions by integrating green and blue infrastructure.

Nature-based solutions (NBS) and green-blue infrastructure (GBI) are key components of sustainable urban development and environmental policies. By integrating green spaces and water bodies into the urban landscape, GBI helps cities address today's challenges, providing practical solutions to mitigate the impact of climate change, biodiversity loss, and the rapid expansion of urban areas. Nature-based solutions and the responsible management of natural resources are acknowledged as fundamental elements of sustainable development (Martin et al., 2020).

Our studies have found that many documents and research investigations, including reports by the European Commission and studies by environmental organizations, feature nature-based solutions as a cross-cutting topic, proposing the use of natural processes to address urban challenges such as climate change, pollution reduction, or increasing the resilience of cities. European documents establish the general framework for integrating nature-based solutions and green-blue infrastructure into environmental, urban planning, and economic development policies (European Parliament, 1998; 2015; 2018). At the national level, Romania's legislation details how these

principles are implemented, with specific laws like Law no. 24/2007 for the regulation and administration of green spaces, Emergency Ordinance no. 114/2007 for flood risk management, and the National Strategy for Sustainable Development of Romania 2030 for urban regeneration (The Government of Romania, 2007). At the European level, the general direction regarding green and blue infrastructure focuses on integrating nature-based solutions into environmental, urban planning, and economic development policies. The European Union promotes a holistic approach that emphasises biodiversity protection through initiatives like the Natura 2000 network, climate change adaptation by implementing emissions reduction targets, and the creation of more resilient and sustainable cities through funding programs for green infrastructure projects. European programs and strategies like the European Green Deal and the 2030 Agenda for Sustainable Development highlight coordinated efforts to enhance quality of life, decrease pollution, and manage natural resources efficiently.

We have observed that NBS has different definitions that vary based on cultural and regional contexts, but the overall goal remains consistent: to harness the power of nature to address environmental challenges. Thus, our research uses the encompassing definition provided by the European Commission's Report on NBS as those actions that enhance existing natural processes and develop innovative approaches that leverage nature's ability to store carbon and regulate water, contributing to disaster risk reduction, well-being, and green growth. The European Commission recognises that the concept aligns with ecosystem-based approaches and emphasises sustainable alternatives inspired by ecological principles (European Commission, 2015).

Romanian legislation has adopted European principles regarding the protection of green spaces, flood risk management, and urban regeneration by adopting and transposing European Union directives and strategies into its national regulatory framework (Ungureanu et al., 2024). In the context of current global challenges such as climate change, biodiversity loss, and rapid urbanization, nature-based solutions and sustainable management of natural resources are recognized as an integral part of sustainable development at both the European and national levels.

MATERIALS AND METHODS

NBS and GBI have become integral to environmental policy and urban planning at the European and national levels. The world's climate change, biodiversity loss, and urbanization challenges have made it imperative for governments to prioritize nature-based solutions and green infrastructure in order to create more sustainable and resilient cities.

The documents selected for this study cover various regulations and strategies that support environmental protection, sustainable development, and urban regeneration. They underscore the critical importance of incorporating NBS and GBI into local and national policy frameworks.

Our analysis examined legislative and strategic documents, offering a comprehensive view of the regulations and policies related to green and blue infrastructure at the European and national levels. These documents cover a wide array of issues, from environmental protection and sustainable resource management to biodiversity conservation, water quality, natural disaster risk reduction, urban regeneration, and sustainable development.

Romania's national legislation outlines the implementation of these principles, focusing on the protection and management of green spaces, flood risk reduction, and urban regeneration efforts.

RESULTS AND DISCUSSIONS

A total of 18 legislative and strategic documents were carefully analysed in the reviewed studies. Among these, 13 were European Union (EU) documents, comprising strategies, directives, and conventions that outline the general framework for green and blue infrastructure and nature-based solutions. Five national documents from Romania were analysed, including laws, emergency ordinances, and national strategies that incorporate European principles into the Romanian framework. One national bill proposal has been examined (Draft Law, 2024).

European Legislation regarding NBS

The European Union places significant emphasis on integrating nature-based solutions into its environmental, urban planning, and economic development policies. This holistic approach aims at biodiversity protection, adaptation to climate change, and the creation of more resilient and sustainable cities. We have identified a series of documents and strategies that support and promote the use of nature-based solutions in the urban environment:

- ***The Green Infrastructure Strategy, 2013*** aims to promote investments in ecological solutions and avoid costly gray solutions. This encourages the use of green infrastructure to protect ecosystems and reduce costs through natural and sustainable solutions (European Commission, 2013). It offers recommendations for using nature-based solutions to replace or complement grey infrastructure, emphasizing that green infrastructure is a planned network of natural and semi-natural areas that contribute to increased resilience and significant savings.
- ***Strategic Research and Innovation Agenda Biodiversa*** supports research in biodiversity and natural solutions to address ecological, climate, and social crises, promoting innovation (Eggermont et al., 2021).
- ***The amendments adopted on October 5, 2023, regarding wastewater treatment*** propose measures to reduce emissions from wastewater treatment and encourage the use of nature-based solutions for water management (European Parliament and the Council, 2015).
- ***The review of progress regarding the implementation of the EU strategy for green infrastructure (2019)*** highlights that green infrastructure is an important tool for ensuring ecosystem services, reducing costs, and supporting biodiversity. It also provides guidance for integrating green infrastructure into spatial planning and sustainable development (European Commission, 2019).
- Major European strategies, such as the ***European Green Deal*** and ***The 2030 Agenda for Sustainable Development***, emphasize the need for concerted actions to improve quality of life, reduce pollution, and use natural resources efficiently (European Commission, 2020; UN, 2015).

Romanian Legislation regarding NBS

Romania has made progress in implementing European principles on green space protection, flood risk management and urban regeneration through the adoption of specific legislation and national strategies, although the implementation and mainstreaming of concepts such as green-blue infrastructure still requires coordinated efforts and a unified approach at local and national level.

Regarding the protection of green spaces, Romania has adopted a legal framework that reflects European concerns for biodiversity conservation and the improvement of quality of life in urban areas. Law no. 24/2007 regarding the regulation and administration of green spaces within urban areas establishes the legal framework for the protection and management of these spaces, including regulations for administration, protection, and penalties for deterioration (Parliament of Romania, 2007). This law was amended and supplemented by Emergency Ordinance no. 114/2007 and Law no. 47/2012, with the aim of the continuous protection of green spaces and the prohibition of changing the destination of green lands (The Government of Romania, 2007; Parliament of Romania, 2012). Moreover, the Technical Norms for the Development of the Local Register of Green Spaces provide guidelines for the inventory, management, and expansion of urban green spaces, establishing criteria for their monitoring (Ministry of Regional Development and Tourism, 2010). These initiatives are in line with European strategies that emphasize the role of expanding green and blue networks to support ecosystems and create connections between natural and urban areas.

In the field of flood risk management, Romania has implemented relevant European directives, such as the Water Framework Directive 2000/60/EC and the Floods Directive (2018/2019). These directives require member states to assess and manage flood risks, encouraging the implementation of ecosystem-based measures and green infrastructure. The Water Framework Directive regulates the protection of water resources, setting standards

for the quality and quantity of water for sustainable uses. The Directive on the assessment and management of flood risks improves cooperation between member states in the assessment and management of flood risks, with an emphasis on green infrastructure.

For urban regeneration, Romania has adopted legislative and strategic measures that align with European objectives for sustainable development and improving the quality of life in urban and rural communities. Emergency Ordinance no. 183/2022 regarding the establishment of measures for the financing of urban regeneration projects regulates the financing of these projects from non-reimbursable funds and establishes the eligibility criteria (The Government of Romania, 2022). This ordinance emphasizes the necessity of conserving and expanding green spaces within urban areas as an integral part of urban policies. The National Strategy for Sustainable Development of Romania 2030 represents the strategic framework for the implementation of the 2030 Agenda in Romania and highlights the need for a transition towards more responsible economic and social practices, aligned with global and European objectives (The Government of Romania, 2018). This includes objectives related to sustainable urban development and the integration of sustainability principles into public policies (Parliament of Romania, 2022).

Nature based solutions as tools for sustainable urban developments

By examining the key documents at both the European and Romanian levels, we have identified the legislative and strategic frameworks that guide the implementation of Nature-Based Solutions (NBS). These policies define the integration of green and blue infrastructure within urban regeneration initiatives, water management systems, and overarching sustainability strategies. The findings underscore the advancements achieved and the obstacles that persist in integrating NBS into policy frameworks, providing insights on how cities can more effectively utilise nature to tackle current urban and environmental issues (Bockarjova et al., 2017).

Green and blue spaces are vital in sustainable urban development, significantly affecting the environment, public health, and residents' quality of life. Integrating them into urban infrastructure offers numerous advantages: better biodiversity, reduced urban heat island effects, and improved stormwater management. Additionally, their contributions help conserve aquatic ecosystems, creating healthier, more enjoyable community environments. Green and blue infrastructure are crucial for building sustainable, climate-resilient cities. These spaces provide numerous environmental and social benefits, enhancing ecological balance and residents' well-being (Semeraro et al., 2021).

Bockarjova et al. (2017) developed a key tool for understanding and quantifying the financial and economic benefits of nature-based solutions in urban contexts. The tool relies on a transdisciplinary classification framework and data from previous research. Based on this research, we utilised and extended this classification, integrating the previously examined local documents, as shown in Table 1. This study presents a detailed classification of green and blue infrastructure and its contributions to better urban living.

Table 1. Nature based solutions as tools for sustainable urban developments throughout types of Green and Blue Urban Infrastructures

Nature based solutions as tools for sustainable urban developments	
Green Infrastructure	**Blue Infrastructure**
Urban park or forest • have many benefits for the city's quality of life: environmental benefits, economic benefits, social and psychological benefits, and planning and design (Sadeghian & Vardanyan, 2013).	**Lake/pond** • the shores can be developed into recreational spaces, becoming areas for relaxation, recreational activities, and ecological education platforms.
Pocket park • neighborhood green spaces, including pocket parks of less than 5000 m², contribute to the health and well-being of residents (Baur &Tynon, 2010; Peschardt et al., 2012; Kerishnan & Maruthaveeran, 2021).	**River/ Estuary** • flowing water bodies with freshwater aquatic communities (or, in the case of estuaries, both freshwater and saltwater).
Botanical garden • showcase plant species from different regions, providing a rich diversity of	**Sea coast** • area of contact between the sea and land, with diverse characteristics (e.g., sandy

Nature based solutions as tools for sustainable urban developments	
Green Infrastructure	**Blue Infrastructure**
flora (Primack & Miller-Rushing, 2009).	beaches, cliffs, dunes).
Green parking lots ● can be considered small heat islands and sources of pollutants from vehicles (Hahn & Pfeifer, 1994; Onishi et al., 2010). ● can lead to lower temperatures, improved water management, and better air quality.	**Delta** ● as a complex aquatic ecosystem, the delta is vital in conserving biodiversity and providing shelter for numerous plant and animal species (Bănăduc et al., 2016).
Community garden ● is established in urban, suburban, or rural areas and is close to schools, hospitals, or residential areas (American Community Gardening Association, 2014);	**Wetland** ● is essential for water purification and flow regulation, filtering pollutants, preventing floods by controlling water levels, and reducing soil erosion (Erwin, 2009).
Green corridor ● network that provides the community ecological, recreational, and cultural benefits (Ndubisi et al., 1995).	**Swale** ● is relatively inexpensive to construct and maintain (Dillaha et al., 1986, cited by Delgado et al., 1995). Their primary purpose is to reduce water pollution by capturing and filtering heavy metals and chemicals.
Green roof ● is classified into four categories: intensive, semi-intensive, single-layer extensive, and multi-layer extensive (Shafique et al., 2018).	**Rain garden** ● is recommended as an effective solution for managing stormwater runoff and enhancing biodiversity in urban environments (Ishimatsu et al., 2017).
Green wall and facade ● the „greening" of building facades represents one of the most effective solutions for energy savings in buildings and reducing the urban heat island effect (Perez et al., 2017).	**Permeable pavements** ● are ideal for a range of applications, including residential, commercial, and industrial settings (Scholz &Grabowiecki, 2007).
Institutional green space ● improve urban aesthetics by creating a pleasant contrast between vegetation and the architecture of the buildings.	**Rainwater harvesting** ● in urban areas, rainwater harvesting involves capturing, collecting, storing, and treating rainwater from rooftops, terraces, courtyards, and other impervious surfaces for on-site use (Campisano et al., 2017)
Riverbank green ● a river with a width of 35 m can lead to a temperature decrease of approximately 1–1.5°C, and this decrease can be more pronounced if	**Green roofs with water retention** ● help manage water flow to reduce flood risks and address drought conditions effectively (Graceson et al.,

Nature based solutions as tools for sustainable urban developments	
Green Infrastructure	**Blue Infrastructure**
there are green spaces on both banks of the river (Heggem et al., 2000).	2013).
Green balcony ● it refers to plants on balconies and terraces, primarily planted in pots.	**Daylighting streams** ● uncovering buried urban streams and restoring them to a natural state (e.g., Cheonggyecheon Stream in Seoul) (Hwang, 2004).
Street trees ● streets with tree alignments can be up to 10 degrees cooler in the summer, and a mature, healthy tree has a cooling effect equivalent to two air conditioning units running 20 hours a day (Voinescu, 2020).	**Riverbank stabilization with vegetation** ● using plants to prevent erosion instead of concrete embankments.
Green playground/ school ground ● the conversion of paved schoolyards by adding green spaces brings children closer to nature, stimulates daily physical activity, and supports social well-being (Raney et al., 2019).	**Canal** ● help manage water flow to reduce flood risks and address drought conditions effectively.
House garden ● include areas around private homes, mainly cultivated for ornamental purposes or non-commercial food production.	**Mangroves** ● protect coastlines from erosion and provide nursery habitats for marine species.
Vertical greeneries (walls, ceilings) ● plant selection must consider climate, building design, and context (Manso & Castro-Gomez, 2015).	**Eco-friendly seawall** ● are designed to minimize environmental impact and enhance habitat potential compared to traditional designs (Fish Habitat Network, 2019).

CONCLUSIONS

The analysis of the documents reveals the importance of nature-based solutions for the sustainable development of green and blue infrastructure in Romania. The analyzed legislative and strategic documents provide a comprehensive overview of the regulations and policies related to green and blue infrastructure, highlighting the importance of integrating it into local and national policies. This is recognised as a central element in environmental and urban planning policies at both the European and national levels in the context of global

challenges such as climate change and biodiversity loss.

The documents emphasise the role of green and blue infrastructure in protecting biodiversity, reducing natural risks, and improving quality of life. European strategies and national legislation promote the integration of these solutions into territorial planning and urban development. Even though not all local strategies explicitly mention the terms nature-based solutions, green infrastructure, or blue infrastructure, the concern for environmental issues and the sustainable use of natural resources is evident.

For a sustainable and resilient future in Romania, it is imperative to embrace and expand a variety of green and blue infrastructure types such as urban parks, wetlands, and green roofs. These solutions effectively manage water, enhance biodiversity, and contribute to sustainable urban development.

Therefore, it is necessary to emphasize the need for an integrated and multidimensional approach to urban development, which prioritises the protection of natural resources and the extensive implementation of nature-based solutions, thus coherently promoting green and blue infrastructure. The efficient integration of NBS in the urban environment brings significant ecological benefits, contributing to biodiversity conservation, sustainable water management, pollution reduction, and climate change mitigation. From an economic perspective, NBS and GBI can stimulate investments in ecological solutions, reduce costs through natural alternatives for grey infrastructure, and support the development of sustainable tourism. Last but not least, the social benefits should be considered in Romanian cities, including the improvement of quality of life through the creation of green spaces for recreation, the promotion of public health, and the increase of urban community resilience. Adopting a holistic perspective that combines environmental protection with economic and social considerations is fundamental to ensuring a sustainable and prosperous urban future in Romania.

Abstract

Agriculture is one of the main sources generating significant quantities of natural agro-industrial by-products, such as stalks, fibrous residues, husks and cobs, etc. Based on the principles of the circular economy, such natural materials can have numerous possibilities for superior valorization, often as biocomposite materials, in various fields, not least in construction. Starting from the recognized potential for valorization of natural agro-industrial by-products in this sector, the paper presents aspects regarding the importance of compatibility and interaction between two natural materials, namely rice husks and industrial hemp fibers, and a synthetic resin as their binder. The implications of the compatibility and interactions between such types of materials and how this can influence the evolution over time of some characteristics of the biocomposite material expected to be used in the construction field as coatings are also presented.

Key words*: adhesion, coatings, hemp, pre-reaction time, rice husks.*

INTRODUCTION

It is currently known that organic raw materials can be used in a sustainable way, with increased efficiency and lower processing costs. The reducing waste, reusing and maximizing the value of resources can generate valuable products, promoting sustainable development and maximizing ecological and socio-economic benefits (Coelho Vianna et al., 2024).

The agricultural sector is one of the main sectors generating impressive amounts of waste (Ufitikirezi et al., 2024; Capanoglu et al., 2022; Pradhan et al., 2024), which has led to concern among public opinion and the scientific community.

Data published by the Food and Agriculture Organization (FAO) shows that agriculture produces over 140 billion tons of biomass each year, with over 2 tons per day in some rural areas (Ufitikirezi et al., 2024). It is also recognized that, by valorizing agricultural waste, farmers and agricultural industries can contribute through sustainable practices to resource efficiency and the development of the circular economy (Ufitikirezi et al., 2024).

Agricultural wastes, such as straw, stalks, fibrous residues, husks and cobs, constitute a significant part of the waste that can be recovered through various techniques, being able to be transformed into fuels and value-added materials (Ufitikirezi et al., 2024; Capanoglu et al., 2022; Wazed Ali et al., 2022). Through such an approach, the circular economy aims to minimize the quantities of waste generated, by optimizing their superior use, through viable processes, in order to increase their value and establish circular practices in the agri-food sector.

At the same time, it promotes the conservation and economic value of products, trying to extend the maximum lifespan of their components and obtain the highest possible added value (Coelho Vianna et al., 2024).

In the spirit of the principles of the circular economy, within the experimental research presented in this paper, the aim is to obtain innovative construction materials in the form of covering products. In order to achieve higher added value, will be integrated two natural local agro-industrial by-products, namely rice husks - plant material resulting from the food industry,

and industrial hemp - in the form of yarn, resulting from the use of seeds in the food sector, in the textile industry, etc.

Rice, one of the staple foods for almost half of the world's population, is cultivated on all continents, in over 100 countries (Pradhan et al., 2024), resulting in one of the abundant natural resources, namely rice husks.

However, this natural by-product is usually abandoned in a post-harvest area, resulting in an average of 2 million tons accumulated per year (Raki-in et al., 2021), a quantity that, if stored uncontrolled, seriously affects the environment (Raki-in et al., 2021; Milawarni et al., 2023; Pradhan et al., 2024).

The construction industry can promote sustainable development and minimize this type of natural agro-industrial by-product considered as waste, by incorporating rice husks into various construction products.

For example, embedded into bricks and blocks as a lightweight aggregate, rice husks lead to improved thermal properties and reduced overall weight (Selvaranjan et al., 2021).

Also, using this natural material as a filler or binder in the production of insulation materials, such as panels, boards or filler insulation, improves the thermal and acoustic insulation properties of the resulting products (Muthuraj et al., 2019; Sembiring et al., 2016; Aravind et al., 2020).

In other cases, combining rice husks with other lignocellulosic materials and binders has resulted in particleboards and fiberboards, which can be used in various construction applications, such as flooring, wall panels and furniture components (Manatura et al., 2023). Moreover, the integrating of these husks into a matrix of natural or synthetic polymers, as a reinforcing material, results in biocomposites that can be used in a number of other construction applications, such as decking, cladding and interior finishes (Faruk et al., 2012; Wang et al., 2020).

As for hemp, especially in the form of hemp pulp, it is currently being exploited through integration into numerous types of building materials, with the recognized role of improving both the thermal insulation properties and acoustic performance of the resulting building product, as well as the humidity and durability of the environment with which it comes into contact.

Among the numerous hemp-containing materials, for example, a few products recognized as being used/usable in construction are mentioned, namely: Hempcrete, a lightweight material obtained by mixing hemp powder with a thermally insulating lime-based binder, the resulting mixture being able to be used as a non-load-bearing filling material in walls, floors and roofs, with very good thermal and acoustic insulation and the ability to regulate humidity levels (Arrigoni et al., 2017; Demir et al., 2020; Piot et al., 2017; Yadav et. al, 2022); insulation materials in the form of panels, sticks or filling insulation (Abdellatef et al., 2020), with good thermal and acoustic insulation properties; boards usable as floors, wall panels and even furniture components, made by mixing hemp pulp with other lignocellulosic materials and binders; floors, cladding elements and interior finishes, practically biocomposite materials resulting from combining hemp pulp with a matrix of synthetic or natural polymers (Cigasova et al., 2015; Dhakal et al., 2015; Requile et al., 2019); hemp concrete which, although it does not have high strength or portability characteristics, has low thermal conductivity, high water vapor permeability, fire resistance, biodegradation, good acoustic properties and therefore can be used for walls, roofs and floors, for insulating walls on their outer side (Gołębiewski, 2017).

All these examples regarding the creation of biocomposite products usable/used in the construction field and the study of their characteristics clearly demonstrate, at an international level, the interest of researchers in obtaining, studying and promoting for use new construction materials that contain natural agro-industrial by-products, with properties comparable to those of traditional materials, made on a synthetic basis.

MATERIALS AND METHODS

In this work, rice husks (Figure 1) and hemp threads (Figure 2) were used, natural agro-industrial by-products provided by local producers.

Figure 1. Rice husks

Figure 2. Hemp fiber

The experimental research aimed at the superior valorization of these natural materials by obtaining innovative materials with ecological characteristics/coating products, with potential for use in the construction field.

Two series of innovative products were obtained and studied, namely: Series 1 - products with added rice husk content and Series 2 - products with mixed content of rice husk and hemp fibers.

In Series 1, two innovative basic products were first obtained, by embedding rice husks in an acrylic binder.

From a compositional point of view, these biocomposite materials were designed in such a way as to mainly study the influence of the constituent elements - the synthetic binder and the vegetable component. Two variants of acrylic resins were used as binder, denoted by R1 - acrylic base for interior/exterior coatings, respectively R2 - silicone acrylic base for interior/exterior coatings, the mass ratio of mixing rice husks: binder being 1:10, resulting in the first stage the products SP1RI, SP1R2.

In addition to the influence that compositional factors have on the main characteristics of the products, it was also aimed to study the influence that the method of preparing the plant material before application would have in this regard. For this purpose, a pre-reaction time was introduced, during which the binder and natural components were maintained in contact, before the application of the biocomposite.

The notion of pre-reaction time, specific to two-component anti-corrosion epoxy protections, is the time in which, before being put into operation, the two components are mixed, homogenized and left to interact, the lack or non-compliance with this time affecting the characteristics and performance of the anti-corrosion protection. Starting from this principle, in the case of coatings made from innovative products that integrated the rice husk, a pre-reaction time of 30 minutes was established for the rice husk-binder mixture. Thus, starting from the initial products, SP1R1 and SP1R2, without pre-reaction time, the corresponding products, SP1R1/30, SP1R2/30, were made, for which the pre-reaction time of 30 minutes was considered.

In order to determine the influence that the nature of the embedded agro-industrial by-products has on the characteristics of the resulting bilayer coatings, additional biocomposites with mixed plant content were made and tested.

Series 2 of innovative materials was made respecting, in principle, the same approach as in the case of the products in the Series 1.

This time, four basic innovative products with mixed plant content were initially obtained from rice husks and hemp threads of an average length of approx. 1 cm, embedded in the same types of binders, namely resin R1 and R2, respectively. The length at which the hemp threads were cut, and the content of this natural component were conditioned by obtaining a homogeneous biocomposite material, with good workability when applied to a concrete substrate. The mixing ratios of the hemp:rice husks:binder components were 1:2.5:40, resulting in the products marked SP1R1T and SP1R2T, and 1:3:40, respectively, for the products marked SP2R1T and SP2R2T.

As in the case of the innovative products in Series 1, for the products in Series 2, the influence of the 30-minute pre-reaction time between the synthetic binder and the mixture of

the two natural agro-industrial by-products was studied. This resulted in four other new recipes of biocomposite materials, denoted as follows: SP1R1T/30, SP1R2T/30, SP2R1T/30 and SP2R2T/30.

It is worth emphasizing that, from the beginning, for each product obtained in the two series, there was compatibility between the synthetic and vegetable components, resulting in homogeneous materials with good workability. As a result, each of the twelve biocomposites was applied to concrete support surfaces, in two layers, with an interval of 24 hours between them, the coatings being applied and subsequently maintained under standard laboratory atmospheric conditions, namely at a temperature of 23 ± 2°C and a relative air humidity of 50 ± 5%.

At this stage of the experimental research, the innovative products obtained were characterized by determining the average total thickness, and adhesion to concrete, a first evaluation of the resulting coatings, from the point of view of the potential for use in construction. Considering the organic, acrylic nature of the R1 and R2 binders used, as well as the average values of the thicknesses of the resulting bilayer coatings, ranging between 3.26 and 6.43 mm, without taking into account at this stage the influence of the pre-reaction time on the total thickness of the coating, the determinations were carried out referring to the condition specified in the technical specification SR EN 15824 - "Specifications for external renders and internal plasters based on organic binders", and the test conditions were those provided for in SR EN 1542 - "Products and systems for the protection and repair of concrete structures. Test methods. Measurement of bond strength by pull-off".

Referring to these documentations, the resulting coatings being atypical in terms of component materials, it was considered appropriate to monitor the evolution of the adhesion values to concrete for 56 days, establishing the measurements to be carried out at 7, 28 and 56 days after application. Since for each series of products obtained, the appearance of the bilayer coatings is very similar, regardless of the resin used, the absence or presence of pre-reaction time, in the following, exemplary images of the samples made will be presented.

Thus, for the products in the Series 1, the appearance of the SP1R2/30 coating is presented as an example, with the addition of rice husks and pre-reaction time, as well as the way the coating breaks when performing adhesion by pulling, after 7 days from the application (Figure 3), respectively after 28 days from the application (Figure 4).

For the coatings in Series 1, without analyzing for the moment the influence of the pre-reaction time, the average thickness values varied between 3.26 mm and 6.43 mm, and the average adhesion values to the concrete substrate, over the 56 days, between 0.22 MPa and 0.36 MPa (Figure 5).

Figure 3. Appearance of the SP1R2/30 coating containing rice husks and the way it breaks when pulled off, for determining adhesion at 7 days

Figure 4. Appearance of the SP1R2/30 coating containing rice husks and the way it breaks when pulled off, for determining adhesion at 28 days

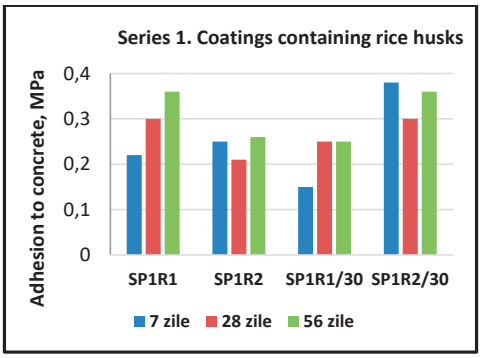

Figure 5. Variation of the adhesion to concrete for the two-layer coatings of Series 1

Given the diversity of materials used to obtain products from the Series 2 and, as a result, the possibility of particular manifestations of these coatings over time, adhesion to the substrate was monitored at shorter time intervals compared to previous cases, namely at 7, 28, 42 and 56 days after the application of the two-layer coatings on concrete substrate surfaces. Also in Series 2, regardless of the resin used, the absence or presence of pre-reaction time, the coatings obtained had a very similar external appearance. As a result, the appearance of the SP1R1T coating, having the hemp: rice husks: binder ratio of 1: 2.5: 40 (Figure 6), respectively of the SP2R1T/30 coating, characterized by the hemp: rice husks: binder ratio of 1:2.5:40 (Figure 7), are presented below as examples, as well as the way the coatings break when performing adhesion by pulling, 28 days after application.

Figure 6. Appearance of the SP1R1T coating, containing rice husks and hemp fibers, and the way it breaks when pulled off, for determining adhesion at 28 days

Figure 7. Appearance of the SP2R1T/30 coating, containing rice husks and hemp fibers, and the way it breaks when pulled off, for determining adhesion at 28 days

For the coatings in Series 2, without analyzing at this time the influence of the pre-reaction time, the average values of the thickness of the bilayer coatings containing rice husks and hemp fibers varied between 3.81 mm and 5.09 mm, and the average values of the adhesions to the concrete support, during the 56 days, between 0.35 MPa and 0.39 MPa (Figure 8).

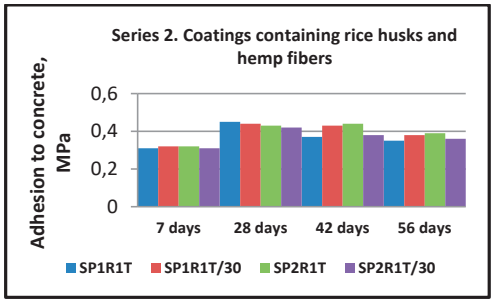

Figure 8. Variation of the adhesion to concrete for the two-layer coatings of Series 2

RESULTS AND DISCUSSIONS

In the experimental research presented in this paper, was mainly studied the possibility of obtaining biocomposite materials, by integrating, in acrylic binders, rice husks or/and mixtures in variable proportions of rice husks and hemp fibers, from the perspective of material compatibility.

At the same time, the evaluation of the potential for use in construction of the obtained materials, in the form of plaster-type coatings, was pursued. The extent to which the adhesion of the resulting coatings to concrete was influenced by

the type and content of the two natural materials, by their application conditions, meaning by the pre-reaction time between the main components, was also studied.

A first response considered favorable under the mentioned aspects was the existence of compatibility between the specified natural and synthetic materials, resulting in biocomposites containing rice husks (SP1R1, SP1R2, SP1R1/30 and SP1R2/30), respectively in those with mixed rice husks and hemp threads (SP1R1T, SP2R1T, SP1R1T/30 and SP2R1T/30). The establishment of the usability of the eight innovative product variants was achieved by analyzing and correlating the experimental results obtained after determining the average total thickness and the adhesion to concrete of each bilayer coating.

Thus, a further positive outcome was the formation of two-layer, rustic-style plaster coatings after applying both categories of biocomposites onto concrete surfaces. The coatings containing rice husks achieved average total thicknesses ranging from 3.26 mm to 6.43 mm, while those with mixed plant content exhibited thicknesses between 3.81 mm and 5.09 mm.

The third favorable aspect was that regarding the potential for use in construction of this category of innovative plaster-type coatings, given the good adhesion to the concrete support surface. This statement is supported by the fact that, at the end of the monitoring period of the coatings, after 56 days from application, the condition specified in the technical specification SR EN 15824 was met, according to which the adhesion of a plaster with an organic binder must be greater than or at least equal to 0.3 MPa.

In this context, from the point of view of adhesion to the support, we consider that six of the eight variants of the innovative coatings obtained have a potential for use in construction, however, additional research is necessary to achieve an experimentally substantiated, detailed and multidisciplinary characterization of the respective coatings. This potential for use as a multidisciplinary coating is suggested by the specific characteristics that each of the two integrated natural agro-industrial by-products has, implicitly by the properties that they are likely to confer on the products, respectively the plasters in which they are included.

All these favorable and encouraging aspects being specified, it is interesting and useful to highlight a series of specific aspects observed regarding the effects of integrating hemp fibers into the composition of such innovative materials.

Reference is made to a series of findings, resulting from the comparison of biocomposites/coatings containing only rice husks vs. those with mixed content, of rice husks and hemp threads.

The first finding is the existence of a good interaction between plant materials and the synthetic binder, with the obtaining of biocomposites with good workability. This allowed their application in two layers on concrete support surfaces. The resulting average adhesion values, at 28 days after application, generally had an upward trend in all eight coatings, those with mixed plant content having higher adhesion than those of coatings containing only rice husks. All the favorable aspects were highlighted during the determination of the adhesion by pulling, in most cases, through an adhesive rupture mode, between the coating and the concrete, which indicated a cohesive character of the coating, with a potential for continued increase in adhesion to the substrate over time.

However, by the end of the monitoring of the adhesion to the substrate for the two series of coatings, 56 days after their application, a slow but clearly different evolution of this characteristic was observed. Namely, if in the case of the coatings in Series 1, containing exclusively rice husks, the adhesions had an upward trend until the end of the analyzed period, in the case of the coatings in Series 2, in which hemp threads were also introduced, the trend was slightly downward, for all four coatings.

Even in this context, the final values of the average adhesions to concrete were higher for coatings with mixed vegetal content, values that even though in a decreasing trend, were above the limit value of 0.3 MPa.

We consider that such an evolution of the adhesion values was generated by the synergistic effect of two aspects: firstly, by the compositional difference, by the addition of hemp threads, and secondly, by the introduction of the pre-reaction time. Comparing the

experimental results obtained on the coatings from the two series, it is found that the effects of the second factor were highlighted both by the increase in the average thickness values of the coatings, and by the average values of the adhesions to the support, during the 56 days. We consider it also useful to point out that the cumulative effect of the two mentioned factors was more pronounced in the case of coatings containing hemp, which underlines the importance of this type of agro-industrial by-product in ensuring compatibility and maintaining good interaction between the natural and synthetic components of this type of innovative coating.

CONCLUSIONS

The paper presents experimental research that had as its main purpose the study of the possibility of obtaining biocomposite materials, by integrating, in a synthetic binder, two local natural agro-industrial by-products, namely rice husks or/and hemp fibres, from the perspective of their compatibility and interaction, as well as the possibility of using the obtained materials in construction.

Eight innovative products were obtained and studied: four products with rice husk content, and four products with mixed content of rice husk and hemp fibers.

In addition to the influence that compositional factors have on the main characteristics of the coatings, it was also aimed to study the influence that the method of preparing the plant material before application would have in this regard. For this purpose, a pre-reaction time of 30 minutes was introduced, during which the binder and natural components were maintained in contact, before application of the resulting biocomposites.

From the point of view of adhesion to the concrete support, we consider that six of the eight variants of the innovative coatings obtained have a potential for use in construction. However, additional research is necessary to achieve an experimentally detailed and multidisciplinary characterization of the respective coatings. After applying each biocomposite–on concrete surfaces, two-layer plaster-type coatings with a rustic appearance were obtained.

At the end of monitoring the adhesion of the coatings to the concrete substrate, it was observed that in the case of those containing exclusively rice husks, the adhesions had an upward trend, and in the case of those in which hemp fibers were also introduced, the trend was slightly downward. Even so, the values fell within the adhesion limits provided by the specifications for classic organic plasters for concrete. Referring to the compatibility and interaction between the synthetic binder and the two natural materials, mainly the hemp fibers, that this research pointed out, we consider that additional research are necessary to establish the long-term evolution of these aspects.

Abstract

The work aimed to show that it is feasible to integrate ceramic waste from the construction industry and demolitions into the content of concrete recipes, as a partial replacement for natural aggregates in standard concrete recipes. The integration of these wastes into the composition of concrete is of particular importance because, on the one hand, we reduce the amount of waste resulting from the construction industry, and on the other hand, we achieve savings of raw materials used in the manufacture of concrete, coming from exhaustible natural resources. Compared to the standard C16/20 concrete recipe used as the control sample in the experimental recipe, the natural aggregates of size 4-8 mm were partially replaced by 50% ceramic waste. Various physical-mechanical tests were performed, such as determining the density of fresh concrete, determining the compressive strength of concrete containing ceramic waste compared to a standard concrete recipe containing natural aggregate. Following tests on experimental recipes, very good results were obtained in determining the compressive strength, which were similar to the test results on standard concrete recipes.

Key words*: ceramic waste, natural aggregates, concrete.*

INTRODUCTION

Concrete, which due to its qualities, strength, durability, versatility and the fact that it can be cast into almost any shape and reproducing any surface texture, is the most used construction material in the world (Shelton et al., 1982). Concrete is a mixture of materials composed of 60-75% sand and gravel, 15-20% water and 10-15% binders, which is the basic ingredient that binds the composition. The Romans used a volcanic ash as a binder in the composition of concrete but currently, the binder used is called Portland cement (Gagg, 2014). Given that aggregates occupy from 60 to 75% of the volume of concrete, this influences its physical-mechanical properties. The strength of normal concrete is affected by the size of the aggregates, therefore optimal dosage is very important to obtain the best results (Albarwary et al., 2017). Very rapid urbanization, coupled with population growth, has led to an increasing consumption of building materials (Kamali et al., 2019). The increase in global consumption of construction materials has inevitably led to high pollutant emissions and an increasing generation of waste. The production of cement, steel and concrete has the heaviest environmental burden during their manufacture (Huang et al., 2020). The construction industry is the largest consumer of material resources (40-60% of the total raw material extractions), water, and energy (40% of energy consumption) (Spence & Mulligan, 1995). Intensive activities in the construction industry are considered to be the main responsible for the scarcity of natural resources (Ghisellini et al., 2018), including water, crushed aggregates , increased pollution and demands for materials (Eray et al., 2019).
Construction waste is primarily caused by demolition activities ,equivalent to 40% of total waste (de Castro & de Brito, 2013) almost half of the total waste generated worldwide (Nasir et al., 2017), causing both noise and pollution (Çimen, 2021). The construction industry is the main generator of waste, accounting for up to 40% of urban solid waste (Chen et al., 2019). Due to the high consumption of natural aggregates, the use of recycled aggregates from construction and demolition waste in concrete is becoming increasingly widespread these days, with concrete made with recycled aggregates

potentially becoming the most widely used material in the coming years (Chitra, 2018).

The use of construction and demolition waste in concrete manufacturing, especially as raw materials replacing natural aggregates, is one of the most efficient ways to utilize these wastes (M. Ramesh & Kumaravel, 2014). Ceramic aggregate is resistant to abrasion. Ceramic products also have high strength, wear resistance over time, etc (Ray et al., 2021). Therefore, the use of these industrial wastes in concrete as a replacement for aggregates can be an effective solution in the recycling process of waste from construction and demolition (Ay & Ünal, 2000).

Aggregates from ceramic waste have similar properties to those from natural rocks (Halicka et al., 2013).

Unlike glass and rubber waste, ceramic waste has a porous structure that allows binder penetration, improving compressive strength in concrete (Sabbrojjaman et al., 2024).

Few studies have explored using ceramic waste as an aggregate substitute in concrete. Given that ceramic waste accounts for about 30% of daily tile production, or roughly 22 billion tons annually worldwide (Ahmad et al., 2023; Alyousef et al., 2021), its incorporation into concrete could help conserve natural resources and benefit the environment (Meena et al., 2022).

The rising cement production over the years, as shown in Figure 1, and the corresponding increase in concrete production, underscore the need to incorporate greater amounts of recycled aggregates in concrete (Production Volume of Cement Worldwide from 1995 to 2023, n.d.).

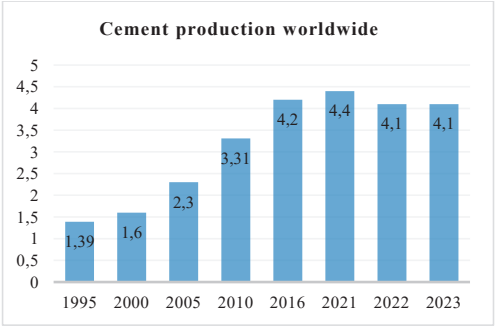

Figure 1.Cement production worldwide from 1995 to 2023 (Billion metric tons)

MATERIALS AND METHODS

According to a study published by Eurostat in 2018, an estimated amount of construction and demolition waste is generated in the European Union at over 850 million tons (Chapter 36:Production and Management - The Problem, n.d.) .This figure represents approximately 25-30% of all waste generated in the EU in 2020, reaching approximately 37.5% of total waste (Villoria Sáez & Osmani, 2019). Waste management is essential because the construction industry generates huge amounts of waste (Can & Taş, 2022). As the construction industry has a major influence on other industries, waste reuse can make a significant contribution to the circular economy (Aboginije et al., 2021). A medium and long-term estimate shows that almost 80% of the construction and demolition waste generated is recyclable and usable (Begum et al., 2010; Huang et al., 2020).

To practically demonstrate the usefulness of various wastes from the construction industry and from demolitions, it is necessary to manufacture some experimental recipes containing waste and then to compare various parameters of these recipes with the parameters of standard concrete recipes.

To do this, scraps of ceramic products (plates and tiles) from construction and demolition waste, 4-8 mm in size, shown in Figure 2, were used.

The samples will be tested for compression resistance and their density will be calculated.

The device for testing compressive strength is the Matest C058-05N automatic concrete press with a maximum capacity of 2000KN, which is shown in Figure 3.

Figure 2. Aggregates from ceramic waste size 4-8 mm

Figure 3. Matest 2000KN concrete press

RESULTS AND DISCUSSIONS

To verify and test the experimental recipes with ceramic waste content from construction and demolition, as a control, a sample prepared according to the standard recipe of concrete C16/20 is used.

C16/20 concrete, also called B250 in the past, is the most popular class of concrete used in constructions in Romania. Mainly used in the structures of houses and in the foundations of low-rise buildings, concrete class C16/20 (B250), is a common concrete preferred in general for civil constructions and various related construction elements.

C16/20 (B250) concrete is used for the construction of foundations, beams, columns, belts, sidewalks and other elements (C16/20(B250) concrete n.d.). The components of the standard recipe for concrete C16/20 in Table 1 are according to the recipe from the concrete station belonging to S.C. ELIS PAVAJE S.A Petrești, the quantities being presented in cubic meters (m^3) but also in percentage of 0.5% of this quantity, being used in the preparation of experimental recipes.

Table 1. Concrete recipe C16/20

Component	kg/m^3	0.5% (kg)
Cement 42.5 R	295	1.475
Aggregate 0-4 mm 43%	789	3.945
Aggregate 4-8 mm 20%	367	1.835
Aggregate 8-16 mm 37%	679	3.395
Water	170	0.85

Figure 4 shows photos of the grades and the cement used in the preparation of the standard C16/20 concrete recipe as well as in the composition of the experimental recipes with the addition of ceramic waste and polystyrene.

Aggregates in concrete recipes can be:

- Natural aggregates from ballast pits - material excavated from pits or riverbeds consists of a mixture of sand and gravel;
- Natural aggregates from quarries - the rock (raw material) is crushed with a crusher and sorted by size using a sorting station.

The aggregates used in these recipes are ballast aggregates.

Figure 4. Components of concrete recipes

In order to prepare these experimental recipes, waste ceramic products from construction and demolition were used (sandstones and earthenware), as a partial substitute for some aggregates. Figure 5 shows the process of crushing ceramic waste manually using a Hammer.

Figure 5. The grinding process of ceramic waste

To sort the crushed ceramic remains, an electric sieving device was used to determine the granularity, as shown in Figure 6. Following this size separation process, the required quantity was obtained to replace the standard 4-8 mm aggregate fraction in the experimental recipe.

Figure 6. Size sorting of shredded ceramic waste

The Figure 7 shows how to prepare the experimental recipes manually by incorporating the waste prepared in the previous stage. These wastes used replaced the 4-8 mm grade with 50% ceramic waste in the experimental recipe.

Figure 7. Preparation of experimental recipes

Figure 8 shows the manual homogenization of the experimental recipe components with the help of a trowel and Table 2 presents the experimental recipe components.

Table 2. Experimental concrete recipe

Component	Quantity (kg)
Cement	1.475
0-4 mm river aggregate	3.945
4-8 mm river aggregate	0.9175
4-8 mm ceramic aggregate	0.9175
8-16 mm river aggregate	3.395
Water	0.85

Figure 8. Homogenization of experimental recipe components

Figure 9 shows the concrete samples resulting from the preparation of the experimental recipes, poured into standard models (3 samples to be tested at 7 days and 3 samples to be tested at 28 days), then it is kept for 24 hours in these patterns, after which it is removed and placed in the sample storage basin for 28 days at a constant temperature of 20 degrees Celsius, according to NE 012/2-2010.

Or performed compressive strength measurement tests 7 days and 28 days after their manufacture according to SR EN 12390-3:2002 Test on hardened concrete. Part 3: Compressive strength of specimens.

The tests were done for the standard recipe as well as for the experimental recipes. Our determinations of the fresh and hardened concrete densities of these samples were also made. Figure 10 shows the tests to determine the compressive strength carried out.

Figure 9. Concrete samples immersed in the storage basin

Following the tests performed regarding the compressive strength at 7 days and at 28 days, as well as the density, the results presented in Table 3 were obtained.

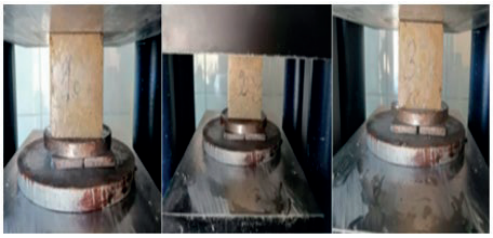

Figure 10. Performing compressive strength tests

Table 3. The results of the tests performed

Concrete type	Sample density (kg/m^3)	Compressive strength 7 days (MPA)	Compressive strength 28 days (MPa)
C16/20	2310	11.850	17.410
C16/20+ ceramic	2274	13.486	19.456

Compared to other research on the use of ceramic waste as a partial substitute for natural aggregates in concrete composition in terms of compressive strength, the basic trend is not significantly different from conventional concrete retention with natural aggregates.
Table 4 presents previous results of researchers who have addressed the topic of partial replacement of natural aggregates with ceramic waste, using different concrete recipes.

Table 4. Results of tests conducted by other researchers

Contains ceramic waste	Results	Authors
For 0% replacement	32.29 MPa	(Bommisetty et al., 2019)
For 25% replacement	33.48 MPa	(Bommisetty et al., 2019)
For 0% replacement	39 MPa	(Siddique et al., 2018)
For 40% replacement	45.16 MPa	(Siddique et al., 2018)
For 0% replacement	52.9 MPa	(Nepomuceno et al., 2018)
For 50% replacement	48.1 MPa	(Nepomuceno et al., 2018)
For 0% replacement	23 MPa	(Awoyera et al., 2018)
For 50% replacement	25 MPa	(Awoyera et al., 2018)
For 0% replacement	46.2 MPa	(Anderson et al., 2016)
For 50% replacement	45.2 MPa	(Anderson et al., 2016)

CONCLUSIONS

Preliminary tests using recipes incorporating construction industry waste were conducted, providing reference quantities for developing subsequent experimental formulations.
The use of construction and demolition of waste offers several benefits:

- Reduction of waste generated by industry;
- Conservation of non-renewable natural resources;
- Decreased demand for storage space.

Recommend and support the idea of using waste in the construction industry in the concrete manufacturing process and the search for the new experimental recipe with the highest possible content of waste.
The results of the tests performed on these experimental concrete recipes confirm that the partial replacement of waste with waste (the natural aggregates of size 4-8 mm were partially replaced by 50% with ceramic waste) is viable and can successfully replace these components in the composition of the concrete. In future experiments, it is intended to integrate as much waste from construction and demolition into the composition of concrete to use them and to get results as close to standard recipes.
The compressive strength of experimental concrete containing ceramic waste increased by up to 12% compared to standard concrete.
The results obtained show that research can be continued by progressively integrating increasing amounts of ceramic waste as a substitute for natural aggregates in the concrete structure. Once this research is continued and practically demonstrated, new paragraphs can be drawn up in construction standards so that ceramic waste can become a more common choice among recycled aggregates.
Future studies should evaluate the long-term behavior of ceramic waste concrete, including freeze-thaw resistance, shrinkage, water absorption, and sulfate attack resistance to ensure its practical application in various environmental conditions.

ACKNOWLEDGEMENTS

This research activity was carried out with the support of SC ELIS PAVAJE SRL, a company

whose object of activity is the manufacture of paving stones and various communication paths, which uses various waste from CDW in their manufacturing process, and which shows a great interest in using as much waste as possible in their products.

Abstract

Significant progress in water conservation and environmental preservation has been made through efforts by worldwide authorities in ecological water management. However, unexpected water pollution events continue to threaten water quality and biodiversity. Monitoring pollution levels in surface waters is essential for supporting aquatic ecosystem services and sustainability. This study aimed to quantify heavy metal pollution in several sampling sites to assess water quality and its impact on biodiversity. Elements like As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, and Zn were analyzed using ICP-OES from samples collected during low-water (September 2024) and high-water (October 2024) conditions due to an upstream flood event. Results were compared to Romanian water quality standards. During low-water conditions, heavy metal concentrations were mostly below the limit for Quality Class I, except for Cd, which exceeded this limit. After the flood event, concentrations of most metals were within the Quality Class I limit. Still, Cd, Fe, and Pb showed varied results, with Ni levels ranging from very good to inferior water quality. Continuous monitoring is needed to prevent further degradation of delta ecosystems.

Key words*: concentration, flood event, heavy metal pollution, quality standard, surface water.*

INTRODUCTION

Fluvial-dominated delta ecosystems are vulnerable to the impacts of climate change induced by exogenous terrestrial pressures (droughts, river floods, intense storms, sediment starvation) and/or exogenous marine influences (erosion, sea-level rise, coastal flooding, saltwater intrusion) (Syvitski et al., 2009). Moreover, anthropogenic stressors represented by industrialization, urbanization, intensified agricultural practices and human intervention in catchment and delta plain land use contributed to significant environmental concerns, including water pollution (Nicholls et al., 2008). These ecosystems accumulate inorganic and organic compounds, heavy metals, nutrients, waste, plastic, pathogens, sediments, and other pollutants that heavily impact water quality (De Jonge, 2002). All these contaminants have harmful consequences on aquatic life, impeding vulnerable ecosystems and threatening biodiversity. Among chemical compounds, special attention must be paid to the toxic heavy metals from water and sediments, that can manifest bioaccumulation and biomagnification processing (Kumar et al., 2017) through the food web, compromising wildlife and ultimately affecting human health (Tovar-Sánchez et al., 2018). In addition to human-related activities, poor water quality may be endangered by flow rate fluctuations, precipitation, intense drought, weathering, soil erosion, etc. Thereby, successfully monitoring and assessing water quality and ecological status involves a multi-faceted approach that covers a wide range of physical and bio-geo-chemical variables and biotics of water in space and time (Chapman & Sullivan, 2022). In this context of concerns about the impacts of climate change on the fate of contaminants through unpredictable weather events, the subject of this scientific paper is included. The Danube River is the second-largest river basin in Europe, after the Volga River (Russia), emptying into the Danube Delta before reaching the Black Sea (Panin et al., 2016). The Danube River runs for a length of 2857 km, drains an area of roughly 801463 km^2, and traverses through or bordering ten European countries. Due to its pan-European character in

socio-economic and cultural aspects (Padło et al., 2021) had attracted administrative authorities and technical governmental departments from several involved countries, supporting and expressing sustain for the environmental policies related to good environmental quality of natural resources. On its lower course (on the Romanian territory), the Danube has three branches: Chilia, Sulina, and Sf. Gheorghe. Chilia, the northern branch, has a length of 104 km, transporting 60% of the river's water and silt. Sulina, the middle arm, with a length of 71 km and carrying 18% of the Danube's flow, is considered the only navigable arm of the Danube, where large ships can enter. The southern branch, namely, Sf. Gheorghe Arm has a length of 112 km carrying 22% of the Danube's alluvial input. In the last few years, acute hydrological events have become more prevalent in the Danube River Basin, due to precipitation in the watershed, and/or a prolonged dry season. For example, the lower course of the Danube River recorded both historical high-flows (*i.e.,* 1970, 1991, 1998, 2002, 2005, 2010, 2013, 2014, 2018, 2019, 2024) and low-flows (*i.e.,* 1921, 2003, 2007, 2010, 2011,2012, 2015, 2017, 2018, 2019, 2020, 2021, 2022, 2023, 2024) than the multi-year average. It is well known that the adaptive capacity and resilience of rivers are attributable to their dynamic characteristic and self-purification potential (Bennett & Rathbun, 1971). However, the acute effects of the Danube River flow fluctuations should not be overlooked, since they may have further ecological repercussions in the stable state of the Danube Delta shallow freshwater lakes assignable to extreme weather and climate events. Data on the flow of the Danube River in Romania are monitored by the National Authority for Romanian Waters and various meteorological and hydrological institutions. The river flow usually varies depending on the season and climatic conditions, and the values can be influenced by factors such as precipitation, snowmelt, the river regime in the upstream surrounding basins etc. The Danube Delta's surface area is roughly 4180 km^2, of which 3510 km^2 stands on Romanian territory. The delta evolved mainly from alternating layers of silt and sand, delivered by the Danube River over the past 10 to 12 thousand years, creating the complex network of channels, islands, and wetlands we see today. Its evolution is closely linked to river dynamics, sediment transport, and changes in sea levels (Gâștescu & Știucă, 2008). The delta is in a state of continuous change, shaped by both natural influences and human activity. It continues to grow and evolve as sediment accumulates, making it one of the most dynamic and recent landforms. The process of its formation is ongoing, with new islands and channels forming, while others may erode, resulting in a landscape that is both young and active. The present study aims to investigate seasonal changes in water quality and decipher the upstream flood event contribution of the lower Danube River to the spatial distribution of heavy metals in the water quality of several sampling sites investigated at the river bifurcations, including several Danube Delta lakes. Accordingly, the contents of ten (As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, and Zn) technophile elements (Ptitsyn, 2018) were analyzed. Consequently, systematic monitoring and assessment of the water quality's status is mandatory in deltaic aquatic environments of inestimable value from an ecological and unique biodiversity point of view.

MATERIALS AND METHODS

Study area

This investigation was performed at the Danube River bifurcations within its delta, specifically, at the *Ceatal Izmail* and the *Ceatal Sf. Gheorghe*, including several lakes attributed to the *Rusca-Gorgova-Uzlina* Hydrographic Unit, Danube Delta Romania. The selected sampling sites for this study illustrate a relevant example of the potential environmental impact of climate change (such as extreme weather events, including drought and flooding, wildfires, heavy rainfall, sea-level rise etc.). The Danube's bifurcations play an important role in the hydrological connectivity between the river's distributary branches and inter-distributary channels, streams, and lakes of the entire Danube Delta edifice. The *Rusca-Gorgova-Uzlina* Hydrographic Unit is situated in the western floodplain area, between the Sulina (north) and the Sf. Gheorghe (south) branches, and east of the Letea-Caraorman Spit (Panin et al., 2016) and is mainly characterized by a

relatively dynamic hydrographic network influenced by the two above-mentioned branches, including, the *Litcov Canal* and the *Perivolovca Stream*.

Field sampling and data analysis

Field measurements and sample collection, preservation, preparation, and storage before any laboratory analyses were accomplished at the R/V "Istros" owed by the National Institute for Research and Development of Marine Geology and Geoecology-GeoEcoMar, Romania. In this study, several spot water samples were considered in two distinct hydrological periods of the Danube River's flow: low-water level (September 2024) and high-water level (October 2024) (Figure 1). During the low-water period (September), the Danube River's flow was at its lowest level, while a maximum amplitude was reached at the peak high-water stage (October), after an upstream flood event.

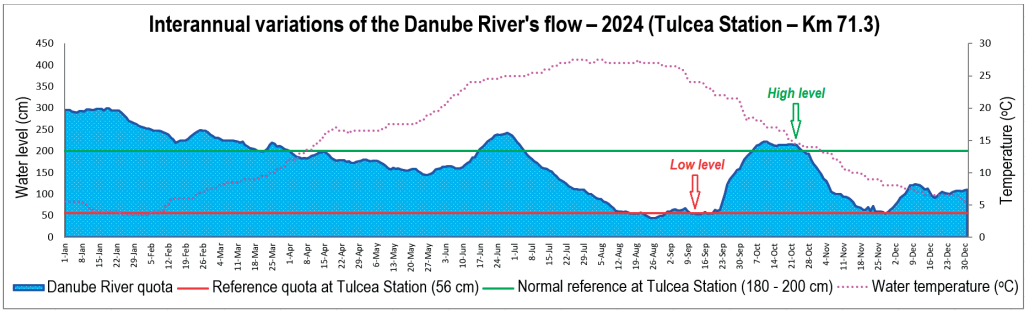

Figure. 1. Interannual variations of the Danube River's flow (Source Data: https://www.afdj.ro/ro/cotele-dunarii)

During the low-water period, the sampling sites were considered: *Ceatal Izmail, Ceatal Sf. Gheorghe*, including lakes such as *Uzlina, Isacova, Durnoliatca, Bleziuc-Pojarnia* and *Pojarnia* (Figure 2). Due to their proximity to the Sf. Gheorghe Branch alluvial input, these lakes are constantly filled, receiving appreciable amounts of water and silts. During the high-water period, the succeeding perimeters were investigated: *Ceatal Izmail*, *Ceatal Sf. Gheorghe*, *Cuzminţul Mare L., Rotund L., Rădăcinos L., Gorgova L., Gorgovăţ L., Potcoava de Sud L.*, *Litcov Canal* and *Old Danube River Meander* (Figure 2). The hydrological connection within these lakes varies mainly seasonally, alternating between relatively consistent connectivity with at least the *Old Danube River Meander via Litcov Canal*, and recurrent water deficiency (insufficient supply from rivers and streams), especially between lakes during the dry periods. The analysis to assess the environmental risk of heavy metals in freshwater deltaic environments was carried out using their spatial distribution, their content, and the possible origin of several investigated heavy metals. The sampling sites were chosen to determine the longitudinal distribution (along the upstream-downstream gradient of the Danube River bifurcations), including the horizontal distribution (along investigated lakes) of some specific heavy metals. For each site, 1-liter surface water samples for the chemical analyses were collected using sterile glass bottles at the sub-surface level (0-0.5 m) and close to the lake bottom. Nitric acid preservation of samples was performed in the field. Then, samples were filtered through a 0.45 µm membrane filter at the R/V "Istros" laboratory. After filtering, the bottle samples were plastic-bagged and iced quickly. Sample bottles were shipped to the analytical laboratory. Water samples were analyzed at a special and accredited (SR EN ISO/IEC 17025:2018) water testing laboratory ("The Pollution Control Department - Laboratory for water, soil, waste control"), from the National Research-Development Institute for Industrial Ecology - ECOIND, Bucharest, Romania. Ten selected heavy metals, namely As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, and Zn, commonly present in surface waters due to anthropogenic sources were determined by inductively coupled plasma atomic emission spectroscopy (ICP-EOS). The method for the

quantification of heavy metals levels in surface waters was performed according to the SR EN ISO 11885:2009 standard. Evaluation of the heavy metals content in the investigated water samples and their potential risk assessment was done in comparison with the Romanian water quality standards (Order 161/2006).

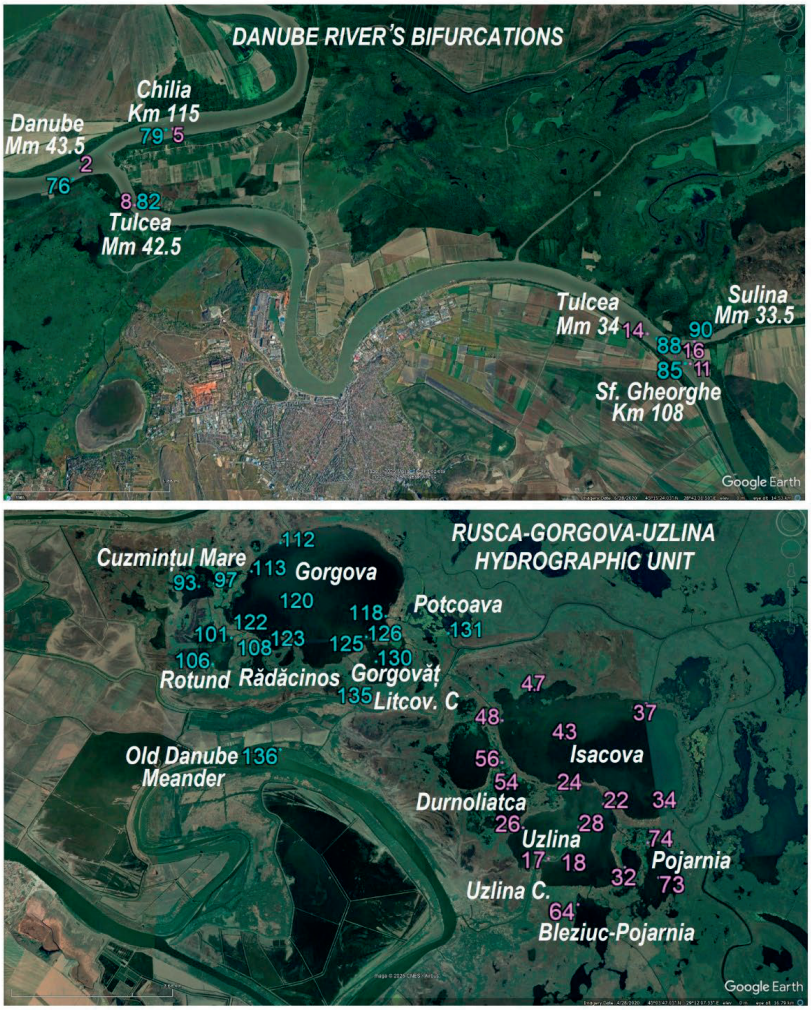

Figure 2. Location of the investigated perimeters. Pink dots mark the sampling sites during the low-water periods; Blue dots mark the sampling sites during the high-water periods (Base Map Source: https://www.google.com/maps/)

RESULTS AND DISCUSSIONS

Water quality and sustainable ecological ecosystems are fundamental to the proper functioning of the Danube River Delta region. The important benefits of healthy ecosystems contribute to maintaining good conditions for the wetlands and aquatic ecosystems of the Danube Delta which are of international ecological importance, being recognized worldwide as UNESCO World Heritage Sites, Biosphere Reserve, and Ramsar Site (Ramsar Convention, 1987). Correspondingly, water quality impairment may impact the ecosystem services provided by the Danube Delta (*i.e.,* unique and fascinating natural landscapes, habitats for flora and fauna species, reed resources, flood control, water supply,

agricultural uses, recreational activities, tourism, fishing activities, etc.) (Cazacu & Adamescu, 2017). The Danube Delta ecosystems are vulnerable to the water quality of the Danube River, which could be contaminated by numerous pollutants such as toxic heavy metals and organic contaminants from upstream and local sources. All these contaminants may often end up in the Danube River and subsequently, the coastal area of the Black Sea. Generally, the Danube River water quality status is mainly correlated to anthropogenic activities (industrial use, wastewater discharges, agricultural practices) (Chitescu et al., 2021), past hydro-technical projects on the river that restrict the flow of water and sediment discharge downstream (Panin & Jipa, 1998), and to some extent to climate change and hydroclimatic extremes (such as floods and rainstorms, droughts and heatwaves etc.) (Leščešen et al., 2024). Consequently, various natural and anthropogenic stressors could be responsible for water quality degradation, water biodiversity loss, and affected ecosystem services (Belacurencu, 2007). In this study, the contents of heavy metals *i.e.,* As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, and Zn, in water samples collected from several sampling locations of the Danube Delta area, were determined by Inductively Coupled Plasma-Optical Emission Spectrometry (ICP-EOS). The reference values were used to determine and evaluate the heavy metals' water quality status and spatial distribution in investigated freshwater samples. The Romanian current legislation imposed the reference values (Order 161/2006 - Normative regarding the classification of surface water quality to establish the ecological status of water bodies). The reference values represent the maximum permissible values of pollutant concentration corresponding to the five-surface water quality standard classes: Class I (Very Good), Class II (Good), Class III (Moderate), Class IV (Poor), and Class V (Bad).

Heavy metals' distribution during the low-water period investigation

During the low-water period (September 2024), at the *Ceatal Izmail* bifurcation area, the *Danube* carried a flow of approximately 2851 $m^3 \cdot s^{-1}$ at the entrance to the delta. This was unequally distributed between the *Tulcea* - 1701 $m^3 \cdot s^{-1}$ and *Chilia* - 1168 $m^3 \cdot s^{-1}$ branches, in favor of the *Tulcea* branch. The average velocities on the profiles were between 0.34 and 0.4 $m \cdot s^{-1}$. The riverbed was symmetrical in the *Ceatal Ismail* bifurcation area, with velocities homogeneously distributed on the cross sections. At the entrance to the second hydrographic node at the *Ceatal Sf. Gheorghe* bifurcation area, the flow of the *Tulcea* branch was at the time of measurements approximately 1572 $m^3 \cdot s^{-1}$. The flow was unequally distributed between the *Sulina* - 643 $m^3 \cdot s^{-1}$ and *Sf. Gheorghe* branches - 955 $m^3 \cdot s^{-1}$. The average velocities on the profiles were between the values of 0.39 and 0.5 $m \cdot s^{-1}$, with higher values on the *Sulina Canal*. The riverbed of the three branches was asymmetric in the bifurcation area at the *Ceatal Sf. Gheorghe*, with velocities homogeneously distributed on the cross sections. The chemical analyses were performed for 24 spot water samples collected from *Ceatal Izmail* (at the *Danube - Mm 43.5, Chilia Arm - Km 115, Tulcea Arm - Mm 43.5*), *Ceatal Sf.* Gheorghe (at the *Tulcea Arm - Mm 43, Sulina Arm - Mm 33.5, Sf. Gheorghe Arm - Km 108*), including lakes such as *Uzlina, Isacova, Durnoliatca, Bleziuc-Pojarnia* and *Pojarnia* (Figure 3). During the low-water period, the values of the investigated heavy metals pointed to an insignificant variability related to the heavy metals' distribution between the collection points, in both investigated Danube River bifurcations, as well as deltaic lakes. The results are illustrated in Table 1. Following the results obtained for samples taken under hydrodynamic conditions of low-water levels of the Danube, it can be observed that the investigated heavy metals such as: As, Co, Cr, Cu, Fe, Mn, Ni, Pb, and Zn recorded low concentrations, close to those corresponding to quality class I (very good condition), while, for the Cd element, the concentrations varied from one sampling station to another, incidentally exceeding the limit of class II (good condition). The dynamics of the investigated heavy metal concentrations during the low-water period will be presented further on.

Arsenic. The As concentration (µg/L) identified in the water samples presented a series of insignificant variations. Most of the obtained values were low, below the detection limit (< 2 µg/L), implicitly, below the limit corresponding to quality class I (10 µg/L).

Cadmium. The Cd concentration (µg/L) determined in the investigated water samples presented a series of interesting variations. Generally, most of the values were below the limit set for water quality Class I. However, values that slightly reached or exceeded the first two quality classes (Class I - 0.5 µg/L, Class II - 1 µg/L) were encountered in different samples taken from the investigated locations. For example, several sampling sites showed results that overpassed the limit set for water quality Class I (Figure 3): the *Sf. Gheorghe Arm - Km 108* (*DD24-11*), *Sulina Arm - Mm 33.5* (*DD24-16*), *Uzlina C.* (*DD24-17*), *Uzlina L.* (*DD24-26*) (situated close to the mouth of the connection canal with *Durnoliatca L.*), *Isacova L.* (*DD24-34*) (located in the south-eastern part of the lake, close to the mouth of the connection canal with *Perivolovca C.*), *Durnoliatca L.* (*DD24-49*) (located in the south-eastern part of the lake, close to the mouth of the connection canal with *Uzlina L.*) and *DD24-56* (situated in the northern part of the lake, close to the mouth of the connection canal with *Isăcel L.*). Alternatively, the concentration of Cd tested in water samples taken from *Tulcea Arm - Mm 42.5* (*DD24-08*) and *Uzlina L.* (*DD24-24*) (situated in the northern part of the lake, close to the mouth of a connection canal with *Isacova L.*) exceeded the limit set for water quality Class II.

Cobalt. The Co concentration (µg/L) tested in all collected water samples showed no significant variations. The majority of the results were below the limit set for water quality Class I (10 µg/L).

Chromium. The Cr concentration (µg/L) identified in the water samples collected during the low-water period showed no significant variations.

All the obtained values were low, below the limit set for water quality Class I (25 µg/L).

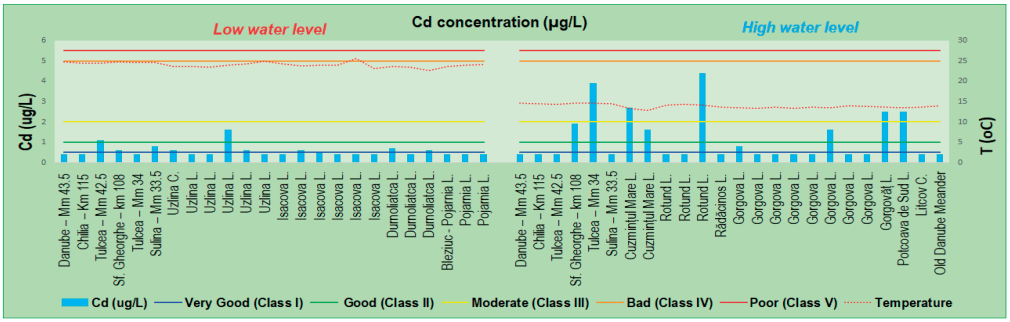

Figure 3. Cd (µg/L) concentration in investigated freshwater samples

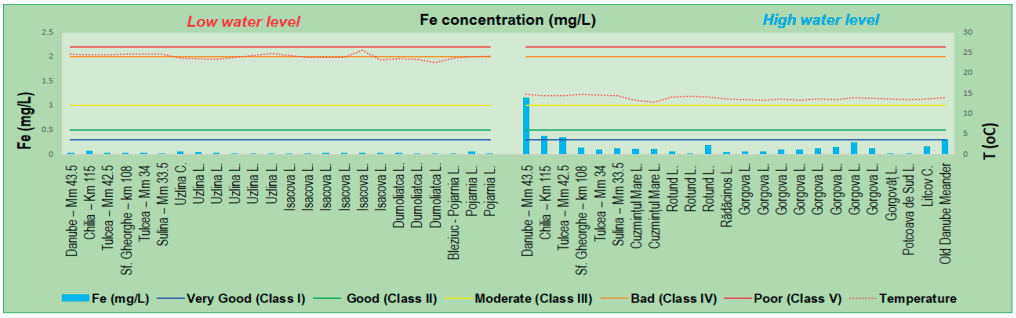

Figure 4. Fe (mg/L) concentration in investigated freshwater samples

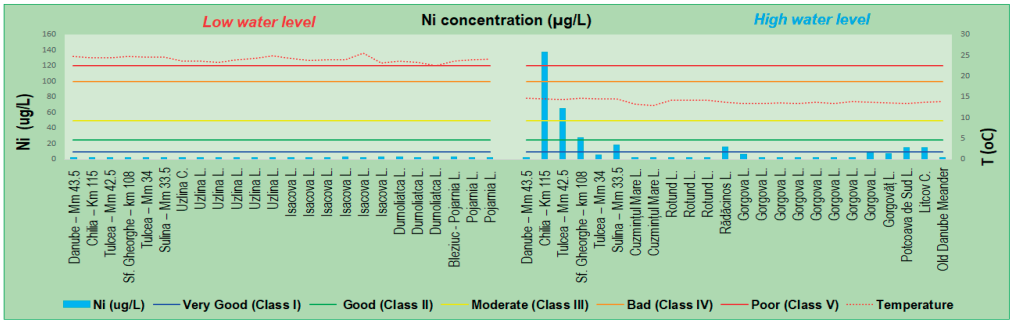

Figure 5. Ni (µg/L) concentration on investigated freshwater samples

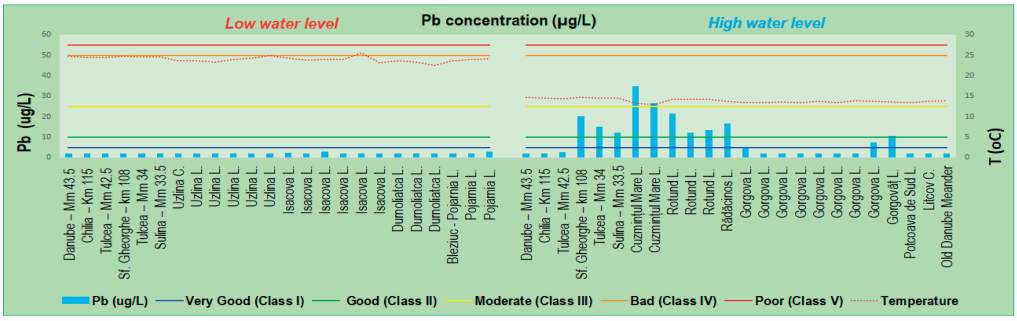

Figure 6. Pb (µg/L) concentration in investigated freshwater samples

Copper. The Cu concentration (µg/L) measured in the water samples collected during the low-water period, showed no significant variations. All the values obtained were low, below the limit set for water quality Class I (20 µg/L).

Iron. During the low-water period, the Fe concentration (mg/L) defined in the water samples collected from all sampling points, showed no significant variations. All the obtained values were low, below the limit set for water quality Class I (0.3 mg/L) (Figure 4).

Manganese. The results showed an inconsiderable Mn concentration (mg/L) detected in the water samples collected from all sampling points. All the values were low, below the limit set for water quality Class I (0.05 mg/L).

Nickel. The Ni concentration (µg/L) spotted in the water samples collected during the low-water period showed no significant variations. All the value obtained were low, below the limit set for water quality Class I (10 µg/L) (Figure 5).

Lead. The Pb concentration (µg/L) observed in the water samples collected during the low-water period showed no significant variations. All the obtained values were low, below the limit set for water quality Class I (5 µg/L) (Figure 6).

Zinc. The Zn concentration (µg/L) noticed in the water samples collected during the low-water period showed no significant variations. All the obtained values were low, below the limit set for water quality Class I (100 µg/L)

Heavy metals' distribution during the high-water period investigation

The field expedition occurred when an impetuous increase in Danube water levels was expected due to a flood wave owing to storms and heavy rainfall coming from upstream countries. Consequently, during the high-water period (October 2024), at the *Ceatal Izmail* bifurcation area, the *Danube* carried a flow of approximately 6970 $m^3 \cdot s^{-1}$ at the entrance to the delta. This was unequally distributed between the *Tulcea* - 3896 $m^3 \cdot s^{-1}$ and *Chilia* - 3032 $m^3 \cdot s^{-1}$ branches. The average velocities on the profiles were between 0.72 and 0.93 $m \cdot s^{-1}$.

Table 2. Results of the heavy metal analysis in the investigated control sections (point samples) (Danube branches, canals, lakes, etc.) (high-water hydrodynamic conditions)

At the entrance to the second hydrographic node at the *Ceatal Sf. Gheorghe* bifurcation area, the flow of the *Tulcea* branch was at the time of measurements approximately 3738 $m^3 \cdot s^{-1}$. The

flow was unequally distributed between the *Sulina* - 1377 $m^3 \cdot s^{-1}$ and *Sf. Gheorghe* branch - 2328 $m^3 \cdot s^{-1}$. The average velocities on the profiles were between 0.76 and 0.95 $m \cdot s^{-1}$, with higher values on the *Sulina* Canal. The chemical analyses were fulfilled for 24 spot water samples collected from *Ceatal Izmail* (at the *Danube - Mm 43.5, Chilia Arm - Km 115, Tulcea Arm - Mm 43.5*), *Ceatal Sf. Gheorghe* (at the *Tulcea Arm - Mm 43, Sulina Arm - Mm 33.5, Sf. Gheorghe Arm - Km 108*), including *Cuzmințul Mare L., Rotund L., Rădăcinos L., Gorgova L., Gorgovăț L., Potcoava de Sud L.*, *Litcov Canal* and *Old Danube River Meander* (Figure 2). During the high-water period, the values of the investigated heavy metals showed a higher variability associated with the heavy metals' distribution between the collection points, in both investigated Danube River bifurcations, as well as in deltaic lakes. The results are shown in Table 2. In general, the content values of certain heavy metals (Cd, Fe, Ni and Pb) acquired within hydrodynamic conditions of high-water levels of the Danube (October 2024) were higher than the values obtained within the low-water level period (September 2024). Regarding the other investigated heavy metals (As, Co, Cr, Cu, Mn and Zn), they maintained a similar trend so that no significant exceedances were registered between the two seasons (September 2024 and October 2024). The distribution trend of these heavy metals had a pattern with low values, close to those corresponding to quality class I (very good condition), registered in all investigated sampling stations. The dynamics and changes in the concentrations of ten investigated heavy metals (As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, and Zn) during the high-water period will be shown below.

Arsenic. The As concentration (µg/L) identified in the water samples presented a series of insignificant variations. Most of the obtained values were low, below the detection limit (< 2 µg/L), implicitly, below the limit corresponding to quality class I (10 µg/L).

Cadmium. The Cd concentration (µg/L) determined in the investigated water samples presented a series of interesting variations. A part of the values was below the limit set for water quality Class I, but also were observed values that slightly reached or exceeded the first three quality classes (Class I - 0.5 µg/L, Class II - 1 µg/L, Class III - 2 µg/L) (Figure 3). The water sample that exceeded class I was encountered in the *Gorgova L.* (*DD24-112*) (situated in the northwestern part of the lake, close to the mouth of the connection canal with *Sulina Arm*). Then, the sampling sites with values higher than class II are represented by: *Sf. Gheorghe Arm - Km 108* (*DD24-85*), *Cuzmințul Mare L.* (*DD24-97*) (situated in the northeastern part of the lake, close to the mouth of a connection canal) and *Gorgova L.* (*DD24-123*) (located in the west southern part of the lake, close to the mouth of a connection canal with *Rădăcinos L.*). The water samples that overpassed the limit set for water quality Class III were noticed in: the *Tulcea Arm - Mm 34* (*DD24-88*), *Cuzmințul Mare L.* (*DD24-93*) (situated in the middle part of the lake), *Rotund L.* (*DD24-106*) (located in the southern part of the lake, close to the mouth of a connection canal with *Litcov C.), Gorgovăț L. (DD24-130)* (located in the middle of the lake) and *Potcoava de Sud L.* (*DD24-131*) (situated in the southern part of the lake, close to the mouth of a connection canal with *Litcov C.*).

Cobalt. The Co concentration (µg/L) identified in all collected water samples showed no significant variations. Most of the results were low values, below the limit set for water quality Class I (10 µg/L).

Chromium. The Cr concentration (µg/L) tested in the water samples collected during the high-water period showed no significant variations. All the value obtained was low, below the limit set for water quality Class I (25 µg/L).

Copper. The Cu concentration (µg/L) noted in the water samples collected during the high-water period showed no significant variations. All the values obtained were low, below the limit set for water quality Class I (20 µg/L).

Iron. During the high-water period, the Fe concentration (mg/L) identified in most of the water samples showed no significant variations, with low values, below the limit set for water quality Class I (0.3 mg/L). For all that, three samples slightly reached or exceeded the first quality class (Figure 4), namely: the *Chilia Arm - km 115* (*DD24-79*), the *Tulcea Arm - Mm 42.5* (*DD24-82*) and the *Old Danube Meander* (*DD24-136*). In addition, it was also noticed one sample overpassed the limit set for water quality

Class III (1.0 mg/L), specifically, the *Danube - Mm 43.5* (*DD24-76*).

Manganese. The results showed an insignificant Mn concentration (mg/L) detected in the water samples collected from all sampling points. All the values were low, below the limit set for water quality Class I (0.05 mg/L).

Nickel. Overall, the Ni concentration (µg/L) spotted in several water samples collected during the high-water period showed no significant variations, with low values, below the limit set for water quality Class I (10 µg/L). Even so, four water samples exceeded the first quality class, namely: the *Sulina Arm - Mm 33.5* (*DD24-90*), *Rădăcinos L.* (*DD24-108*) (situated in the northern part of the lake), *Potcoava de Sud L.* (*DD24-131*) (situated in the southern part of (situated close to the mouth of the connection canal with *Durnoliatca L.*), (situated close to the mouth of the connection canal with *Durnoliatca L.*), *135)*. The other two samples overpassed the limit set for water quality Class II (25 µg/L), namely, *Sf. Gheorghe Arm - Km 108* (*DD24-85*), and respectively, Class III (50 µg/L) at the *Tulcea Arm - Mm 42.5* (*DD24-82*). Finally, at the *Chilia Arm - Km 115* (*DD24-79*) was depicted a Ni concentration overpassed the limit set for water quality Class V (>100 µg/L) (Figure 5).

Lead. Almost half of the water samples investigated showed lower Pb concentration (µg/L), with values below the limit settled for water quality Class I (5 µg/L). Instead, the other half of the samples showed values that exceeded the first three quality classes (Class I - 5 µg/L, Class II - 10 µg/L, Class III - 25 µg/L). So, the following sampling sites revealed Pb concentration (µg/L) higher than Class I: *Gorgova L.* (*DD24-126*) (located in the south-eastern part of the lake, close to the mouth of a connection canal with *Gorgovăț L.*) and *Gorgovăț L.* (*DD24-130*) (located in the middle part of the lake). Then, the upcoming water samples were included in the quality class II: *Sf. Gheorghe Arm - km 108* (*DD24-85*), *Tulcea Arm - Mm 34 (DD24-88)*, *Sulina Arm - Mm 33.5* (*DD24-90*), *Rotund L.* (*DD24-101*) (located in the eastern part of the lake, close to the mouth of a connection canal with *Gorgova L.*), *Rotund L.* (*DD24-102*) (located in the northern part of the lake, close to the mouth of a connection canal with *Cuzmințul Mare L.*), *Rotund L.* (*DD24-106*) (located in the southern part of the lake, close to the mouth of a connection canal with *Litcov C.*), and *Rădăcinos L.* (*DD24-108*) (located in the northern part of the lake, close to the mouth of a connection canal with *Gorgova L.*). Relatively, higher values of Pb concentration corresponding to the quality class III were identified in: *Cuzmințul Mare L.* (*DD24-93*) (located in the middle part of the lake) and *Cuzmințul Mare L.* (*DD24-97*) (located in the eastern part of the lake, close to the mouth of a connection canal) (Figure 6).

Zinc. The Zn concentration (µg/L) determined in the water samples collected during the high-water period, showed no significant variations. All the obtained values were low, below the limit set for water quality Class I (100 µg/L).

The heavy metals investigated in the surface water samples collected under distinct hydrodynamic conditions (low and high water levels of the Danube River in 2024) show a varying degree of distribution, ranging from very low values below the detection limit, implicitly below the limit corresponding to Class I quality (very good status) to relatively higher values (in certain stations) that exceed the maximum allowed limit, corresponding to Class II (good status), Class III (moderate status), Class IV (poor status), and Class V (bad status). To some extent, the results obtained in this study are similar to those of previous research conducted on the Danube Delta ecosystems (Vignati, 2013; Vasiliu, 2021; Catianis, 2022). It is assumed that the increased concentrations of particular heavy metals (*i.e.,* Cd, Fe, Ni and Pb) observed during the high-water period may be due to the flood wave. When the flow of a river increases (*e.g.,* due to heavy rains, snowmelt, etc.), it can transport pollutants from the upstream areas of the watercourse. These pollutants may include chemicals, heavy metals, waste, and even pathogens. Increased flow can lift pollutants from upstream soil, sediments, and waters, transporting them downstream and affecting water quality. Particularly, during flooding, contaminants can be carried in much greater quantities than under normal flow conditions. Generally, even areas located far from the potential pollution sources can suffer from the transport of these pollutants, which may reach sensitive ecosystems or even drinking water sources. Higher concentrations of Cd, Fe,

Ni and Pb in the investigated freshwater samples can be attributed to several natural and anthropogenic factors. Among the most relevant factors that could contribute to the increase in Cd, Fe, Ni, and Pb concentrations are industrial activities, mining, transportation, agricultural waste and fertilization practices, upstream contamination, atmospheric particle deposition, urban and industrial waste, illegal or uncontrolled discharges, soil erosion, sediment input, in-lake processes, etc. However, it should be noted that in the Danube Delta, there are sediments that may contain nickel in higher concentrations due to the natural geochemical background. Additionally, soil and rock erosion in the upstream areas of the delta may release nickel into the water. More than that, the combination of natural sedimentation, erosion, flood-induced transport, anthropogenic pollution, and geochemical factors leads to the higher concentration of heavy metals near the mouths of connecting channels with lakes. These areas may act as collection points for pollutants, both from upstream sources and from local environmental processes.

The impact of heavy metals on the aquatic environment. Higher concentrations of Cd, Fe, Ni and Pb in the Danube and the lakes of the Danube Delta represent a complex phenomenon, generated by both natural sources and anthropogenic influences, which requires constant monitoring. Their impact on the ecosystems of the Danube Delta depends not only on the concentrations of these metals but also on their interactions with other biological and physical-chemical factors in the area. Higher concentrations of Cd, Fe, Ni and Pb can lead to water pollution, affecting the health of aquatic ecosystems either through direct toxicity or by modifying the physical-chemical characteristics of the water. This can also disrupt biodiversity and the normal functioning of the ecosystem. Therefore, monitoring and managing this type of pollution are essential for protecting the environment of the Danube Delta.

Tracking heavy metal contamination in water and sediments is important for developing targeted management strategies to mitigate their impact on deltaic ecosystems. Heavy metal pollution disrupts ecosystem functions, such as nutrient cycling and water purification, leading to habitat degradation. It also threatens biodiversity by accumulating in aquatic organisms and affecting the food chain. Human health risks arise from contaminated fish and water, while economic impacts include reduced fish stocks, harmed agriculture, and decreased eco-tourism. To ensure long-term sustainability, advanced remediation, stronger policies, ecosystem restoration, and community involvement are essential to mitigate the effects of heavy metal contamination in the Danube River-Danube Delta-Black Sea system, which is important for both the surrounding regions and Europe.

CONCLUSIONS

The natural and anthropogenic factors leave their mark on the water quality of the Danube Delta ecosystems. The most evident impact of anthropogenic stressors is the influence of climate change (i.e., floods, droughts, geological factors, sediment matrix, etc.). The effects of climate change, particularly extreme weather events, have the potential to abruptly modify the physical-chemical, biological, and heavy metal characteristics of the Danube Delta ecosystems. Instantly, the contaminant load and soil processes may make the water more vulnerable to pollution, consequently affecting its ecological functions.

The water quality status within the Danube Delta region is primarily linked to seasonal fluctuations and, to a lesser extent, spatial variations in the hydrological regime of the Danube River. This study highlighted the influence of the Danube River during the high-water period, which showed a considerable increase in some heavy metal concentrations at certain sampling stations, compared to the low-water period when most of the values were negligible. Although the results were not alarming, being recorded only at specific stations, this study provided evidence that systematic monitoring and assessment of the water quality's status is essential in such deltaic aquatic environments, which are of inestimable ecological and biodiversity value.

Abstract

Organic matter plays a crucial role in maintaining lake health and trophic balance. It mainly originates from autochthonous sources like phytoplankton, microorganisms, and macrophytes, as well as allochthonous inputs from the surrounding terrestrial ecosystem. Understanding the origin of organic matter is important for assessing ecosystem quality and trends in lake evolution. This study uses the Loss of Ignition method to estimate the distribution, sources, and quantity of total organic matter (TOM %) in lakes of the Gorgova-Uzlina hydrographic unit in the Danube Delta, Romania. Results indicate that TOM concentrations (15-30%) in surface sediments primarily originate from in-situ lacustrine production, with minor contributions from upstream terrestrial inputs. Accomplished analysis revealed recent organo-sedimentary accumulations based on lithological components (TOM %, carbonates - CAR %, and minerogenic fraction - SIL %). The organic matter in these sediments may reflect both natural processes and anthropogenic impacts, emphasizing the need for monitoring to understand the dynamics and vulnerability of the delta ecosystem and perform conservation efforts.

Key words*: areal distribution, lacustrine ecosystems, LOI method, surface sediments, total organic matter.*

INTRODUCTION

Delta shallow lakes, which are formed at the mouths of rivers, are vital ecosystems that support a rich diversity of flora and fauna while also providing significant key ecosystem services (Verpoorter et al., 2014; Laignel et al., 2023). These lakes are highly dynamic systems, shaped by sediment deposition, hydrological flow, and anthropogenic influences. However, one of the critical issues facing delta lakes is the phenomenon of clogging or siltation, wherein excessive sediment accumulation results in a reduction of water quality, decreased oxygen levels, and altered habitat conditions for aquatic species (Walton et al., 2024; How et al., 2024; Wang et al., 2024). The process of siltation in delta lakes is primarily driven by the deposition of fine sediments, such as silt and clay, which can accumulate at the lakebed due to changes in flow velocity, river damming, land-use changes, and climate variability (Zhang et al., 2022; Wang et al., 2024). Siltation not only affects the sedimentary structure of the lakebed but also contributes to the loss of biodiversity and can significantly alter the hydrodynamics of the lake (Ho & Goethals, 2019; Tammeorg et al., 2024). Additionally, autochthonous aquatic vegetation contributes to the clogging of deltaic lakes. Aquatic vegetation plays a vital role in the ecological health of wetlands (Sun et al., 2023), providing habitat for various aquatic animal species and contributing to water quality by stabilizing sediments. However, excessive growth of aquatic vegetation can lead to challenges (Tan et al., 2020), particularly, dealing with clogging water channels and reducing flow, ultimately accumulating organic matter and sediments. Studies have shown that several plant species may exacerbate these issues by rapidly colonizing large areas of delta lakes, forming dense mats that could restrict water movement or create other impediments to the overall health of aquatic ecosystems (Oteman et al., 2021; Schneider et al., 2024). The overabundance of these plants is often a result of nutrient-rich conditions in the water, frequently fueled by agricultural runoffs and industrial discharges. The Danube Delta, one of Europe's largest and most biodiverse wetlands,

plays a key role in regulating water quality, supporting wildlife, and providing livelihoods for local communities. The delta, which spans across Romania and Ukraine, consists of a complex network of lakes, channels, and marshes (Gâștescu & Știucă, 2008). However, over the past several decades, deltaic aquatic ecosystems have been increasingly susceptible to being impacted by the phenomenon of clogging or siltation (Tiron Duțu et al., 2022). Siltation refers to the accumulation of fine sediments, such as silt and clay, that degrade water quality and ecosystem health and obstruct various connecting channels or other deltaic aquatic systems (Constantinescu et al., 2023). This process is primarily driven by changes in riverine sediment load, hydrological modifications, and anthropogenic activities, including damming the Danube River upstream. The Danube Delta's lakes are particularly vulnerable to siltation due to the reduced sediment transport caused by upstream river regulation via the construction of dams or diversions and altered flow patterns (Panin & Jipa, 2002; Duțu et al., 2022). As sediments accumulate, they can clog channels, reducing water flow, oxygen levels, and habitat quality for aquatic species such as fish, birds, and invertebrates (Năstase et al., 2022). This study intends to investigate the responses of several selected middle Danube Delta floodplain lakes to natural siltation or clogging by studying the main lithological components dissemination in lakebed sediment samples. The selected lakes with relatively different hydrological conditions, situated in the same catchment area *(i.e., Rusca-Gorgova-Uzlina* Hydrographic Unit), include hydrologically connected lakes such as *Uzlina, Isacova, Durnoliatca, Bleziuc-Pojarnia* and *Pojarnia*, as well as relatively hydrologically isolated lakes, namely *Cuzmințul Mare, Cuzmințul Lat, Rotund, Rădăcinos, Gorgova, Gorgovăț* and *Potcoava de Sud*. Even though the natural processes of siltation and organic deposit accumulations are characteristic of the Danube Delta aquatic ecosystems, the intensification of processes from the last periods demands special attention. Given the importance of these lakes for biodiversity and human activities, understanding the processes and consequences of siltation/clogging is essential for effectively conserving and managing Danube Delta's aquatic ecosystems.

MATERIALS AND METHODS

Study area

This investigation was realized at the *Rusca-Gorgova-Uzlina* Hydrographic Unit (Figure 1), the Danube Delta, Romania. The unit is included in the fluvial western area of the Danube Delta, being delimited by the *Sulina* (north) and the *Sf. Gheorghe* (south) branches, and east of the *Letea-Caraorman* Spit (Panin et al., 2016). In the southern part, this hydrographic unit is represented by lakes such as *Uzlina, Isacova, Durnoliatca, Isăcel, Pojarnia, Bleziuc-Pojarnia* etc. Then, the northern part consists of the *Gorgova* lake and other satellite lakes such as *Gorgovăț, Cuzmințul Mare, Cuzmințul Lat, Rotund, Rădăcinos, Potcoava de Sud*. The southern part is separated from the northern part by the *Litcov Canal*. The freshwater input in the southern part of the *Rusca-Gorgova-Uzlina* Hydrographic Unit is assured mainly by the *Sf. Gheorghe* Branch via *Uzlina Canal*, including several connecting channels between lakes and streams (*i.e.*, *Perivolovca Stream*). Contrarily, the northern part has an inconstant water supply, through the *Old Danube River Meander via Litcov Canal* and other connecting channels between lakes. The chosen sampling sites for this study portray a notable example of the potential environmental impact of both mineral and/or organic recent sediment accumulations yielded by the allochthonous sources from the Danube River flowing alluvial input and streams, or due to the local autochthonous sources.

Field sampling and data analysis

The lakebed sediment samples, and field data collection (including field observations and measurements) were performed at the R/V "Istros" belonging to the National Institute for Research and Development of Marine Geology and Geoecology-GeoEcoMar, Romania. The field surveys were carried out during two distinct hydrological periods of the Danube River's flow: *low-water level* (06-13 September 2024) and *high-water level* (21-28 October 2024). In the low-water period, the Danube River's water level height (cm) registered at the

Tulcea hydrometric station was the lowest level, *i.e.,* 70.25 cm *versus* 180-200 cm normal reference quota, whilst the maximum value was measured in October 2024, *i.e.,* 205.12 cm versus the above-mentioned reference quota. Sediment samples were collected at a depth of ~25 cm using a Van Veen grab sampler. The macroscopic description of the sedimentary material was made *in situ*, such as the structure, texture, main litho-clastic elements (clay, mud, silt, sand, gravel etc.), and bioclastic components (detritus, shells, other organic fragments), color, odor etc. Then, the samples were transferred to sterile plastic recipients maintained at a constant temperature (4°C) and shipped to the specific laboratory for analysis.

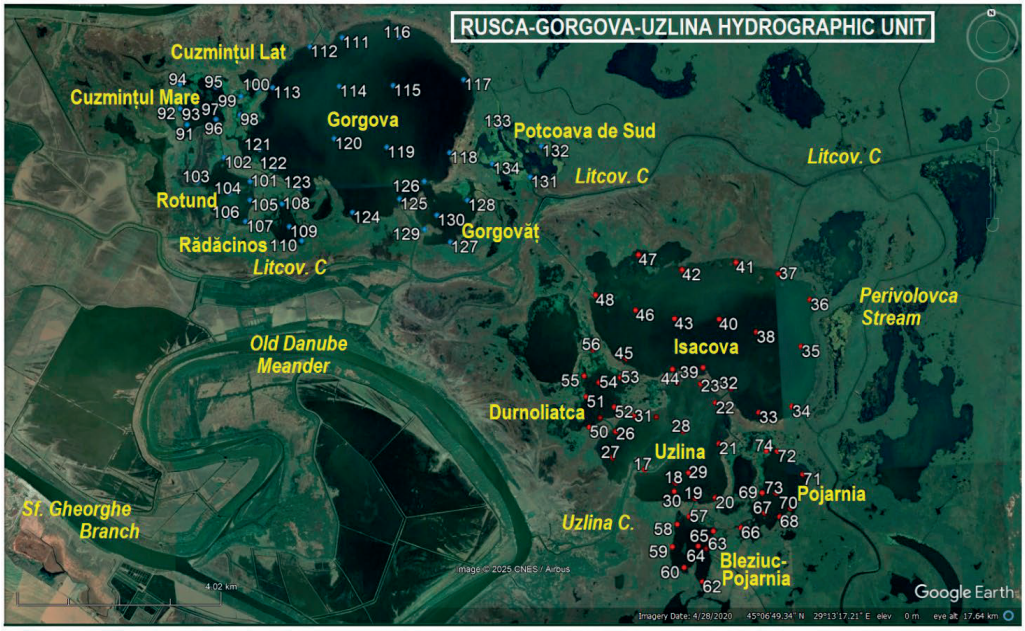

Figure 1. Location of the perimeters investigated. Red dots mark the sampling sites during the low-water periods; Blue dots mark the sampling sites during the high-water periods
(Base Map Source: https://www.google.com/maps)

A percentage quantitative analysis standard technique for the review of the main lithological components was used. In the preparatory phase, the sediments were probed for their moisture content (%) by the Loss On Drying (LOD) method, using a laboratory heater (Universal Memmert Oven) at 105°C temperature (Smith & Mullins, 2000; ASTM-D221). Subsequently, the percentage proportion of the main lithological components was performed in line with the LOI (Loss of Ignition) method. The sediment samples were subjected to sequential heating to distinguish the organic matter (TOM %), carbonates (CAR %), and siliciclastic fraction (SIL %) constituents. The loss in mass by combustion at 550°C was attributed to total organic matter content (Dean, 1974; Bengtsson & Enell, 1986). The total organic matter content was related to a standard classification (Perrin, 1974; Tate, 1987; Van der Veer, 2006), that allows the grouping of *organic matter-rich sediments (≥ 15-30% organic matter)* and *mineral-rich sediments (≤ 15-30% organic matter)*. The loss in mass by calcination at 950-1000ºC was related to the total carbonate content (Digerfeldt et al., 2000; www.geog.cam.ac.uk). The total carbonate content was correlated with the well-known sedimentary systematization (Emelyanov & Shimkus, 1986), presenting: *non-carbonated sediments ($CaCO_3 \leq 10\%$)*, *low calcareous sediments ($10\% < CaCO_3 \leq 30\%$)* and *calcareous sediments ($30\% < CaCO_3 \leq 50\%$)*. Finally, the remaining residual sediment mass after calcination was associated with the siliciclastic fraction content. The obtained

results were assessed as percentages of the TOM %, CAR % and SIL % content from the total sample mass by weight loss procedure. The spatial distribution of the data points has been plotted by the Surfer software package (Golden Software Inc., 2010, Golden, CO, USA) using the kriging method of gridding.

RESULTS AND DISCUSSIONS

The sites represent a good example of environmental exposure to different types of recent sedimentary depositional environments of allochthonous or autochthonous origins. The extent to which the allochthonous or autochthonous source may have a potential impact on the sedimentary depositional environment is mainly determined by the alluvial input contribution brought by the Danube River, and subsequently, is given by the processes that take place in the catchment area *i.e.,* small and shallow reservoirs, the fluvial-dynamic conditions, and the hydrogeochemical background susceptibility to siltation/clogging. In the present study, the main lithological components (*i.e.,* TOM %, CAR %, SIL %) were used as proxy indicators to reflect changes in sediment composition resulting from allochthonous or autochthonous sources. Generally, the freshwater/marine sediments, (porous, soft, or lithified) are composed of three main components, *i.e.,* organic matter, carbonate, and siliciclastics, representing their solid fraction (Ricken, 1993). The lithological analysis of the aquatic sediments in the Danube Delta is important for several reasons, as these data help to gain insight into the processes of formation and evolution of the Danube Delta, as well as to manage natural resources and protect the environment. Among the main reasons for which lithological analysis (*e.g.,* organic matter, carbonates and siliciclastic fraction) is important, the following are specified:

• ***Understanding sedimentary processes***: the lithological analysis facilitates the identification of the sources of sediments and deciphering how they are transported and deposited in the Danube Delta. The composition of the sediments (*e.g.,* organic matter content, carbonates and siliciclastic fraction) can provide information about the environment of transport and deposition of sedimentary particles (the sedimentary environment of the fluvial zone, the marine zone and the transition zone between them).

• ***Study of the evolution of the Danube Delta***: the Danube Delta is a dynamic system being in a constantly changing status. Lithological analysis of sediments allows the reconstruction of the history of geological processes and the geomorphological evolution of the delta, helping to gain an overview of the formation of various habitat types (lakes surrounded by dense reed beds, adjacent channels, reeds formations etc.) and how they have evolved;

• ***Biodiversity and habitat assessment***: Danube Delta sediments, especially those containing organic matter (e.g., plant and animal remnants), are fundamental for supporting biodiversity in the Danube Delta ecosystems. Organic matter in sediments influences substrate fertility and nutrient availability, which affects aquatic and terrestrial ecosystems. Knowledge of the distribution of organic matter in sediments can help assess the state of ecosystems in the Danube Delta;

• ***Impact of climate change***: the lithological analysis can provide information on the impact of climate change on the delta. For example, changes in the ratio of siliciclastic to carbonate fractions may indicate changes in the hydrological regime or water level, which are consequently influenced by climatic factors.

• ***Natural resource management***: the Danube Delta is an important area for fishing, tourism, and agriculture, and sediment analysis can help assess the natural resources of the region. For example, carbonate sedimentation can be an indicator of the potential for the formation of fertile soils, while the analysis of siliciclastic material can contribute to the identification and assessment of natural resources, which represent both ecological and economic value.

• ***Pollution and conservation studies***: sediment analysis can identify contaminants in the Danube Delta ecosystems, such as heavy metals or toxic substances from industrial or agricultural activities. Therefore, lithological analysis may contribute to the assessment of pollution risks and the development of strategies for the conservation of the delta and the protection of biodiversity.

• ***Water management and wetland protection***: the Danube Delta is an important wetland

ecosystem with multiple ecological functions. Lithological analysis may contribute to understanding the interaction between sediments, water and vegetation, essential for the efficient management of water resources and the protection of sensitive habitats. In this study, the percentage concentration of the main lithological components (TOM %, CAR %, SIL %) noticeably ranged between the investigated sampling sites based on their geographical position and lithological content.
The study case situations will be presented below.

The lithological components areal distribution during the low-water period investigation

During the low-water period (September 2024), several lakes in the southern part of the Rusca-Gorgova-Uzlina depression were investigated. Accordingly, lakes such as *Uzlina, Isacova, Durnoliatca, Bleziuc-Pojarnia* and *Pojarnia* (Figure 1) illustrated different patterns of the main lithological components' horizontal distribution. The results are shown in Table 1.

Total organic matter fraction (TOM %). The organic matter of lake sediments is subjected to various sources. Generally, allochthonous sources (terrestrial material) may enter the lake's receiving basin along with plant fragments, eroded sediments, wastewaters, sewages, organic contaminants, and long-range transport associated with the potentially contaminated water of the Danube River. Autochthonous sources are mainly attributed to the primary production of lakes, such as algae, macrophytes, zooplankton, and a mixture of decomposed vegetal and animal organisms. An overall assessment of the investigated sediment samples indicated that the TOM (%) content fractions dominate in most samples, presenting values included in a wide range of variations ($34.31\% < TOM \leq 90.24\%$), of the total weight of the dry residue (Table 1). This distribution trend is evident in most of the lakes investigated. However, the highest values were found in very small, shallow lakes such as *Durnoliatca* (90.24% TOM), *Bleziuc-Pojarnia* (87.66% TOM) and *Pojarnia* (87.65% TOM). These lakes have plenty of underwater vegetation, are characterized by slower hydrodynamic conditions and are less disturbed by the bottom water currents. Regarding the *Uzlina* and *Isacova*, it was noticed that the inlet/outlet parts of the investigated lakes are characterized by relatively decreased TOM % values in the sediments compared to other sectors of the lakes (Figure 2).

Table 1. Results expressed as the percentage concentration (%) of the main lithological components

Location	Tested samples	TOM (%)			CAR (%)			SIL (%)		
		Min.	Max.	Ave-rage	Min.	Max.	Ave-rage	Min.	Max.	Ave-rage
Uzlina	(n=15)	49.40	72.57	65.02	6.51	20.05	12.10	14.53	44.09	22.89
Isacova	(n=16)	34.31	78.37	69.57	1.35	18.16	12.23	8.37	56.00	18.19
Durnoliatca	(n=8)	80.20	90.24	84.66	2.25	11.28	7.06	5.60	11.80	8.29
Bleziuc-Pojarnia	(n=9)	77.94	87.66	83.28	2.99	11.30	6.42	5.91	15.60	10.30
Pojarnia	(n=9)	80.13	87.65	84.02	2.96	12.96	8.69	5.83	10.38	7.29

Total carbonates fraction (CAR %). The presence of carbonates in aquatic environments could be both biogenic (*e.g.,* tests of benthic and pelagic organisms, skeletal parts, shells, and shell debris) and inorganic (*e.g.,* calcite, aragonite) in origin.
The contents of the carbonate fractions identified in the set of tested samples showed a notable surface area variation along the investigated lakes (Table 1). Generally, the range of variation for the CAR % content was relatively lower ($2.25\% < CAR \leq 12.96\%$) in lakes such as *Durnoliatca*, *Bleziuc-Pojarnia* and *Pojarnia*. The other investigated lakes revealed relatively higher ranges of variations, *i.e., Uzlina* ($6.51\% < CAR \leq 20.05\%$) and *Isacova* ($1.35\% < CAR \leq 18.16\%$). The maximum values of the CAR% contents encountered in certain sediment samples (Figure 2) are about to the extent of local or short-range differences in data points, due to the incorporation of shells and shell debris abundance within the sediment matrices.

Siliciclastic fraction (SIL %). The content of siliciclastic fractions in the bottom sediments may be owed to upstream allochthonous fluvial

sediment supply (*e.g.,* siliciclastic material, like quartz-rich sand, gravel, and silt, from the surrounding weathered rock, soils, and other materials) or autochthonous sediment supply (*e.g.,* siliciclastic materials such as sand, silt, and clay that are generated or derived locally, within the lake's drainage basin or directly from the surrounding environment by weathering of lake shoreline materials, river inputs from nearby watersheds, suspension and settlement of fine silts and clay, erosion). Broadly, the investigated lakes illustrated lower contents of the siliciclastic fractions (SIL %) (Table 1). The smallest ranges of variation were found in lakes such as *Durnoliatca* (5.60% < SIL ≤ 11.80%), *Bleziuc-Pojarnia* (5.91% < SIL ≤ 15.60%) and *Pojarnia* (5.83% < SIL ≤ 10.38%). Next, *Uzlina* (14.53% < SIL ≤ 44.09%) and *Isacova* (8.37% < SIL ≤ 56%) exposed relatively higher ranges of SIL% variations, especially near the inlets/outlets or connecting channels between the lakes (Figure 2). Generally, a significant inverse correlation was found between the SIL% and TOM% variables.

Conclusively, according to the organic matter (TOM%) and the siliciclastic (SIL%) fraction (calculated from the total dry sediment weight), the following types of mixed sediments were differentiated in the investigated sediment samples from *Uzlina, Isacova, Durnoliatca, Bleziuc-Pojarnia* and *Pojarnia* (Figure 3):

- *the organic-rich sediments*, subsequently followed by the *silica-rich sediments*;
- *organic-rich sediments* (> 15-30% TOM). From the total number of 57 analyzed samples, 12 samples are included in the range of variations with values between 30 and 70% TOM, and the rest of the 45 samples had increased values, more than 70% TOM;
- *silica-rich sediments* (> 15-30% SIL). From the total number of 57 analyzed samples, 52 samples are included in the range of variations with values between 0 and 30% SIL, and the rest of the 5 samples had increased values, between 30 and 70% SIL.

Subsequently, based on the total carbonate content (CAR%) the following types were spotted:

- *non-carbonated sediment* (CAR ≤ 10%). In this regard, from the total number of 57 analyzed sediment samples, 34 samples had lower values of ≤ 10%;
- *slightly carbonated sediments* (10% < CAR ≤ 30%). From this perspective, from the total number of 57 analyzed sediment samples, 23 samples had values included in the 10% < CAR ≤ 30% range interval.

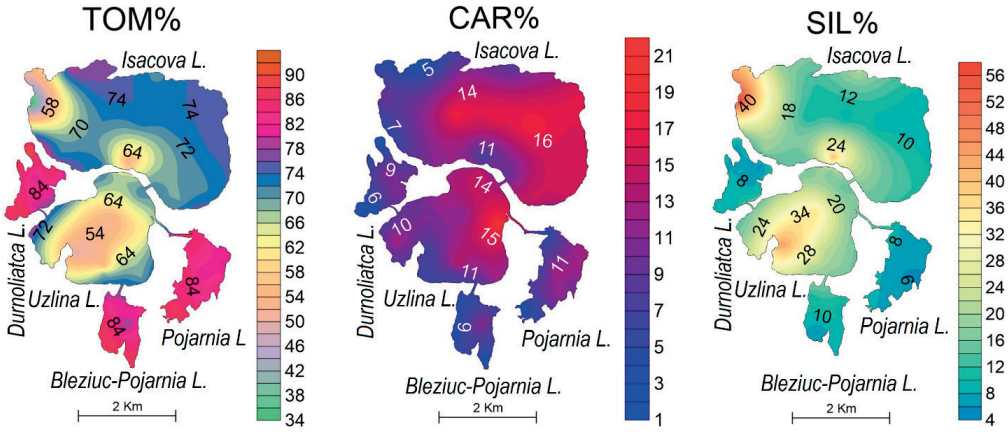

Figure 2. Spatial distribution of TOM, CAR and SIL (%) fractions according to their spatial distribution in the lake sediments of *Uzlina, Isacova, Durnoliatca, Bleziuc-Pojarnia* and *Pojarnia*

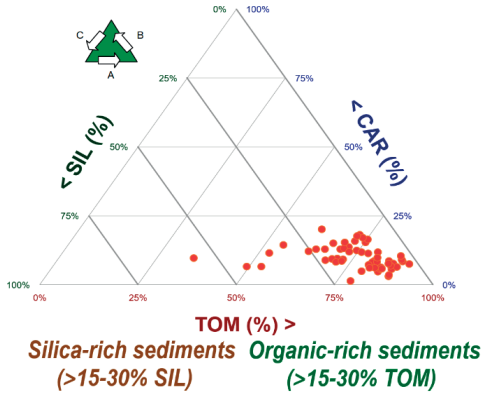

Figure 3. Ternary diagrams showing the percentage distribution (%) of the lithological parameters in the lake sediments of *Uzlina, Isacova, Durnoliatca, Bleziuc-Pojarnia* and *Pojarnia*

The lithological components areal distribution during the high-water period investigation

Within the high-water period (October 2024), several lakes in the northern part of the Rusca-Gorgova-Uzlina depression were surveyed. Therefore, lakes such as *Cuzmințul Mare, Cuzmințul Lat, Rotund, Rădăcinos, Gorgova, Gorgovăț* and *Potcoava de Sud* (Figure 1) displayed different patterns of the main lithological components' horizontal distribution. The results are shown in Table 2.

Total organic matter fraction (TOM %). Generally, the sediment samples taken from *Cuzmințul Mare, Cuzmințul Lat, Rotund, Rădăcinos, Gorgova, Gorgovăț* and *Potcoava de Sud* are characterized by a relatively higher organic matter content (TOM %), with values included in a wide range of variations (28.18% < TOM ≤ 89.99%), of the total weight of the dry residue (Table 2). The highest values of TOM% were found in the superficial sediments of the shallow plant-dominated lakes as *Cuzmințul Mare* (89.23% TOM), *Cuzmințul Lat* (85.03% TOM), *Rădăcinos* (89.99% TOM) and *Gorgovăț* (71.11% TOM), but also in certain sectors of the lakes like *Rotund* (85.80% TOM), *Gorgova* (81.93% TOM) and *Potcoava de Sud* (87.90% TOM) (Figure 4). In shallow plant-dominated lakes, the organic matter content is typically higher than larger, deeper lakes due to a combination of factors such as higher biological productivity, better light penetration, greater interaction with surrounding land, and specific physical characteristics that favor organic matter accumulation.

Table 2. Results expressed as the percentage concentration (%) of the main lithological components

Location	Tested samples	TOM (%)			CAR (%)			SIL (%)		
		Min.	Max.	Ave-rage	Min.	Max.	Ave-rage	Min.	Max.	Ave-rage
Cuzmințul Mare	(n=7)	76.50	89.23	84.43	1.46	9.11	4.25	7.61	19.32	11.32
Cuzmințul Lat	(n=3)	71.81	85.03	77.82	4.36	11.61	6.78	10.61	23.80	15.40
Rotund	(n=7)	35.30	85.80	63.02	2.22	14.79	8.69	11.97	56.03	28.29
Rădăcinos	(n=3)	81.76	89.99	84.76	0.89	8.61	5.84	9.12	9.63	9.41
Gorgova	(n=16)	30.89	81.93	62.23	5.60	34.78	12.29	10.48	56.33	25.48
Gorgovăț	(n=4)	52.34	71.11	63.55	6.77	17.42	11.33	19.13	40.90	25.12
Potcoava de Sud	(n=4)	28.18	87.90	70.02	2.26	12.57	7.28	9.05	59.26	22.70

Total carbonates fraction (CAR %). In general, the contents of the carbonate fractions spotted in the investigated sediment samples did not show a significant surface area variation along the investigated lakes (Table 2), excepting some sectors of the *Gorgova* and *Gorgovăț* lakes. The range of variation for the CAR% content was relatively lower (0.89% < CAR ≤ 14.79%) in lakes such as *Cuzmințul Mare* (1.46% < CAR ≤ 9.11%), *Cuzmințul Lat* (4.36% < CAR ≤ 11.61%), *Rotund* (2.22% < CAR ≤ 14.79%), *Rădăcinos* (0.89% < CAR ≤ 8.61%) and *Potcoava de Sud* (2.26% < CAR ≤ 12.57%). The other investigated lakes revealed relatively higher ranges of variations, *i.e., Gorgova* (5.60% < CAR ≤ 34.78%) and *Gorgovăț* (6.77% < CAR ≤ 17.42%) (Figure 4). The maximum values of the CAR % contents identified in some samples are owed to shells and shell debris abundance within the sediment matrices. The provenance of the carbonate content in delta lake sediments comes from a combination of biogenic processes (such as the precipitation of calcium carbonate by aquatic organisms),

detrital input (weathering of carbonate rocks in the catchment area), chemical precipitation (from lake water under certain conditions). Each of these sources contributes to the overall carbonate content found in the sediment of delta lakes.

Siliciclastic fraction (SIL %). Mostly, the investigated lakes displayed lower contents of the siliciclastic fractions (SIL %) (Table 2). The smallest ranges of variation were found in lakes such as *Cuzminţul Mare* (7.61% < SIL ≤ 19.32%), *Cuzminţul Lat* (10.61% < SIL ≤ 23.80%) and *Rădăcinos* (9.12% < SIL ≤ 9.63%). Further, lakes as *Rotund* (11.97% < SIL ≤ 56.03%), *Gorgova* (10.48% < SIL ≤ 56.33%), *Gorgovăţ* (19.13% < SIL ≤ 40.90%), and *Potcoava de Sud* (9.05% < SIL ≤ 59.26%) disclosed relatively higher ranges of SIL % variations, especially near the mouth of the connection canals with lakes (Figure 4).

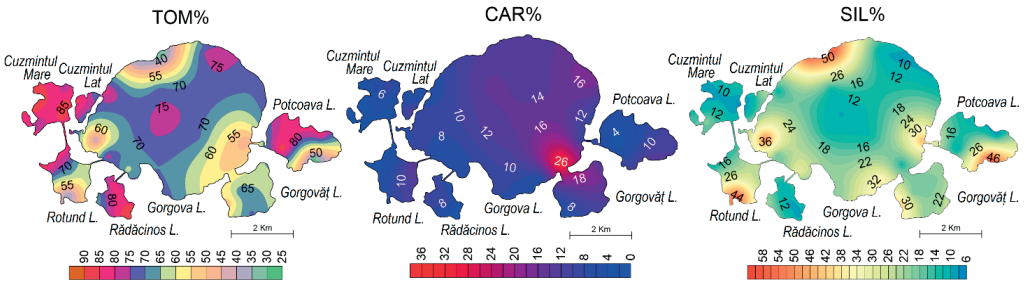

Figure 4. Spatial distribution of TOM, CAR and SIL (%) fractions according to their spatial distribution in the lake sediments of *Cuzminţul Mare, Cuzminţul Lat, Rotund, Rădăcinos, Gorgova, Gorgovăţ* and *Potcoava de Sud*

Near the mouth of the connection canals with delta lakes, there is more siliciclastic fraction content because of the higher energy environment, which allows for the deposition of coarser materials, such as sand and gravel. In contrast, inside the lakes, where water flow is slower, the energy is lower, the finer sediments (such as clay and silt) dominate the sediment composition. The hydrodynamic conditions of the currents near the canal mouth and slower currents inside the lake, largely, determine the grain size distribution and sediment composition in these areas.

Based on the organic matter (TOM %) and the siliciclastic (SIL %) fraction (calculated from the total dry sediment weight), the following types of mixed sediments were differentiated in the investigated sediment samples from *Cuzminţul Mare, Cuzminţul Lat, Rotund, Rădăcinos, Gorgova, Gorgovăţ* and *Potcoava de Sud* (Figure 5):

- *the organic-rich sediments*, subsequently followed by the *silica-rich sediments*;
- *organic-rich sediments* (> 15-30% TOM). From the total number of 45 analyzed samples, 2 samples had values less than 30% TOM, 15 samples were included in the range of variations with values between 30 and 70% TOM, and the rest of the 28 samples had increased values, more than 70% TOM.
- *silica-rich sediments* (> 15-30% SIL). From the total number of 45 analyzed samples, 34 samples are included in the range of variations with values between 0 and 30% SIL, 10 samples had increased values between 30 and 70% SIL, and 1 sample had values more than 70% SIL.

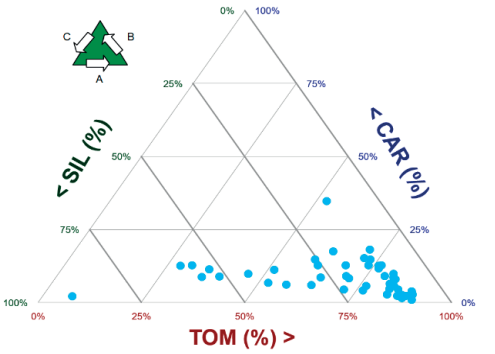

Figure 5. Ternary diagrams showing the percentage distribution (%) of the lithological parameters in the lake sediments of *Cuzminţul Mare, Cuzminţul Lat, Rotund, Rădăcinos, Gorgova, Gorgovăţ* and *Potcoava de Sud*

Subsequently, based on the total carbonate content (CAR %) the following types were spotted:
- *non-carbonated sediment* (CAR ≤ 10%). Accordingly, from the total number of 45 analyzed sediment samples, 29 samples had lower values ≤ 10%;
- *slightly carbonated sediments* (10% < CAR ≤ 30%). Considering this, from the total number of 45 analyzed sediment samples, 15 samples had values included in the 10% < CAR ≤ 30% range interval;
- *carbonated sediments* (30% < $CaCO_3$ ≤ 50%). Consequently, from the total number of 45 analyzed sediment samples, 1 sample had values included in the 30% < CAR ≤ 50% range interval.

CONCLUSIONS

The present study was performed in a transitional depositional environment in several lacustrine ecosystems, belonging to the Danube Delta, Romania. No significant seasonal variation (September vs. October 2024) was observed in the distribution of lithological components. Generally, the investigated lakes showed favorable conditions for accumulating the organic matter-rich sediments due to the inputs of autochthonous organic matter derived mainly from the underwater herbaceous plants and local specific arboreal vegetation. The accumulation of autochthonous organic matter in these shallow plant-dominated lakes may facilitate detrimental long-term challenges both in the size distribution of lakes and in the vertical sediment profiles, promoting shifts in shallow lake water levels, and ultimately causing the installation of the clogging phenomenon. The results obtained within this study are conducive to a better understanding of the total organic matter content and its horizontal distribution in deltaic aquatic environments, especially shallow-plant-dominated lakes, that are prevalent in the Danube Delta region. While these changes are part of the natural evolution of aquatic environments, long-term monitoring is essential to manage the impact of aquatic vegetation clogging in delta lakes. The ecological consequences of these physical changes considerably differ in function of the lake location, the lake depth and size, mixing regime and trophic status.

ACKNOWLEDGEMENTS

This research work was carried out through the support of the Romanian Ministry of Research, Innovation and Digitalization of the Research Core Program, within the National Plan for Research, Development and Innovation 2022-2026, implemented with the support of MCID, Project - PN 23 30 03 02, PN 23 30 03 04 and PN 23 30 01 03.

ADAPTING ROMANIA'S IRRIGATION INFRASTRUCTURE TO CLIMATE CHANGE: OPPORTUNITIES AND CHALLENGES

Mihai Teopent CORCHEȘ

"1 Decembrie 1918" University of Alba Iulia, 5 Gabriel Bethlen Street, 510009, Alba Iulia, Romania

Corresponding author email: mihai.corches@uab.ro

Abstract

In the context of climate change, where Romania faces increasingly frequent droughts, significantly impacting water availability in several regions, the issue of efficient water resource management is becoming more pressing. The phenomenon of drought is having a growing impact on agriculture, necessitating the development of new irrigation systems and the modernization of existing ones, which may need to be more efficient in water use, such as drip irrigation, subsurface irrigation, or sprinkler irrigation, which can also be equipped with smart irrigation technologies (soil moisture sensors, automatic control, remote monitoring and management, aerial surveillance of agricultural crops, etc.). This study analyzes the opportunities for adapting irrigation infrastructure in the current context, focusing on the possibility of implementing best practices and modern technologies used worldwide in Romania. It also critically examines the challenges Romania faces in the development of irrigation systems, as well as the solutions adopted by other countries to overcome these challenges.

Key words*: climate change, irrigation, water management.*

INTRODUCTION

Climate change represents one of the most complex and pressing challenges of the 21st century, having a profound impact on the dynamics of extreme meteorological phenomena. The increasing frequency and intensity of floods, because of climate change, put pressure on existing infrastructure and risk management capacity (IPCC, 2021). Global climate changes and the intensification of climate risk events, such as changes in precipitation patterns and intensity, combined with modifications in land use practices and improper management of agricultural lands, have a significant impact on soil (Sestras et al, 2023). This reality necessitates not only the modernization and expansion of irrigation systems but also their integration into a unified water management strategy, including effective flood prevention measures. Such a holistic approach is essential for reducing risks associated with extreme climatic events and minimizing damages caused by sudden variations in the hydrological regime. In this regard, a fundamental shift in planning and implementing adaptation strategies is necessary so that irrigation infrastructure and flood prevention works are designed in correlation with future climate risks, based on scenario analyses and advanced predictive models. At present, there are a number of climate models, some of which are global, such as CMIP6 (Coupled Model Intercomparison Project, Phase Six) and HadGEM3 (Hadley Centre Global Environment Model version 3), which are used to simulate long-term climate change. There are also regional climate models, such as REMO (The Regional Climate Model REMO) developed at the Max Planck Institute for Meteorology, currently managed and further developed by the Climate Service Center Germany (GERICS) in Hamburg, Germany; the CNRM-ALADIN model (Aire Limitée Adaptation dynamique Développement InterNational), developed at the National Centre for Meteorological Research in France; or the COSMO-CLM model (Consortium for Small-scale Modeling – Climate Limited-area Model), managed by the European Consortium COSMO. At the European Union level, data can be accessed through the European Climate Adaptation Platform Climate-ADAPT, which was created through a partnership between the European Commission and the European Environment Agency (EEA), with the aim of

supporting Europe's adaptation to climate change.

In this context, adapting irrigation infrastructure to new climatic realities becomes an urgent necessity. This involves not only modernizing existing systems but also adopting innovative strategies that consider uncertainties and future risks (Jongman et al., 2012). Thus, the modernization of irrigation infrastructure in Romania represents not only a complex challenge but also a significant opportunity to strengthen the resilience of the agricultural sector to climate change. The implementation of appropriate policies and the efficient use of available financial resources are essential for establishing a sustainable irrigation system that meets both current and future agricultural needs. In light of intensifying climate change, reducing the national water footprint has become imperative for all countries, including Romania (Sandu & Vîrsta, 2021).

MATERIALS AND METHODS

This study analyzes the current state of irrigation infrastructure in Romania, highlighting both the main deficiencies and limitations, as well as the existing opportunities for attracting investments and developing sustainable solutions. In this regard, aspects related to available funding sources are addressed, both at the national level through government funds and at the European level through support mechanisms offered by the European Union, such as the National Strategic Plan 2023-2027, which was approved by the European Commission through Commission Implementing Decision C(2022) 8783 of December 7, 2022, under which Romanian farmers can benefit from up to €15.83 billion to improve outcomes and enhance the performance of Romanian agriculture. Additionally, major challenges that may arise in the implementation process of irrigation projects, such as soil and biodiversity impact, are identified.

The study is based on an analysis of recent research in the specialized literature that highlights these aspects. Furthermore, certain considerations such as the energy efficiency of pumping systems, the use of modern irrigation technologies to reduce water losses, and the necessity of an integrated water resource management approach are also discussed.

For the creation of maps, the open-source software QGIS was used, along with publicly available vector datasets from the website https://geo-spatial.org/vechi/download/romania-seturi-vectoriale.

RESULTS AND DISCUSSIONS

Water Resources of Romania

According to data presented by the National Institute of Statistics (INS, 2025), Romania possesses considerable water resources; however, their distribution shows significant regional variability. As shown in the figure below, Romania's water resources are unevenly distributed across the country, being more abundant in the northern half, while the southern regions face a significantly lower level of water availability. This variation directly affects irrigation needs, as the southern areas - being more water-scarce - require more extensive and efficient irrigation systems to support agricultural activities and cope with frequent drought conditions. Moreover, the southern part of Romania is characterized by larger expanses of arable land compared to the north, making it a key agricultural zone. This combination of extensive farmland and limited water resources further intensifies the pressure on irrigation infrastructure, highlighting the need for targeted investments and climate-resilient water management strategies in the region.

In 2023, the total volume of available water resources, based on the level of infrastructure development, was estimated at 50,150 million m³/year. The volume of water for each hydrographic basin, according to the source, was graphically represented in Figure 1.

Surface waters contributed approximately 37,644 million m³/year, while groundwater sources provided 12,506 million m³/year. The distribution analysis reveals that the southern and eastern regions are more vulnerable to drought, primarily due to low precipitation levels and high water demand for irrigation and industry.

These regional discrepancies highlight the necessity of implementing efficient water resource management strategies, including optimizing storage and distribution infrastructure and promoting sustainable water use practices in key economic sectors.

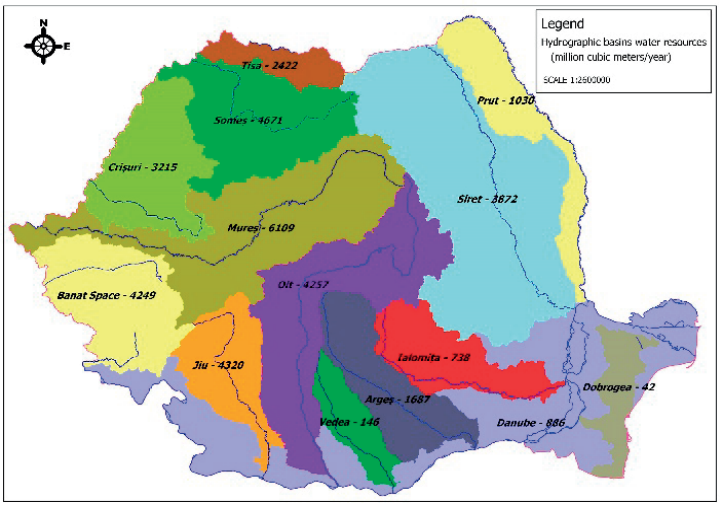

Figure 1. Water resources ensured, according to the development level, in 2023 (original)

Irrigation Network in Romania

The irrigation network in Romania is a complex system, primarily developed during the communist period (1960-1989) to support agriculture by ensuring water availability for crops during drought periods. This infrastructure was built in key agricultural areas of the country, such as the Romanian Plain, the Banat Plain, the Crișuri Plain, and other regions in southern and eastern Romania. Currently, the irrigation network is undergoing rehabilitation and modernization, with support from European funds, to address climate challenges and increase agricultural productivity. During the communist period, Romania invested heavily in irrigation infrastructure, constructing a network covering over 3 million hectares. These systems included canals, pipelines, pumping stations, reservoirs, and dams, designed to capture, store, and distribute water from natural sources such as rivers and lakes. The primary goal was to ensure food self-sufficiency and support intensive agriculture. After the 1989 Revolution, many of these systems were neglected or abandoned due to a lack of funding and changing economic priorities. Currently, the area prepared for irrigation is approximately 1,606,847.97 hectares, according to data published on the ANIF website. Of these, the contracted irrigation area is 1,047,301.55 hectares, and the filled irrigation canals total 2,827.33 km, serving an area of 827,404.19 hectares (ANIF, 2024).

According to ANIF data, the total area designated for irrigation in Romania is 2,989,390 hectares, and the primary irrigation infrastructure includes (ANIF, 2024):

- 10,422 km of adduction and distribution canals;
- 24,547 km of buried pipeline networks;
- 2,568 pumping stations, both floating and fixed.

Adapting irrigation infrastructure to climate change

Adapting irrigation infrastructure to climate change is a complex process requiring significant investments, strategic planning, and cooperation at all levels. This adaptation is essential for ensuring agricultural sustainability and food security. To achieve this objective, the following steps are necessary:

1. ***Assessing vulnerability and climate risks***

The first step in ensuring the resilience of irrigation infrastructure in the face of climate change is assessing the vulnerability of existing systems. This involves conducting detailed studies to identify agricultural areas most exposed to extreme climatic events, such as droughts or floods. Current climate models indicate that many regions will experience more intense and frequent precipitation, which may exceed the design capacity of existing infrastructure (Kundzewicz et al., 2014). Vulnerability assessment allows for the

prioritization of investments and adaptation measures. It is necessary to develop detailed climate forecasts for all regions of the country to support decision-making.

2. ***Modernization and optimization of existing infrastructure**:*

A crucial first step is conducting a detailed inventory of the existing infrastructure using GIS spatial analysis to determine the condition and design capacity of the systems. The use of advanced satellite imagery is essential for monitoring climate change and managing water resources, minimizing uncertainty, and helping to establish optimal mitigation measures (Burghila D., et al 2015). Understanding this information enables the proper design of irrigation works, considering the agricultural areas that require irrigation and the available water resources. Additionally, a quantitative assessment of losses in existing systems is essential to establish a plan for their reduction.

The design of rehabilitation and expansion works for irrigation systems should be based on studies and hydrological simulations to estimate the climate impact on water sources. Rehabilitation should include measures to optimize water consumption, such as:

- using buried pipes or covered channels to reduce evaporation losses;
- implementing drip irrigation;
- utilizing IoT sensors and artificial intelligence to monitor water flow, soil moisture, and optimize water consumption.

3. ***Diversification of water sources for irrigation**:*

Climate change and the increasing frequency of drought periods require the diversification of water sources for irrigation to enhance agricultural resilience.

Currently, irrigation in Romania relies primarily on water from rivers and reservoirs but exploring efficient and sustainable alternatives is necessary. Exploring and utilizing alternative water sources, such as constructing rainwater collection basins or reusing treated wastewater, can reduce dependence on traditional sources and ensure a stable water supply for irrigation. However, these water collection systems are suitable mainly for small land areas and using wastewater for irrigation - although beneficial for recycling nutrients and improving soil fertility - requires modern treatment plants, advanced purification technologies, and continuous water quality monitoring to prevent potential health risks if not treated properly.

4. ***Implementation of sustainable agricultural practices**:*

Sustainable agricultural practices play a crucial role in conserving water resources, ensuring the long-term viability of agriculture, and protecting the environment. Implementing efficient water management methods not only improves productivity but also reduces negative impacts on aquatic ecosystems. Promoting soil water conservation techniques, such as conservation agriculture - which focuses on minimizing soil disturbance and mulching (Bojariu et al., 2021) and crop rotation can reduce irrigation needs and enhance crop resilience to variable climate conditions.

5. ***Strengthening institutional capacity and legislative framework**:*

Better cooperation between central authorities, local authorities, farmers, and other water users is necessary to efficiently manage available water resources and ensure a more coherent and effective approach. The development of centralized irrigation infrastructure reduces the burden on farmers to secure their own irrigation water resources and can lead to more efficient water use and conservation.

Developing policies and regulations that support climate change adaptation, including financial incentives for farmers adopting sustainable practices and efficient irrigation technologies, is essential. Promoting financing programs or subsidies for the implementation of efficient irrigation systems could encourage farmers to adopt solutions that reduce water consumption.

Adapting these steps to the specific context of each region can lead to a more resilient and efficient irrigation infrastructure, capable of addressing the challenges posed by climate change. Educating farmers and engaging local communities are essential for the success of adaptation measures. Farmers must be aware of the risks posed by climate change and be prepared to take preventive measures.

Opportunities for the rehabilitation and construction of irrigation infrastructure in Romania

Funding for irrigation infrastructure is crucial for modernizing and expanding existing systems, particularly in the context of climate change and the need to support sustainable agriculture.

Available funding sources for irrigation projects include the National Strategic Plan 2023-2027, which allocated €400 million for the 2024 funding session under the DR-25 intervention: "Modernization of Irrigation Infrastructure". The public support was 100% non-reimbursable for eligible costs. This plan also includes an additional €1.5 billion for modernizing the primary irrigation infrastructure, managed by the National Agency for Land Improvements.

Challenges in the rehabilitation and construction of irrigation infrastructure in Romania

Developing irrigation infrastructure can impact biodiversity, bringing both benefits and risks to ecosystems. The Natura 2000 network in Romania (Figure 2), covering approximately 23% of the country's territory, is an extensive system of protected areas aimed at conserving biodiversity and protecting natural habitats, as well as significant flora and fauna species at the European level.

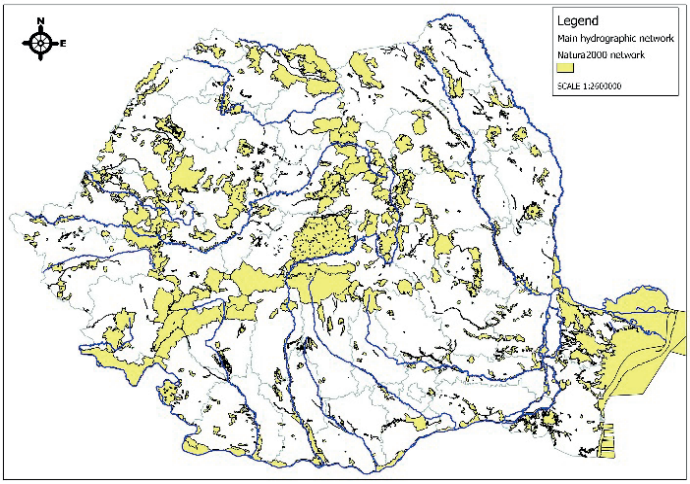

Figure 2. The Natura 2000 network in Romania (original)

Some areas, such as the Danube Delta, are globally recognized for their biodiversity and are also included in other protection programs, such as the Ramsar Convention (on wetlands).

To ensure effective conservation, conservation objectives have been established for all sites, and for some of them, management plans have been developed, outlining conservation measures for the habitats and species present in these sites.

A significant portion of these sites, designated for the protection of aquatic and water-dependent habitats and species, overlaps with watercourses and other wetlands. Therefore, the implementation of irrigation projects should consider the measures set in the conservation objectives and management plans. Carrying out such projects in these areas could significantly impact the conservation status of habitats and species of community interest, as well as the ecological condition of watercourses, which is a key parameter for the preservation of these habitats and species.

1. ***The positive impact of irrigation on biodiversity***

Irrigation can support biodiversity in arid or semi-arid areas by providing the water necessary for plant and animal survival and improving soil fertility. Recent studies show that drip irrigation significantly impacts soil properties, both on the surface and deeper within the profile,

influencing soil conditions and plant development (Tsurkan O. et al., 2021). As demonstrated by Olinic et al. (2024), the development of plant root systems plays a crucial role in improving soil structure and enhancing its water retention capacity, especially when integrated with geosynthetic materials for erosion control.

2. ***The negative impact of irrigation on biodiversity***

Irrigation infrastructure can have significant adverse effects, including:

Dams and irrigation channels can disrupt natural water flow, affecting aquatic ecosystems. A study examining the ecological impact of dam construction on river environments, using intertidal nematode communities as bioindicators, found that interrupting longitudinal connectivity and accumulating contaminants upstream altered nematode structures, affecting abundance, diversity, dominant genera, and community compositions (Tran et al., 2022).

A recent study (Cabodevilla et al., 2022) highlights a significant impact of irrigation systems and associated land-use changes on bird communities in an arid Mediterranean ecosystem. The study found that 55% of bird species responded negatively to irrigation (with a reduced probability of occurrence), while only 11% showed a positive response. These changes led to a 24% overall decline in species richness at the site level. The impact was particularly pronounced in ground-nesting bird species, followed by those associated with shrubs and forests, suggesting that the effects of irrigation on biodiversity may be more extensive and complex than initially assumed. The implementation of irrigation, combined with landscape transformations, changes in agricultural practices (such as monoculture), and the intensive use of agrochemical products, can induce substantial modifications in the composition and dynamics of local bird communities. Another study (Poff et al., 2010) indicates that alterations in river flow regimes can lead to the loss of aquatic habitats and the decline of species.

Excessive irrigation can cause soil salinization, reduce fertility and harm native plant species (Qadir et al., 2014).

A crucial aspect to consider when designing irrigation systems is energy efficiency, as these systems can significantly increase operating costs.

CONCLUSIONS

In the context of increasingly evident climate change in recent years in Romania, adapting irrigation infrastructure to new climate realities is a strategic priority for ensuring food security and agricultural sustainability. One of the most cited global examples of irrigation and technological reform comes from Israel, a country with limited water resources and uneven water distribution, which has become a world leader in efficient irrigation systems. In the 1960s, the Israeli company Netafim pioneered drip irrigation. The use of this irrigation method on over 75% of agricultural crops, combined with the reuse of treated wastewater for irrigation at over 86%, rainwater harvesting, seawater desalination, the construction of numerous reservoirs for storing irrigation water, controlling the consumption behavior of the population through media and online campaigns, and the use of IT solutions, has made Israel a global example to follow (Kaplan, 2022). The increasing frequency of extreme weather events, such as prolonged droughts or intense rainfall, necessitates urgent and effective measures to modernize and expand irrigation systems, optimize water resource use, and reduce the agricultural sector's vulnerability.

Abstract

The study of the influence of drip irrigation on electrophysical parameters and water-soluble salt content in soil and strawberry plants (petioles and fruits) under different fertilization systems is presented. The mineralization and pH of the water used to irrigate the strawberries were measured. The increased content of water-soluble sodium cation salts in irrigation water leads to soil salinization (typical chernozem) and an increase in its amount in the thickness of 0-50 cm during the study period. At the same time, the electrical conductivity of the soil-water suspension decreases. Water pH and salt pH tend to change to an alkaline reaction. The highest amount of calcium, sodium and potassium cations is found in the plants of the control variant, the lowest - in the mineral and organic-mineral variants, and the intermediate amount - in the organic system of fertilization with drip irrigation. Adjusting and regularly monitoring the salinity and pH of irrigation water will help grow healthy and beautiful plants, and plant sap analysis complements soil solution analysis.

Key words*: chernozem, drip irrigation, pH, soil conductivity, water-soluble salts.*

INTRODUCTION

Soil is the most key component of agricultural biocenoses. The condition and nature of the soil cover, its water, air, salinity, nutrient, thermal and microbiological regimes and its bioproductivity have a critical impact on crop yields.

Irrigation is the most powerful factor of human intervention in the natural environment and a strong factor in the transformation of chernozem soils. Irrigation, by increasing water inputs into the landscape, can significantly alter soil characteristics. These alterations include changes in soil morphology, such as the formation of dense soil layers or the breakdown of aggregates, as well as shifts in soil composition, such as the accumulation of salts or the loss of organic matter (Zeng et al., 2013).

In contemporary agriculture, drip irrigation technology is rapidly gaining popularity due to its numerous benefits. Drip irrigation ensures optimal moisture conditions for plant roots over extended periods. This fosters both robust physiological activity and enhanced crop development (Yan et al., 2022). In this context, local irrigation methods ensure minimal environmental impact on the landscape and soils, while maintaining optimal crop productivity, and are the most appropriate and promising in terms of conserving soil and land resources with naturally insufficient and unstable atmospheric moisture (Brovarets, 2017; Neilsen et al., 2004).

Salinization, a major consequence of irrigation, refers to the accumulation of easily soluble salts such as sodium carbonate, chlorides, and sulfates in the soil. Primary or residual salinization occurs when salts build up in the soil column due to natural processes or the intrusion of saline groundwater and surface water. For instance, in arid and semi-arid regions, high evaporation rates can draw salts from deeper soil layers to the surface, leading to primary salinization. Similarly, the use of saline irrigation water can contribute to the accumulation of salts in the soil over time. This accumulation of salts negatively affects soil health by hindering water and nutrient uptake by plants, ultimately reducing crop yields and potentially leading to land degradation. Soils are considered saline if they contain more than 0.1% by weight of salts toxic to plants or more than 0.25% of salts in the dense residue. The main mechanism of this process is the introduction of salts in dissolved form with irrigation water and the precipitation of salts in the soil column from mineralized groundwater. Large areas of irrigated land become unsuitable for cultivation

due to the accumulation of large amounts of salts in the soil.

The accumulation of salts in the soil is activated in the first years of irrigation and decreases 3-5 years after the start of irrigation (Neilsen et al., 2004). Over time, the soil salinity regime reaches a dynamic equilibrium.

The process of sodium sorption in irrigated soils starts with active absorption in the first 2-3 years of irrigation, then slows down and reaches a quasi-stationary state in 3-5 years (Gamkalo, 2009). The duration of irrigation also affects the progression of salinity and salinization processes deeper in the soil profile.

The soil parameters most affected by drip irrigation are primarily the amount and composition of water-soluble salts and carbonate content. According to scientific sources, drip irrigation with water of different content and quality in Ukraine shows trends in the accumulation of water-soluble salts in the soil, changes in the composition of their absorption complex, i.e. the development of salination and salinization processes.

The underestimation of the possible negative impact of drip irrigation on soil properties due to the low irrigation rates compared to traditional methods and the local character of soil moisture makes research on this issue irrelevant. However, the localized nature of the wetting and the much larger specific volumes of water applied to the wetted part of the soil surface are associated with the potential risk of negative soil effects from drip irrigation.

So far, the technical and technological aspects of using this method of supplying moisture to plants have been well studied. At the same time, various aspects of the impact of drip irrigation on the dynamics and direction of processes in soils during long-term use of this irrigation method, and differences in their direction both in the wetting zones and beyond, remain insufficiently studied.

To improve soil fertility and obtain high and stable crop yields, it is necessary to create favourable chemical, physico-chemical and physical properties of irrigated chernozems based on the study of the nature and direction of their changes (Dehtiar'ov et al., 2021; Zhernova et al., 2022).

The aim of the study is to investigate the effect of drip irrigation on soil electrophysical parameters and water-soluble salt content under different fertilization systems, as well as to determine the degree of water mineralization and pH.

MATERIALS AND METHODS

For the fourth consecutive year, garden strawberries (*Fragaria ananassa*) have been cultivated at the "Dokuchaevske Experimental Field" Educational, Research and Production Center (ERPC) of the State Biotechnological University, located in the forest steppe zone of Ukraine (49.899434, 36.452007). This research employed both field and laboratory methods to investigate the effects of drip irrigation and fertilizer application on strawberry growth and yield (Figure 1).

Figure 1. Location of the study area

The "Dokuchaevske Experimental Field" ERPC was selected for this study due to its representative soil and climatic conditions typical of the forest steppe zone. By conducting research at this location, the findings can be applied to a wider range of strawberry cultivation areas in similar environments. Strawberry plants are highly susceptible to salt damage. While all irrigation water contains dissolved mineral salts, the concentration and composition of these salts can differ significantly. Higher salt concentrations in irrigation water led to increased salinity problems in the root zone. Factors influencing root zone salinity include water quality, fertilizer application rates, and irrigation depth.

It is important to note that it is not only drought in the soil that affects strawberry yields, but also drought in the atmosphere. When the air temperature is between 28-30ºC, additional watering should be done in addition to the main watering.

The "Roxanne" strawberries were irrigated using a drip irrigation system (Figure 2). The strawberries were cultivated on raised ridges covered with black PVC sheeting to suppress weeds and conserve soil moisture. A drip irrigation hose was positioned in the center of each ridge beneath the sheeting to deliver water directly to the plant roots. The strawberry plants were arranged in two rows per ridge, spaced 25 cm apart, with a 25 cm gap between the rows.

Figure 2. General view of a strawberry field

Drip irrigation keeps the topsoil constantly moist at the capillary moisture capacity level, but keeps the space between the rows dry, which helps to reduce weeds. The advantages of drip irrigation are water savings, i.e. minimal evaporation from the free surface, no soil crust and preservation of the soil structure.

The experimental design incorporated the following drip-irrigated variants:

Control: strawberries grown without any fertilizer application. This variant serves as a baseline to assess the effects of fertilization.

Mineral System: nitroammophoska (N16P16K16) applied at a rate of 400 kg/ha. This variant evaluates the impact of mineral fertilizer on strawberry growth and yield.

Organic-Mineral System: a combination of mineral fertilizer (nitroammophoska (N16P16K16) at 400 kg/ha) and organic fertilizer (semi-rotted manure at 50 t/ha). This variant investigates the potential synergistic effects of combining mineral and organic fertilizers.

Organic System: semi-rotted manure applied at a rate of 50 t/ha. This variant assesses the effects of organic fertilization on strawberry growth and yield.

The experimental field is characterized by typical chernozem, a fertile black soil rich in organic matter known for its excellent water-holding capacity and nutrient content.

During 2018-2020, analytical studies were conducted on soil, irrigation water, and strawberry plants (petioles and fruits) using portable equipment to assess various parameters:

- electrical conductivity, total dissolved solids, salinity, and pH were measured using the EZODO 8200M conductometer (Figure 3).
- the content of calcium, sodium, and potassium cations in the soil, petioles, fruits, and irrigation water was determined using HORIBA LAQUAtwin ionometers: Na-11 (Na^+); K-11 (K^+), and Ca-11 (Ca^{2+}) (Figure 4).

Figure 3. EZODO 8200M

Figure 4. HORIBA LAQUAtwin ionometers

The results were summarized in 2024 within the project "Development of measures to ensure sustainable productivity of agrophytocenoses under the influence of abiotic and biotic stress factors" (state registration number 0124U000457).

RESULTS AND DISCUSSIONS

Dynamics of changes in soil electrophysical parameters

A modern soil monitoring system on agricultural land includes a system for monitoring, collecting, processing, transmitting, storing and analyzing information on changes in soil quality and fertility, and for developing practical and scientifically based recommendations for decision-making on the prevention and elimination of various types of negative processes.

High agricultural productivity is only possible with comprehensive soil management and prevention of soil degradation. This is done through ongoing research into the use of agrochemicals on farmland, based on monitoring the condition of the soil cover and developing proposals for the effective and environmentally friendly use of agrochemicals.

Comprehensive soil analysis, including determination of basic and additional agrochemical parameters (soil pH, organic matter, content of available forms of nitrogen, phosphorus, potassium, trace elements, sulphur, electrical conductivity, and soil texture) to determine soil potential and optimize mineral nutrition for plants (Yatsuk et al., 2019).

The research conducted from 2018 to 2020 examined the changes in electrophysical parameters in soil where garden strawberries were cultivated (Figures 5, 6 and 7). Electrophysical parameters, such as electrical conductivity, offer insights into the soil's ability to retain and transport water and nutrients, crucial factors for plant growth. Focusing on the control variant which represents the typical cultivation practices without any experimental treatments we observed fluctuations in these parameters across different soil depths and years. In 2020, the highest values were recorded at depths of 30-40 cm and 40-50 cm, reaching 249 and 302 µs/cm, respectively. This suggests potentially higher salt concentrations or compaction at these depths. Interestingly, the ridge part of the field showed the highest value in 2018, measuring 268 µs/cm (Figure 5).

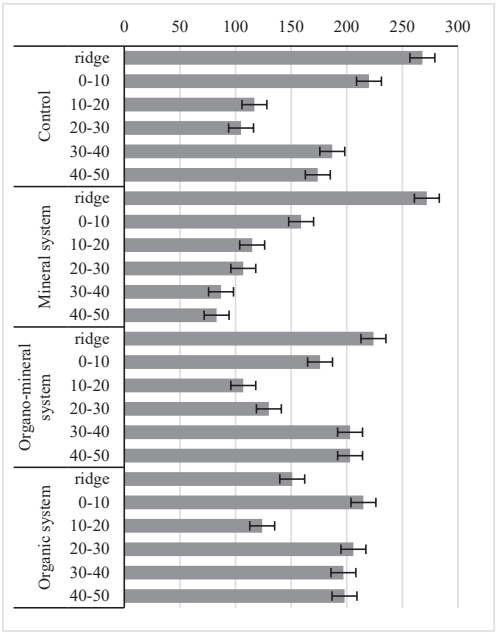

Figure 5. Change in electrical conductivity of typical chernozem in 2018, µs/cm

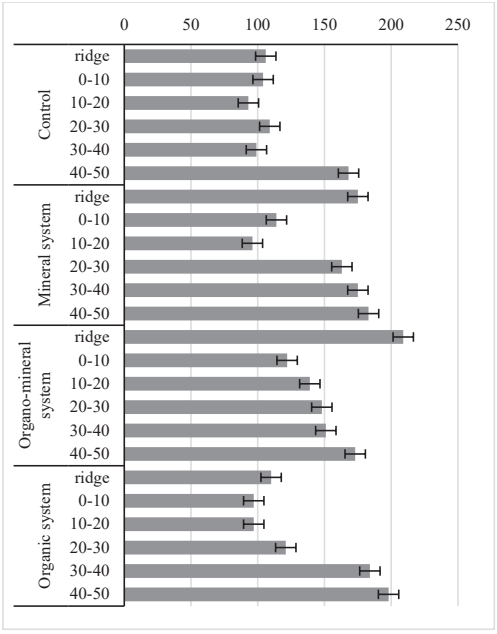

Figure 6. Change in electrical conductivity of typical chernozem in 2019, µs/cm

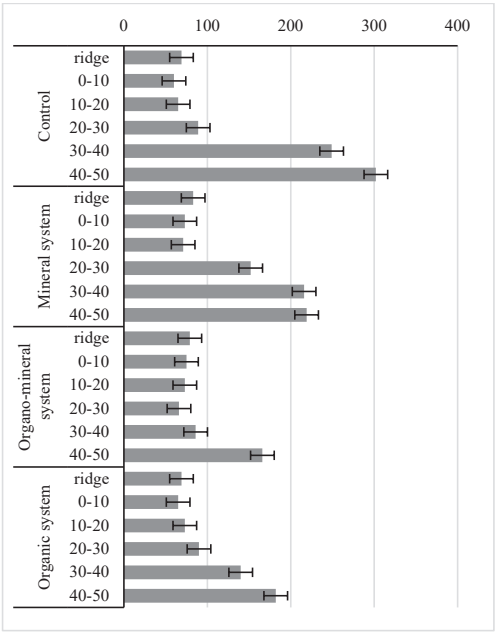

Figure 7. Change in electrical conductivity of typical chernozem in 2020, µs/cm

Conversely, the lower soil layers exhibited average electrophysical parameter values in 2018 and 2019. The lowest values were consistently found in the middle layer in 2018 and the upper layer in 2019 and 2020, ranging from 60 to 106 µs/cm. These variations highlight the dynamic nature of soil properties and their potential influence on strawberry growth (Figure 5 and 7).

The dynamics of the maximum values of the variant with mineral fertilizers shows the highest values in the ridge part in 2018 with 272 µs/cm and the lowest in 2020 with 219 µs/cm. The average electrical conductivity of most of the samples analyzed in 2019 is 163-183 µs/cm (Figure 6).

The lowest values in the soil thickness from 10 to 50 cm in 2018 were 83-115 µs/cm and in the upper part up to 20 cm in 2020 were 71-83 µs/cm.

In 2018, the highest electrical conductivity of soil-water suspensions was observed in the organic-mineral fertilizer variant in the upper and lower parts of the depth studied. In most cases, electrical conductivity averaged 122-151 µs/cm in 2019 and low 66-86 µs/cm in 2020.

The organic fertilizer variant displayed a distinct pattern in electrophysical parameters. In 2018, this variant showed the highest electrical conductivity values, ranging from 197 to 215 µs/cm in certain soil layers, with an overall average conductivity of 124-151 µs/cm. This suggests that organic fertilizers may have initially increased the soil's electrical conductivity. However, in 2019 and 2020, the lowest values were observed in the upper soil layers (20-30 cm), decreasing to 97-110 µs/cm and 65-90 µs/cm, respectively. Conversely, the deeper soil layers (30-50 cm) exhibited the highest conductivity, reaching 182-198 µs/cm. This shift in conductivity over time and depth may indicate changes in the soil's properties due to the continuous application of organic fertilizers (Figure 6 and 7).

Thus, in most cases, the electrical conductivity of soil-water suspensions decreased in 2020 compared to 2019 and 2018. The largest changes occurred in the control variant in the ridge part, where values decreased from 268 µs/cm in 2018 to 69 µs/cm in 2020, the mineral system variant (decrease of 189 µs/cm) and the organo-mineral variant (decrease of 146 µs/cm). On the contrary, there was an increase in electrical conductivity in 2020 compared to previous years in the lower investigated layer of the control and mineral fertilizer system. The 30-40- and 40-50-centimetre thicknesses of the organic fertilizer variant have been almost constant for three years.

Total dissolved solids and salinity indicators show a similar trend in the dynamics of change, but with slightly different numerical values.

Dynamics of the content of water-soluble salts of sodium, calcium, and potassium cations in soil

The soil parameters most affected by drip irrigation are primarily the amount and content of water-soluble salts and carbonates. According to scientific sources, drip irrigation with water of different composition and quality in Ukraine shows trends in the accumulation of water-soluble salts in the soil, changes in the composition of their absorption complex, i.e. the development of salination and salinization processes. The speed and direction of these processes depend on quantitative and qualitative indicators of irrigation water, irrigation regime, amount and type of autumn and winter rainfall (Balyuk et al., 2009).

For example, in 2018, the highest water-soluble sodium salts were observed in the control 360 ppm and mineral 300 ppm systems in the ridge. In 2019, these values decreased slightly but were also the highest in the control 172 ppm, organo-mineral 200 ppm and organic 166 ppm systems in the ridge. In 2020, in the control and organic systems, the highest values were recorded in the lower part of the profile, up to 200-220 ppm. In the first two years, the lowest values were observed in the 30-40 cm and 40-50 cm depths in the soil of all fertilization systems studied, while in the third year, the lowest values were observed in the top layer (ridge).

Conversely, the highest levels of water-soluble calcium salts were found in the 30-40 cm and 40-50 cm thickness sections of all the variants studied over the three years. In the same period, the lowest calcium salt content was found in the ridge part and up to the limit of 10-20 cm of the control variant of the experiment 88-106 ppm.

The content of water-soluble potassium salts was not detected in any of the samples analyzed, with the exception of two. For example, the lowest potassium content in the first year of the study was found in the control and organic-mineral fertilized plots, at 8-10 ppm in the samples taken from the ridge.

The reason for the increased content of water-soluble salts in the soil is therefore the irrigation with mineralized water, which was confirmed by the analysis of the content of soluble salts (electrical conductivity, total dissolved solids, salinity as well as calcium, sodium and potassium) in the irrigation water.

Dynamics of soil pH

The chemical properties of the aqueous soil solution are determined by the acidity or alkalinity of the soil (soil pH); the salinity or total salt content of the soil; the content of inorganic trace elements, such as most alkaline earth metals, transition metals and heavy metals; and the content of organic trace elements.

According to the Food and Agriculture Organization of the United Nations (FAO), only 1/10 of the world's soils have favourable acid-base conditions for growing major crops. At the same time, more than a third of the world's soils are characterized by various forms of 'acid stress' associated with changes in the actual and exchangeable acids present in natural soils.

Acidification of the pedosphere is a global environmental problem. However, most scientists tend to believe that it is of natural rather than anthropogenic origin. Even small changes in natural biogeochemical cycles have a much greater effect on the acid-base balance of soils and surface waters than acid precipitation.

In recent years, however, the rate of acidification of the pedosphere and the biosphere in general has increased. As a reliable relationship between precipitation acidity and changes in the pH of different environmental components can rarely be established, it is advisable to compare the acid-base properties of soils under different anthropogenic pressures.

Plants are the main source of hydrogen ions that cause the acidification of the environment. During their vital activity, they exchange them for equivalent amounts of biophilic ions: Ca^{2+} for $2H^+$, K^+ for H^+, etc. This is what cationic plant nutrition looks like. It is characteristic of most trees. In contrast, herbal plants are characterized by a mixed - cationic-anionic - type of nutrition. In addition to H^+, they actively release OH^- and HCO_3^- into the environment. This mechanism is based on the need to maintain a certain electrical potential across the membranes of root cells to protect them from electrical damage (Gamkalo, 2009). The phenomenon described is called 'trophic acidification' - a shift in the acid-base balance of the soil towards an acid reaction - and is a criterion for an integrated assessment of soil health. Therefore, quantitative assessment of active (water extract pH) and exchangeable (salt extract pH) soil acidity is a prerequisite for determining the edible comfort and ecological quality of the soil in general.

In control, there is a general tendency towards acidification in the lower soil layers. For example, at depths of 30-40 cm and 40-50 cm, the water pH decreased significantly from 8.81 and 8.70 to 7.55 and 7.42. Up to a depth of 20-30 cm there is no increase in pH. The indicator ranges from 7.32 to 7.94.

The mineral system shows a general increase in alkalinity at most depths, apart from 30-50 cm where a slight acidification is observed. The maximum increase in alkalinity is observed at a depth of 20-30 cm from 7.81 to 8.45.

The organo-mineral system shows a general increase in alkalinity at all depths over the years

of investigation. The maximum values were recorded at a depth of 30-40 cm, where the water pH increased from 7.21 to 8.20, and 40-50 cm - the reaction changed from 7.33 to 8.47.

In the organic system we have a significant increase in alkalinity at all depths. In contrast to the other variants, the maximum increase in water pH is observed in the crestal part, from 7.24 to 8.45.

In the control, there is a general tendency towards acidification at most depths, except at 20-30 cm, where the salt pH increases from 5.66 to 5.92. This is particularly noticeable at depths of 30-40 cm and 40-50 cm, where the salt pH has decreased significantly from 7.79 to 6.68 and from 7.64 to 6.52 respectively.

The mineral system shows a general increase in alkalinity at most depths. The soil reaction changes from slightly acidic to slightly alkaline from the surface down to 20-30 cm. A slight acidification of 0.15-0.17 units is observed at depths of 30-50 cm.

The organic-mineral system shows a general increase in alkalinity at all depths. Over the years of research, the salt pH increased from 5.97 to 6.35 in the crestal part and from 6.12 to 6.34 in the 0-10 cm part. There is also an increase in alkalinity of more than one unit from 6.71 to 7.75 at a depth of 40-50 cm.

The organic fertilizer system demonstrated a notable increase in soil pH across all depths, indicating a shift toward alkalinity. Over the research period, an average increase of 0.50 to 1.00 pH units was observed. This change moved the soil reaction from slightly acidic to nearly neutral. So, in most cases, over the years of research, we have seen a change in the pH water and pH salt towards an alkaline reaction.

Electrical Conductivity (EC), Total Dissolved Solids (TDS), Salinity (Salt) and water suitability for irrigation

In drip irrigation systems, where watering is frequent, the electrical conductivity (EC) of the irrigation water can be considered a reliable indicator of the soil solution's EC. This is because the frequent application of water closely maintains the equilibrium between the two. Crops have established thresholds for EC, beyond which their growth is inhibited. To estimate potential yield loss due to salinity, measuring the EC of the irrigation water provides a practical alternative to measuring the EC of the soil (Bedernichek et al., 2009; Hamkalo et al., 2012).

By comparing the water's EC with the established limits for soil EC, one can assess the risk of salinity-induced yield reduction. If the water's EC is lower than the threshold value, yield reduction due to salinity is unlikely. However, if the water's EC exceeds the limit, it indicates potential salinity stress, which can hinder water and nutrient uptake by the plants, ultimately leading to reduced yields.

Electrical conductivity was measured in microSiemens (µs/cm). The unit of mineralization is usually milligrams per liter (mg/l). Salinity can also be expressed in parts per million of water particles (ppm). The ratio between mg/l and ppm is almost the same - 1 mg/l = 1 ppm.

During the electrophysical analysis of the water, it was found that the electrical conductivity is 1047 µs/cm, the total amount of all salts dissolved in the water is 708 mg/l (ppm) and its salinity reaches 540 mg/l (ppm).

The maximum value of water conductivity when strawberries are grown on loamy soils (such as the typical chernozems of the experimental field) is 900 µs/cm. In our case, the value is 147 µs/cm higher. For further cultivation, it is therefore necessary to normalize the level of electrical conductivity of the irrigation water according to the stage of development and variety of garden strawberries.

In addition, water can be classified as medium saline based on the number of dissolved salts (electrical conductivity in the range of 650-1300 µs/cm).

Therefore, determining the actual salinity of the irrigation water through its electrical conductivity becomes crucial for making informed decisions about crop suitability. If salinity exceeds the tolerance of the desired crop, alternative salt-tolerant crops, such as barley or cotton, could be considered to maintain yields. This proactive assessment helps ensure sustainable agricultural practices and optimizes crop production in varying salinity conditions.

The water mineralization rate for strawberry plants is 1260-1540 mg/l (ppm). This means that the salinity of the water is 1.6-2.0 times lower than optimal.

Plants need not only constantly access to minerals, but also the conditions in which they

can be well absorbed. The most important parameter in determining the availability of nutrients to the plant is the pH of the water. The optimum pH of the aqueous solution is different for each type of plant; for some crops it is around 6.8-7.5, for others around 5.5-6.8.

The optimum pH for strawberries is around 6.00. According to the measurement results, the pH of the irrigation water is 6.78, which is 0.78 units higher than the optimum value.

Different chemicals can be used to adjust the pH of the water. For example, you can lower the pH by adding phosphoric, nitric or citric acid to the water. To raise the pH, add baking soda, carbonate or potassium hydroxide.

Using the electrical conductivity indicator, you can quickly determine the suitability of water for irrigating the proposed crop with a known soil particle size distribution, assess a yield reduction or select an alternative crop.

Calcium, sodium, and potassium content of irrigation water

The total content of water-soluble salts, or salinity, indicates the toxicity of water irrigation to agricultural crops and the risk of soil salinization. Prolonged irrigation with high salinity water contributes to the accumulation of salts in the upper layers of the soil, which disrupts the stability of agroecosystems and reduces the yield and quality of crop production. Excessive salt content in irrigation water reduces the osmotic activity of plants and prevents normal soil aeration. The concentration of water-soluble salts in irrigation water, which can be used without restriction, should not exceed 450 mg/l. Water with a concentration of water-soluble salts up to 2000 mg/l is considered to be of limited use for irrigation. The use of water with a salt content of more than 2000 mg/l is risky and strictly limited. The salinity of irrigation water is not strictly regulated by state standards in Ukraine, but for drip irrigation the optimum salinity of water is up to 1000 mg/l (Hamkalo, 2000).

The content and ratio of cations and anions in irrigation water is of great importance in assessing its effect on the soil-plant system. Thus, an excessive content of monovalent sodium and potassium cations compared to divalent calcium and magnesium cations indicates a risk of disruption of soil permeability, soil structure, development of peptization processes, transition of soil colloids to an unnatural ash state, etc. In addition, the increased content of hydrocarbonates, against a background of high concentrations of monovalent sodium and potassium cations in irrigation water, contributes to a more pronounced deterioration of soil permeability.

In turn, changes in soil conditions affect plants: their growth and development deteriorate (sometimes to the point of complete failure), yields decrease, and the quality of the crop deteriorates significantly. The effect and interaction of monovalent and divalent cations in irrigation water is assessed by the sodium adsorption ratio. This considers the electrical conductivity of the irrigation water (EC_W), which is a proxy for the salinity of the water, and the absorption capacity of the soil.

Elevated levels of hydrocarbonate, sulphate and chloride anions in irrigation water indicate potentially high mineralization and the presence of toxic salts. Even tiny amounts of these salts can be harmful to plants. The complete absence of these elements is detrimental to crops, but their levels should not exceed the maximum allowable concentration. The content of non-toxic salts (calcium sulphate, calcium bicarbonate, etc.) up to 1 g/l is safe for plants (Hamkalo et al., 2012; Shum et al., 2013). Thus, the water used for irrigation contains a small amount of water-soluble potassium salts - 6 mg/l (ppm); much more water-soluble calcium salts - 93 mg/l (ppm); and most of all water-soluble sodium salts - 190 mg/l (ppm) (Table 1).

Table 1. Cation content in irrigation water, mg/l (ppm)

Cation content	Na	Ca	K
	190	93	6

The calcium (Ca^{2+}) content of irrigation water affects the hardness of the water. Excessive amounts of calcium salts can cause damage to irrigation systems, particularly by depositing on the nozzles of sprinklers or other irrigation equipment. Using such water to prepare fertilizer solutions, particularly sulphate fertilizers, can lead to the formation of calcium sulphate and affect the pH of the soil.

High sodium (Na^{+}) in irrigation water displaces calcium and magnesium from the soil colloidal absorption complex and increases the sodium

content. If such water is used over a long period, salinization of the soil can occur.

The potassium (K^+) content of irrigation water is usually low, and its infiltration into the soil increases the supply of this element. However, too much potassium together with sodium cations in relation to the total cations can lead to salinity.

At the same time, the ratio of calcium, magnesium, sodium and potassium cations in the water makes it possible to predict their effect on the soil and consequently on the plant.

In our studies, the ratio of water-soluble calcium salts to sodium (Ca:Na) in water is 1:2, and Ca:Na:K is 1:2:0.06. Thus, we can say that the increased content of water-soluble sodium salts in irrigation water leads to soil salinization and an increase in their amount in the studied soil thickness during the research period.

Calcium, sodium and potassium content of strawberry plants

Regular monitoring of essential nutrients like nitrate nitrate (NO_3^-), potassium (K^+) and calcium (Ca^{2+}) in various components of the strawberry production system plant stems, soil solution, irrigation water, and wastewater offers multiple benefits. It not only contributes to achieving optimal yields and fruit quality but also helps reduce fertilizer costs and minimize environmental impact.

Strawberry plants require adequate root space and a balanced supply of nutrients for optimal growth, fruit quality, and yield. Soil pH plays a crucial role in nutrient availability. For instance, nitrate (NO_3^-) influences fruit size, potassium (K^+) affects flavor, and Ca^{2+} contributes to firmness. Maintaining the correct soil pH ensures that these nutrients are readily available to the plants in the right proportions, preventing competition or incorrect assimilation. In addition to pH, careful and frequent monitoring of electrical conductivity is vital, as strawberry plants are sensitive to high salinity levels. By managing both soil pH and electrical conductivity, growers can optimize nutrient availability and create a favorable environment for strawberry production.

Plant sap analysis is a valuable tool for growers to actively manage nutrient levels and refine their fertilizer strategies. By providing a snapshot of the nutrients currently available to the plant for growth and development, this method can quickly identify nutrient deficiencies or excesses. However, to gain a more complete understanding of the plant's nutritional status, it's essential to consider the soil environment as well.

Soil analysis offers crucial information about the overall nutrient levels and salinity within the soil. It also helps assess the potential for nutrient leaching outside the root zone. Analyzing the soil solution, the water held in the soil that carries dissolved nutrients absorbed by the roots provides further insights into the actual nutrients accessible to the plants.

Combining plant sap analysis with soil and soil solution analysis empowers growers with a comprehensive picture of nutrient dynamics. This integrated approach enables more informed decisions about fertilizer application, ensuring that plants receive the necessary nutrients at the right time and at the right amounts.

To assess the nutritional status of strawberry plants, sap analysis was conducted using a calibrated LAQUAtwin pocket meter. This meter measures the ion concentrations in the sap, providing insights into nutrient availability. Before conducting the analysis, the meter was calibrated according to the manufacturer's instructions to ensure accurate readings.

A consistent sampling protocol is crucial for obtaining reliable results. The last mature trifoliate leaf was selected for analysis because it serves as the best indicator of essential nutrients like phosphorus (P), potassium (K), and calcium (Ca). The petiole of this leaf is specifically used to determine the levels of nitrate-nitrogen (NO_3-N). For optimal sampling, the plant's temperature should be between 20-25°C. This standardized approach ensures consistent and comparable results across different measurements.

The examination of the content of cations in the stems should be carried out in accordance with the following scheme:

1. Sample collection: gather the two most recently mature trifoliate leaves, along with their petioles, from 20 different strawberry plants. This ensures a representative sample of the plant population. Tear the petioles from the plant near the crown to avoid damaging the main stem.
2. Sample preparation: separate the petioles from the leaves and cut them into small pieces to increase the surface area for sap extraction.

3. Sap extraction: place the petiole pieces in a garlic press or hydraulic press and apply pressure to extract the sap.
4. Measurement: place a drop of the extracted sap directly onto the corresponding sensors of the LAQUAtwin pocket meter. The meter will provide readings for the different cations present in the sap.
5. Analysis: compare the obtained results with the reference values provided in Table 2. This comparison helps assess the current nutritional status of the plants.
6. Cleaning: rinse the sensors thoroughly with clean water before testing another sample or storing the device. This prevents cross-contamination and ensures accurate reading for future measurements.

Table 2. Reference nutrient levels for petiole sap in strawberry cultivation (Cadahía et al., 2008)

Days after sowing	NO_3-N	P	K
	ppm		
30	500-700	150-350	4000-5000
60	550-750	150-350	4000-5000
90	400-600	150-350	4000-5000
120	500-300	150-350	4000-5000

In addition to plant sap analysis, monitoring the soil solution provides valuable information for optimizing irrigation programs and nutrient management strategies. While soil solution analysis may not reflect the overall nutrient reserves in the soil, it offers insights into the nutrients readily available to plants at a given time. Specifically, soil solution analysis helps growers fine-tune their fertilizer applications and irrigation practices. For example, by tracking nitrate levels in the soil solution, growers can identify potential issues with nitrogen management. Excessive nitrate accumulation in the root zone can lead to nutrient imbalances and environmental concerns due to leaching.
Soil solution analysis allows for timely adjustments to fertilizer application rates, ensuring that nitrogen is supplied in the right amounts at the right time. Furthermore, monitoring salinity levels in the soil solution helps prevent the adverse effects of high salt concentrations on strawberry growth. By tracking these key parameters, growers can make informed decisions to maintain a balanced and productive growing environment.
While potassium and calcium are predominantly bound to soil particles, making their levels in the soil solution less indicative of their overall availability to plants, regular monitoring of these nutrients in the soil, irrigation water, and wastewater remain crucial. This comprehensive assessment provides a broader understanding of their presence and potential movement within the growing system.
Monitoring salinity levels in the soil solution allows for proactive management of potential salinity issues. By detecting rising salinity levels early on, growers can take corrective actions, such as adjusting irrigation practices, before they negatively impact plant health, yield, or fruit quality. This preventive approach helps maintain optimal growing conditions and ensures consistent production.
Excessive irrigation leading to waterlogging can also be detrimental. It washes essential nutrients, including fertilizers, out of the root zone, reducing their availability to plants. Moreover, this leaching process poses environmental risks, such as groundwater pollution. Analyzing the soil solution throughout the growing season helps identify potential nutrient deficiencies or excesses, enabling timely adjustments to irrigation and fertilization practices.
Regarding the calcium content in strawberry petioles, the organic fertilization variant exhibited the highest levels, reaching up to 104 mg/l (ppm) (Figure 8). In contrast, the mineral fertilization variant showed the lowest calcium content, averaging 79 mg/l (ppm). The control variant and the organic-mineral system variant had slightly higher calcium levels, measuring 82 mg/l (ppm) and 84 mg/l (ppm), respectively. These variations suggest that different fertilization regimes can influence calcium uptake and accumulation in strawberry plants. Further investigation is needed to understand the underlying mechanisms and implications of these differences.
Compared to the highest calcium content, the sodium content of strawberry plants in the organic system variant is 60 mg/l (ppm) (Figure 9). The value is even lower, at 56 mg/l (ppm), in the variant with simultaneous application of organic and mineral fertilizers. A slight increase in the indicator is observed in the variant with

mineral fertilization - 69 mg/l (ppm). The highest amount of sodium in petioles was found in the control variant of the experiment - 87 mg/l (ppm).

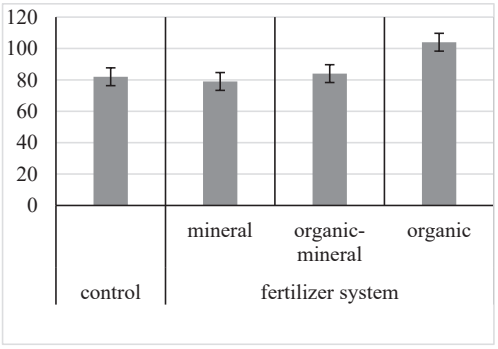

Figure 8. Calcium content in strawberry petioles, mg/l (ppm)

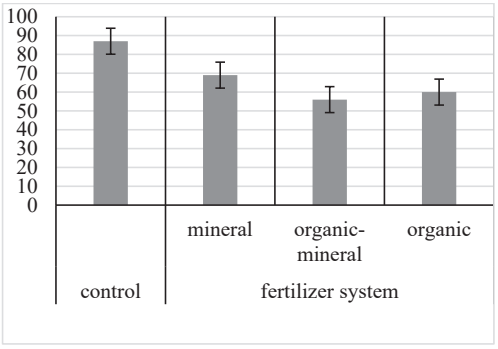

Figure 9. Sodium content in strawberry petioles, mg/l (ppm)

The potassium content of strawberry petioles is at least 20 times higher than that of calcium and sodium (Figure 10). The highest amount of potassium was found in the plants of the control variant - 2600 mg/l (ppm), and the lowest - 2167 on average - in the variant with the organic-mineral system. Average values of 2300 mg/l (ppm) were obtained for two variants with mineral and organic fertilizer application systems.

Based on the data presented in Figure 10, we can say that at least the amount of potassium in the petioles of garden strawberry plants is almost 2 times less than the optimum value.

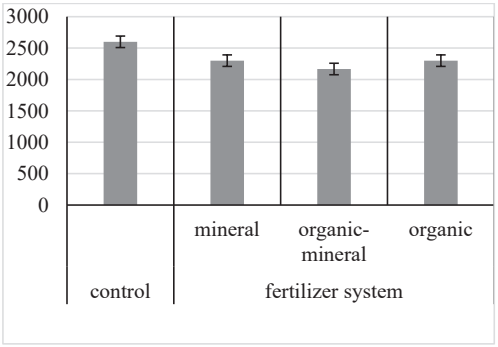

Figure 10. Potassium content in strawberry petioles, mg/l (ppm)

While the analysis of cations in strawberry fruits follows a similar procedure to petiole analysis, with no significant deviations, the specific steps involved are as follows:

1. Sample collection: gather fruit from various strawberry plants to ensure a representative sample.
2. Sap extraction: place small pieces of the fruit in a garlic press or hydraulic press and apply pressure to extract the sap.
3. Measurement: place a drop of the extracted sap directly onto the corresponding sensors of the LAQUAtwin pocket meter.
4. Cleaning: rinse the sensors thoroughly with clean water before testing another sample or storing the device. This prevents cross-contamination and ensures accurate reading for future measurements.

The highest level of calcium in garden strawberry fruit was found in the control variant of the study at 24 mg/l (ppm). The level is slightly lower, at 5 mg/l (ppm), in the variant with the mineral fertilizer system. The lowest level of calcium in the sap analysis was found in the variant with simultaneous application of organic and mineral fertilizers - 13 mg/l (ppm). The calcium content in the fruit is about 20 mg/l (ppm) when an organic fertilizer system is used (Figure 11).

The sodium content is 3.75 times higher than the calcium content in strawberries from the control variant of the study. The element content was also almost three times lower in the mineral and organo-mineral fertilizer variants - 27 mg/l (ppm). In the samples of fruit from the organic fertilization system, we have 39 mg/l (ppm) of

sodium, which is two times less than in the control variant (Figure 12).

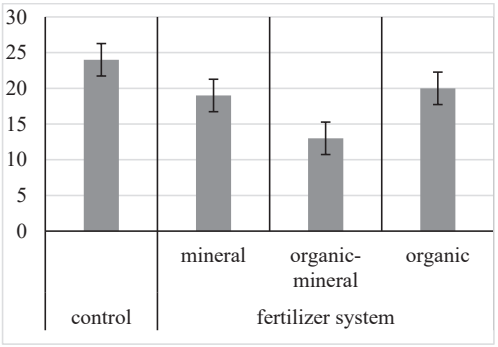

Figure 11. Calcium content in strawberry fruit, mg/l (ppm)

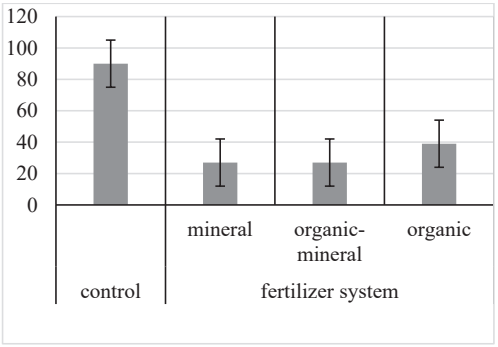

Figure 12. Sodium content of strawberry fruit, mg/l (ppm)

In contrast to the low potassium levels observed in the petioles, the strawberry fruits exhibited significantly higher potassium concentrations (Figure 13). The potassium content in the fruits ranged from 900 mg/l (ppm) to 1300 mg/l (ppm), demonstrating a substantial accumulation of this nutrient in the fruits. Among the different fertilization variants, the control variant showed the highest potassium content, averaging 1267 mg/l (ppm). The mineral fertilizer variant had the lowest potassium content, measuring 330 mg/l (ppm). The variants with organo-mineral and organic fertilization systems exhibited similar potassium levels, averaging 1107 and 1167 mg/l (ppm), respectively. These findings suggest that fertilization practices can significantly influence potassium uptake and distribution in strawberry plants. While the control variant showed the highest potassium content in fruits, the organic and organo-mineral systems also resulted in substantial potassium accumulation. The lower potassium levels in the mineral fertilizer variant may indicate a need for adjustments in fertilizer composition or application rates to optimize potassium availability for fruit development.

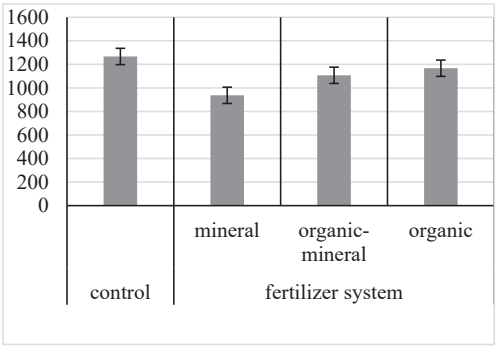

Figure 13. Potassium content of strawberry fruit, mg/l (ppm)

The analysis of strawberry fruits revealed distinct variations in cation content across the different fertilization variants. The control variant exhibited the highest concentration, followed by the organic system. The mineral and organic-mineral variants showed the lowest cation content. These differences highlight the influence of fertilization practices on nutrient uptake and accumulation in strawberry fruits, potentially affecting fruit quality and nutritional value.

CONCLUSIONS

This study revealed several key trends in the electrical conductivity of soil-water suspensions. Notably, most variants showed a decrease in electrical conductivity in 2020 compared to 2019 and 2018. This decline was particularly pronounced in the control variant's ridge part, where values dropped from 268 µs/cm in 2018 to 69 µs/cm in 2020. Similar reductions were observed in the mineral system variant (189 µs/cm decrease) and the organo-mineral variant (146 µs/cm decrease). Conversely, the lower soil layers of the control and mineral system variants exhibited an increase in electrical conductivity in 2020 compared to previous years. This contrasting trend suggests potential differences in soil

properties or nutrient dynamics at varying depths. Interestingly, the 30-40 cm and 40-50 cm depths of the organic fertilizer variant maintained relatively constant electrical conductivity throughout the three-year study period. This stability may indicate a more balanced nutrient distribution and reduced leaching under organic fertilization. These findings highlight the dynamic nature of soil electrical conductivity and its response to different fertilization regimes. Further investigation is needed to elucidate the underlying mechanisms and their implications for optimizing nutrient management practices in strawberry cultivation.

According to preliminary research results, we can state that the increased content of water-soluble sodium salts in irrigation water leads to a slight salinization of soils and an increase in its amount in the studied soil layer during the research period (2018-2020).

Water pH and salt pH tend to change the reaction of the soil environment towards alkaline.

The water used for irrigation has the following electrophysical characteristics: electrical conductivity - 1047 µs/cm; total dissolved solids - 708 mg/l (ppm); salinity - 540 mg/l (ppm); pH - 6.78, which is characterized as water with an average level of dissolved salts.

The water used for irrigation has a small amount of water-soluble potassium - 6 mg/l (ppm); much more water-soluble calcium - 93 mg/l (ppm); and the highest amount of water-soluble sodium - 190 mg/l (ppm).

The potassium content of strawberry petioles is at least twenty times higher than that of calcium and sodium. In the control variant of the research, the cation content in the fruits of garden strawberries is the highest. The lowest levels of calcium and sodium are found in the fruit of plants from the organic-mineral fertilizer system and the mineral fertilizer system. The average calcium, sodium and potassium content of the organic fertilizer system among the variants studied.

Plant sap analysis offers real-time insights into the nutritional status of plants, enabling growers to fine-tune nutrient applications, optimize yield and quality, and potentially extend the fruiting season. By complementing soil solution analysis, plant sap analysis provides a comprehensive picture of nutrient dynamics, facilitating informed decisions about fertilizer management.

Maintaining optimal salinity and pH levels in irrigation water is crucial for cultivating healthy and productive plants. Regular monitoring and adjustments of these parameters ensure a favorable environment for nutrient uptake and overall plant growth.

WATER RESOURCE MANAGEMENT IN FRUIT AND VEGETABLE PRODUCTION USING ALTERNATIVE MULCHES

Gary L. HAWKINS

University of Georgia, 1420 Experiment Station Road, Watkinsville, GA 30677, USA

Corresponding author email: ghawkins@uga.edu

Abstract

Water management and conservation tillage practices can be important when producing fruit and vegetable crops in areas of limited water resources. This study evaluated six alternative mulching materials - compost, biofilm plastic, newspaper, craft paper, compost with glycerin, and a no-mulch control - against standard low-density polyethylene (LDPE) plastic in a bedded watermelon production system. Three replications of each treatment (mulches) were randomly placed in sections of watermelon rows. Weed density, soil moisture, and temperature were monitored to assess the performance of each mulch. Results showed that all treatments, except for the control and compost, provided effective weed suppression comparable to LDPE. Soil temperature and moisture levels varied across treatments, with compost producing the highest and lowest recorded temperatures. These findings suggest that several alternative mulches, when used in combination with conservation tillage, offer viable, sustainable options for small-scale fruit and vegetable production.

Key words*: sustainability, alternative mulches, water, conservation practices.*

INTRODUCTION

Farmers produce a wide variety of crops that supply the food and fiber essential to our daily lives. In the cultivation of many of these crops - particularly fruits and vegetables - plastic mulches have been used since the 1950s to conserve soil moisture, suppress weeds, stabilize soil temperature, reduce insect pressure, and enhance crop yield (Goldberger et al., 2013; Ibarra-Jimenez et al., 2006; Anderson et al., 1995; Diaz-Perez, 2023; David & Kumar, 2023; Kasirajan & Ngouajio, 2012). These mulches are typically made from low-density polyethylene (LDPE) (Beriot et al., 2023; Kasirajan & Ngouajio, 2012) and are usually removed after one or more production cycles. However, during removal or repeated use, LDPE fragments often remain in the soil, where they do not degrade, or they may be carried to marine environments via runoff (Serrano-Ruiz et al., 2021). When left in the field over multiple seasons, these fragments can form concave pockets that trap water and nutrients, potentially limiting root penetration and affecting plant health (David & Kumar, 2023; Beriot et al., 2023).

A conceptual illustration of these issues is provided in Figure 1.

While recycling may appear to be a potential solution, the processes of removing, cleaning, and repurposing LDPE are complex and largely impractical for most producers (Kasirajan & Ngouajio, 2012). This raises an important question: what are the viable alternatives?

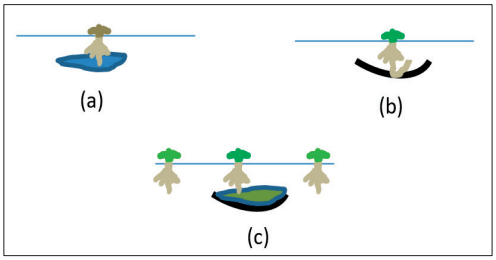

Figure 1. Conceptual illustration of the potential negative effects of residual plastic mulch in the soil: (a) Plastic traps water, leading to root rot and plant death; (b) Plastic impedes downward root growth; (c) Plastic creates isolated zones of water and nutrients, preventing their uptake by surrounding plants (Illustration by G. Hawkins)

Farmers are generally recognized as responsible stewards of the land they manage for food and fiber production (Carmichael et al., 2023; Sherval et al., 2018). While the use of plastic mulch is common and not inherently problematic, many producers seek alternative

approaches that allow them to maintain soil moisture, suppress insect pressure, and, in some cases, protect crops from wind. These approaches often involve the use of alternative mulches in fruit and vegetable production systems (Anderson et al., 1995; David & Kumar, 2023; Kasirajan & Ngouajio, 2012). The farmer collaborating on this project employs conservation tillage practices, incorporating cover crops to enhance soil organic matter, reduce erosion, support soil biota, and provide wind protection for young watermelon plants. He currently uses LDPE plastic mulch to achieve many of these agronomic benefits. However, he has expressed concerns about the long-term accumulation of LDPE in the soil, particularly the potential for creating perched water tables or obstructing root penetration - issues illustrated in Figure 1b. As a result, the objective of this study was to evaluate practical alternatives to LDPE mulch, particularly those that may be better suited for adoption on small farms or in conservation-oriented production systems.

MATERIALS AND METHODS

The project was conducted in the watermelon-growing region near Cordele, Georgia, USA. The collaborating farmer employs conservation tillage practices and plants a cover crops each fall following the harvest of his commercial crop. He also practices crop rotation. In late winter or early spring, he terminates strips of the cover crop in preparation for bedding and planting watermelon. Once the cover crop has fully died back, he prepares the watermelon beds by tilling, forming raised beds, and laying plastic mulch over the planting rows (Figure 2). The plastic is applied using a custom-built plastic layer designed to form beds with a width of 0.45 meters (18 inches), as shown in Figure 2b.

After the plastic mulch was laid, the author cut 8.8-meter (29-foot) sections to install three randomized, replicated treatments: (1) control (no alternative cover), and contractor-grade or brown craft paper. Due to limited availability, treatments using compost and compost mixed with glycerin (a byproduct of biodiesel production) were restricted to shorter sections measuring 2.7 meters (9 feet) in length. A portion of the installed treatments is shown in Figure 3, along with the dataloggers used to monitor soil temperature and moisture.

As shown in Figure 3a and 3b, various sensors were installed during the treatment setup to monitor environmental conditions. Soil moisture sensors (Decagon Devices 10HS Capacitance Sensors; see NOTE), temperature sensors (Decagon Devices), a rain gauge (Decagon Devices ECRN-50), and a datalogger (Decagon Devices EM-50) were used to collect data on soil moisture and temperature at 15-minute intervals. Soil moisture sensors were installed vertically to monitor the top 15 cm (6 inches) of the soil profile, while temperature sensors were placed directly on the soil surface beneath each mulch treatment.

(a) Multiple treatment rows with various mulch types; (b) Newspaper mulch with planted watermelon seedlings; (c) Craft paper mulch with planted watermelon seedlings (Images by G. Hawkins)

Throughout the growing season, weed density was also monitored. Weeds were counted, averaged by treatment, and normalized to a per-acre basis to enable comparison.
All collected data were stored, analyzed, and graphed using Microsoft Excel.
After sensor installation and treatment setup, the farmer mechanically planted the watermelon crop

RESULTS AND DISCUSSIONS

The findings from this study are presented in the following figures and categorized by key parameters: weed count, temperature, and soil moisture.

Weed Count

As shown in Figure 4, the standard LDPE plastic mulch resulted in minimal weed emergence, with yellow nutsedge being the only species able to penetrate the mulch, averaging fewer than 444 plants per acre across five weekly sampling events (Webster, 2005). Similarly, biodegradable plastic, newspaper, craft paper, and compost with glycerin treatments also exhibited low weed pressure, with the newspaper treatment recording the highest among them - averaging 900 plants per acre.
Microbial activity trends corresponding to these treatments are summarized in Table 1, which presents colony counts over a five-week period. Compost treatment showed a steady increase in microbial populations, peaking at 47,329 CFU by May 17. In contrast, the control treatment had the highest microbial counts overall, while treatments like biofilm, newspaper, and craft paper exhibited moderate microbial activity. Compost with glycerin showed minimal microbial growth until the final sampling date, when a notable increase was observed.
In contrast, significantly higher weed densities were observed in the compost and no-mulch (control) treatments. The compost treatment averaged over 20,000 weeds per acre, while the control plot had the highest count, averaging over 48,000 plants per acre across the sampling period.

Tabel 1. Temporal dynamics of microbial populations under different organic amendments and controls

Sampling Date	Control	Biofilm	Newspaper	Craft Paper	Compost Gly	Compost
4/19/2010	18000	0	0	0	0	4303
4/26/2010	32333	0	0	333	0	6454
05/03/2010	48000	1000	667	333	0	15059
05/10/2010	63333	1500	1333	1000	0	31194
5/17/2010	78667	500	2667	0	2151	47329

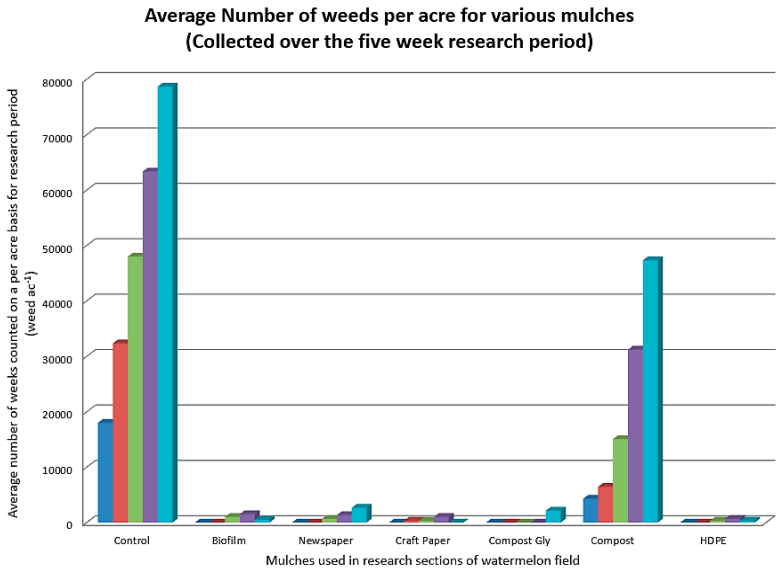

Figure 4. Graph and associated table showing the number of weeds collected from each mulch type during the five-week research period as indicated standardized to a per acre basis

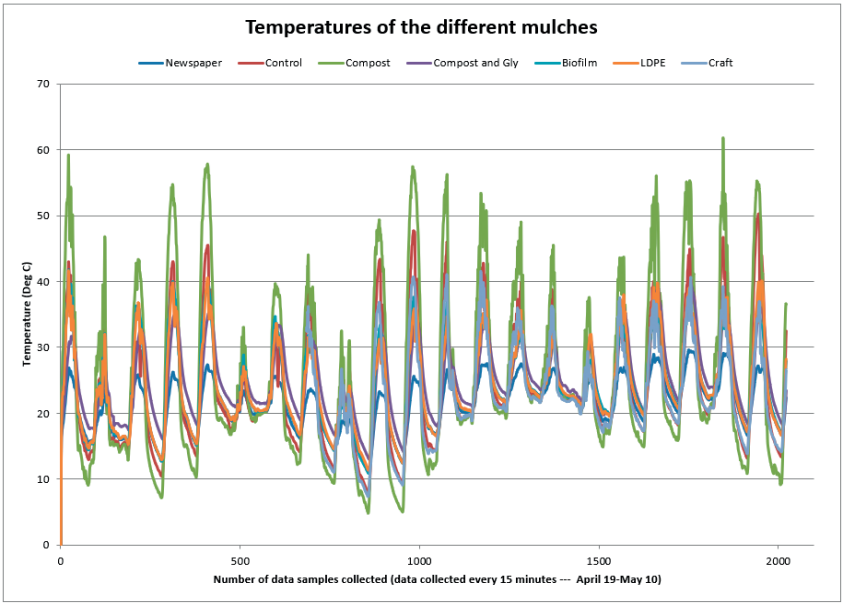

Figure 5. Temperatures as measured for the different treatments

Soil Moisture

Figure 6 illustrates the soil moisture dynamics under each mulch treatment throughout the study period. Soil moisture was measured to evaluate how different mulches influenced water retention in response to precipitation, which in this case included both natural rainfall and supplemental irrigation via a center pivot system.

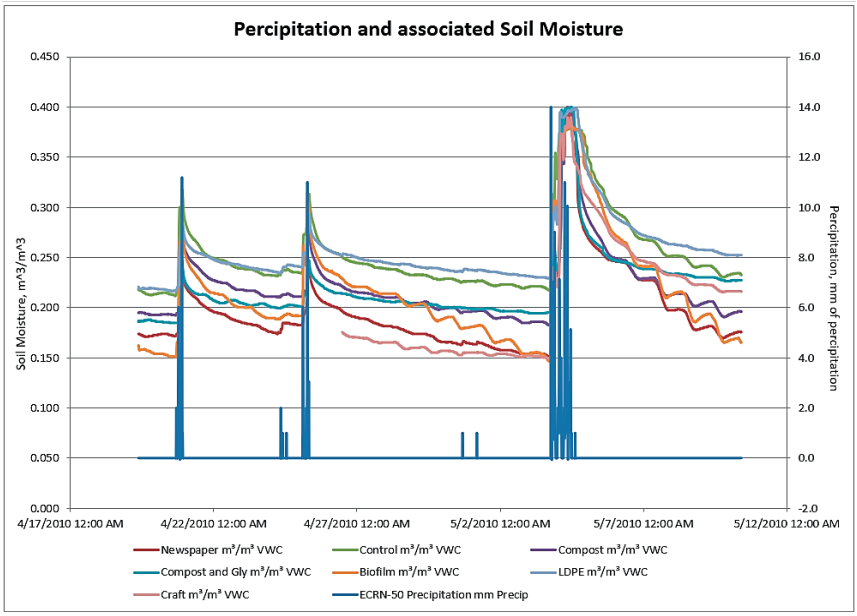

Figure 6. Precipitation and associated soil moisture under each mulch as measured in the top vertical 15 cm (6 inches) of soil

Soil moisture levels under the LDPE and control treatments were generally the highest, ranging from 0.22 to 0.40 $m^3 m^{-3}$. In contrast, the craft paper and newspaper treatments exhibited lower soil moisture levels, ranging from 0.15 to 0.40 $m^3 m^{-3}$. These differences suggest that denser or less permeable mulches like LDPE are more effective at conserving soil moisture.

Moisture loss patterns also varied based on precipitation intensity. Following small rainfall events (e.g., 10 mm), water infiltration and retention were relatively steady across treatments. However, during larger precipitation events (e.g., around May 4, which included multiple days with up to 14 mm of rainfall), the rate of moisture loss increased -likely due to higher soil saturation and increased evapotranspiration from expanding watermelon vines.

Overall, the soil moisture under all treatments was reasonably well maintained, aided by the irrigation system. For smaller-scale farms, drip or solid-set irrigation systems could offer similar benefits. Despite differences in volumetric water content across treatments, the rate of soil moisture decline remained consistent, highlighting the importance of mulch type in managing soil water retention.

CONCLUSIONS

This project demonstrated that several alternative mulches can be viable options for fruit and vegetable production, particularly for farmers seeking more sustainable practices. All tested mulches, except for compost, were effective in suppressing weeds and maintaining soil moisture levels comparable to those under standard LDPE plastic.

However, soil temperature responses varied among treatments, and some materials - such as compost - produced extreme temperature fluctuations that could pose risks depending on the crop. Additionally, practical considerations such as ease of deployment remain important. While all alternative mulches in this study were hand-laid, scaling their use for larger operations may present logistical challenges without specialized equipment.

Overall, with appropriate selection based on crop needs and farm scale, alternative mulches offer promising potential to support sustainable and conservation-oriented production systems.

ACKNOWLEDGEMENTS

This research was conducted under a grant from the Southern SARE located in Griffin, Georgia. The author would also like to thank his technician for all his help with the project.

NOTE

Mention of specific company names does not imply recommendation by the author, or the University of Georgia, USA and other products may provide the same data. Decagon Devices were used in this study, but the company has been purchased by METER Group since the date of this research, but the current sensors are the same capacitance sensors as used in the research.

Abstract

This study assesses the groundwater quality at the CET HIDROCARBURI ARAD site using a Global Pollution Index (I^*_{GP}) methodology that integrates multiple water quality indicators concerning legal thresholds. Water samples from three monitoring wells were collected annually over 11 years (2010-2020) and analyzed for pH, total suspended solids, fixed residue at 105°C, and chemical oxygen demand. The findings reveal that 93.94% of the samples exceeded acceptable limits based on 2008 regulatory references, with pollution levels surpassing ecological thresholds, particularly in Control Well No. 3, indicating persistent ecological stress. Despite this, long-term trends suggest overall groundwater stability, with 78.79% of historical data (2008-2017) falling within permissible ranges. Statistical analysis highlighted variations in pH and COD, suggesting localized impacts from nearby facilities such as a reagent store. The study recommends implementing a sustainable, site-specific water management plan supported by real-time monitoring and targeted assessments of emerging contaminants to enhance environmental protection and risk mitigation.

Key words*: groundwater quality, global pollution index, hydrocarbon power plant, environmental risk, statistical analysis.*

INTRODUCTION

Water is a fundamental resource essential for human development and ecological stability. It plays a critical role in agriculture, industry, and domestic use; however, only a tiny fraction of the Earth's water is readily accessible and of acceptable quality.

One critical concern is the degradation of groundwater due to industrial activities. Modern industrialization and population growth have amplified pollutant loads in surface and subsurface waters, surpassing nature's regenerative limits. This imbalance threatens aquatic ecosystems and poses risks to human health (Ahmed et al., 2022; Bashir et al., 2020).

Water quality, therefore, is not only an immediate environmental issue but a strategic national priority. It intersects local, regional, and global geospheres, which is key in maintaining Earth's ecological balance (Ullah et al., 2024). Protecting water resources requires the integration of comprehensive environmental policies into urban planning, especially in densely populated areas where contamination risks are highest (Guan et al., 2024).

Groundwater, a vital resource for drinking and irrigation, is increasingly vulnerable to pollution from surface-level industrial and technological activities (Ahmed et al., 2022; Al-Awah et al., 2023; Jayaswal et al., 2018; Zaharia, 2012; Zaharia et al., 2009). Such activities often discharge hazardous substances that pose immediate and long-term threats to environmental and public health (Biswas et al., 2014; Jalali et al., 2024; Krenkel, 2012; Sutadian et al., 2016; Ullah et al., 2024; Zainudin et al., 2024).

Among industrial sources, district heating plants present a significant risk to groundwater safety. Ageing infrastructure, corroded pipes, and fuel storage failures can lead to the release of heavy metals, hydrocarbons, salts, and industrial chemicals into soils and aquifers (Xiao et al., 2020; Liu et al., 2019). Understanding the migration of these contaminants through hydrogeological modeling enables early risk

identification, remediation planning, and legal compliance.

Pollutants associated with heating plants vary by fuel type and may include heavy metals (Bashir et al., 2020; Deshmukh et al., 2021; Hu & Shan, 2020a), nutrients like phosphates and nitrates (Isiuku & Enyoh, 2020), salts (Al-Aboodi et al., 2018), hydrocarbons (Jiang et al., 2022), and even radioactive substances in the case of nuclear facilities (Aly et al., 2020). Their monitoring is essential to maintaining water safety (Mokarram et al., 2023).

Pollution indices are widely used, cost-effective tools for evaluating water quality and informing environmental policy, especially in resource-limited settings (Berhanu et al., 2024; de Rosemond et al., 2009; Ravindiran et al., 2024; Thirumoorthy et al., 2024; Zaharia, 2012; Kumar et al., 2024). When combined with hydrogeological data, these indices offer a practical framework for understanding and managing contamination risks near industrial sites.

In line with EU regulations, including Directive 2000/60/EC and Directive 2006/118/EC, continuous groundwater monitoring is required to prevent and detect anthropogenic pollution, particularly where groundwater is a primary drinking water source. Romanian legislation reinforces these directives through national acts such as Water Law no. 107/1996 and Government Decision no. 188/2002, although explicit pollutant thresholds are sometimes lacking.

At CET H Arad, groundwater monitoring follows these legal frameworks, with four key indicators - pH, total suspended solids, fixed residue at 105°C, and COD-Cr - specified in the water management permit. These values are benchmarked against a 2008 reference sample (Analysis Bulletin, 14.11.2008). Any exceedance triggers immediate response to limit environmental harm.

To evaluate groundwater quality from 2010 to 2020, this study applied the Global Pollution Index (I_{GP}^{*}), integrating multiple parameters into a single, comprehensive score. Measurements at three monitoring wells revealed spatiotemporal variations in pollution levels linked to plant operations and well proximity, particularly in downstream locations.

These findings support the development of a robust, site-specific water management strategy and provide a replicable methodology for similar industrial environments. By coupling long-term data with integrated assessment tools, this research advances interdisciplinary knowledge at the intersection of environmental monitoring, regulatory policy, and industrial ecology.

MATERIALS AND METHODS

The municipality of Arad is situated in western Romania, bridging the southern Crisana and northern Banat regions within the expansive Tisza River plain. Geographically, it lies in the alluvial Arad Plain - part of the Western Plain - at 46°11′N latitude and 21°19′E longitude. The city spans 252.85 km² and is located at an altitude of 107 meters above sea level, alongside the Mureș River near the Deva-Lipova corridor. CET H Arad is located in the eastern central area of the municipality, approximately 1 km from the Arad railway station. Positioned on both sides of the Mureșel Canal - a branch of the Mureș River and a discharge route for treated wastewater – the plant occupies 3.62 hectares. It is not part of any protected area.

Commissioned in 1897 as Arad's first electricity source, the plant began with steam-driven generators and transitioned through various fuels: coal dust (1897-1953), fuel oil (1953-1963), a fuel oil-natural gas mix (1963 onward), and exclusively natural gas since 2009. It has long served the region’s thermal and industrial energy needs via combined heat and power systems.

No other major external pollution sources are identified in the study area. However, a sewage reservoir located roughly 15 meters from Control Well No. 1, belonging to a neighboring facility, may pose a potential risk. Similarly, a reagent store near Control Well No. 3 handles substances used for chemical water treatment, representing another possible contamination source.

Historically, CET H Arad operated four large combustion facilities, totaling over 50 MW of thermal output, regulated under EU industrial emission directives. These included two steam generators, a TA1 turbogenerator, and two hot water boilers, with a combined 362 MWt thermal and 12 MWe electric capacity. Electricity production ceased in 2008, and the facility is currently undergoing modernization, with older units scheduled for decommissioning.

Two medium combustion units remain in operation, providing 99 MWt of thermal energy. Groundwater quality at the site is monitored through three boreholes designated as control wells. Positioned in relation to the plant, Well No. 1 lies upstream, while Wells No. 2 and No. 3 are located downstream (Figure 1 and Table 1).

Control well No. 2	217343.56	526687.81
Control well No. 3	217182.34	526835.62

Methodology

Groundwater samples were analyzed for four key parameters: pH, Total Suspended Solids (TSS), Fixed Residue at 105°C, and Chemical Oxygen Demand (COD-Cr). Sampling was conducted annually over an 11-year period (2010–2020), following national standards and regulatory frameworks, including the Water Law no. 107/1996, Government Decision no. 188/2002, and the Ministry of Environment's Monitoring Plan (Romanian Parliament, 1996; Romanian Government, 2002; MMGA, 2006). A minimum of four duplicate samples were collected and analyzed each year, in accordance with officially approved methods outlined in Romanian legislation (MMGA, 2006). The measured values were compared against multiple reference points:

- Authorized baseline values from CET H Arad's 2008 test report.
- Historical groundwater quality levels (2008-2017).
- National standards for drinking water (STAS 1342/91; Romanian Standards Institute, 1991).
- Legal thresholds for wastewater discharged into the aquatic environment.

Sampling was limited to the three existing control wells on-site, as mandated by the

operational permits, which stipulate annual testing per well. The results, including the calculated Global Pollution Index ((I^*_{GP}), were graphically represented for each sampling location to visualize trends and deviations.

Reference data, including authorized and historical limits, are detailed in Table 2, while national drinking water standards used for comparative analysis are presented in Table 3.

To evaluate groundwater pollution, the study employed the methodology developed by Zaharia (Zaharia, 2012; Zaharia & Murarasu, 2009), which is particularly well-suited for regulatory assessments focused on legal compliance. This approach offers a practical and straightforward means of aggregating multiple pollutant measurements into a single standardized index. Its simplicity, combined with its ability to track trends and facilitate comparisons, makes it an effective tool for communicating findings to policymakers, regulators, and other stakeholders.

The first step involves calculating a quality index (EQ_i) for each parameter using the following formula:

$$EQ_i = \frac{C_{i,measured}}{MACi} \quad (1)$$

where:

- EQ_i is the quality index for parameter I;
- C_i is the measured concentration of parameter I;
- MAC_i is the maximum allowable concentration according to applicable standards.

Following the calculation of the quality index (EQ_i), each parameter was assigned an Evaluation Score (ES_i) based on the scale provided in Table 4.

Table 2. Reference levels for groundwater at CET H ARAD
(Water Management Authorization, 2018*Aut. G. Water; Integrated Environmental Authorization *AIM CET H Arad, 2018; Dumescu, 2018)

Sampling point	Legal reference level *Test control_ Year 2008 cf. *Aut. G. Water CET H and *AIM				Historical reference level CET H cf.

Control well No. 3	7.00	1.60	458.20	4.90	7.00-7.50	9.40-13.00	192.00-421.60	4.90-5.50

Table 3. The admissible values according to STAS 1342/91 - drinking water
("Romanian Standards Institute, STAS 1342-91, Drink Water" 1991) for the quality indicators considered in the study

STAS 1342-91-DRINKING WATER Quality indicators (i)							
Allowed values (A)				Exceptionally allowed values (EA)			
pH	TSS	Fix residue at 105°C	COD-Cr	pH	TSS	Fix residue at 105°C	COD-Cr
[pH units]	[mg/l]	[mg/l]	[mg/l]	[pH units]	[mg/l]	[mg/l]	[mg/l]
6.50 -7.40	-	100.00-800.00	3.00	max. 8.50	-	30.00-1200.00	5.00

Both the Specific Quality Index and corresponding Evaluation Score were computed for each monitored parameter in the groundwater samples. These calculations referenced four benchmarks:

- Legal thresholds defined in the water management and integrated environmental authorizations;
- Historical groundwater data from CET H Arad (2008-2017);
- National drinking water standards (STAS 1342/91);
- Regulatory limits for wastewater discharge into aquatic environments.

Subsequently, the groundwater pollution status at each sampling location was evaluated using

the Global Pollution Index (I^*_{GP}), integrating all reference cases.

The overall Global Pollution Index for each sample was calculated using the following equation (Zaharia, 2012; Zaharia & Murarasu, 2009):

$$I^*_{GP} = (100 * n)/(ES_1 * ES_n + \sum_{i=1}^{n-1} ES_i * ES_{i+1}) \quad (2)$$

where:

- I^*_{GP} is the Global Pollution Index,
- n is the number of parameters,
- ES refers to the assigned Evaluation Score for each parameter.

The final pollution classification for each sampling point was determined using the interpretation scale provided in Table 5.

Table 4. Correlation scale between Quality Index (EQi), Evaluation Score (ESi), and environmental impact on the pollution level for the sampling points monitored on the CET H Arad sit (Zaharia, 2012)

Quality Index (EQ_i)	Evaluation Score (ES_i)	Environmental Impact
$EQ_i = 0$	10	Water bodies are unaffected by industrial activity.
$0.00 < EQ_i \leq 0.20$	9	Industrial influence is present but not quantifiable.
$0.20 < EQ_i \leq 0.70$	8	Impact detected, but below first alert threshold. Alert level: Possible consequences.
$0.70 < EQ_i \leq 1.00$	7	Impact within second-level permissible limits. Intervention level: Potential outcomes expected.
$1.00 < EQ_i \leq 2.00$	6	Pollution exceeds the first legal limit. Effect: Noticeably strong impact.
$2.00 < EQ_i \leq 4.00$	5	Pollution surpasses the second limit. Effect: Environmentally detrimental.
$4.00 < EQ_i \leq 8.00$	4	Third limit exceeded. Effect: Clear negative consequences.
$8.00 < EQ_i \leq 12.00$	3	Severe degradation – Level 1. Impact: Fatal effects over average exposure duration.
$12.00 < EQ_i \leq 20.0$	2	Severe degradation – Level 2. Impact: Rapid onset of fatal effects.
$EQ_i > 20.00$	1	Environment rendered unsuitable for life.

Table 5. Correlation of Global Pollution Index, I^*_{GP}, with effects in the water body (Zaharia, 2012)

Values I^*_{GP}	Consequences in the body of water
1	Water body unaffected by human activity.
$1 \leq I^*_{GP} < 2$	Minor anthropogenic influence; human activity is within acceptable environmental bounds.
$2 \leq I^*_{GP} < 3$	Noticeable stress on aquatic life is caused by human activity.
$3 \leq I^*_{GP} < 4$	Significant disruption of biological processes due to pollution.
$4 \leq I^*_{GP} < 6$	Serious ecological damage; aquatic life is endangered.
$I^*_{GP} > 6$	degraded body of water unfit for all living forms

To evaluate whether the monitored parameters varied significantly across the control wells, the F-test (ANOVA: Single Factor) was applied. This statistical approach was essential in determining whether differences in parameter values could be attributed to the wells' positions relative to the potential pollution source.

The analysis involved hypothesis testing as a structured method to assess statistical significance using the variables detailed in Table 6. The null and alternative hypotheses were defined as follows:

- H_0 (Null Hypothesis): The parameter values across the wells do not significantly differ; any observed variations are random, indicating that the well's location does not influence the results.
- H_1 (Alternative Hypothesis): The parameter values differ significantly, suggesting that variations are influenced by the sampling well's proximity to the potential source of contamination.

This framework provided the basis for interpreting spatial trends and assessing localized impacts on groundwater quality.

Table 6. Variables considered in the statistical analysis of groundwater quality at CET H Arad

Independent variable	Dependent variable	Constant elements
Control well No. 1	pH, COD-Cr, Total Suspended Solids (TSS), Fixed Residue	Well position relative to the pollution source
Control well No. 2		Temperature periodicity
Control well No. 3		Precipitation regime periodicity

RESULTS AND DISCUSSIONS

Evaluation of the power plant activity on the quality of groundwater based on global pollution index

To assess the impact of CET H Arad's operations on groundwater quality, multiple evaluation scenarios were considered. Maximum permissible values for the monitored parameters - pH, TSS, fixed residue at 105°C, and COD-Cr - were derived from the site's Water Management Authorization and Integrated Environmental Authorization.

After calculating the Global Pollution Index, the results were illustrated in Figure 1. These indicate a general deterioration of groundwater quality, with pollution levels causing discomfort to aquatic life - except in 2016, when I^*_{GP}, values remained within allowable limits (Figure 2).

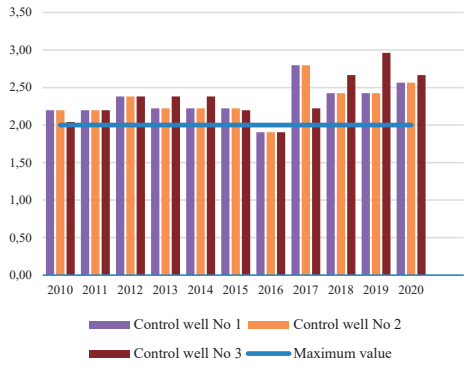

Figure 2. Results of groundwater quality assessment based on the referential values from the Water Management Authorization and Integrated Environmental Authorization for CET H Arad

A second scenario involved benchmarking results against the site's historical baseline values. As illustrated in Figure 3, groundwater quality generally remained within acceptable historical limits. However, notable exceptions were observed:

- Control Well No. 1 in 2017 and 2020;
- Control Well No. 2 in 2018, 2019, and 2020;
- Control Well No. 3 in 2019 and 2020.

In these cases, the I^*_{GP}, values exceeded thresholds, signaling environmental stress and potential ecological discomfort.

While many values did not surpass regulatory limits, a concerning upward trend in I^*_{GP}, values over the last three years suggest emerging risks. This trend warrants closer investigation into potential operational changes or external factors influencing groundwater quality during that period.

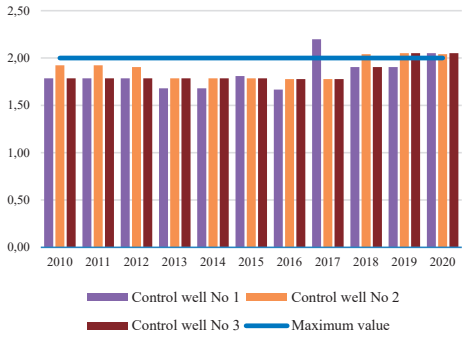

Figure 3. Groundwater quality results based on historical annual mean values (2008-2017) for CET H Arad

The analysis also included a comparison of groundwater quality results against standardized drinking water values: the Accepted (A) limits shown in Figure 4, and the Exceptionally Accepted (AE) limits presented in Figure 5.

These reference values were sourced from national standards for drinking water quality (Romanian Standards Institute, STAS 1342-91, 1991).

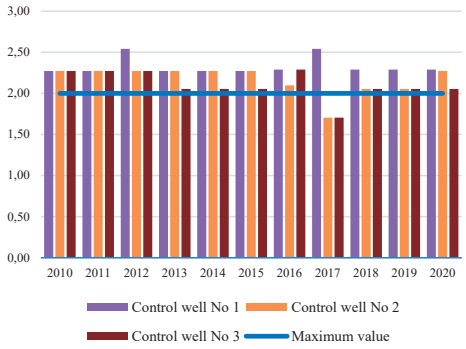

Figure 4. Results obtained according to STAS 1342-91 - Drinking water - Permissible values (A)

Although this comparison does not imply that groundwater from the CET H Arad site is intended or suitable for human consumption, it serves as a meaningful benchmark for evaluating the aquifer's environmental condition. This approach strengthens the broader purpose of the study, which is to understand, monitor, and manage groundwater quality in proximity to hydrocarbon power plant operations.

Assessing the site's groundwater status was a central objective of this investigation. It provides critical insights into the environmental impact of CET H Arad's activity and supports the formulation of preventive strategies to mitigate pollution and maintain groundwater quality.

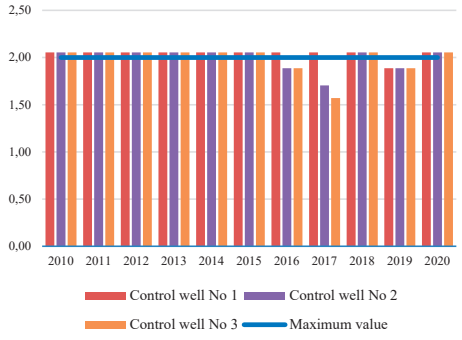

Figure 5. Results obtained in accordance with STAS 1342-91 drinking water - Exceptionally permissible values (EA)

When compared to the accepted drinking water standards (A), the I^*_{GP} values generally indicate discomfort to life forms throughout the study period, except for Control Wells 1 and 3 in 2017, where values fell within acceptable limits (Figure 4). Similarly, when assessed against the exceptionally accepted values (AE), discomfort was still observed in most years, except for Control Well No. 1 in 2019, and Control Wells No. 2 and 3 in 2016, 2017, and 2019, which showed groundwater quality within acceptable bounds (Figure 5).

Despite these occasional acceptable readings, groundwater from the CET H Arad site is not suitable for drinking, as contaminants from hydrocarbon-related processes pose potential health risks if leaked into the aquifer.

Further analysis was performed using Romanian regulatory standards for wastewater discharged into aquatic environments ("Romanian Government, Decision No. 188/2002"). When comparing I^*_{GP} values against these permissible limits, groundwater quality was again generally poor, with discomfort levels indicated across most years. Exceptions were noted in:

- Control Well No. 1 in 2019,
- Control Well No. 2 in 2016 and 2019,
- Control Well No. 3 in 2016, 2017, and 2019 (Figure 6).

These findings reinforce the need for continued monitoring and risk management at the site, especially considering localized pollution trends.

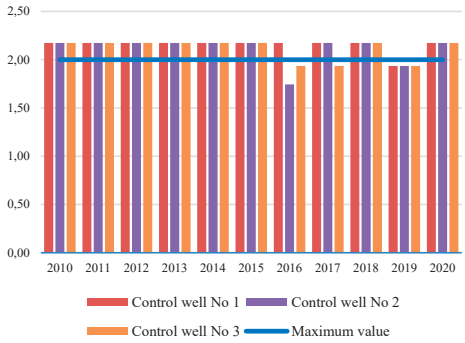

Figure 6. Groundwater quality assessment results compared to the permissible values for technological wastewater discharged into the aquatic environment, as specified by *Government Decision No. 188/2002* (HG 188/2002)

Across the 2010-2020 study period, various referential benchmarks were used to calculate the Global Pollution Index (I^*_{GP}) for groundwater at the CET H Arad site. The results consistently indicate a state of environmental discomfort for life forms in most cases, except for comparisons to historical site-specific values from 2008-2017. When evaluated against this Historical Level, 78.79% of the samples remained within permissible limits.

In contrast:

- Using the Water Management Authorization and Integrated Environmental Authorization thresholds, 93.94% of values exceeded acceptable levels, with only 6.06% falling within legal limits.
- The same proportion (93.94%) was observed when compared to standardized drinking water values (A).
- For exceptionally accepted values (AE) for drinking water, 78.79% of samples were categorized as causing discomfort, while 21.21% were within limits.

- A similar distribution was found when comparing I^*_{GP} results against the permissible values for technological wastewater discharge, mirroring the percentages associated with AE.

These findings emphasize the groundwater body's vulnerability to industrial impact, highlighting the need for continuous monitoring and targeted mitigation strategies.

Evaluation Based on Statistical Analysis

In addition to index-based evaluation, the study incorporated statistical analysis of four key groundwater parameters - pH, COD-Cr, TSS, and fixed residue - monitored at the three control wells from 2010 to 2020. Given the nature of hydrocarbon power plant operations, impacts may arise from combustion byproducts, chemical treatments (acids or alkalis), or accidental spills.

A Fisher F-test (ANOVA: Single Factor) was used to determine whether variations in these parameters were statistically significant across the wells. The analysis was grounded in the previously defined null (H_0) and alternative (H_1) hypotheses regarding spatial variation due to the plant's location.

As an example, pH variation is shown in Figure 7. Between 2010 and 2015, pH levels in Control Well No. 2 (downstream) were consistently higher than those in Well No. 3 (also downstream). Interestingly, the pH values for Well No. 1 (upstream) closely resembled those of Well No. 2 during this period, suggesting minimal or no influence from plant operations on this parameter.

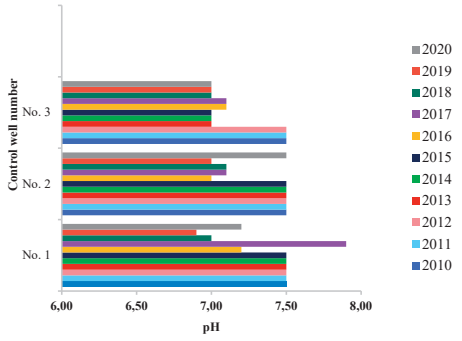

Figure 7. Variation in pH levels across the three control wells (Wells 1, 2, and 3) at CET H Arad during the 2010–2020 monitoring period

To visualize potential trends and deviations, the average pH values across the wells were plotted (Figure 8). This graph highlights long-term fluctuations and can be used to assess whether pH variations fall within standardized limits, potentially revealing early signs of deviation or pollution influence.

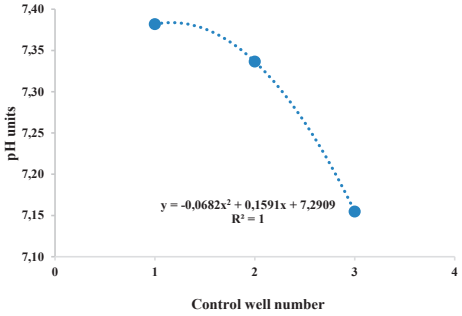

Figure 8. The function for calculating the pH variation in the three sampling points

A distinct pattern emerged when analyzing the variance in Chemical Oxygen Demand (COD-Cr) across the wells. Statistically significant differences were identified between Control Wells 1 and 2 and Wells 1 and 3, indicating that well location relative to the power plant (upstream vs. downstream) may influence COD-Cr concentrations.

This conclusion is further supported by the lack of significant variation between Wells 2 and 3, both situated downstream of the CET H Arad facility. These findings validate hypothesis H_1 (the location affects parameter variation), rejecting H_0 (no significant difference). Specifically:

- For Wells 1 and 2, $P = 0.045 < 0.05$ and $F = 4.57 > F_{crit} = 4.35$.
- For Wells 1 and 3, the variation is even more pronounced, with $P = 0.013$ and $F = 7.51 > F_{crit} = 4.35$.

Average COD-Cr values exhibited a descending trend from Well 1 to Wells 2 and 3, indicating a reduction in oxidizable substances and oxygen demand. This may be explained by a sewage collection reservoir located approximately 15 meters from Well 1, which likely contributes to higher concentrations of organic compounds upstream. As groundwater flows downstream, these substances appear to dilute, improving aerobic conditions for aquatic life.

In recent years, Well 1 consistently recorded higher COD-Cr values, especially from 2016

onward, except for 2017. That year, Wells 2 and 3 showed a nearly 80% drop in COD-Cr levels compared to the previous year (Figure 9). This anomaly may correlate with significant rainfall and elevated Mureș River discharge in 2017, leading to increased groundwater recharge and dilution of pollutants in the aquifer. The trend of COD-Cr over time is best represented by a second-degree polynomial function, reflecting the non-linear pattern of concentration changes (Figure 10).

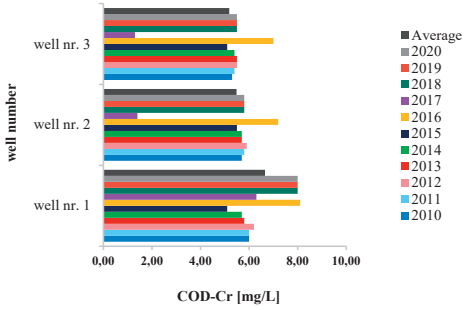

Figure 9. Variation in Chemical Oxygen Demand (COD-Cr) across the three control wells at CET H Arad during the 2010–2020 monitoring period

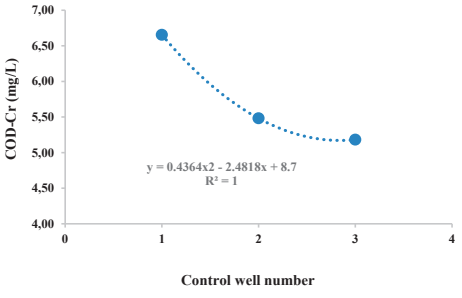

Figure 10. The function for calculating the COD-Cr variation in the three sampling points

A consistent pattern was observed across all control wells for Total Suspended Solids (TSS) (Figure 11). From 2010 to 2016, TSS concentrations remained relatively stable, averaging around 2 mg/L. However, a sharp increase was noted during 2017–2019, with average values rising by approximately eightfold. In 2020, TSS levels declined by about 30% compared to the peak period, suggesting a potential link with annual rainfall volume and temperature fluctuations.

Unlike other parameters, TSS exhibited a linear variation across the three wells (Figure 12), indicating a consistent spatial distribution pattern unaffected by well location.

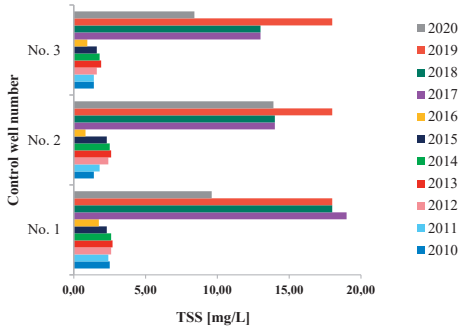

Figure 11. TSS variation in the three wells during the studied period

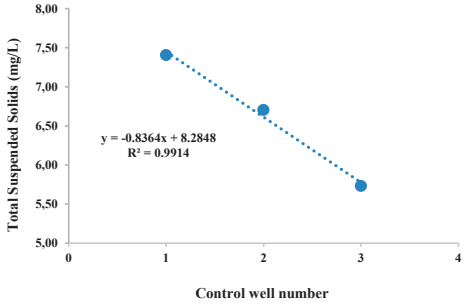

Figure 12. The function for calculating the TSS variation in the three sampling points

As expected, Fixed Residue followed a similar trend to TSS over the study period (Figure 13), given that suspended particles significantly contribute to the residual solids in water samples.

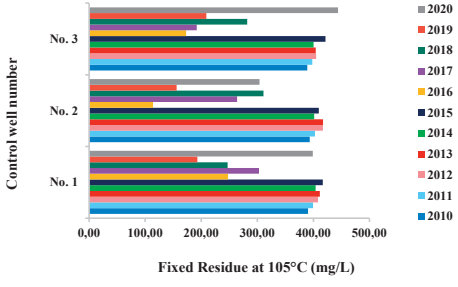

Figure 13. Fixed residue variation in the three wells during the studied period

The inter-well variation in Fixed Residue (Figure 14) showed a second-degree polynomial trend, comparable to the observed pattern in pH variations, highlighting non-linear distribution influenced by both suspended load and water chemistry dynamics.

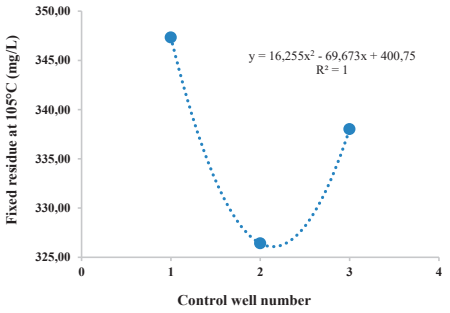

Figure 14. The function for calculating the fixed residue variation in the three sampling points

As shown in Table 7, the statistical comparison of pH values between control wells revealed no significant differences among most pairings.

For Wells 1 and 2, the *P-value = 0.683 > 0.05* and $F = 0.172 < F_{crit} = 4.351$, indicating that variations are likely due to random factors rather than spatial influences. A similar outcome was observed between Wells 2 and 3, where $P = 0.082 > 0.05$ and $F = 3.521 < F_{crit} = 4.351$. These results suggest that pH levels remained relatively stable across the sampling points and were not significantly influenced by the wells' positions in relation to the power plant.

The results summarized in Table 7 support the acceptance of the null hypothesis (H_0) in the comparisons of pH values between Wells 1 and 2, and Wells 2 and 3, where no statistically significant differences were found. These variations appear to result from arbitrary or random factors rather than systematic spatial influences.

Table 7. The ANOVA F and P parameters resulted after the comparison of the measured groundwater quality parameters for the control wells

Comparison Between Wells	Parameter	F Value	F Critical	p Value	Significant Difference*
Well No. 1 vs Well No. 2	pH	0.172	4.351	0.683	No
	COD-Cr	4.571	4.351	0.045	Yes
	TSS	1.11	4.351	0.314	No
	Fixed Residue at 105°C	0.793	4.351	0.388	No
Well No. 1 vs Well No. 3	pH	4.358	4.351	0.05	Slight (borderline)
	COD-Cr	7.511	4.351	0.013	Yes
	TSS	2.136	4.351	0.181	No
	Fixed Residue at 105°C	3.14	4.351	0.103	No
Well No. 2 vs Well No. 3	pH	3.521	4.351	0.082	No
	COD-Cr	2.401	4.351	0.145	No
	TSS	1.893	4.351	0.203	No
	Fixed Residue at 105°C	0.922	4.351	0.356	No

This pattern extends to Total Suspended Solids (TSS) and Fixed Residue, where all inter-well comparisons, including Wells 2 and 3 for COD-Cr, showed no significant differences. As with pH, the lack of significance suggests that these parameters were largely unaffected by well positioning or hydrocarbon plant activity during the evaluated period.

However, in contrast, a slight but statistically significant difference in pH was detected between Wells 1 and 3 ($P = 0.0498 < 0.05$; $F = 4.358 > F_{crit} = 4.351$), implying potential localized influence. More pronounced effects were observed for COD-Cr:

- Between Wells 1 and 2: $P = 0.0451 < 0.05$; $F = 4.5708 > 4.351$.
- Between Wells 1 and 3: $P = 0.0126 < 0.05$; $F = 7.511 > 4.351$.

These findings partially reject H_0 and weakly support H_1, suggesting that well positioning relative to the power plant may influence groundwater chemistry - particularly for parameters like pH and COD-Cr.

On average (2010-2020):

- pH at Well 3 was approximately 3% lower than at Well 1.
- COD-Cr was 28% higher at Well 3, and 21% higher at Well 2, compared to Well 1.

This may reflect the effects of chemical reagent use and disposal near downstream wells, potentially linked to the hydrocarbon plant's daily operations. While the differences are not

universally significant, the results warrant further investigation and highlight the need for a targeted environmental management strategy to monitor and mitigate potential impacts.

CONCLUSIONS

This study applied the Global Pollution Index (I^*_{GP}) to evaluate the groundwater quality at the CET H Arad hydrocarbon power plant site. Annual water quality data collected over an 11-year period (2010-2020) from three control wells formed the basis for assessing key environmental indicators.

The findings reveal that, in 93.94% of cases - when measured against legal thresholds outlined in the Water Management Authorization and Integrated Environmental Authorization - pollution levels were high enough to cause discomfort to aquatic life. This conclusion is based on comparisons with a 2008 baseline sample defined as legal reference.

Control Well No. 3, located downstream of the plant, emerged as the most impacted, consistently exhibiting I^*_{GP}values indicative of ecological stress. Nonetheless, the overall groundwater system appeared stable during the studied period. When compared to the site's historical quality baseline (2008-2017), 78.79% of the readings fell within permissible limits, suggesting no significant long-term degradation. Statistical analysis further confirmed that Control Well No. 3 is most affected, especially in terms of pH and COD-Cr levels. These differences are likely linked to the well's proximity to potential pollutant sources, supporting the idea of localized environmental influence from plant activities.

Given the high proportion of samples exceeding authorized values and the aquifer's connection to the ROMU20 and ROMU22 groundwater bodies, which serve as sources for drinking water downstream, the potential risk to human health and ecosystems is significant. This underscores the urgent need for a sustainable and adaptive groundwater management plan.

Although the Global Pollution Index and statistical tools provide valuable insight, their effectiveness is limited by their reliance on historical or annual data, which may fail to capture temporal fluctuations or short-term pollution events. Thus, a more robust monitoring strategy is recommended, incorporating:

- Quarterly or monthly sampling to improve data resolution;
- Expanded monitoring networks with additional wells positioned at varying distances from the plant;
- Real-time data collection systems and assessment of emerging contaminants,
- Consideration of pedological and hydrogeological variability that may affect pollutant migration and sample integrity.

Further, it is advised to:

- Establish protective perimeters around existing wells to minimize external contamination;
- Investigate the chemical status of the deeper ROMU22 aquifer supplying the CET H Arad area;
- Develop protocols for new well placements, especially considering planned new plant infrastructure on the same site.

Ultimately, long-term protection of groundwater resources in industrial settings like CET H Arad depends on an integrated strategy - combining science-based monitoring, stricter regulatory enforcement, and proactive infrastructure planning.

Abstract

The study presents the first data on the accumulation circulation of Al, Ba and Cd in the samples of skin, muscles and liver of the European perch (Perca fluviatilis Linnaeus, 1758), its dominant parasite species Eustrongylides excises Jägerskiöld, 1909 larvae, water and sediments from the freshwater ecosystem of the anthropogenically affected protected area Mandra-Poda, Black Sea Basin, Bulgaria. The potential of European perch and E. Excises for bioaccumulation towards the studied elements has been studied. The bioindicator significance of P. fluviatilis and E. Excises for assessing the pollution of the freshwater ecosystem with Al, Ba, and Cd has been revealed. The risk to human health and living organisms has been evaluated. Measures for the protection of the ecosystem have been indicated.

Key words*: aluminium, barium, cadmium, bioindication, European perch.*

INTRODUCTION

The Mandra-Poda Complex is located south of the industrial zone of Burgas, along the sea coast. It is part of the Burgas Wetlands, within the Black Sea Basin Region and Ecoregion 12: Pontic Province, Sub-Ecoregion 12-2: Black Sea, in southeastern Bulgaria. The Mandra-Poda Complex is recognized as a wetland of international importance under the Ramsar Convention on Wetlands (1971). The site is also protected under the Habitats Directive (Directive 92/43/EEC) and the Birds Directive (Directive 79/409/EEC). Additionally, it is designated as a Corine Biotope (Corine, 1985) and classified as an Important Bird Area by BirdLife International. According to national legislation (Law on Protected Areas, 1989), three protected areas have been designated within the territory of the Mandra-Poda Complex: "Poda" (State Gazette No. 37/1989), "Ustie na reka Izvorska" (State Gazette No. 18/1990), and "Uzungeren" (State Gazette No. 102/2005). These areas were established for the conservation of habitats supporting endangered and rare bird species. The Complex lies along the "Via Pontica" migration route. Four rivers - Izvorska, Fakiyska, Sredetska, and Rusokastrenska - flow into the Complex.

Despite its international and national significance for habitat protection and exceptional biodiversity, the Mandra-Poda Complex is under significant anthropogenic pressure. Nearby, the Lukoil Neftochim Burgas oil refinery utilizes water from the Complex for industrial purposes.

Serious threats to the protection of biodiversity and water resources are the great anthropogenic pressure from the construction around the wetland, associated with the destruction of natural habitats (wet meadows and others), eutrophication of the wetland, pollution with industrial wastewater, household waste, overfishing, poaching, disturbance of birds and other organisms. Studies on parasites and parasite communities of freshwater fish from the Complex Mandra-Poda are scarce (Margaritov, 1959; Ilieva & Kirin, 2024). There were established single scientific studies on the chemical indicators of water pollution and the content of pollutants in the muscles of freshwater fish species (Georgieva et al., 2015; Peycheva et al., 2022), as well as on the contamination of Se in organs and tissues of

European perch and its parasite *Eustrongylides excisus*, in waters and sediments (Ilieva & Kirin, 2024).

The study aims to present ecohelminthological and monitoring results for contamination with aluminium (Al), barium (Ba), and cadmium (Cd) in tissues and organs of *Perca fluviatilis* Linnaeus, 1758 its dominant helminth species *Eustrongylides excises* Jägerskiöld, 1909 larvae, waters and sediments, as well as an assessment of their bioindicator significance for the condition of the Complex Mandra-Poda.

MATERIALS AND METHODS

The helminthological and environmental monitoring study was conducted on thirty specimens of *Perca fluviatilis* collected from the Mandra-Poda Complex. The perch samples were obtained using multi-mesh gillnets in accordance with BSS EN 14757:2015 - *Water quality: Sampling of fish with multi-mesh gillnets*. Sampling was performed with permission from the Executive Agency for Fisheries and Aquaculture, under the Ministry of Agriculture of Bulgaria.

The scientific names of the studied fish species were verified using the FishBase database (Froese & Pauly, 2024).

Sampling was carried out at three sites located in the eastern (Poda), northern (Meden Rudnik), and western (Konstantinovo) areas of the Mandra-Poda Complex (42°24′12.31″N, 27°19′18.05″E; 309 m; Figure 1).

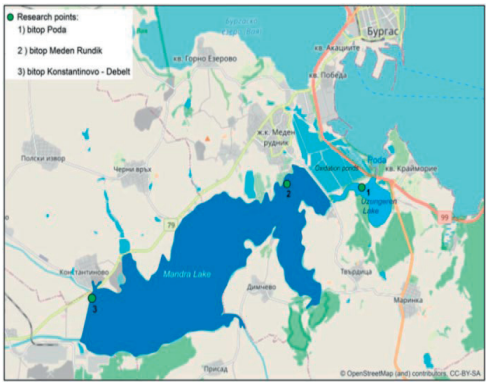

Figure 1. Studied biotopes from the Complex Mandra-Poda

The helminthological examination of *Perca fluviatilis* was conducted following the methodologies outlined by Zashev and Margaritov (1966), Bauer (Ed.) (1987), and Moravec (2013). Collected helminth specimens were preserved in 70% ethyl alcohol. Dominant nematode specimens were identified using temporary slides, in accordance with Moravec (2013). The predominant species, *Eustrongylides excisus* (Jägerskiöld, 1909), was selected as a model helminth for subsequent monitoring studies.

Tissue samples (skin, muscle, and liver) from *P. fluviatilis*, along with *E. excisus* larvae, were prepared to assess aluminium (Al), barium (Ba), and cadmium (Cd) concentrations, following the protocol of Nachev et al. (2013). Pre-weighed and thawed samples of fish tissues (up to 300 mg wet weight) and helminths (up to 100 mg wet weight) were subjected to acid digestion using aqua regia and microwave heating (Method B: Microwave heating with temperature control at 175 ± 5 °C). Approximately 2 g of each sample were digested in closed vessels under pressure with 6.0 mL HCl and 2.0 mL HNO_3. Elemental concentrations were determined using inductively coupled plasma optical emission spectrometry (ICP-OES), in accordance with EN ISO 16170:2016.

In addition, concentrations of Al, Ba, and Cd in surface water and sediment samples were measured using EN ISO 11885:2009 (*Water quality - Determination of selected elements by ICP-OES*) and ISO 22036:2024 (*Environmental solid matrices - Determination of elements by ICP-OES*).

The Bioconcentration Factors for determining the capacity for accumulation of Al, Ba, and Cd in the muscles, skin, and liver of European perch and *E. excisus* from freshwater environments (Bioconcentration Factor, $BCF=C_{Al,Ba,Cd_Skin}/C_{Al,Ba,Cd_Liver}/C_{Al,Ba,Cd_Muscle}/C_{Al,Ba,Cd_E.excisus}/C_{Al,Ba,Cd_Water}/C_{Al,Ba,Cd_Sediments}$) (Sures et al., 1999), as well as the Bioaccumulation Factor for determining the capacity for accumulation of Al, Ba, and Cd in *E. excisus* from organs and tissues of European perch (Bioaccumulation Factor, $BAF=C_{Al,Ba,Cd_E.excisus}/C_{Al,Ba,Cd_fish_tissues_organs}$) (Sorensen, 1991; Zaharieva, 2022a) are presented. Spearman's rank correlation coefficient (rs) values were determined to

establish the relationship between the concentrations of Al, Ba and Cd in environmental samples (water, sediments), in samples of liver, muscle and skin of host fish and in samples of the nematode *E. excisus* (Sokal & Rohlf, 1981). The coefficient of determination (r_s^2) was presented to determine what percentage of the factor variable would cause changes in the output variable. The Friedman test (Friedman's ANOVA test) was calculated to assess the significance of the differences between the contents of Al, Ba and Cd in the studied tissues and organs of fish and *E. excisus* (Sokal & Rohlf, 1981). The results are statistically processed using Statistic 10 (Stat Soft Inc., 2011) and MS Excel (Microsoft 2010).

RESULTS AND DISCUSSIONS

Characteristics of the studied fish species

European perch, *Perca fluviatilis* Linnaeus, 1758 (Percidae), was chosen as a model freshwater fish species due to its dominant behavior in the samples and as a predatory species. *P. fluviatilis* is also a demersal and brackish fish species. The perch feeds mainly on zooplankton, zoobenthos and small fish. *Perca fluviatilis* is in the category of Least Concern species according to the International Union for Conservation of Nature Red List (LC; IUCN) (Kottelat & Freyhof, 2007; Froese, & Pauly 2024). The species are not protected in the territory of Bulgaria (Karapetkova & Zhivkov, 2006). The perch inhabits various water bodies in the country and is widely distributed. *P. fluviatilis* is mainly targeted by recreational fishing. Each specimen's maximum length (TL, cm) and weight (B, g) were measured. The maximum length of the studied specimens ranged from 12-22.50 cm (17.77±3.06), and the weight from 21-227 g (75.77±57.09).

Characteristics of the studied endohelminth species

The ecohelminthological study of 30 specimens of European perch, *Perca fluviatilis* Linnaeus, 1758 from the Complex Mandra-Poda shows a clear dominance of the nematode *Eustrongylus excisus* (Jägerskiöld, 1909) (P%=90). The definitive hosts of *Eustrongylus excisus* (Jägerskiöld, 1909) are cormorants (*Phalacrocorax carbo* (Linnaeus, 1758), *Ph. pygmaeus* (Pallas, 1773)). The adult nematodes are localized in the glandular stomach of the host. The life cycle of *E. excisus* occurs with the participation of two intermediate hosts: the first intermediate hosts are aquatic oligochaetes (*Lumbricus variegatus* (Müller, 1774), *Tubifex tubifex* (Müller, 1774), *Limnodrilus* sp.). The first stage of larvae development is localized in the intestine and then in the body cavity. The second stage larva is localized in the abdominal blood vessel, and the third stage larva with the bloodstream passes to the head and tail of the host. Benthic fish species are the second intermediate host (*Ponticola kessleri* (Günther, 1861), *Neogobius melanostomus* (Pallas, 1814), *Rutilus rutilus* (Linnaeus, 1758)). The intermediate hosts and the final host are infected by feeding. In the body of the second intermediate host, the fish and the third-stage larvae are localized in the body cavity or coiled in a circle under the serous coating on the surface of the internal organs. After another moult, they migrate into the muscles of the fish. The fourth stage larva is invasive, coiled and encapsulated. *P. fluviatilis* is a reservoir host of *E. excisus*. Other species, reservoir hosts of *E. excisus* are: *Leuciscus aspius* (Linnaeus, 1758), *Silurus glanis* Linnaeus, 1758, *E. lucius*, *Sander lucioperca* (Linnaeus, 1758), *Sander volgensis* (Gmelin, 1789), *G. cernua*, *Alburnus chalcoides* (Güldenstädt, 1772), *Bentophilus macrocephalus* (Pallas,1787), *Huso huso* (Linnaeus, 1758), *Acipenser ruthenus* Linnaeus, 1758, *A. gueldenstaedtii* Brandt & Ratzeburg, 1833, *Leuciscus idus* (Linnaeus, 1758), *Luciobarbus brachycephalus* (Kessler, 1872). Accidental hosts can also be amphibians (frogs, *Pelophylax ridibundus* (Pallas, 1771)), reptiles (*Natrix tessellata* (Laurenti, 1768), turtles and others), mammals (rabbits, rats, seals, even humans) (Bauer, 1987; Kakacheva-Avramova, 1983; Honcharov et al., 2022). *E. excisus* has been reported in Bulgaria for *P. fluviatilis* from Lake Srebarna (Shukerova, 2010; Shukerova et al., 2010; Hristov, 2013; Kirin et al., 2013a); from the Arda River (Kirin et al., 2013b); from the Danube River (Atanasov, 2012; Kirin et al., 2013a; Zaharieva, 2022b). *E. excisus* has been reported for the Mandra-Poda complex from *S. lucioperca* as a reservoir host and from *Gobius* sp. as an intermediate host (Margaritov, 1959); from

P. fluviatilis (Ilieva & Kirin, 2024 and in the present study).

Concentration of aluminium (Al), barium (Ba) and cadmium (Cd) in the system Water - Sediments - *P. fluviatilis* – *E. excisus*

Chemical analyses were performed to determine the Al, Ba, and Cd content in the skin, muscle, and liver of *P. fluviatilis*, in samples of *E. excisus*, water, and sediments (Table 1).

Table 1. Contamination with aluminium (Al), barium (Ba), and cadmium (Cd) in tissues and organs of *P. fluviatilis*, its nematode species *E. excisus*, waters and sediments [mg/kg]

Samples	**Min.-Max. Mean±SD**	**Min.-Max. Mean±SD**	**Min.-Max. Mean±SD**
Wet weight	**Al**	**Ba**	**Cd**
Skin	3.38 – 86.16	1.18- 4.07	0.00-0.00

MAFF			0.2

Cd is a major toxic metal until Ba is a minor toxic metal (Mostafa et al., 2022). Human exposure to aluminium can and will result in toxicity (Exley, 2016). Cd causes toxic effects at very low concentrations (Sorensen, 1991; Peycheva et al., 2014). The maximum permissible concentration (MPC) for Cd, according Regulation No. 31/2004), is 0.05 mg/kg fish; according to FAO, it is 0.5 mg/kg, and according to MAFF, it is 0.2 mg/kg. Sources of pollution are industrial wastewater (Yablanski, Petkov (eds.), 2011). In nature, sources of Ba are fossil fuels, igneous rocks, feldspar and mica deposits. The entry of soluble $BaCl_2$, $Ba(NO_3)_2$, or $Ba(OH)_2$ is important for aquatic ecosystems. Ba is quickly released and binds to naturally occurring sulfates or carbonates, forming less soluble compounds - $BaSO_4$ and $BaCO_3$, most found in soils and waters (Verbruggen et al., 2020). Therefore, the toxicity of Ba is closely related to the hardness of the water and the amount of sulfates/carbonates. As the pH decreases, the solubility of Ba increases. This explains the higher concentrations of Ba in sediments (precipitation of poorly soluble barium compounds). A dissolved Ba value of 0.022 $mg \cdot L^{-1}$ has been adopted for human health (Verbruggen et al., 2020).

The highest concentrations of Ba and Cd were found in sediments. The lowest contamination was in water samples for the three elements. The results of the studied tissues and organs of the perch and its parasites showed the highest value of Al in the muscles, followed by those in the skin. The lowest values of Al were found in the liver. The Al content in *E. excisus* was 2.63 times lower than in the muscles. Therefore, the Al content decreased in the order muscles - skin - *E. excisus* - liver - sediments - water. The Al content in the muscles was 7.54 times higher than in the liver and in the parasite - 2.85 times higher than in the liver of the European perch. The highest concentrations of Ba were found in the skin of *P. fluviatilis*. The Ba content decreased in the order sediments - skin - muscles - *E. excisus* - liver - water. The Ba content in the skin was 16.37 times higher than in the liver samples, and the parasite – 1.18 times higher than in the liver samples. No Cd was detected in the skin and muscle samples. The Cd content decreased in the order sediments - liver - *E. excisus* - water. The cadmium (Cd) concentration detected in the liver samples of *Perca fluviatilis* was 1.85 times higher than that found in *Eustrongylides excisus* (Table 1).

According to Regulation No. 31/2004, the MPC for Al in freshwater fish is 30 mg/kg wet weight. Exceedance of the norm was not found only in liver samples. The Al content in muscle samples is 3.58 times higher than the approved MPC, in the skin - 1.95 times, and in the parasite - 1.36 times. According to the same regulation, the MPC for Cd is 0.05 mg/kg wet weight. The exceedances are respectively 2.48 times in the liver and 1.32 times in the nematode. The Al content in water samples is within the norm and has been approved according to Regulation No. H-4/2012. No exceedances of the Cd content

were found according to the approved norms by FAO and WHO for food (FAO/WHO (1998)) (0.2 and 20 mg/kg wet weight, respectively), according to Regulation No. 3/2008 on the standards for permitted content of Harmful Substances in soil, and Regulation on environmental quality standards for priority substances and certain other pollutants. Exceedances of these norms were found in liver and *E. excisus* samples.

The obtained results show excesses in the content of Al in skin (1.96 times), in muscles (3.58 times), and in *E. excisus* (1.36 times) according to the national legislation (Regulation No. 31/2004) for the content of Al in freshwater fish species (MPC 30 mg/kg); excesses in water samples (0.005 $mg.l^{-1}$ norm according to Regulation No. 18/2002) when using surface waters for irrigation. The content of Ba was exceeded in skin samples (119.09 times) and muscles (33.18 times). Cd concentrations were exceeded in liver samples (1.8 times) and *E. excisus* (1.4 times), according Regulation No. 31/2004. Cd concentrations were exceeded in water samples (3000 times, Regulation No. 18/2002). Cd concentrations were exceeded in sediment samples on average 2.31 times (Regulation No. 18/2002) (Table 1).

The bioconcentration factors (BCF) and bioaccumulation factors (BAF) are presented. The highest BCF and BAF were obtained for Al and the lowest for Cd (Table 2).

Very high correlations (r_s) were found between all the results obtained for Al, Ba and Cd content in water, sediments, skin, muscles and liver of *P. fluviatilis* and the dominant parasite species *E. excisus* (Table 2).

Significant differences were found between contaminations with Al and Ba in *E. excisus* and the samples of skin, muscles, liver of European perch, waters and sediments, as well as between contaminations with Cd in *E. excisus* and in the samples of liver (Friedman's ANOVA, $p<0.05$). The coefficient of determination (r_s^2) in all cases is 100%. This gives reason to believe that all changes in the concentrations with Al, Ba, and Cd in the waters and sediments of the Complex Mandra-Poda and the specific habitats of *P. fluviatilis* will lead to changes in the concentrations of these elements in the skin, muscles, and liver of the fish and the dominant nematode *E. excisus* in them.

Table 2. Bioconcentration factor (BCF), Bioaccumulation factor (BAF), and Spearman correlation coefficient (r_s) between the content of Al, Ba, and Cd in water, sediments, *P. fluviatilis* and *E. excisus*

r_s **** - very significant correlation, $p = 0.001$.

In this study, the liver accumulated higher concentrations of Cd than the parasite. Similar results have been obtained by other authors regarding the content of the studied elements (Al, Ba and Cd) in the liver of freshwater fish species, followed by that in the intestine and muscle (Leite et al., 2019; Mostafa et al., 2022). This is explained by Cd's affinity for proteins rich in the liver (Dallinger et al., 1987). In contrast to these results for Ba in the liver, the skin accumulated the highest concentrations of Ba in this study. According to other studies (Mazhar et al., 2014), Al is one of the few metals that accumulate in the highest concentrations in the muscles, which was also revealed by the present study. The highest content of Al was found in the samples from *E. excisus*, followed by that of Ba and Cd. The L4 larvae (fourth-stage larvae) were studied, localized in the body cavity, where they feed on blood and tissues before being encapsulated, which is associated with higher levels of Al (Nachev et al., 2013; Honcharov, 2022). Al, Ba and Cd contents are much higher in sediment samples than in water samples. This has also been found in other studies and is explained by the fact that metals attach to suspended particles or are adsorbed to

organic matter and thus precipitate and accumulate at the bottom of reservoirs (Mostafa et al., 2022). Only about 1% dissolves in water during the hydrological cycle (Salomons & Stigliani, 1995).
According to the results obtained in this study, it could be assumed that the main source of Al, Ba and Cd for *P. fluviatilis* is food and, to a lesser extent, water.

CONCLUSIONS

As a result of the study it was found that the highest concentrations of Al accumulate in the muscles, the highest concentrations of Ba in the skin, and the highest concentrations of Cd in the liver. The main sources of Al, Ba and Cd for *P. fluviatilis* are food and to a lesser extent water. *E. excisus* can be used as a sensitive bioindicator for Al pollution of freshwater ecosystems. Sediment samples contain much higher concentrations of Al, Ba and Cd than water samples. Very significant correlations were found between the content of the observed metals (Al, Ba and Cd) and their amounts in water, sediments, organs and tissues of *P. fluviatilis* and its dominant nematode species *E. excisus*.

Abstract

The study presents the data on the contamination of Cd, Cu, Hg, Ni, and Pb in the samples of skin, muscles, and liver of freshwater bream (Abramis brama (Linnaeus, 1758)), as well as in water and sediments samples from the studied ecosystem of the protected wetland Mandra-Poda, Black Sea Region, Bulgaria. Basic ecological indices have been determined. New data for the bioindicator significance of freshwater bream for the accumulation of trace elements in skin, muscles, and liver has been reported. Basic correlation dependencies have been indicated. Discussions on the use of freshwater bream as a food resource have been attached. The risk of pollution to human health and the environment has been assessed.

Key words*: bioindication, chemical status, ecological state, freshwater bream, risk assessment.*

INTRODUCTION

Wetlands play a crucial role in regulating water regimes and supporting unique habitats for diverse plant and animal communities. One such ecologically significant site in Bulgaria is the Mandra-Poda Complex, recognized for its national and international importance. It forms part of the Burgas Wetlands, situated in the Black Sea Basin Region—Ecoregion 12: Pontic Province, Sub-Ecoregion 12-2: Black Sea, in southeastern Bulgaria. The complex is located south of the industrial zone of Burgas, adjacent to the Black Sea coast. The Mandra-Poda Complex is designated as a wetland of international importance under the Ramsar Convention (1971) and is protected by the Habitats Directive (92/43/EEC), the Birds Directive (79/409/EEC), as well as through its status as a Corine Biotope and an Ornithologically Important Site. In accordance with Bulgaria's Law for the Protected Areas (1989), three protected zones have been established within the Complex: "Poda," "Ustie na reka Izvorska," and "Uzungeren," aimed at preserving habitats for endangered and rare bird species. Despite these protections and its recognized ecological value, the area remains under significant anthropogenic pressure. The Lukoil Neftochim Burgas oil refinery uses waters from the Complex Mandra-Poda for industrial needs. Intense anthropogenic pressure from construction activities around the wetland - leading to the destruction of natural habitats (such as wet meadows), eutrophication, pollution from industrial wastewater and household waste, overfishing, poaching, and disturbance of birds and other organisms - poses significant threats to the biodiversity and water resources of the area. Scientific studies examining water pollution indicators and the accumulation of pollutants in freshwater fish species remain limited (Georgieva et al., 2015; Peycheva et al., 2022; Ilieva & Kirin, 2024). The present study aims to provide ecological monitoring data on contamination levels of cadmium (Cd), copper (Cu), mercury (Hg), nickel (Ni), and lead (Pb) in the skin, muscle, and liver of *Abramis brama* (Linnaeus, 1758), as well as in water and sediment samples. The findings are intended to support an assessment of the species' potential as a bioindicator of environmental conditions in the Mandra-Poda Complex.

The freshwater bream, *Abramis brama* (Linnaeus, 1758) (family Cyprinidae), was selected as a model species for this study due to its ecological role as a benthopelagic, brackish-water predator. This species feeds primarily on zooplankton, insects, crustaceans, mollusks, aquatic plants, and small fish. According to the International Union for Conservation of Nature (IUCN) Red List, *A. brama* is classified as a species of Least Concern (LC) (Kottelat & Freyhof, 2007; Froese & Pauly, 2024). In Bulgaria, the species is not legally protected (Karapetkova & Zhivkov, 2006). *A. brama* is widely distributed across the country's aquatic ecosystems and is an important species for both sport and commercial fisheries.

MATERIALS AND METHODS

The study was conducted on ten specimens of freshwater bream (*Abramis brama* Linnaeus, 1758) collected from the Mandra-Poda Complex. Sampling was carried out using multi-mesh gillnets in accordance with BSS EN 14757:2015 (*Water quality – Sampling of fish with multi-mesh gillnets*), following approval from the Executive Agency for Fisheries and Aquaculture, Ministry of Agriculture, Bulgaria. The scientific name of the species was verified using the FishBase database (Froese & Pauly, 2020). Specimens were obtained from three locations within the complex: the eastern site (Poda), the northern site (Meden Rudnik), and the western site (Konstantinovo), situated at coordinates 42°24'12.31″N, 27°19'18.05″E, at an altitude of 309 meters (Figure 1).

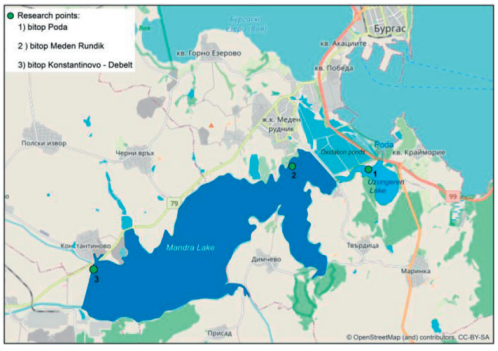

Figure 1. Studied biotopes from the Complex Mandra–Poda

Maximum length (TL, cm) and weight (W, g) were measured for each specimen. Samples of skin, muscle, and liver of A. brama were prepared for determination of Cadmium (Cd), Copper (Cu), Mercury (Hg), Nickel (Ni), and Lead (Pb) content. The pre-weighed and thawed samples of liver, muscle and skin of *A. brama* (to 300 mg wet weight) were subjected to acid digestion with aqua regia and microwave heating - Method B: “Microwave heating with temperature control at 175±5°C”. Samples of 2 g were used in closed vessels under pressure with 6.0 ml HCl and 2.0 ml HNO_3, and the element was determined using ICP-OES, according to EN ISO 16170:2016. In surface water and sediment samples, concentrations of Cd, Cu, Hg, Ni, and Pb were determined according to EN ISO 11885:2009 Water quality - Determination of selected elements by inductively coupled plasma optical emission spectrometry (ICP-OES) and EN ISO 22036:2024 Environmental solid matrices - Determination of elements using inductively coupled plasma optical emission spectrometry (ICP-OES). The Bioconcentration Factors are presented for determining the capacity for accumulation of Cd, Cu, Hg, Ni, and Pb in the muscles, skin, and liver of European perch, waters and sediments from freshwater ecosystem Mandra-Poda (Bioconcentration Factor, $BCF=C_{Cd,Cu,Hg,Ni,Pb_Skin}/C_{Cd,Cu,Hg,Ni,PbLiver}/C_{Cd,Cu,Hg,Ni,Pb_Muscle}/C_{Cd,Cu,Hg,Ni,Pb_Water}/C_{Cd,Cu,Hg,Ni,Pb\ Sediments}$) (Sorensen, 1991; Zaharieva, 2022). Spearman's rank correlation coefficient (r_s) values are determined to establish the relationship between the concentrations of Cd, Cu, Hg, Ni, and Pb in environmental samples (water, sediments), in samples of liver, muscle and skin of fish. The coefficient of determination (r_s^2) was presented to determine what percentage of the factor variable would cause changes in the output variable. The Friedman test (Friedman's ANOVA test) was calculated to assess the significance of the differences between the contents of Cd, Cu, Hg, Ni, and Pb in the studied tissues and organs of fish (Sokal and Rohlf, 1981). The results are statistically processed using Statistica 10 (StatSoft Inc., 2011) and MS Excel (Microsoft 2010).

RESULTS AND DISCUSSIONS

Characteristics of the studied fish species

The maximum length of the studied specimens ranged from 8.5-21.0 cm (12.27±3.49), and the weight from 11-203 g (37.27±59.39).

Concentration of Cadmium (Cd), Copper (Cu), Mercury (Hg), Nickel (Ni), and Lead (Pb) in the system Water – Sediments - *A. brama*

Chemical analyses were performed to determine the concentrations of Cd, Cu, Hg, Ni, and Pb in the skin, muscle, and liver of *A. brama*, water, and sediments (Table 1).

Cd is toxic in very low concentrations (Sorensen, 1991; Peycheva et al., 2014), and a non-degradable cumulative pollutant (Ghosh, 2021). The MPC for Cd, according to the Bulgarian Food Codex (Regulation № H-4/2012), is 0.05 $mg.kg^{-1}$ fish; according to FAO, it is 0.5 $mg.kg^{-1}$. Sources of pollution are industrial wastewater. Sources of Cd in the environment are plant protection products, fertilizers, pesticides, wastewater, and mining activities (Yablanski, Petkov (eds.), 2011). Biomagnification of Cd is observed when the concentration of the element increases from one level to higher levels of the food chain (Ghosh, 2021). Sources of Cu are the mining and ore processing industries. It is contained in insignificant quantities in natural waters. According to national legislation, the norm for Cu content in freshwater fish is 10 $mg.kg^{-1}$ (Regulation № 31/2004). According to FAO, it is 30 $mg.kg^{-1}$, and according to WHO regulations, it is 20 $mg.kg^{-1}$. Sources of Hg contamination are organic mercury compounds. Entry into freshwater fish occurs through contaminated food (Ghosh, 2021). According to the Bulgarian Food Authority (Regulation 31/2004), the maximum level permitted of Hg is 0.5 $mg.kg^{-1}$, and according to FAO/WHO, the permissible weekly intake is 0.3 $mg.kg^{-1}$ for humans (FAO/WHO, 1998; Regulation № 31/2004). Sources of Ni pollution for aquatic organisms are Ni-laden water and food from mining. It is necessary for living organisms as a microelement, but high concentrations are toxic to organisms. According to Regulation № 31/2004 provisions, the norm for Ni content in freshwater fish species is 0.5 $mg.kg^{-1}$. Sources of Pb are lead ore deposits and industrial wastewater. Pb is a highly toxic element for living organisms, especially aquatic ones. Pb is one of the most persistent toxic elements. The transfer to aquatic organisms occurs with food (Yablanski & Petkov (eds.), 2011; Peycheva et al., 2014; Ghosh, 2021). According to Regulation № 31/2004, the norm for Pb in freshwater fish is 0.2 $mg.kg^{-1}$.

Table 1. Contamination of Cadmium (Cd), Copper (Cu), Mercury (Hg), Nickel (Ni), and Lead (Pb) in tissues and organs of *A. brama* [$mg.kg^{-1}$], waters [$mg.l^{-1}$], and sediments [$mg.kg^{-1}$]

The standards for the content of Cd, Cu, Hg, Ni, and Pb in water samples are respectively MPC of 0.015 $mg.l^{-1}$ Cd (Regulation № H-4/2012), 0.02 $mg.l^{-1}$ Cu AAC EQS (Average Annual value, Environmental Quality Standarts, Regulation № H-4/2012) and 2 $mg.l^{-}$

[1] according to WHO, 0.07 $mg.l^{-1}$ Hg (Regulation № H-4/2012), MPC 0.034 $mg.l^{-1}$ Ni (Regulation № H-4/2012), AAC EQS 0.012 $mg.l^{-1}$ and MPC 0.014 $mg.l^{-1}$ Pb and according to WHO 0.01 $mg.l^{-1}$. The standards for Cd, Cu, Hg, Ni, and Pb content in sediment samples are 3 $mg.kg^{-1}$, 150 $mg.kg^{-1}$, 1.5 $mg.kg^{-1}$, 110 $mg.kg^{-1}$, 100 $mg.kg^{-1}$. The liver samples found the highest concentrations for the five studied elements. The average values in the bream liver show excesses compared to Regulation № 31/2004 norms for the samples from the three studied biotopes. The most considerable excess compared to the norms in Regulation № 31/2004 was registered in terms of the content of Hg (14.44 times), followed by that of Cu and Pb (4.64 and 4.29 times, respectively), of Ni (2.65 times), of Cu (1.65 times). Regarding the samples from the three biotopes, the excesses in the concentrations of Cd compared to the norm under the same regulation are 3.6-5.6 times; of Cu – from 0.98-1.58 times; of Hg – from 49.7-81.98 times; of 8.04-16.01 times; of Pb – from 13.53-25.51 times. The highest exceedances of Cd, Hg and Pb are recorded in the "Konstantinovo" Biotope and the lowest in the "Poda" biotope. The highest excesses of Cu were recorded in the biotope "Meden Rudnik", followed by the biotope Konstantinovo and Poda. According to the FAO norm (0.2 $mg.kg^{-1}$ Cd in food), the excess in the liver is, on average, 1.16 times for the three biotopes and 1.4 times for the biotope "Konstantinovo". According to the WHO human health norm (20 mg Cu/kg fresh weight), the excess in the liver samples is, on average, 1.65 times for the three biotopes and 0.04 times for the biotope "Meden Rudnik". Muscles accumulate more significant amounts of Cu and Ni than the skin (on average, 2.33 and 2.3 times, respectively). Compared to the liver samples, the content in Cu, Ni, and Pb muscle was 2.45, 3.57, and 7.74 times lower, respectively. No excesses of Cu and Ni were detected in skin and muscle samples, and no excesses of Pb were detected in muscle samples. No Cd, Hd, and Pb were detected in skin samples of *A. brama*, and no Cd, Hg were detected in muscle samples (Table 1). In the water samples, exceedances of the MPC for Cd (0.015 $mg.l^{-1}$) were found, respectively 1.67 times, 1.87 times and 2.67 times in the Poda, Meden Rudnik and Konstantinovo biotopes; of the MIC for Pb (0.014 $mg.l^{-1}$) - 28.57 times in the Poda biotope, 33.36 times in the Meden Rudnik biotope, 31.5 times in the Konstantinovo biotope or on average for the three biotopes - 31.14 times, regulated in the Regulation on Environmental Quality Standards for Priority Substances and Certain Other Pollutants/2010 under national legislation (Table 1). The analyses of sediment samples show excesses in the Cd content in the Poda biotopes (2.567 $mg.kg^{-1}$ dry matter – 1.28 times) and Meden Rudnik (2.755 $mg.kg^{-1}$ dry matter – 1.39 times), as well as in the Cu content in the Poda biotope (172.2 $mg.kg^{-1}$ dry matter – 1.15 times) compared to the norms regulated in Regulation No. 3/2008 of the national legislation. According to the Effects Range-Low (ERL), developed by the US Environmental Protection Agency (US ERA) to assess the ecological significance of concentrations in sediments, the excesses of Cd concentrations (norm 1.2 $mg.kg^{-1}$ dry weight) are 2.14 times in the Poda biotope, 2.3 times in the Meden Rudnik biotope or an average of 1.54 times for the studied freshwater ecosystem; excesses of Cd are not reported only for the Konstantinovo biotope. According to the same document, the excesses of Cu concentrations (norm 34 $mg.kg^{-1}$ dry weight) were obtained for all three studied biotopes – 5.07 times, 23.73 times, 1.59 times, respectively. Regarding the content of Ni (ERL=21 $mg.kg^{-1}$ dry weight) in the sediments, excesses were found in the biotopes Poda and Meden Rudnik (1.60 and 2.35 times, respectively), as well as about Pb (ERL=47 $mg.kg^{-1}$ dry weight) for both biotopes (1.48 times and 0.40 times, respectively). Exceedances of the norms for Ni and Pb were not found in the samples from the biotope Konstantinovo. Adverse effects on organisms are expected at values of the elements below the ERL (Assessment criteria for contaminants in sediment) (Table 1). Therefore, Cd concentrations decrease in the order sediments – liver – waters – skin – muscles; of Cu and Ni: sediments – liver – muscles – skin – waters; of Hg: liver – sediments – waters – skin – muscles; of Pb: liver – sediments – waters – muscles – skin. The bioconcentration factors (BCF) and bioaccumulation factors (BAF) are presented. The highest BCF were obtained for

Cu in liver and the samples of water and the lowest for Pb in muscles, as well as highest BCF for Hg in liver and lowest for Ni in skin and in the samples of sediments. Very significant positive correlations were established between contamination of Cd in liver and water; of Cu in skin, muscle, liver and in waters and sediments; of Hg in liver and sediments; of Ni in skin, muscle, liver and waters and sediments; of Pb in muscle, liver and water and sediments. A significant but negative correlation ($-r_s$) was determined only between contamination of Hg in the liver and in water samples (Table 2).

Table 2. Bioconcentration factor (BCF), and Spearman correlation coefficient (r_s) between the content of Cd, Cu, Hg, Ni, and Pb in water, sediments, *Abramis brama*

Fish – Water (wet weight)	**Cd BCF**	**Cu BCF**	**Hg BCF**	**Ni BCF**	**Pb BCF**
Skin – Water	0.00	963.00****	0.00	53.67****	0.00
Muscle – Water	0.00	2242.00****	0.00	123.34****	0.25****
Liver – Water	7.48****	5494.00****	557.00****	441.00****	1.97****
Fish – Sediments (dry weight)	**Cd BCF**	**Cu BCF**	**Hg BCF**	**Ni BCF**	**Pb BCF**
Skin – Sediments	0.00	0.057****	0.00	0.01****	0.00
Muscle – Sediments	0.00	0.129****	0.00	0.02****	0.82****
Liver – Sediments	0.125****	0.756****	416.71****	0.21****	15.19****

r_s **** - very significant correlation, p=0,001.

Significant differences were found between contaminations of Cu and Ni in the samples of skin, muscles, and liver of Freshwater bream, waters and sediments, between contaminations of Cd and Hg in water and sediments and the samples of liver, as well as between contaminations of Pb in water and sediments and in the samples of muscles and liver (Friedman's ANOVA, $p<0.05$). The coefficient of determination (r_s^2) in all cases is 100%. This gives reason to believe that all changes in the concentrations of Cd, Cu, Hg, Ni, and Pb in the waters and sediments of the Complex Mandra-Poda and the specific habitats of *A. brama* will lead to changes in the concentrations of these elements in the skin, muscles, and liver of the fish. The content of heavy metals in *A. brama* from the Mandra-Poda complex has been studied only by Peycheva et al., 2022. The authors studied the content of As, Cd, Cr, Cu, Fe, Mn, Ni, Pb, and Zn in muscle samples. They found much lower values for Cu (0.12 and 6.73 $mg.kg^{-1}$ fresh weight, respectively) and Ni (0.06 and 0.37 $mg.kg^{-1}$ fresh weight, respectively) than in this study and slightly higher values for Pb content (0.15 and 0.11 $mg.kg^{-1}$ fresh weight, respectively).

Cd, Hg, Ni, and Pb are major toxic metals, and Cu is in the group of essential metals with potentially toxic effects (Yablanski & Petkov, 2011; Mostafa et al., 2022). According to Peycheva et al. (2014a), even at low concentrations, Hg is a very toxic element in metabolically active tissues and is associated with an ecological risk for aquatic organisms. They point out that Hg concentrations increase towards higher levels in the food chain, which is why predatory fish species can be suitable bioindicators. Conversely, for Cd, no such increase was found along the food chain (Peycheva et al., 2014b). According to studies by several authors, the liver accumulates Cd, Cu, Hg, Ni, and Pb in much higher concentrations than other tissues and organs of fish, which was also found in this study (Leite et al., 2017; Mostafa et al., 2022).

The content of the studied elements is higher in sediments than in water samples, as also obtained in other studies, which is explained by the fact that they are adsorbed by organic particles and precipitate and accumulate at the bottom, with only 1% of the pollutants participating in the hydrological cycle (Salomons & Stigliani, 1995; Mostafa et al., 2022).

CONCLUSIONS

As a result of the ecological monitoring study of liver, skin and muscle samples of *A. brama* from the Mandra-Poda complex, the highest content of heavy metals was found in the liver samples. The liver of the Freshwater bream appears as a sensitive bioindicator for the Cd, Cu, Hg, Ni, and Pb content.

Abstract

This study investigates sediment transport dynamics in the Dognecea River, located in Caraș Severin County using MIKE 11. Numerical simulations were conducted to analyze sediment deposition, erosion patterns, and structural interactions. The sediment transport model considers multiple factors, including riverbed sediment characteristics, hydrodynamic conditions, and structural modifications. The sediment transport model has several applications, with variations in parameters such as study objectives, allocated resources, time scale, space, context of the study team, required accuracy, etc. The characteristics of the sediments in the riverbed are a necessary component to know for modeling sediment transport. It is proposed to collect additional sediment samples from the sediments of the layer. The samples obtained will be analyzed according to the size of the particles in the bed. To address sediment transport issues in the Dognecea River, advanced water flow modeling programs are used. Numerical modeling was performed using the MIKE11 software, incorporating hydraulic flow simulations to analyze sediment transport dynamics. Transport models can be used in the case of small alluvium, such as mud or clay, to non-cohesive deposited alluvium, such as boulders, small ballast and sand, but also mixed sediments. MIKE 11 provides several options for modeling the movement over time of alluvial transport, as well as structural changes in the riverbed. The results provide insights into alluvial transport behavior and offer solutions for mitigating sediment-related challenges such as riverbed clogging and erosion control. The findings demonstrate the effectiveness of MIKE11 in modeling hydraulic and sediment transport processes, making it a valuable tool for water resource management and flood risk mitigation.

Key words*: bed roughness, hydraulic modelling, sediment transport.*

INTRODUCTION

The Dognecea River, located in Caraș Severin County is affected by significant sediment transport processes. These issues impact infrastructure, water quality and flow parameters, necessitating advanced modeling techniques for effective management.

The Dognecea River originates in the Dognecea Mountains and flows through valleys and hilly areas, carrying alluvial materials, including loess deposits.

The upstream section is the built-up area, where the process of riverbed erosion manifests itself, this erosion threatens the stability of the county road, houses, as well as in the lower region of the village, where new households appeared in the area and the riverbed was completely clogged, which led to the overflow of the stream and the riverbeds.

Near the dam, built in 1750 to supply industrial water to the furnaces in Dognecea, sediment deposition occurs along the entire stretch from upstream to downstream, even starting from upstream to downstream, the sediments are deposited by transporting water to a depth of 265 m that causes erosion up to the rock, the banks being eroded, thus washing away the existing works, and the area presents phenomena of unconsolidated erosion. As a result of the floods, the existing works on the downstream section of the dam as well as the town hall are damaged. The masonry constructions have also been affected; the stone walls have been washed and the bridges destroyed.

Downstream, due to the low slopes and lack of excessive banks, the materials released from upstream are deposited downstream of the village. This leads to the accumulation of fine sediments that cause clogging and flooding of roads and households (Figure 1) (ANIF, 2024).

To mitigate flood-related damage, erosion protection measures have been implemented along the Dognecea River, aiming to stabilize the banks and safeguard the surrounding settlements. At the confluence with the Calina

River, upstream, the hydrograph of the Dognecea River has the following characteristics: route length 18 km, basin area 61 km, upstream altitude 420 mdM, downstream altitude 151 mdM, average altitude 388 mdM, average slope of 15%, convolution coefficient 1.27, forest area 4741 ha. In order to verify the capacity of the natural riverbed, transition calculations of the probability of exceeding Q5% flow were performed for determining the appropriate section sizing.

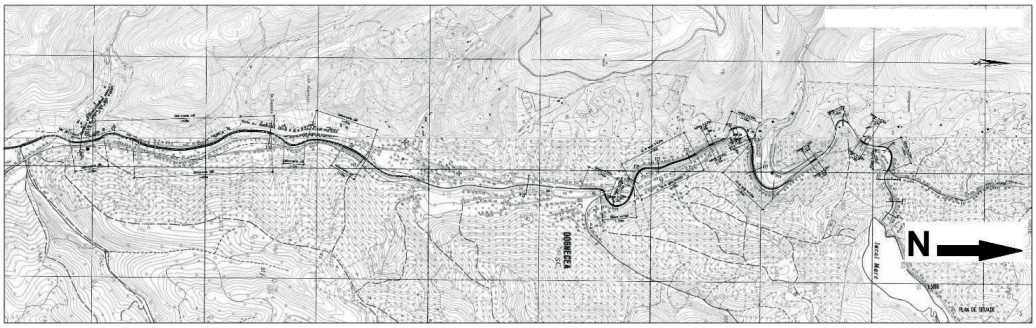

Figure 1. Plan view of Dognecea River

As a result, a remodeled, the remodeled section of the Dognecea stream was established between two predetermined trapezoidal points, which have a slope of 1:1.5 and 8 m wide at the base and a length of 2000 m.

Following the excavations, the resulting embankment material will be used for filing or lateral reinforcement, ensuring profile compensation across sections.

The weight of the stone retaining wall, L = 1000 m is applied in the major riverbed of the Dognecea stream (causing erosion and soil overload). Reinforcement bench with gabion boxes along a length of 1165 m with a section of 1.0×1.0×3.0 m, 1.0×1.5×3.0 m made of OB37 concrete steel frames, with a diameter of 16mm located at a distance of 1.00 m and OB37, with a diameter of 10 mm internally welded at a distance of 0.5 m, galvanized mesh with a size of 40×40 mm.

The foundation will be made on a bed of fascines 0.3 m thick and 3.0 m in length, and the boxes are filled with ballast of different sizes. The stone elements will be arranged similarly to plasterboard layers for enhanced load distribution. The cassettes are connected from all directions with OB steel (6 mm diameter), with a 2 mm gap (NARW, 2024).

The boxes are mounted on both banks of the stream to protect riparian roads, stabilize the riverbanks, and prevent sediment entrainment. These structures will also help reinforce existing constructions along the river. To mitigate bank erosion, gabion boxes will be applied on the fascines and a layer of earth on the calculation slope h = 2.0 m total length L = 2130 m. The studied section features a box gabion structure with the following dimensions of 1.0×1.0×3.0 m, the section is based on an elastic mattress with a thickness of 0.3 m and a free length of 1.0 m.

To achieve the required height, the transit flow measurements of the embankment were ensured by tilting the embroidery by 1.00 m from 0.30 m of broken stone for the drainage of aggregates to 0.15 m. Box gabions shall be at least 1.0 m thick. The installation of gabion boxes will help achieve the following objectives the reduction of drainage tariffs, the reduction of the longitudinal slope and the stabilization of the riverbed.

This study aims to model sediment transport dynamics using MIKE 11 software to assess potential mitigation measures and improve flood risk management.

MATERIALS AND METHODS

The MIKE 11 program is a hydraulic modeling software designed to simulates water flow and level, water quality, sediment transport in rivers, canals, estuaries, sewage systems and different types of water systems. The MIKE 11 model was used to simulate unsteady flow and sediment transport, following methodologies

similar to those applied in previous studies (Ivanescu et al., 2014), where MIKE 11-UHM and MIKE 11-HD were used for hydrodynamic modeling and runoff simulations. Connecting MIKE 11 can be integrated with GIS and ArcGIS enabling them to extract cross-sections, watershed contouring and which assist in risk assessment and mitigation. Flax to achieve these objectives or to be used as a forecasting tool. Hydrotechnical structures such as: spillways, canals/galleries, ridges, staves, pumps or control and regulation structures; or even the breaking of dams and dams (Huai et al., 2021).

Because of accumulation, we get a modeling dynamic that:

- Consider accumulation volume available in the canals and in the adjacent major riverbeds;
- Flood mitigation by delaying the peak of the flood, it allows a slow accumulation in the riverbeds Major;
- Allows water to retreat into riverbeds as flooding subsides.

Within the MIKE 11 software package, the MIKE Zero interface provides access to a range of modeling options.

Once in the actual numerical modeling phase, a program will be created. simulation (Simulation Editor - .sim11) that will be always kept open (valid for any type of work in MIKE 11), this is the main control center in MIKE 11. Access all the files necessary for running the program and their intercommunication.

The simulation editor also specifies the type of models that will be used and the simulation mode (permanent/non-permanent). The files used in the simulation will be added, depending on the type. The simulation we want to create. These will be:

- Network configuration;
- Cross sections data;
- Boundary conditions;
- Precipitation and runoff parameters;
- Hydrodynamic parameters;
- Advection/dispersion parameters;
- ECOLab parameters for water quality modeling;
- Time series data;
- Frost related parameters, etc.

The "Simulation" table within the simulation editor contains the initial conditions, the time step taken into account and aditional details regarding the simulation.

The period can also be calculated from here maximum simulation, based on the data entered the system; Time step can be entered as fixed, tabular or adaptive. Also, the time step can be set from seconds to days depending on the scale and precision required for the simulation. The difference between the start and end times of the simulation is proportional to the selected time step and the total duration of the model run.

In the "Start" section of the Simulation Editor, the system validates whether all input files are correctly set up. If any file is not marked in green, it is considered invalid, preventing the simulation from running. Once all files are validated (green indicators), the simulation can proceed, generating a text file ("Simulation") that can be edited in any text editor.

The Network Editor (.nwk11) defines the plan view, river network, and hydrotechnical structures. Users can upload graphical visualizations of the network, import saved files (e.g., JPEG, ASCII), and modify dimensions as needed. The interface also allows integration with MIKE 21 (DFS2) files, enabling overlaying and adjusting data layers (Hausler et al., 2019).

The hydrological network data can be modified within the network options settings, allowing users to select or deselect connected components dynamically. The river network is displayed graphically, enabling adjustments to nodes, river arms, and structures, while maintaining a record of all applied settings.

The tabular module provides a list of all digitized points in the model, which can be edited via the "Overview" or "Data Entry Panel". Users can import/export data from Excel tables for efficient data handling. In the Network Editor, the "Network" option facilitates watercourse discretization and node spacing, while the "Structures" option lists all hydrotechnical works, categorized by structure type and model settings.

Upon completing the simulation, a "Network" text file is generated, which can be edited in any text editor.

The Section Editor (.xns11) operates on a binary database, allowing multiple sections to be registered. Each section is identified by the river name (tributary), Topo identifier (Topo ID), and

route number (increasing downstream). Sections include:

- Raw data (X, Z coordinates, roughness markers);
- Processed data (hydraulic radius, storage area, width, and flow mode).

Users can modify node positions, rename sections, interpolate multiple sections, or adjust tabular data. The editor supports five common graphical markers affecting data calculations:

- Left bank pier;
- Low flow on the left bank;
- Left coordinate;
- Minimum riverbed height;
- Reduced flow on the right bank;
- Right coordinate.

Embankment markers define the active simulation area, and global modifications can be applied to both raw and processed data. Before running the simulation, a pre-check is recommended to ensure all sections are precalculated.

The Edge Conditions Editor (.bnd11) allows the inclusion of advection-dispersion and multilayer flow conditions, providing a structured panel for managing boundary conditions and simulation parameters.

The overview panel includes a description box (open, global, structures, closed), one for the type of condition (supply, levels, Q-h curves, bed level), one for for user identification and 3 for location (rich name, start (km), end (km). The specification panel contains a box for the type of download; one for the type temporal step (fixed, tabular, adaptive); one for values (used for editing time series) and one for information about the passage of time.

The conditions file, once created, can be modified with a text editor. The Time File Editor (.dfs0) is an editor and database for time series and communicates directly with the edge condition editor.

It can be viewed both tabular and graphically. Selected points in the view are drawn. The visualization is done only in the Time Series (TS) file.

You can also change or add/delete the type and units of time from here.

In the "Tools" menu, you can select the subset or the entire period of interest.

You can zoom in on the area of interest (zoom) or move the area (pan).

Files of type * DFS0 (TS) can be created from a blank document or from a ASCII document.

You can also create hydrograph files for projects in the Time Series editor Developed.

The HD Parameter Editor (.hd11) contains the initial conditions and resistance data.

The table of initial conditions includes the local conditions superimposed on the global ones, the values specified globally, local values (strings), etc. The initial conditions will set the water level to the first step of time.

The lateral resistance factor in the section applies to the overall values or locally. If lateral resistance is specified as the value, then the file in question will be ignored. The resistance of the bed results from the overwriting of local values over the global value, along the course.

The local approximation can be solved for an entire sector or only for a part of it. Kinematic or diffusive waves can be associated with fast channels without shaking. In this editor, additional results will be given to the default constants in the simulation (which will create an additional editable file with the name from "Simulation" and the extension "HDAdd"). All other panels in the editor can be used for more advanced use of MIKE 11 (DHI, 2021).

These are the interconnection editors, required by MIKE 11 for the creation of all numerical modeling projects. The MIKE 11 program is created by DHI Water•Environment•Health, Denmark, to solve the Saint-Venant equations, the basic component of the model was used in the simulation, i.e. the hydrodynamic module (HD), which contains a 6-point Abbott-Ionescu default scheme with finite differences (Lagos et al., 2024).

MIKE 11 was created to make detailed modeling of gate and dam openings, special treatment of floodplains, road overflows, bridges, rivers.

The program has the ability to use vertically integrated, diffusive, kinematic, or fully dynamic momentum and mass equations. Types of limits include Q-h relationship, water level, resistance factor, flow rate, wind field, dam failure. The limit of the Q-h relation can only be applied to the downstream limit. The water level limit applies to the model either downstream or upstream. The flow limit applies in the same way as the water level limit, either downstream or upstream, and can also be used at the lateral

tributary flow (flow). To describe the leakage, lateral flow is applied.

MIKE 11 is a well-known program since the beginning of its use, that could be operated through an efficient interactive menu, menu sequencing and systematic layouts.

The latest generation of the "classic" MIKE 11 has been developed - version 3.20, which usefully uses the experiences and features of the "classic" era with the Windows-based user interface, including calculation speed and graphical editing.

In many applications around the world it has been used over time, among its main areas of application being flood mitigation analysis and design, dam failure analysis, flood forecasting today, improvement of channel and reservoir sources, sediment transport and morphological studies, ecological estimates of water in rivers and wetlands, saline intrusion into estuaries and rivers (Merz et al., 2021).

The MIKE 11 program has a variety of options for modeling morphological changes and sediment transport dynamics in the riverbed (Lee et al., 2021).

RESULTS AND DISCUSSIONS

Numerical flow modeling was performed using MIKE 11, which proved effective for unsteady flow simulation with MIKE 11-HD. Figure 2 shows the model layout, and Figure 3 presents the channel cross-section profiles based on topographic surveys.

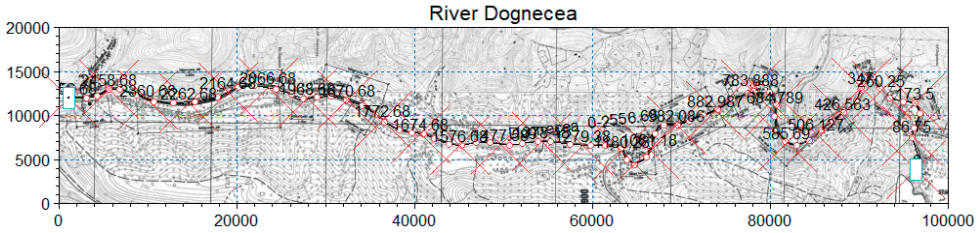

Figure 2. Plan view with the network model

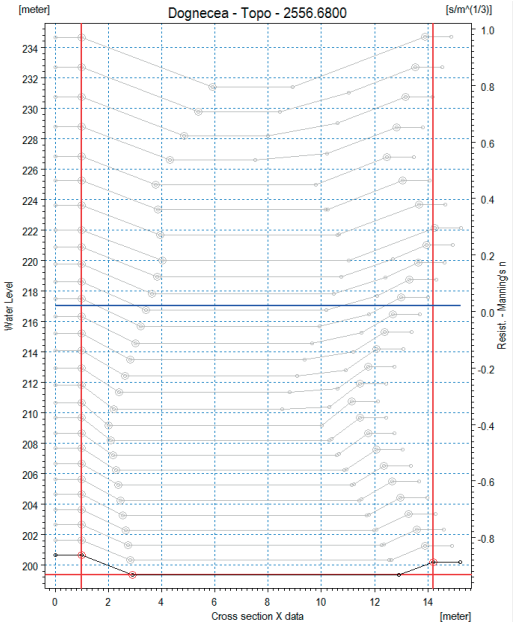

Figure 3. Cross sections

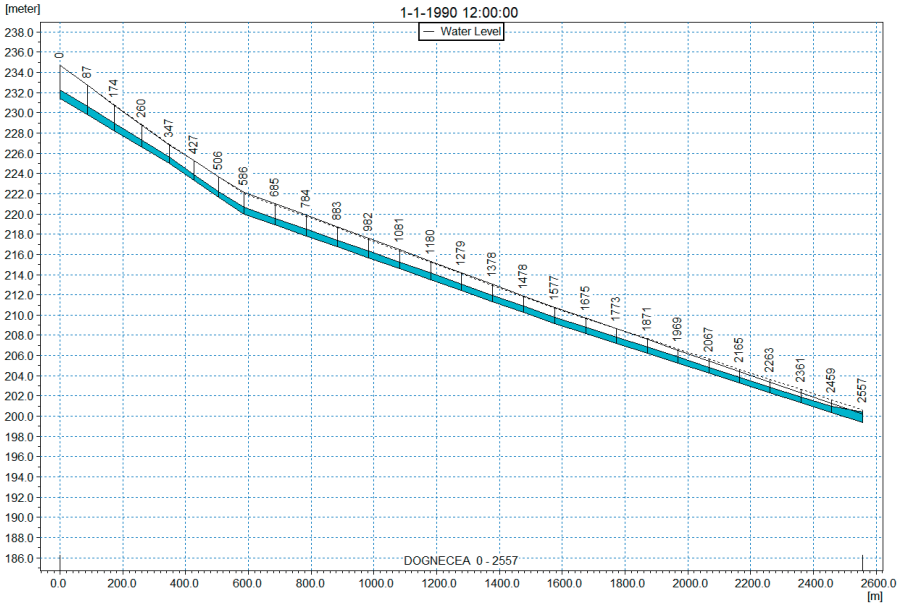

Figure 4. Water Level in longitudinal profile

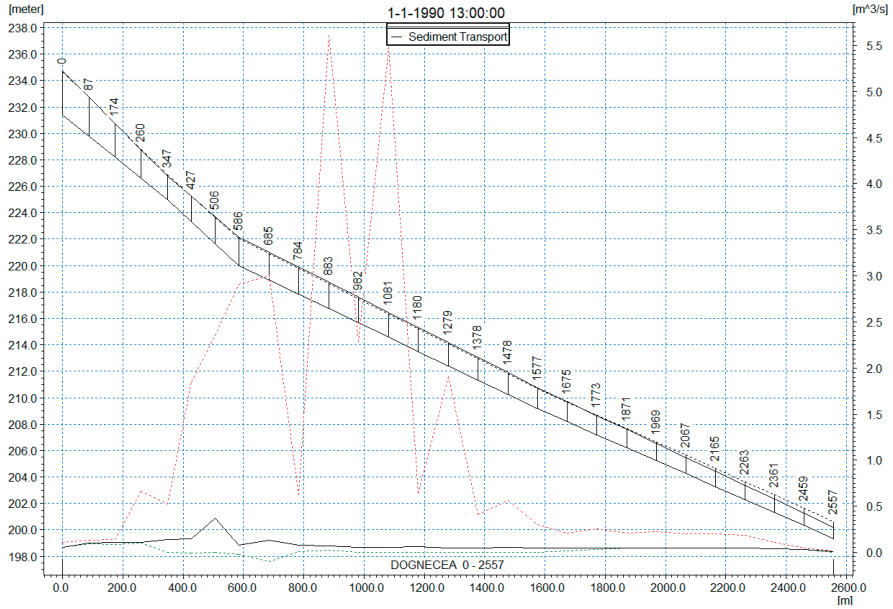

Figure 5. Sediment transport in longitudinal profile

According to the introduction of the data or the limit conditions formulated, the upstream flow at chain 0 is constant Q 19.9 mc/s the downstream flow at chain 2556, the key to the curve of the downstream river sector (Biali et al., 2022). Following modeling with the MIKE11 program, the longitudinal profile of the existing canal was obtained (Figure 4).

The downstream boundary condition is important in terms of alluvial flow in a morphological and dynamic model between sediment transport, bed level, hydrodynamics

and plane shape changes, and another condition is the simulation time which should be as long as possible. (Damian et al, 2022).

The following boundary conditions are required: the boundaries of the sediment beds in the riverbed and the level of displacement of the alluvial at the limit. The first applies when it is considered with a certain precision that the riverbed remains at the same level as the upstream limit. The second applies if it is accurately known for alluvium transport (e.g. zero transport) (Grozav et al, 2018).

According to the formulated boundary conditions or data, the sediment flow upstream to chain 0 and downstream to chain 2556 is 0.

The MIKE 11 ST module simulated sediment transport dynamics along the canal, showing variations in transport rates over time. The longitudinal profile (Figure 5) highlights areas of significant sediment accumulation and erosion, which are critical for understanding flood risks and designing mitigation strategies.

The results from the sediment transport model show the variation over time across the entire river section of erosion and deposition, which aligns with the expected results (Najafi et al., 2021).

There are areas with higher erosion in zones where the river slope changes, while higher deposition occurs in areas with a lower slope.

Over time, if the deposited sediments are not removed, they will reduce certain river sections, decreasing the river's water discharge capacity, ultimately leading to an increase in water levels, which will negatively impact flood control.

The water levels from the initial results were compared with measured levels in several sections. To correct the differences, the roughness values were adjusted in certain river sections until values close to the measured ones were obtained. After validating the model regarding water movement, the sediment transport model was then run.

The calculation of the transport capacity of non-cohesive sediments, the morphological changes and the transformation of the alluvial resistance in relation to a water system can be done with the MIKE 11 program.

The input data for the properties of non-cohesive sediments are:

- Diameter of sediment grains;
- Data for graded ST;
- Transport model;
- Calibration factors;
- Bed level without cleanliness;
- Passive branches;
- Predetermined distribution of sediments in nodes.

CONCLUSIONS

This study applied a one-dimensional hydraulic model to simulate unsteady flow using the MIKE 11 software.

The MIKE 11 model demonstrated several advantages easy to view and extract results analyses, short simulation time, accurate hydraulic description in flowing waters/channels of hydrotechnical structures.

The MIKE 11 program presents a complex and efficient modeling and design system in various engineering applications, water sources, water quality management and planning, extraordinary flexibility, speed, as well as a very easy use of the program.

The core of the MIKE 11 modeling system, the hydrodynamic module (HD) forms the basis for almost all modules, including water quality, flood forecasting, advection spread, as well as alluvial displacement modules of various sizes and non-cohesive.

The MIKE 11 model successfully simulated sediment transport, identifying key areas of erosion and deposition. These insights are valuable for improving flood risk assessment and designing effective river management strategies.

However, one-dimensional models have limitations, particularly in capturing complex flow interactions in floodplains. Future research should consider integrating 2D or 3D hydraulic models to improve accuracy in predicting morphological changes and extreme flood events.

Abstract

This study aims to carry out ecological monitoring of the surface water of the Parvenetska River (Eastern Aegean Sea region, Southern Bulgaria). For the study, samples of macrozoobenthos were collected in the spring of 2024 – a basic biological quality element according to the Water Framework Directive. The taxonomic affiliation of macroinvertebrates was determined, and 26 taxa were ident3ified. The number of EPT taxa, % (Oligochaeta & Diptera), % Filtering feeders, % EPT taxa, German trophic index, and species diversity indices were calculated. As a result of the study, it was established that in the studied biotope, macroinvertebrate taxa of sensitivity group C (relatively tolerant forms) dominate, followed by taxa of group B (less sensitive forms).

Key words*: chemical status, ecological state, indices, metrics, river ecosystem.*

INTRODUCTION

The Parvenetska River (Tamrashka River; Dermendere River) rises from the Modar Peak in the Chernatitsa Ridge, Western Rhodopes, at 1 816 m above sea level.

The river flows in a north-northeast direction, and at the village of Parvenets, it leaves the Rhodopes and enters the Upper Thracian Lowland (Pazardzhik-Plovdiv Plain), passes through the city of Plovdiv and flows from the right into the Maritsa River at 164 m above sea level. The riverbed in the river's lower reaches (after the village of Parvenets) has been corrected with dikes. The length of the Parvenetska River is 37 km. The river passes through the lands of the villages of Hrabrino, Parvenets and the city of Plovdiv. The river's waters are used for irrigation, electricity generation and water supply to industry. The river is at its highest point in April-May (Kiradzhiev, 2013; Integrated Development Plan of Municipality of Plovdiv, 2021-2027; Integrated Development Plan of Municipality of Rhodope, 2021-2027). According to the typology of rivers in Bulgaria, the Parvenetska River is of type R3 "Mountain Rivers" (Tamrashka River to the village of Hrabrino and tributaries - Dormushevska and Pepelasha Rivers) and of type R5 "Semi-Mountain Rivers" (Parvenetska River from the confluence of the Pepelasha River to the mouth) in Ecoregion 7 (East Aegean River Basin Directorate, 2018).

The Water Framework Directive aims to achieve good water state in Europe and reduce harmful impacts on them. The qualitative elements for assessing the ecological state of rivers are biological, hydromorphological and physico-chemical elements. The latter two elements support the biological elements. The main biological quality elements are macroinvertebrates (Directive 2000/60/EU). At present, no studies have been established on the ecological state of the water of the Parvenetska River in the area of the village of Parvenets based on biological elements (macrozoobenthos) and physicochemical quality elements. Such studies have been conducted for other rivers in the

Maritsa River basin, for example the Luda Yana River (Vidinova et al., 2008; Georgieva et al., 2014; Gartsiyanova et al., 2020; Gartsiyanova et al., 2021; Gartsiyanova et al., 2022; Zaharieva et al., 2024), the Topolnitsa River (Gartsiyanova et al., 2020; Irikov & Atanasova, 2008; Kancheva, 2016; Park et al., 2022; Varadinova et al., 2022), Sazliyka River (Vidinova et al., 2008; Park et al., 2022; Varadinova et al., 2022), Chepelarska River (Kirin, 2002; Vidinova et al., 2008; Boyanov et al., 2011a; 2011b; Park et al., 2022; Patronov & Kirin, 2024; Zaharieva et al., 2024). Data on macroinvertebrates of Ephemeroptera, Plecoptera, and Trichoptera from water bodies in the Plovdiv city region, including Parvenetska River, were given by Vidinova et al. (2018).

This study aims to conduct ecological monitoring of the surface water of the Parvenetska River, part of the Maritsa River basin in Southern Bulgaria.

MATERIALS AND METHODS

The macroinvertebrate samples were collected in the spring of 2024 from the Parvenetska River, on the outskirts of the village of Parvenets (designated as Parvenets biotope; 42°04'53.1"N 24°39'41.1" E), Plovdiv district. The village is located at 454 m above sea level. The selected biotope is located northwest of the village and is characterized by a fast current and a rocky bottom (Figures 1 and 2).

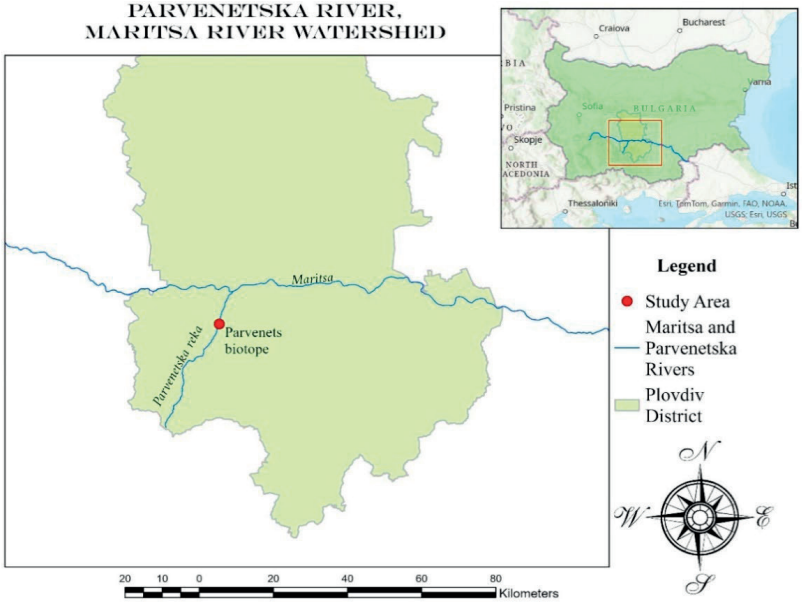

Figure 1. Researched section of the Parvenetska River

Figure 2. View from the Parvenets biotope

The studied section of the river belongs to type R5, "Semi-mountainous rivers". Macroinvertebrate sampling was carried out by national standards (Cheshmedjiev et al., 2011; EN ISO 10870:2012; EN 16150:2012; Regulation No. H-4 of 14.09.2012; Belkinova et al., 2013).

Macroinvertebrate samples were taxonomically defined and counted. The main metrics were determined: total number of taxa, number of Ephemeroptera, Plecoptera and Trichoptera (EPT) taxa, % (Oligochaeta & Diptera), % Filtering feeders; % EPT taxa; German trophic index RETI and species diversity indices according to Cheshmedjiev et al. (2011) and Belkinova et al. (2013).

RESULTS AND DISCUSSIONS

During the ecological monitoring of the Parvenetska River (Parvenetska biotope), 26 taxa (*Haliplus lineolatus* Mannerheim, 1844; *Oulimnius tuberculatus* (Müller, 1806); *Lumbricus rubellus* Hoffmeister, 1843; *Atherix ibis* (Fabricius, 1798), larva; Ceratopogonidae; *Chironomus plumosus* (Linnaeus, 1758), larva; *Tipula* sp., larva; *Baetis* sp., nymph; *Caenis horaria* (Linnaeus, 1758), nymph; *Ecdyonurus* sp., nymph; *Oligoneuriella rhenana* (Imhoff, 1852), nymph; *Serratella ignita* (Poda, 1761), nymph (*Ephemerella ignita* (Poda, 1761)); *Gerris* sp., nymph; *Nepa cinerea* Linnaeus, 1758, nymph; *Plea minutissima* Leach, 1818, nymph; *Physella acuta* (Draparnaud, 1805); *Bithynia tentaculata* (Linnaeus, 1758); *Aeshna* sp. larva; *Enallagma cyathigerum* (Charpentier, 1840), larva; *Gomphus* sp., larva; *Hydropsyche* sp., larva; *Hydropsyche ornatula* McLachlan, 1878, larva; *Hydroptila* sp., larva; *Limnephilus rhombicus* (Linnaeus, 1758), larvae; *Oligotricha striata* (Linnaeus, 1758) (syn. Phryganea striata L.); *Sericostoma personatum* (Kirby & Spence, 1826), larva) with 316 specimens of macroinvertebrates belonging to 9 orders were found.

The largest number of taxa and specimens are the macroinvertebrates belongs to the order Trichoptera (Figure 3). Due to the high number of taxa, the ecological state of the Parvenetska River in the studied biotope is very good.

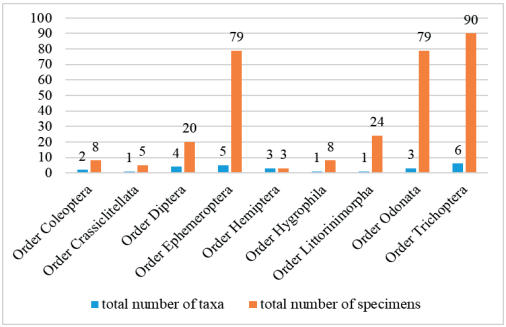

Figure 3. Total number of taxa and specimens of macroinvertebrate organisms from the Parvenetska River

Eleven EPT taxa with a total of 169 specimens of macroinvertebrates were identified in the Parvenetska biotope. Of these, 5 and 6 taxa (79 and 90 specimens) are from Ephemeroptera and Trichoptera, respectively. The ecological state of the river in the studied biotope based on the number of EPT taxa is very good. In previous studies (Vidinova et al., 2018), 9 EPT taxa were reported for the Parvenetska River (five from Ephemeroptera and four from Trichoptera). Of these, two taxa - *S. ignita* (Ephemeroptera) and *Hydropsyche* sp. (Trichoptera) were also found in the Parvenets biotope of the present study.

One taxon, Oligochaeta, and four taxa, Diptera, were found, represented by 5 and 20 specimens, respectively, which represent 7.91% of the total abundance. Two taxa (with five specimens) from the ecological group of filtering feeders were found. Therefore, the filtering feeders group represents 1.58% of the total abundance. The percentage of EPT taxa is high - 53.48% of the total abundance.

According to the mode of feeding, macroinvertebrate organisms in the Parvenets biotope are distributed as follows: "scrapers (SC)" - 91 specimens (7 taxa); "collectors (CL)" - 52 specimens (2 taxa); "shredders (SH)" and "deposit feeders (DF)" - 38 specimens (4 and 3 taxa, respectively); "filtering feeders (FL)" - 5 specimens (2 taxa). The studied biotope is dominated by scrapers and collectors, typical of mountain areas without anthropogenic load. Based on the distribution of macroinvertebrates from the Parvenetska River by trophic groups, the German Trophic Index (RETI) was calculated.

The index value was 0.58, indicating that the river's ecological state in the studied biotope is good.

The Shannon-Weaver species diversity index (H') is 2.62 and indicates β-mesosaprobic conditions for the studied section of the Parvenetska River. The Pielou's evenness index (E) is high, and the Simpson's dominance index (C) is low, indicating good environmental conditions (Table 1).

Table 1. Species diversity indices

Indices	Parvenets biotope
Species richness index of Margalef (Dmg)	4.34
Shannon-Weaver species diversity index (H')	2.62
Pielou's evenness index (E)	0.805
Simpson's dominance index (C)	0.102

Of the 26 macroinvertebrate taxa identified, 23 belong to 9 saprobity groups. By number of taxa, macroinvertebrates dominate for 0-β-mesosaprobic conditions (7 taxa), and by number of specimens - for β-mesosaprobic conditions (91 specimens) (Figure 4).

The results obtained for the value of the saprobic index (SPUB = 1.97) indicate a good state of the water of the Parvenetska River at the Parvenets biotope.

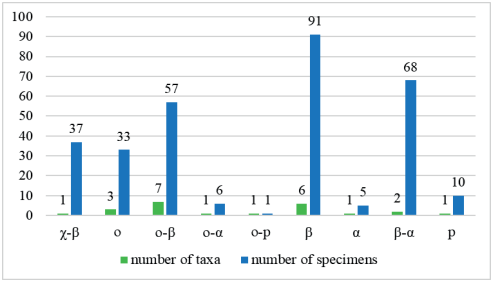

Figure 4. Number of macroinvertebrates from the Parvenetska River by saprobity groups

The bioindicator macroinvertebrate organisms from the Parvenetska River include 23 taxa belonging to the five sensitivity groups - Group A (sensitive forms), Group B (less sensitive forms), Group C (relatively tolerant forms), Group D (tolerant forms), Group E (the most tolerant forms). Group C is distinguished by the largest number of taxa and specimens and groups A and E by the smallest (Figure 5).

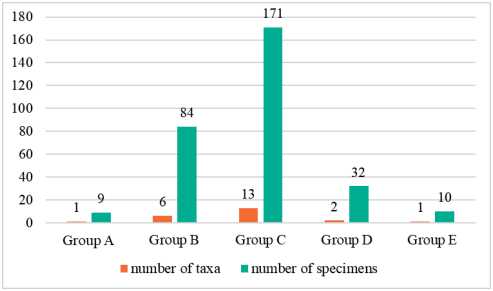

Figure 5. Number of macroinvertebrates from the Parvenetska River by sensitivity groups

The ecological state of the Parvenetska River in the studied biotope has a biotic index of 3 (nEQR=0.6) (moderate ecological state).

According to a report from the East Aegean River Basin Directorate (EARBD), by 2023, the ecological state of the section of the Tamrashka River to the village of Hrabrino and tributaries - the Dormushevska and Pepelasha rivers is good. The ecological state is moderate in the section of the Parvenetska River from the confluence of the Pepelasha River to the mouth (Table 2).

According to the EARBD database, in the period March-June 2024, only in April was pollution with dissolved aluminium (32 µg/l) recorded at a maximum permissible concentration -environmental quality standards (MPC-EQSs) of 25 µg/l, in the section of the Parvenetska River from the confluence of the Pepelashka River to the mouth, where the studied biotope is located. In 2024, based on the study conducted, we established a deterioration of the ecological state from good (2022-2023) to moderate (2024).

Table 2. Comprehensive ecological assessment for the period 2020-2023 (EARBD) (ES - ecological state; EP - ecological potential; BQEs - biological quality elements; PQEs - physicochemical quality elements)

	Overall assessment of the ES/EP on the BQEs	Overall assessment of the ES on the PQEs	Overall assessment of the ES/EP	Chemical state

2020	good	moderate	moderate	good

CONCLUSIONS

During the ecological monitoring of the Parvenetska River (Parvenets biotope), 26 taxa of bioindicator macrozoobenthos were identified. Based on the determined ecological indices, the biotic index with the lowest indicators indicates a moderate ecological state.

ACKNOWLEDGEMENTS

The results of this study have been published with the financial support of the Centre of Research, Technology Transfer and Protection of Intellectual Property Rights at the Agricultural University-Plovdiv under project No. 17-12 in the direction of “Support for publication activities”.

Abstract

This study assesses the ecological state of the Borovitsa River, a tributary of the Arda River sub-basin, and the Maritsa River basin using a methodology approved for the European Union and Bulgaria. For the purpose of the study, in the spring of 2024, macroinvertebrates samples were collected from the Borovitsa River near the village of Nenkovo (in the section between Borovitsa Reservoir and Kardzhali Reservoir, according to Bulgarian river typology, this section is classified as R14:"Sub-Mediterranean small and medium-sized rivers" according to the typology of rivers in Bulgaria. The collected macrozoobenthos were taxonomically identified. Fourteen taxa were identified, based on which key ecological metrics were calculated - EPT taxa, Margalef species richness index (Dmg), Shannon-Weaver species diversity index (H'), Pielou's evenness index (E), Simpson's dominance index (C) and biotic index (BI). The findings provide valuable insights into the biodiversity and ecological status of the Borovitsa River, contributing to regional water quality assessments and conservation efforts.

Key words*: biotic index, chemical status, ecological state, macrozoobenthos, Maritsa River basin.*

INTRODUCTION

The Arda River originates from the northeastern foothills of Ardin Peak, located in the Western Rhodopes, and flows for 241 km before reachingthe Bulgarian-Greek border. It then joins the Maritsa River in Turkey. The Arda River is one of the largest tributaries of the Maritsa River. Major tributaries of the Arda River include the Varbitsa River (98.1 km), Krumovitsa River (58.5 km), Cherna River (48.1 km), Perperek River (44 km), and Borovitsa River (42.1 km). Its highest water levels occur between December and April. The Borovitsa River originates in the Rhodopes and flows into the Arda River, eventually draining into the Kardzhali Reservoir. The Borovitsa River catchment area is 301 km^2 (Kiradzhiev, 2013; East Aegean River Basin Directorate, 2018). The Borovitsa Reservoir supplies drinking and domestic water. The surrounding area is lightly inhabited (Kiradzhiev, 2013; Integrated Development Plan of Municipality of Kardzhali, 2021-2027). The European Water Framework Directive (Directive 2000/60/EU) mandates that all surface waters achieve a "good ecological status".

The Borovitsa River falls into Ecoregion 7 and belongs to type R14 "Sub-Mediterranean small and medium-sized rivers" (Belkinova et al., 2013). A key role in the assessment of the ecological state of surface water is played by biological quality elements (BQEs) includingphytoplankton, macrophytes, phytobenthos, macrozoobenthos and fish. Additionally, physicochemical and hydromorphological parameters contribute to the evaluation. The final assessment of the ecological state is determined on the principle of "one out – all out" (Cheshmedjiev & Marinov, 2008; Belkinova et al., 2013). Despite extensive research on the Arda River and its sub-basin, no previous studies have assessed the Borovitsa River's ecological state using macrozoobenthos

as a BQE. Such studies exist for the Arda River (Kirin et al., 2002; Kuzmanov et al., 2002; Kirin et al., 2003; Kirin, 2006) and for the Arda River sub-basin - from the Borovitsa Reservoir (Varadinova et al., 2019). Vidinova (2006) studied mayflies (Ephemeroptera, Insecta) from the Rhodopes Mountains, including from the Arda River, the Malka Arda River, the Varbitsa River, the Krumovitsa River, the Borovitsa River and others. Vidinova et al. (2016) presented a taxonomic list of macroinvertebrates from various standing water bodies in Bulgaria, including the Borovitsa Reservoir.

This study aims to evaluate the ecological state of the Borovitsa River, a tributary of the Arda River sub-basin and the Maritsa River basin, using macrozoobenthos - based bioindicators. The results contribute to regional water quality assessments and environmental management strategies.

MATERIALS AND METHODS

Macrozoobenthos samples were collected from the Borovitsa River in the spring of 2024. The selected biotope (designated as the Nenkovo biotope) is located between the Borovitsa Reservoir and Kardzhali Reservoir, next to the Roman Bridge (41°43'59.8"N 25°13'11.7" E) (Figures 1-2), south of the village of Nenkovo, at an altitude of 420 m. In this section, the river bed is represented by stones and sand.

Figure 1. Borovitsa River, Arda River sub-basin, Maritsa River basin

Figure 2. Views from the Borovitsa River, Nenkovo biotope

Macroinvertebrate sampling followed EU and Bulgarian legislative requirements and standards (Cheshmedjiev et al., 2011; EN ISO 10870:2012; EN 16150:2012; Regulation No. H-4 of 14.09.2012; Belkinova et al., 2013). The taxonomic identification and abundance assessment of the collected macroinvertebrates were conducted under laboratory conditions using a stereo zoom microscope, KERN OZL 464T24. According to Regulation No. H-4 of 14.09.2012 and Belkinova et al. (2013), the following metrics were calculated: - total number of taxa; - number of Ephemeroptera, Plecoptera and Trichoptera (EPT) taxa; - Trichoptera taxa was the dominant group.

Additionally, the following indices were calculated: 1) Margalef species richness index (Dmg) (Margaleff, 1958); 2) Shannon-Weaver species diversity index (H') (Shannon & Weaver, 1963); 3) Pielou's evenness index (E); 4) Simpson's dominance index (C) (Magurran, 1988); 5) Saprobic index (SPUB) and 6) Biotic index (BI) based on Flanagan & Toner (1972), modified by Clabby (1979), Clabby (1982).

The indices were calculated using the following formulas:

1) $\mathbf{Dmg} = \frac{(\mathbf{S-1})}{\mathbf{\log_2 N}}$,

where:

S - number of species in the sample;

N - total number of organisms in the sample.

2) $\mathbf{H'} = (\mathbf{P})(\mathbf{\log P})$,

where:

H' - index of individual species diversity;

P - the proportion of the taxon (amount of the taxon divided by the total number of organisms in the sample).

3) $\mathbf{E} = \frac{\mathbf{H'}}{\mathbf{\log_2 N}}$,

where:

H' - index of individual species diversity;

N - number of specimens.

4) $\mathbf{C} = \sum \left(\frac{\mathbf{n_i}}{\mathbf{N}}\right)^{\mathbf{2}}$,

where:

n_i - number of specimens of each i-species;

N - number of specimens of all species (total abundance)

5) $\mathbf{SPUB} = \sum(\mathbf{s_i h_i I_i}) / \sum(\mathbf{h_i I_i})$,

where:

s_i - saprobic importance of species/taxon i;

h_i - relative abundance of species/taxon i;

I_i - indicator weight of species/taxon i.

RESULTS AND DISCUSSIONS

In the study of macrozoobenthos from the Borovitsa River, Nenkovo biotope, 14 taxa with 219 specimens belonging to 6 orders were identified. Trichoptera taxa were the most dominant group. The most abundant taxon was *Schmidtea polychroa* (Schmidt, 1861) (order Tricladida; 79 specimens) (Table 1). The number of identified taxa suggests a very good ecological state of the water of the Borovitsa River in the studied biotope.

More than half of the macroinvertebrate taxa in the Nenkovo biotope belong to the EPT taxa (8 taxa). Taxa from these orders are sensitive to anthropogenic pressure, and their presence indicates a good ecological status for the river in the selected biotope. A previous study (Vidinova, 2006) reported four taxa of Ephemeroptera for the Borovitsa River - *Electrogena lateralis* (Curtis, 1834), *Electrogena macedonica* (Ikonomov, 1954), *Electrogena quadrilineata* (Landa, 1970) and *Choroterpes picteti* (Eaton, 1871), but these species were absent in the Nenkovo biotope.

In the Borovitsa Reservoir a total of 14 macrozoobenthos taxa were recorded, including:

- 1 taxon Oligochaeta (*Limnodrilus* sp. juv.),
- 1 taxon Ephemeroptera (*Caenis macrura* Stephenes, 1835),
- 1 taxon Odonata (*Gomphus vulgatissimus* (Linnaeus, 1758)),
- 2 taxa Trichoptera (*Ecnomus tenellus* (Rambur, 1842), *Holocentropus stagnalis* (Albarda, 1874)) and
- 9 Diptera taxa (*Chironomus* gr. *riparius* Meigen, 1804, *Chironomus* sp., *Cricotopus* sp., *Cryptochironomus* gr. *defectus* Kieffer, 1913, *Dicrotendipes* sp., *Eukiefferiella* sp., *Tanytarsus* gr. *gregarius* Kieffer, 1909, *Tvetenia* sp., Chironomidae, gen. sp.) (Vidinova et al., 2016). None of these taxa were recorded in the present study for the Nenkovo biotope of the Borovitsa River.

The abundance of macroinvertebrate fauna is represented by the metrics: % (Oligochaeta & Diptera), % Filtering feeders and % EPT taxa. In the present study, no representatives of Oligochaeta were found. Two Diptera taxa were found (with 33 specimens). Only one taxon (9 specimens) belongs to the filtering feeders

group. EPT taxa contributed the highest proportion of macrozoobenthos (Table 2).
The Margalef species richness index (Dmg) is low. The Shannon-Weaver species diversity index (H') is also low, indicating α-mesosaprobic conditions. However, the Pielou's evenness index (E) is high, the Simpson's dominance index (C) is low, which indicates favourable environmental conditions (Table 3).

Table 1. Taxonomic composition and abundance of bioindicator macroinvertebrate organisms from the Borovitsa River, Nenkovo biotope

No.	Taxa	Number of specimens	Genus	Family	Order
1	*Limnephilus rhombicus* (Linnaeus, 1758), larva	36	*Limnephilus* Leach, 1815	Limnephilidae	Trichoptera
2	*Hydropsyche* sp., larva	2	*Hydropsyche* Pictet, 1834	Hydropsychidae	Trichoptera
3	*Hydropsyche ornatula* McLachlan 1878, larva	40	*Hydropsyche* Pictet, 1834	Hydropsychidae	Trichoptera
4	*Psychomyia pusilla* (Fabricius, 1781), larva	1	*Psychomyia* Latreille, 1829	Psychomyiidae	Trichoptera
5	*Chironomus plumosus* (Linnaeus, 1758), larva	24	*Chironomus* Meigen, 1803	Chironomidae	Diptera
6	*Hydroptila* sp., larva	5	*Hydroptila* Dalman, 1819	Hydroptilidae	Trichoptera
7	*Simulium* sp., larva	9	*Simulium* Latreille, 1802	Simuliidae	Diptera
8	*Baetis* sp., nymph	3	*Baetis* Leach, 1815	Baetidae	Ephemeroptera
9	*Schmidtea polychroa* (Schmidt, 1861)	79	*Schmidtea* Ball, 1974	Dugesiidae	Tricladida
10	*Gomphus* sp., nymph	10	*Gomphus* Leach, 1815	Gomphidae	Odonata
11	*Enallagma cyathigerum* (Charpentier, 1840), larva	2	*Enallagma* Charpentier, 1840	Coenagrionidae	Odonata
12	*Platambus maculatus* (Linnaeus, 1758)	1	*Platambus* Thomson, 1859	Dytiscidae	Coleoptera
13	*Oligotricha striata* (Linnaeus, 1758) (syn. *Phryganea striata* L.), larva	3	*Oligotricha* Rambur, 1842	Phryganeidae	Trichoptera
14	*Ecdyonurus* sp., nymph	4	*Ecdyonurus* Eaton, 1868	Heptageniidae	Ephemeroptera

Table 2. Abundance of macroinvertebrate organisms from the Borovitsa River, Nenkovo biotope

Metrix	% (Oligochaeta & Diptera)	% Filtering feeders	% EPT taxa
14 taxa (219 specimens)	15.07%	4.11%	42.92%

A total of five macrozoobenthos taxa were associated with 0-β-mesosaprobic conditions; three taxa corresponded to β-α-mesosaprobic conditions, three to β-mesosaprobic conditions and one taxon each - χ-0 saprobic; χ-β-mesosaprobic and p saprobic conditions. The study reports a saprobic index SPUB of 2.38, indicating a moderate ecological state of the Borovitsa River.

Table 3. Biotic indices of the bioindicator macrozoobenthos from the Borovitsa River, Nenkovo biotope

Indices	Margalef species richness index (Dmg)	Shannon-Weaver species diversity index (H')	Pielou's evenness index (E)	Simpson's dominance index (C)
14 taxa (219 specimens)	2.41	1.9	0.721	0.208

The macroinvertebrate organisms discovered in this study belong to four sensitivity groups. The largest number of taxa and specimens (9 taxa with 99 specimens) were classified as relatively tolerant forms (group C), followed by the group of less sensitive ones (group B) - 3 taxa with 92 specimens. With one taxon each (4 and 24 specimens), the groups of sensitive (group A) and the most tolerant forms (group E) are represented, respectively. Notably, no taxa belonged to the tolerant group (Group D). The determined biotic index (BI (nEQR) = 3 (0.6)) indicates a moderate ecological state.

According to a report from the East Aegean River Basin Directorate (EARBD) covering the period 2020-2023, the ecological state of the Borovitsa River varies along different sections. The section from the river's source to the Borovitsa Reservoir is classified as good, while the section from the Borovitsa River and tributaries from the Borovitsa Reservoir to the confluence with the Kardzhali Reservoir is categorized as having a moderate ecological state (Table 4). In the spring (March-June) of 2024, there were no exceedances of key physicochemical parameters, specific pollutants, or priority substances in the Borovitsa River's freshwater ecosystem (East Aegean River Basin Directorate, 2018).

Table 4. Comprehensive ecological assessment for the period 2020-2023 (EARBD) (ES - ecological state; EP - ecological potential; BQEs - biological quality elements; PQEs - physicochemical quality elements)

	Overall assessment of the ES/EP on the BQEs	Overall assessment of the ES on the PQEs	Overall assessment of the ES/EP	Chemical state
Source of the Borovitsa River to the Borovitsa Reservoir - R14				
2023	good	good ES	good	good
2022			good	good
2021	good		good	unknown
2020	good		good	unknown
Borovitsa River and tributaries from Borovitsa Reservoir to the confluence with Kardzhali Reservoir - R14				
2023	moderate	good ES	moderate	Good
2022			moderate	Good
2021	good		good	Unknown
2020	good		good	Unknown

The findings of this study confirms preserving the ecological state from 2022-2023 - moderate ecological state.

CONCLUSIONS

This study assessed the ecological state of the Borovitsa River, focusing on macrozoobenthos as a biological quality element.

The identification of 14 macroinvertebrate taxa comprising 219 specimens confirmed that the Borovitsa River exhibits a moderate ecological state.

The relatively high proportion of EPT taxa (Ephemeroptera, Plecoptera, Trichoptera) indicates good ecological integrity, although the absence of certain previously recorded species suggests potential environmental pressures. It is hypothesized that this moderate classification is primarily influenced by reduced water levels, potentially leading to habitat degradation and adverse effects on macroinvertebrate communities.

Although no physicochemical exceedances were detected during the study period, long-term monitoring is required to evaluate potential

impacts from seasonal variations, climate change, and anthropogenic activities on water quality.

Abstract

The Sânnicolau Mare-Saravale Canal covers an area of 20,060 ha, with land rehabilitation works accounting for 19,998 ha. Sânnicolau Mare is located in the western part of Romania, in Timiș County. The MIKE11 program was used for numerical modelling. MIKE 11 has flow calculation modules that include hydraulic structures, and ways to describe the operation of the structure. With the MIKE 11 model, they draw up flood risk maps. The keywords are productivity, reliability, quality and versatility for professional engineers who use the MIKE 11 program. The MIKE 11 model has been shown to be highly reliable for generating flood risk maps.

Key words*: advanced modelling, flood maps irrigation channel.*

INTRODUCTION

The objective of this paper is to model the movement of water in the Aranca channel in the area of Sânnicolau Mare, with the aim of determining water levels and flow rates along the channel.

This allows for the anticipation of situations that may arise under different inflow conditions in extreme precipitation or drought scenarios. The numerical modelling was carried out using the MIKE11 program.

Sânnicolau Mare drainage system - in the northern part of Timiș county there are Saravale and the Tisa - Mureș basin; subsection II Aranca being delimited as follows:

- North Mureș sewerage system and left Mureș dam km 32+000 - 43+400;
- South Basin, subsection III Aranca Galatca;
- To the west, subsection IV Aranca;
- East under the Aranca I compartment - the limit of Arad County;

Sânnicolau Mare System - The rehabilitation works of the lands belonging to Saravale occupied 19,998 ha of the total area of 20,060 ha (Figure 1).

The excess moisture in the drainage system manifests itself differently on different surfaces in local orographic, solar and hydrogeological conditions, created as a result of rainfall in the area of the drainage system and the Mureș River that produce an abundant supply of groundwater in the area.

Figure 1. Map of Timiș County, Romania

The land has a natural slope from east to west 0.02-0.05%.

The emissary is generally the Mureș River. The depression of the main collector Aranca, the regularized discharges made at Mureș being carried out through a system of dams near the Silvia Canal and SP Cenad at Aranca have reached the border restrictions, the rest is done through the periods of flow of the Aranca canal over the border with Yugoslavia through the discharge of the Tisza canal or the canal into the DTD.

The main collector system for all departments is the Aranca Canal, which conducts the inland waters generally collected across the Yugoslav Roman border to the height of 77.60 m recorded share the miraculous smiles - the confluence of the Tisza when the Yugoslav border dam closes on the Aranca.

At that time, the gates of Sections IV and II (Aranca km 40+250) and Compartments II and

I (Aranca km 77+940) are closed, and the appropriate distribution of the collected domestic wastewater and drainage subunits is carried out.

Existing natural conditions - partitioning perimeter imposed by Sânnicolau Mare - Saravale drainage system, four independent functional units as follows:

1. UD Sânnicolau Mare - Tomnatic an area of 6,390 ha located on the left bank of the Aranca between 40+250 - 53+300 km forming the northern limit, Dc27 Simpetru-Lovrin the eastern limit of the drainage system compartment III Aranca and Section IV the southern limit of the southern limit.
2. Simpetru Lovrin UD, area of 3,885 ha located on the left bank of the canal, also Aranca, between 53+300 - 59+700 km, northern limit, bordered to the northeast and south, Periam UD, compartment III (Galatca), to the west, is limited to the DU. Sânnicolau Mare-Tomnatic.
3. Saravale UD - the Igris area of 3,690 ha on the right bank of the Aranca canal (km 40+250 - 59+700) and Silvia (km 0+000 - 0+300) limited to the northern Mureșan and left Mureș dam system (km 31+000 - 35+000) and to the east by the Periam UD dam system.
4. The Periam UD area, 6,033 ha, is located in the upstream compartment II, Aranca (km 59+700 - 77+940) to the left with the dam north of the Mures river (35+000 - 43+500 km) to the east the Aranca subdivision dam with section. I, the southern limit of the Checea - Jimbolia Aranca drainage system compartment III and UD Lovrin Simpetru - and west - Lovrin Simpetru UD and UD Saravale - Igriș.

The Aranca originates from the Felnac Mureș Valley - where dam construction began in 1816 - and flows into the Tisza River. It passes through the center of Sânnicolau Mare, having been channelized in 1888 following severe spring floods. The Aranca hydraulic system was developed between 1887 and 1894 (Figure 2). The crossing of the Aranca Sânnicolau Mare canal was aimed at draining the flooded lands, being widened and deepened in 1959 and 1960. The canal has a total length of 10.532 km, a depth ranging from 1 to 3 meters, and a width between 6 and 16 meters. It has a slope of 0.1 to 0.15 per km, with a difference in elevation between the entry points and the exit points outside the city. The maximum flow occurs in spring, reaching 2.5 m³/s, while the minimum flow is observed in summer (Biali et al., 2022).

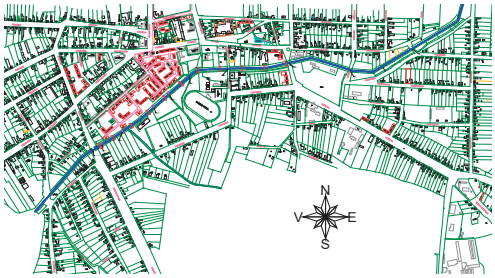

Figure 2. Map of the Aranca Canal, Timiș county

MATERIALS AND METHODS

The movement of water is free on watercourses, rivers, canals and pipes.

"Level-free, straight, and prismatic channels exhibit uniform flow. In straight, artificial, and prismatic channels, uniform flow occurs under free surface conditions (gutters, canals, galleries, ditches, etc.). Hydraulic calculation formulas are the Chezy-type analytical solutions that are obtained by the Manning relation.

$$Q = \frac{1}{n} \frac{S^{\frac{5}{3}}}{P^{\frac{2}{3}}} \sqrt{i} \quad (1)$$

For the trapezoidal section we have:

$$Q = \frac{1}{n} \frac{(\beta+m)^{1.5+y}}{(\beta+m')^{1.5+y}} h^{2.5+y} \sqrt{i} \quad (2)$$

where:

- $m' = 2\sqrt{1+m^2}$ (David, 1984).

Given the complexity of water movements in surface courses, it is an analytical calculation that considers the natural conditions of the land. Modeling the water flow and displacement in the Aranca Canal requires numerical simulation using the MIKE 11 program.

Description of MIKE 11 modules (input data, results)

Input data HD:
- Longitudinal profile;
- cross-sections;
- boundary conditions: hydrograph of flows, levels and boundary key.

Input data ST:
- data on sediments.

Input data RR:
- precipitation, temperature, evapotranspiration;

- data on the hydrographic basin (area, average slope and uses).
Input data ECO-LAB:
- water quality measurements.
Output Data HD:
- hydrograph of flows and levels in each cross-section (flow and level);
- the variation of the water level in longitudinal profile.
Output Data ST:
- Dragged suspended solid flow;
- modification of the levels of the bottom of the riverbed (small erosions, deposits).
Output Data RR:
- hydrograph of flows in the outlet section of the hydrographic basin.
Output Data ECO-LAB:
- the variation of the water quality parameters in the longitudinal profile (Paudel et al., 2022).
MIKE 11 is a widely used tool for simulating flow, water quality, and sediment transport in irrigation canals, rivers, estuaries, and other surface water bodies.
It provides a wide range of solutions, from basic flow routing to complex dynamic modeling, while remaining efficient and user-friendly. The efficient, fast, and robust hydrodynamic simulation engine is the computing core of this program-MIKE 11.
Every aspect of watercourse modeling is a combination of modules and extensions.
The calculation of unsteady flows in rivers and estuaries is performed using a default finite difference scheme of the MIKE 11 hydrodynamic module.
Depending on the local flow conditions, (in space and time) the module can describe both subcritical and supercritical flow conditions through a numerical relationship.
Calculation modules are included for the operation of the hydraulic structure and flow description. On floodplains of flow (Lagos et al., 2024) quasi-two-dimensional formulations and simulations of loop networks can be applied.
From river flows to tidally influenced estuaries, calculation schemes for homogeneous vertical flow conditions are applied (Nannawo et al., 2022). This System is used worldwide for engineering studies
For river management, hydraulic models are applied. For flood warning or planning the operation of reservoirs in forecasting systems, certain flood mitigation potential analysis applications are used (Kumar et al., 2021).
The models provide descriptions of the variations in flow and water level at certain points along, which are then interpreted by the user of the model regarding the consequences it may have on the population and properties in the vicinity of the river (Pareta et al., 2023).
The calibration of the model was performed for fixed inflow discharges measured upstream, which corresponded to water levels measured downstream by National Agency for Land Reclamation (ANIF). After calibration, by adjusting the roughness coefficients, validation was carried out for other measured values, resulting in an accuracy of approximately 96%.

RESULTS AND DISCUSSIONS

The results of the topographic studies for the Aranca Canal are: width at the bottom b = 3.0 m, slope inclination m = 2, slope i = 0.0002, roughness n = 0.02.
For the existing channel curve Q = Q (h) is presented in Figure 4.
The MIKE11 program was used for numerical modeling. Initially, the existing conditions of the Aranca Canal were modeled. Figure 3 shows the location of the canal, and in Table 1 nods coordinates for the model.
The cross-sections through the canal in the form of topographic studies in Figure 6 and raw data in Figure 7 respectively de processed data in Figure 8.
The input of the data according to the formulated boundary conditions, of the upstream flow to the 35+600 chainage are the flood evacuation hydrograph and downstream to the 34+600 chainage the graph of the key curve of the downstream section presented in Figure 5 (Damian et al., 2022).
The flow hydrograph is shown in Figure 9 and the discharges in all periods are presented in Table 2.

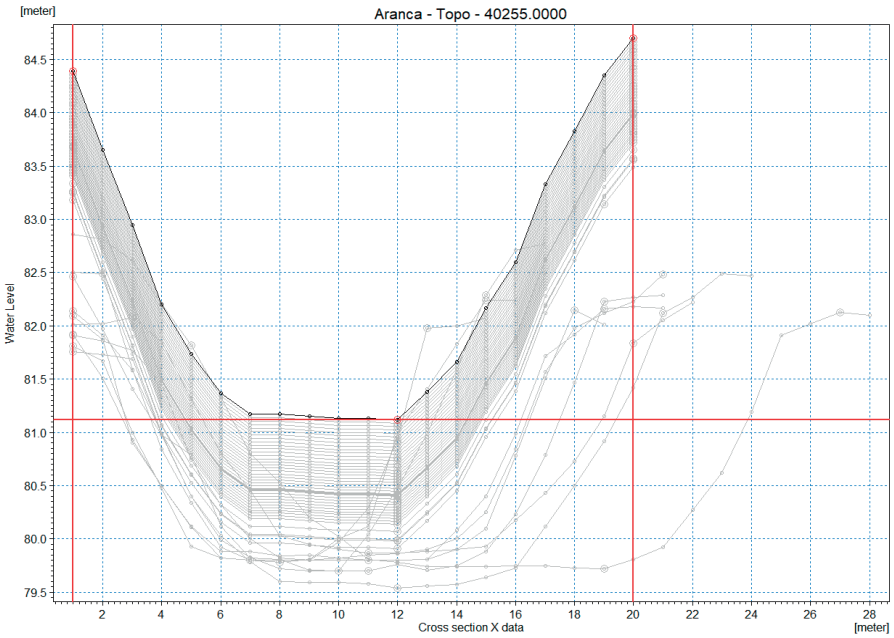

Figure 6. Cross-section for the Aranca Canal

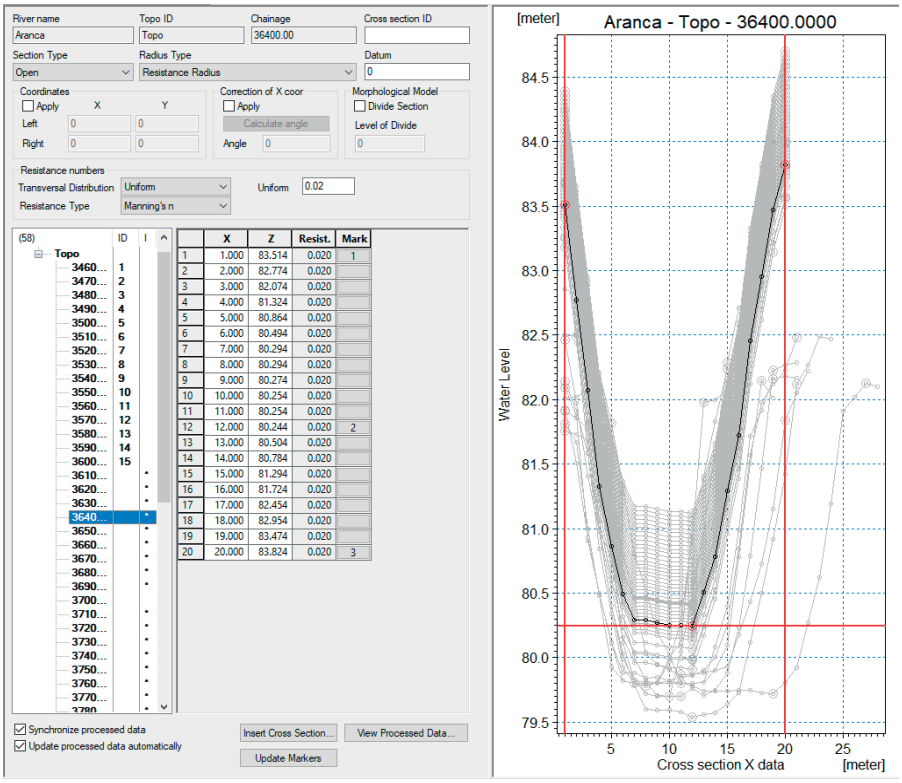

Figure 7. Raw data in Cross-sections

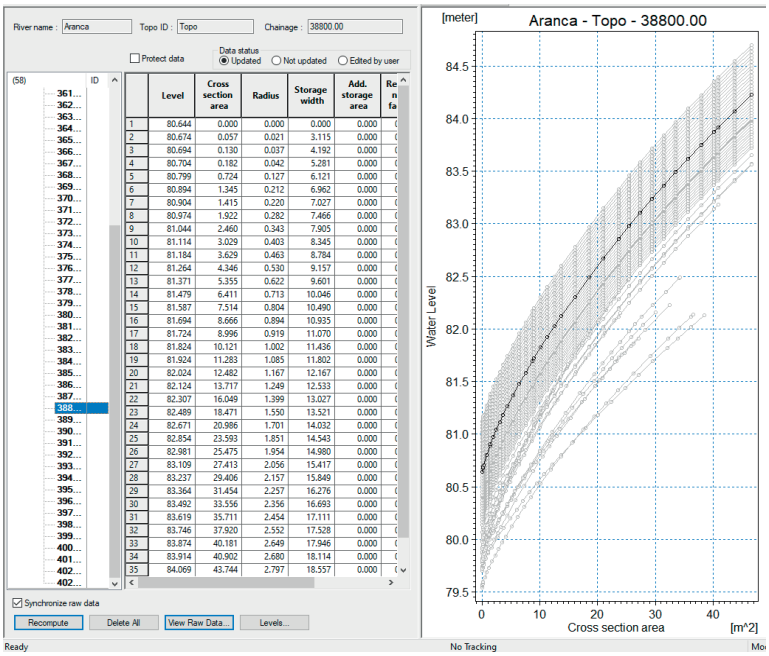

Figure 8. Processed data in Cross-sections

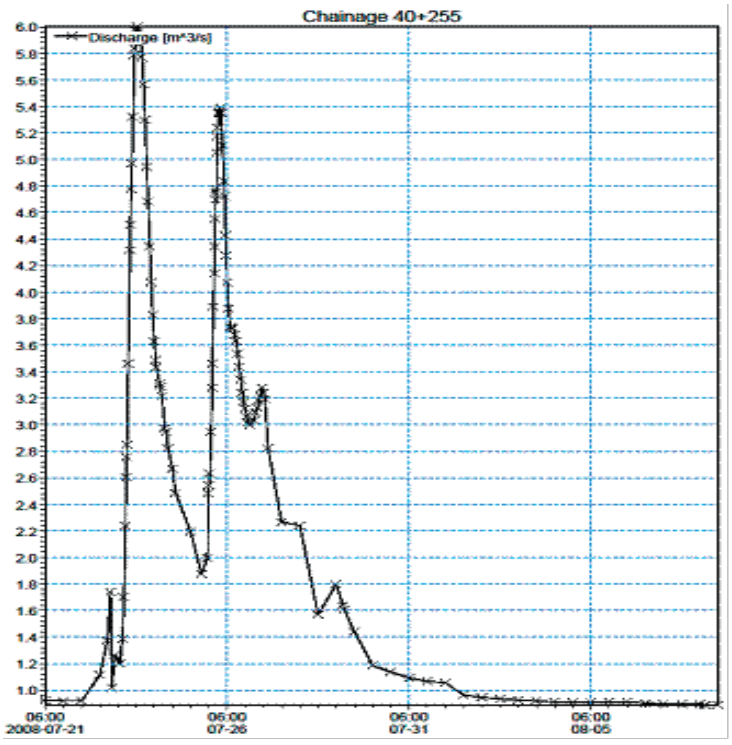

Figure 9. Flood evacuation hydrograph

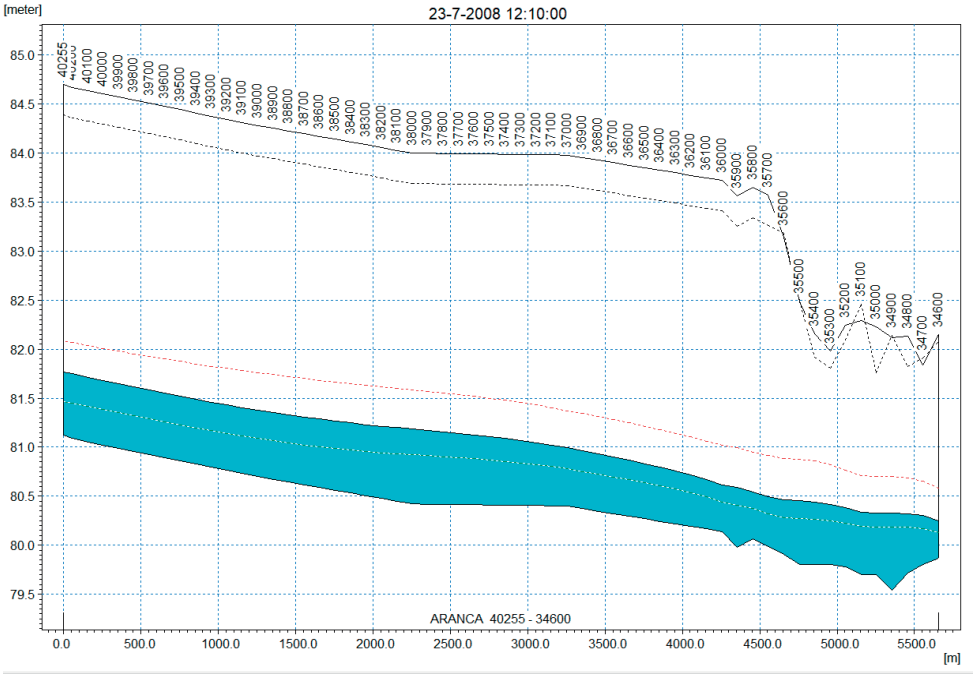

Figure 10. Longitudinal profile whit water level

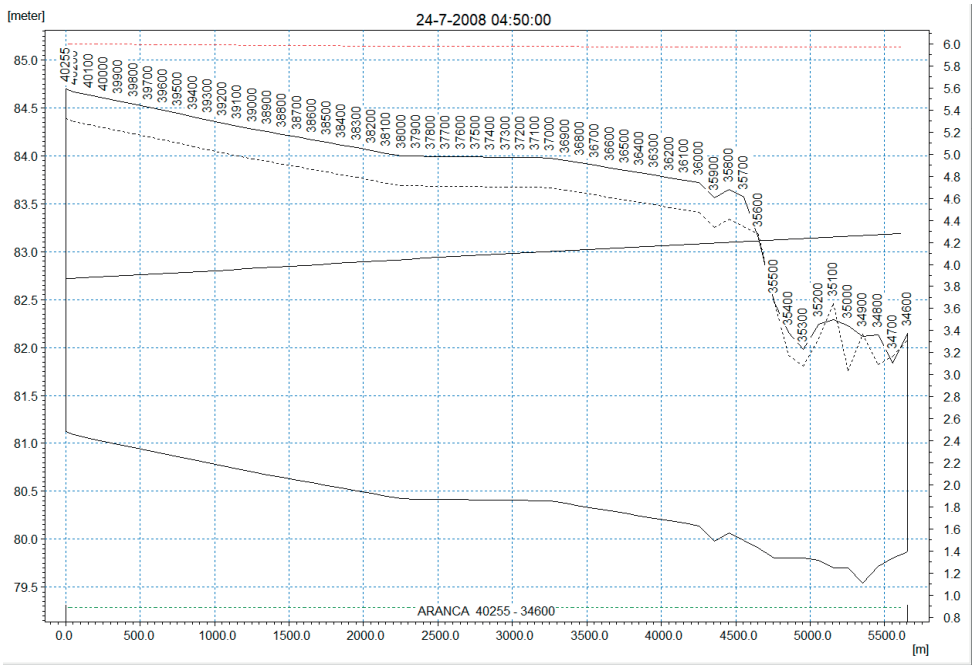

Figure 11. Longitudinal profile with discharge

By carrying out the MIKE11 program, a longitudinal profile of the canal was obtained with the water level for the entire period. (Figure 10) respectively with the discharge for the entire period (Figure 11). From Figures 10 and 11, it follows that for the hydrograph of the inflows introduced in 2008 on the Aranca Canal, the maximum water transport capacity of the canal was not exceeded, with the flood risk occurring for flows greater than those considered.

CONCLUSIONS

The model simulation using the MIKE 11 program showed that the Aranca Canal can manage a maximum flow of 58 m³/s, at which the town of Sânnicolau Mare does not experience flooding. This indicates that under current hydrological conditions, the canal is adequately designed to handle major flood events. However, changes in climate patterns or land use may alter these conditions, requiring periodic reassessment.

The model can provide real-time data or predict water levels and flow rates along the canal for any measured or hypothetical inflows from future flood events. Authorities can manage defense or prediction methods for any high-water events real-time flood forecasting, and optimization of irrigation water distribution. By leveraging MIKE 11's predictive capabilities, stakeholders can enhance proactive flood mitigation strategies and ensure efficient water resource management in the region.There are usually constraints in the modeling process due to the availability of data regarding the roughness of the canal bed along the entire studied section.

Future studies should compare MIKE 11 results with real flood events observed in the past to validate the model's accuracy. The Danish Institute of Hydraulics (DHI) simulates the flow in rivers with the MIKE 11 program and creates models.

Abstract

Climate change significantly impacts agriculture, especially in Romania's semi-arid and sub-humid regions, such as Dobrogea, Southern Moldova, and Muntenia. This study analyzes water use efficiency in irrigated agriculture, considering the increase in average annual temperatures and its effect on water consumption. The three irrigation methods – drip, sprinkler, and furrow irrigation – were compared to identify the most efficient strategies. The results indicate that drip irrigation is the most efficient, with minimal water losses and optimized consumption, although high initial costs may pose a disadvantage. Sprinkler irrigation demonstrates moderate efficiency but is influenced by weather conditions, while furrow irrigation has high water losses and low efficiency. In scenarios where temperatures increase by 2°C and 5°C, water consumption for major crops – maize, sunflower, soybean, and sugar beet – increases by up to 25%. The study emphasizes the need to modernize irrigation infrastructure and adopt sustainable technologies to address climate challenges. Financial support for implementing drip irrigation and educational programs for farmers is strongly recommended.

Key words*: adaptation, climate change, evapotranspiration modeling, irrigation efficiency.*

INTRODUCTION

This study aims to test the hypothesis that climate-induced evapotranspiration changes significantly affect irrigation efficiency in southeastern Romania, and that drip irrigation provides superior water use efficiency under these conditions.

Globally, drought and desertification affect approximately 47% of arid lands, manifesting in varying degrees of aridity. In recent years, drought-affected areas have progressively expanded across most regions of Romania, accompanied by a decline in water resources available for irrigation (Humă, 2004). Climate variability impacts all sectors of the economy, but agriculture remains the most vulnerable, with its effects becoming increasingly severe as climate change intensifies (Chitu et al., 2015). In Romania, the effects of climate change are already evident and are expected to manifest through rising temperatures, altered rainfall patterns, melting ice and snow, and rising sea levels. The impact on ecosystems, economic sectors, public health, and regional vulnerability varies across the country (Daniel et al., 2019).

Without appropriate mitigation and adaptation measures, climate change is projected to significantly reduce agricultural productivity. Plant breeders play a crucial role in developing varieties and hybrids with low evapotranspiration requirements, thereby supporting agricultural adaptation to changing climatic conditions (IPCC Press Release, 2018). Increasing temperatures and intensifying aridification are expected to lead to higher evapotranspiration rates and greater water deficits, severely impacting crop yields. Adapting to these conditions requires the development of efficient water management strategies and the implementation of optimized irrigation systems. Adapting to these climatic conditions requires the development of efficient water management strategies and the use of optimized irrigation systems. A crucial role belongs to breeders, who must create drought-resistant genotypes capable of maintaining productivity under water stress conditions (Nițu

et al., 2023). Choosing an appropriate irrigation scheduling strategy is essential to optimize plant physiological processes, thus enhancing crop yields (Kumar Jha et al., 2018). Moreover, a well-designed irrigation plan significantly reduces water and energy use. Conversely, improper irrigation practices-such as excessive or insufficient water application-generally result in lower grain yields, reduced irrigation water productivity, and environmental problems including land flooding, soil salinization, and rising groundwater levels (Yohannes et al., 2019; Almeida et al., 2022; Quiloango-Chimarro et al., 2022). The impact of climate change on the yields of major agricultural crops worldwide is expected to be negative (Roudier et al., 2011), while the exact effect remains highly uncertain when high temperatures, increased atmospheric CO2 concentrations, and changes in precipitation patterns occur simultaneously (Roudier et al., 2011). In Romania, the effects of climate change are being felt through rising temperatures, altered precipitation patterns, melting glaciers and snow, and rising sea levels. Extreme weather events, which cause negative environmental impacts (floods and droughts), are expected to become more frequent and intense in many regions (Rummukainen, 2012).The effects of water stress resulting from various sowing dates and irrigation rates is not yet fully understood. In the absence of weeds, diseases, nutritional deficiencies, or other limiting factors, the reduction in yield caused by water shortage depends on the phenological stage of the plant. Research has shown that soybeans exhibit varying sensitivity to water stress at different developmental stages, such as the vegetative phase, flowering, pod formation, and seed filling (Brevedan & Egli, 2003). Studies suggest that supplementary or deficit irrigation applied during specific periods of the growing season can significantly improve water use efficiency and positively influence soybean yield (Giménez et al., 2017; Jha et al., 2018). Drip irrigation, an advanced and water-efficient method, ensures the maintenance of plant roots in optimal moisture conditions for extended periods, thus promoting both physiological activity and crop development (Yan et al., 2022).

MATERIALS AND METHODS

The study was conducted using climatic data from five meteorological stations located in southeastern Romania: Constanța, Tulcea, Galați, Brăila, and Călărași. These regions are representative for irrigated agriculture and are frequently exposed to water stress caused by increased temperatures and rainfall variability.

The selected crops - corn, soybean, and wheat - are among the most important in Romanian agriculture, each with specific sensitivities to water deficits. The decision to evaluate these crops was based on their widespread cultivation and different growing periods and evapotranspiration demands.

Climatic data, including, the annual average temperature and precipitation data used in the study were obtained from the Romanian National Meteorological Administration (ANM), corresponding to the year 2024. To calculate the reference evapotranspiration (ET_0), the Penman-Monteith FAO-56 equation was used, which incorporates air temperature, solar radiation, wind speed (3.2 m/s), and relative humidity (65%). A constant average net radiation of 15.5 MJ/m²/day was used for the southeastern region.

The specific crop evapotranspiration (ETc) was calculated by applying crop coefficients (Kc) for each growth stage-initial, development, and maturity-following FAO guidelines. The crop growth stages were defined as follows:

- Corn: 30–50–40 days
- Soybean: 25–55–35 days
- Wheat: 30–60–45 days

The calculations were carried out using Microsoft Excel and Python to ensure accuracy in the estimation of evapotranspiration and for the structured presentation of results.

Soil conditions were considered in three standard texture scenarios-sandy, loamy, and clayey-because soil water retention capacity significantly affects irrigation efficiency.

In 2024, southeastern Romania was severely affected by extreme climate events, with high temperatures and heavy rainfall during certain periods. The summer was dominated by an exceptionally intense and prolonged heatwave, considered the most severe in the country's recent history. Between May 31 and July 31, heatwave conditions persisted for 46 out of 62

days, accounting for 75% of this period. The average summer temperature was 0.69°C higher than the 1991-2020 reference period, surpassing the previous record set in 2023. At the end of summer, on august 30 and 31, a quasi-stationary extratropical cyclone over the Black Sea brought heavy rainfall, causing floods in several coastal towns. In just 24 hours, precipitation exceeded 100 mm in numerous areas, with maximum recorded values of 225.9 mm in Mangalia, 145 mm in Agigea, and 118 mm in Tuzla (Tabel 1).

Table 1. Climatic data for Southeastern Romania - 2024

Weather station	Annual average temperature (°C)	Annual precipitation (mm)
Constanța	14.8	450
Tulcea	14.5	420
Galați	14.2	480
Brăila	14.3	460
Călărași	14.6	440

To calculate the total evapotranspiration (ETc) for corn, soybean, and wheat at each weather station in southeastern Romania, the Penman-Monteith FAO 56 equation was used to determine the reference evapotranspiration (ET_0), and then the values were adjusted for each crop using crop coefficients (Kc).

$$ETo = \frac{0{,}408\ x\ \Delta\ x(Rn-G)+\gamma\ x\frac{900}{T+273}\ x\ u\ 2(es-ea)}{\Delta+J\ x(\ 1+0{,}34\ x\ u\ 2)} \quad (1)$$

where:

- ET_0 - reference evapotranspiration (mm/day);
- R_n - net radiation at the crop surface (MJ/m²/day) - the average value used for southeastern Romania: 15.5 MJ/m²/day;
- G - soil heat flux - considered 0 for long periods;
- T - average air temperature (°C), obtained for each weather station;
- u_2 - wind speed at 2 m (m/s) – the average value used for southeastern Romania: 3.2 m/s;
- e_s - saturation vapor pressure (kPa);
- e_a - actual vapor pressure (kPa);
- Δ - slope of the vapor pressure curve (kPa/°C);
- γ - psychrometric coefficient (kPa/°C).

These values were calculated for each weather station (Constanța, Tulcea, Galați, Brăila, Călărași) using the annual average temperature specific to each location.

After calculating ET_0 for each weather station, crop coefficients (Kc) were applied to obtain the specific evapotranspiration for each crop.

$$ETe = ETo \times Kc \quad (2)$$

where:

- ETe - specific evapotranspiration for each crop;
- ETo - reference evapotranspiration (mm/day);
- Kc - crop coefficients.

For each crop, the Kc coefficients vary depending on the growth stage (Tabel 2).

Table 2. Coefficients vary depending on the growth stage (Kc)

Crop	Initial stage	Development stage	Maturity stage
Corn	0.3	1.2	0.6
Soybean	0.4	1.15	0.5
Wheat	0.4	1.1	0.5

The duration of each phase (in days) is presented in Table 3.

Table 3. The duration of each phase, in days

Crop	Initial stage (days)	Development stage (days)	Maturity stage (days)
Corn	30	50	40
Soybean	25	55	35
Wheat	30	60	45

For each crop and weather station, the total evapotranspiration was calculated as follows:

$$ETc\ total = (ET_0 \times Kc_0 \times number\ of\ days) + (ET_0 \times Kc_1 \times number\ of\ days) + (ET_0 \times Kc_2 \times number\ of\ days) \quad (3)$$

The formula (3) was applied for corn, soybean, and wheat at each of the five weather stations.

RESULTS AND DISCUSSIONS

The total evapotranspiration for each crop was calculated for each station, with the highest values observed in Constanța and Călărași. For example, wheat reached a seasonal ETc of 437.03 mm in Constanța and 434.09 mm in Călărași, followed by corn and soybean.

In Galați and Brăila, where temperatures were slightly lower and precipitation somewhat higher, ETc values were reduced by up to 10%, suggesting a lower irrigation requirement. This confirms that regional climatic differences significantly affect irrigation planning.

Among irrigation methods, drip irrigation - due to its localized application and minimal evaporative losses - proved to be the most efficient system for meeting crop water demands. Sprinkler irrigation performed well in loamy soils, while furrow (surface) irrigation showed the lowest efficiency, particularly in sandy soils.

Figure 1 illustrates the variation in total crop evapotranspiration (ETc) across the five weather stations for corn, soybean, and wheat.

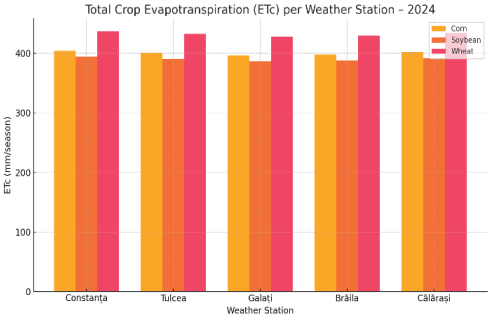

Figure 1. Seasonal crop evapotranspiration (ETc) by weather station - 2024

The graphical comparison highlights the higher ETc values observed for wheat across all stations, especially in Constanța and Călărași, and confirms the lower water requirements of soybean. This visual representation supports the numerical findings and emphasizes the impact of regional climatic differences on crop water needs.

Climate projections indicate that an increase of 2°C in average temperature could lead to a 6-10% increase in evapotranspiration, while a 5°C rise may result in a 15-20% increase, especially in already water-stressed regions such as Dobrogea. These estimations highlight the urgency of adapting irrigation strategies to cope with climate variability.

The results are consistent with previous studies (Chitu et al., 2015), confirming that crop water requirements in southern and southeastern Romania are increasing in response to climate trends. This underscores the need for investment in modern irrigation systems and support programs for farmers.

After performing all calculations, the total seasonal evapotranspiration was obtained for each crop and each weather station. These values represent the total amount of water required to ensure optimal plant growth under irrigation conditions (Tabel 4).

Tabel 4. Total seasonal evapotranspiration for each crop and each weather station

Weather station	Crop	Total Evapotranspiration (mm/season)
Constanța	Corn	404.41
Constanța	Soybean	394.63
Constanța	Wheat	437.03
Tulcea	Corn	400.34
Tulcea	Soybean	390.66
Tulcea	Wheat	432.63
Galați	Corn	396.28
Galați	Soybean	386.69
Galați	Wheat	428.24
Brăila	Corn	397.63
Brăila	Soybean	388.01
Brăila	Wheat	429.7
Călărași	Corn	401.7
Călărași	Soybean	391.98
Călărași	Wheat	434.09

The total evapotranspiration varies slightly between weather stations, being influenced by the annual average temperature and the specific precipitation levels of each area.

Călărași and Constanța record higher evapotranspiration values for all crops, indicating a greater need for irrigation, probably due to higher temperatures and lower precipitation compared to other stations. Galați and Brăila show lower total evapotranspiration values, suggesting a reduced water demand for crops, possibly due to higher precipitation levels or slightly lower temperatures.

Wheat requires the highest amount of water for the growing season across all weather stations (values ranging from 428.24 mm in Galați to 437.03 mm in Constanța). This is explained by its longer vegetative cycle and constant moisture requirements, especially during the stem elongation and grain filling stages.

Corn has a moderate water requirement, ranging from 396.28 mm in Galați to 404.41 mm in Constanța, which confirms the high water demands of this crop during the vegetative growth and flowering stages.

Soybean requires the least amount of water, with values ranging from 386.69 mm in Galați to 394.63 mm in Constanța, as it is a drought-adapted crop with a root system that efficiently absorbs water from the soil.

Constanța and Călărași counties have the highest total evapotranspiration values for all analyzed crops. This is due to higher temperatures and lower precipitation levels, which increase the risk of water stress. Under these conditions, implementing efficient irrigation systems is essential to maintain high agricultural yields.

Solutions for optimizing irrigation in Constanța and Călărași:

- Drip irrigation - ensures efficient water use by applying precise amounts directly to the plant roots, reducing evaporation losses.
- Sprinkler irrigation - an effective method for uniform water distribution, especially in areas with well-drained soils.
- Controlled deficit irrigation - adjusting the volume and frequency of irrigation according to the crop development stage and water availability.

In these regions, it is also essential to apply soil water conservation techniques, such as mulching, minimum tillage, and crop rotation, to reduce evapotranspiration and optimize water use.

Galați and Brăila counties have lower total evapotranspiration values, indicating a reduced need for irrigation compared to Constanța and Călărași. This may be due to more frequent precipitation or slightly lower average temperatures.

Optimizing water use in Galați and Brăila:

- Supplemental irrigation - can be applied only during critical periods, such as flowering and grain formation in wheat, soybean, or corn.
- Soil moisture monitoring - using moisture sensors to adjust irrigation frequency and volume based on the actual water needs of plants.
- Rainwater harvesting and storage – implementing rainwater collection systems to reduce dependency on irrigation.

These measures can help reduce water consumption and increase the efficiency of available resource utilization.

CONCLUSIONS

Climate change, characterized by rising temperatures and altered precipitation patterns, directly affects water use efficiency in agriculture, especially in the southeastern regions of Romania. The results obtained show that total evapotranspiration varies depending on geographic location, crop type, and local climatic conditions, with the highest values recorded in Constanța and Călărași counties.

Among the analyzed irrigation methods, drip irrigation proved to be the most efficient in terms of water consumption, offering minimal losses and precise control over applied volumes. Sprinkler irrigation is a viable alternative in areas with well-drained soils, while furrow irrigation is less efficient due to significant water losses.

To address current and future climate challenges, it is essential to modernize irrigation infrastructure, implement soil water conservation practices, and adapt irrigation strategies to the specific conditions of each region.

Financial support for the implementation of modern technologies, along with training programs for farmers, is recommended to improve water use efficiency and ensure the sustainability of agricultural production.

Promoting drip irrigation in regions affected by water scarcity or high temperatures is essential for efficient resource management. It is necessary to subsidize efficient irrigation systems to support farmers in transitioning to modern methods. Irrigation technologies must be adapted according to soil type, with particular attention to avoiding furrow irrigation in sandy soils. Additionally, investments in agricultural research are needed to evaluate the performance of different irrigation methods under various

climatic conditions. Last but not least, farmer education and training on best water management practices represent a key pillar for the success of these measures.

Abstract

The aquatic ecosystems of the Danube Delta are highly vulnerable to ecological pressures caused by natural and anthropogenic factors. This study investigates the surface water quality along the Sfântu Gheorghe Branch, (km 85-km 15), including control sections such as Mahmudia Meander, Uzlina Lake, Isac Lake, Dunavăț Meander, Dranov Meander, and Ivancea Meander. Surface water samples were collected from 58 locations during spring and autumn (May and September 2024). Physico-chemical parameters were measured in situ using the multiparameter EXO2 probe. Key indicators assessed included water temperature, pH, dissolved oxygen, chlorophyll "a", conductivity, total dissolved solids, salinity, turbidity, and redox potential (ORP). The results revealed generally stable seasonal and spatial trends, with most parameters falling within Class I and II water quality categories, as defined by Romanian Order 161/2006. Noteworthy findings include well-oxygenated waters (>5 mg/L DO), low chlorophyll "a", concentrations (<25 µg/L), and stable pH values, all indicative of good to very good ecological status. Variations in turbidity and ORP were primarily localized and attributed to sediment resuspension or flow dynamics. Overall, the findings suggest that the monitored sections of the Sfântu Gheorghe Branch maintain resilient freshwater conditions, with limited signs of ecological degradation.

Key words*: chlorophyll a, Danube Delta, ecological status, nutrient input, physico-chemical indicators, seasonal variation, Sfântu Gheorghe Branch, surface water quality.*

INTRODUCTION

Aquatic ecosystems are characterized by remarkable diversity, shaped by both the concentration of dissolved salts (freshwater vs. brackish water) and the dynamic movement of water masses (Chapman, 1996). In the predeltaic region of the Black Sea, brackish waters cover approximately 100,000 hectares, supplemented by the expansive Razelm-Sinoe lagoon complex, which spans 1,015 km². This system falls into the oligo-mixohaline category, with salinity levels ranging between 0.50 and 6.00 g/L (Coteț, 1960; Almazov et al., 1963; Bondar & Panin, 2000; Cazacu & Adamescu, 2017). Despite this, freshwater ecosystems are predominant within the Danube Delta's aquatic environment (Chiriac & Udrescu, 1965; Kirschner et al., 2009).

The rheophilic ecosystems of the Danube Delta encompass the river's main branches and a secondary network of channels. These watercourses vary in flow permanence and intensity - from channels with a continuous, column-wide current to shallow gullies where flow is weak and generally restricted to near-bottom layers, becoming more pronounced during floods (Driga, 2004; Gâștescu & Știucă, 2008). Compared to the main river channel, the Danube branches exhibit distinct ecological characteristics due to biotopic variations such as reduced depth and current velocity, greater isolation from adjacent land, consolidated alluvial banks, and differences in nutrient concentrations and turbidity levels (Gâștescu, 2009).

At the apex of the deltaic triangle, the Danube splits into two main branches: the Chilia to the north and the Tulcea to the east. Seventeen kilometers downstream from Izmail Ceatal, the Tulcea Branch divides again at Sfântu Gheorghe Ceatal into the Sulina Branch (continuing eastward) and the Sfântu Gheorghe Branch (turning southward) (Panin & Jipa, 2002; Romanescu, 2013). Each branch has unique morphological and hydrological features. Water discharge is unevenly distributed: 58% flows through the Chilia

Branch, 22% through the Sulina, and 20% through the Sf. Gheorghe (Panin, 2003; Driga, 2004; Sommerwerk et al., 2022). Sediment transport also varies significantly, with the Chilia Arm carrying about 66% of the annual alluvium load (80,000-300,000 tons), followed by the Sulina (14%) and Sfântu Gheorghe (20%) Arms, with considerable interannual variability (Tiron Duțu, 2014; Syeed et al., 2023).

The Sfântu Gheorghe Arm, due to its substantial solid discharge, experiences significant sediment accumulation, resulting in higher banks compared to the other branches. Unlike the Chilia Arm, neither the Sulina nor the Sf. Gheorghe Arms form internal deltas, though they feature sinuous courses with multiple meanders. This is particularly true for the Sf. Gheorghe Arm, which originally extended 109 km with a high meandering coefficient (2.35). Before discharging into the Black Sea, it forms a secondary delta (Sfântu Gheorghe Secondary Delta II). Rectification efforts carried out between 1985 and 1990 eliminated six meanders, reducing the arm's length to approximately 70 km. While these modifications improved navigability, they significantly impacted flow distribution among the Danube's branches (Habersack, 2016; Oaie, 2015; Madhav et al., 2020; Duțu, 2023).

This study aims to evaluate the overall surface water quality along the Sf. Gheorghe Arm by analysing the spatial distribution and variability of key environmental indicators across several control sections. Specifically, the research investigates water quality along a longitudinal gradient from upstream (km 85) to downstream (km 15) on the Sf. Gheorghe Arm.

Relevance and impact of the study

This research provides a comprehensive assessment of water quality using advanced analytical techniques, enabling immediate and accurate measurement of multiple physicochemical parameters. Such an approach offers valuable insights into the spatial variability of essential water quality indicators.

The findings significantly enhance our understanding of both anthropogenic influences and natural dynamics affecting aquatic ecosystems within the Danube Delta. The study holds substantial environmental relevance by supplying critical data for ecosystem monitoring, resource management, and policy decision-making. Ultimately, it not only advances scientific knowledge but also supports practical, sustainable strategies for the conservation and management of one of Europe's most important wetland ecosystems.

MATERIALS AND METHODS

Study area

The study was conducted in the Danube Delta, a vast wetland system covering approximately 5,600 km², which serves as the primary source of freshwater and sediment input to the Black Sea via its three main distributary branches: Chilia, Sulina, and Sfântu Gheorghe (Botnariuc, 1985). The Sfântu Gheorghe Branch, the southernmost of these, originates at the Ceatal Sfântu Gheorghe bifurcation and flows approximately 108 km before discharging into the Black Sea. This branch conveys about 23-24% of the Danube's total water discharge and approximately 21% of the suspended sediment load (Bondar & Panin, 2000; 2001). It is characterized by a pronounced morphological dynamic, having a sinuous course with active, migratory meanders (Popa, 1997; Jugaru et al., 2006; Tiron, 2010; Tiron Duțu et al., 2014), as well as a rapid evolution of the mouth, manifested by the progradation of the deltaic lobe and significant displacements of the Sakhalin barrier island throughout the 20th century (Panin, 2003). The width of the Sf. Gheorghe arm varies between 150 and 550 m, and the water depth is between 3 and 27 m compared to the local low water level (Bondar & Panin, 2000). The banks of this arm are covered by dense and continuous vegetation, consisting of poplars, trees and reed communities. During the period 1984-1988, significant anthropogenic interventions were carried out to facilitate navigation. Six natural meanders were artificially cut, reducing the total length of the arm from 108 km to approximately 70 km. The newly created navigable channels were initially 7-8 m deep and 75-100 m wide (Popa, 1997). These hydrotechnical works caused substantial changes in the local dynamics of water and sediments, increasing water flows and sediment flux through the Sf. Gheorghe arm and

influencing sedimentary processes at the level of the entire deltaic system (Ichim & Rădoane, 1986; Popa, 1997; Panin & Jipa, 2002; Panin, 2003; Tiron, 2010). During the same period, earthen dams, with heights of approximately 2-3 m, were built along the banks.

Methodology

To evaluate the overall condition of surface water quality, the study investigated the longitudinal distribution of key environmental indicators along a gradient from upstream to downstream. Sampling was conducted at multiple control points located across the Sfântu Gheorghe Branch, including rectified meanders, natural channels, and adjacent lakes, covering the river stretch between kilometer 85 and kilometer 15.

Notable locations included Mahmudia Meander, Uzlina Lake, Isacova Lake, Dunavăț Meander, Dranov Meander, and Ivancea Meander. Surface water samples were collected at 58 sites during two separate field campaigns in May and September 2024, as shown in Figure 1, which maps the spatial distribution of sampling points. Several sampling points were strategically positioned in zones where water and sediment are redistributed from the main branch to the secondary network of channels, smaller distributaries, and adjacent floodplain depressions (such as lakes and temporary shallow ponds).

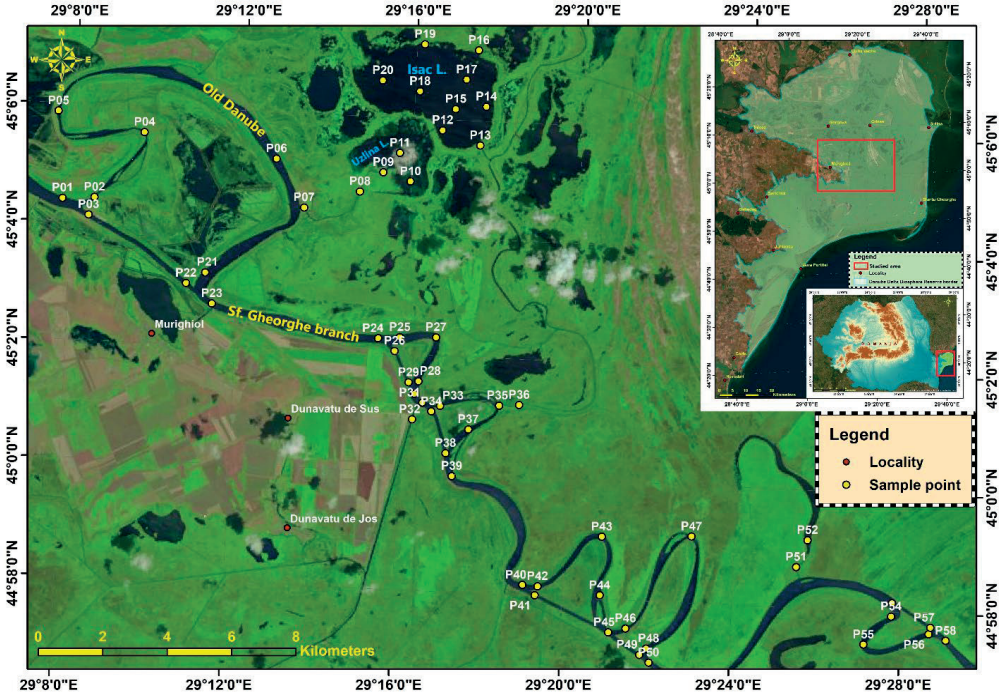

Figure 1. Sampling stations from the Sf. Gheorghe Arm

The general characterization of surface water quality was conducted through *in situ* measurements of various physico-chemical parameters using the EXO2 multiparameter probe (YSI, USA) (Figure 2).

This device is equipped with advanced sensors that utilize physical, optical, and electrochemical detection methods to measure a wide range of water quality indicators (Lipps et al., 2023).

Figure 2. Multiparameter probe, model EX02

The recorded parameters include: temperature (°C), pH (pH units), turbidity (FNU), total dissolved solids (TDS, mg/L), conductivity (µS/cm), dissolved oxygen (ODO, mg/L), oxygen saturation (ODO, %), oxidation-reduction potential (ORP, mV), salinity (PSU), nitrate (NitraLED, mg/L), chlorophyll-a (RFU), and total algal content (TAL–PC, RFU).

Water quality classification was primarily based on the criteria set out in Order No. 161/2006, which defines five quality classes: Class I (very good), Class II (good), Class III (moderate), Class IV (poor), and Class V (bad). For a more comprehensive evaluation, both national standards (Order No. 161/2006 regarding reference objectives for surface water quality classification) and international standards, particularly the European Water Framework Directive (WFD 2000/60/EC), were applied. The WFD provides a unified framework for the qualitative and quantitative management of water resources and the preservation of aquatic ecosystem health across member states.

All physicochemical analyses followed internationally recognized methodologies and standard procedures. These included: SR EN ISO 5667-1:2023 for water sampling; SR EN ISO 10523:2012 for pH determination; and SR EN ISO 5814:2013 for measuring dissolved oxygen concentrations.

Statistical analysis

Statistical analyses were conducted using xlSTAT version 7.5.2 software (Addinsoft, 2020) and PAST version 4 (https://past.en.lo4d.com/download). To examine the relationships between physicochemical parameters, Pearson correlation analysis was applied. This method was chosen to identify the strength and direction of linear associations among the measured variables.

All analyses were performed on data sets obtained from the two sampling campaigns (May and September 2024), with significance levels set at $p < 0.05$ unless otherwise specified.

RESULTS AND DISCUSSIONS

The lotic ecosystems formed by the Danube and its deltaic network fall within the Pontic Ecoregion (Ecoregion 12), as defined in Annex XI of the European Union Water Framework Directive (EU-WFD, 2000).

According to the Synthesis of the Draft Management Plans for River Basin Districts (2022), a total of 19 natural watercourse types has been identified within the Danube and Danube Delta regions. The areas investigated in this study fall within the classification RO15 – Danube River (Isaccea) to Danube Delta.

The results presented in this study provide valuable input for enhancing current water quality databases and contribute to fulfilling the data requirements outlined in the EU-WFD. By integrating multiple data sources and conducting high-resolution, in situ analyses, this study enables a more detailed and spatially explicit assessment of water quality conditions across the Sfântu Gheorghe Branch. In line with the objectives of the EU-WFD, which mandates all member states to ensure that rivers, lakes, groundwater, estuaries, and coastal waters reach at least "good" ecological status by 2027, this research offers insight into the current state of surface water in a critical section of the Danube Delta.

Physico-chemical parameters of surface water

Table 1 summarizes the physicochemical properties of surface water - minimum, maximum, and mean values (± standard deviation) - recorded at control points during the May and September 2024 campaigns. Measurements along the Sfântu Gheorghe Branch (km 85 to km 15) showed typical seasonal and spatial variations, with no major anomalies, though some local deviations were noted.

Water temperature (°C). Water temperature followed seasonal trends and was strongly influenced by air temperature fluctuations typical of the spring and early autumn periods (AccuWeather, 2024). In May, values ranged from 16.31 to 20.30°C with a mean of 18.50 ± 0.70°C, remaining within the expected seasonal variation for the region. The lowest temperature was recorded at station P36 (Gârla Perivolovca), while the highest occurred at station P19 (Isacova Lake). In September, temperatures increased notably, ranging from 23.82 to 29.98°C with an average of 25.90 ± 0.98°C. The coolest site was station P20, while the warmest was station P27 (Figure 3).

Table 1. A synopsis of the physico-chemical parameters of water surface samples from Sf. Gheorghe Arm in May and September 2024

May			
Parameter	**Min.**	**Max.**	**Mean ± SD**
Temperature (°C)	16.31	20.30	18.50±0.70
pH	8.06	9.42	8.58±0.21

Nitrate (NitraLED mg/L)	0.04	9.34	1.70±1.87
Chlorophyll (RFU)	0.27	12.65	2.55±3.78
Total Algal Content (TAL - PC RFU)	0.01	14.62	2.13±3.85

Water pH (pH units). pH levels across the study area generally conformed to acceptable limits for freshwater ecosystems (6.5-8.5 pH units, Order 161/2006), although slight alkalinity was observed at several stations. In May, pH ranged between 8.06 and 9.42 (mean 8.58 ± 0.21), with values exceeding the upper guideline limit at station P16 (Isacova Lake). The lowest value was recorded at P36 (Gârla Perivolovca). In September, pH ranged from 7.88 to 8.83 (mean 8.19 ± 0.24), remaining mostly within the regulatory threshold. Elevated values were observed at P12, while P35 showed the lowest pH (Figure 4).

Turbidity (NTU). The turbidity values measured in the water samples from the control sections showed variations within the normal limits for surface waters (1-1000 NTU) (Chapman, 1996). In May, turbidity values varied widely between 0.18 and 61.61 NTU, with an average of 11.42 NTU. In September, turbidity varied between 2.58 and 53.86 NTU, with an average of 10.17 NTU. The lowest turbidity in May was recorded at station P20 (Isacova Lake), while in September, the lowest was at station P22. The highest turbidity in May occurred at station P42 (M. Dranov – bifurcation – rectified mead), while in September, the highest was measured at station P24. Remarkably, some samples showed higher turbidity levels compared to the values provided by SR ISO 5667-5:2017 (5 NTU – permitted, 10 NTU – exceptionally permitted), indicating a localized deterioration of water quality. In general, increased turbidity is due to Danube River inflows, which carry dissolved and suspended organic and inorganic materials through secondary necks and internal channels (Figure 5).

Total dissolved solids (TDS, mg/L). TDS concentrations, representing the sum of dissolved organic and inorganic substances, were well within freshwater standards (<1000 mg/L) (Lehr, 1980; De Zuane, 1997). In May, values ranged from 182.36 to 290.38 mg/L (mean: 246.02 ± 17.49 mg/L), and in

September from 228.91 to 277.73 mg/L (mean: 242.13 ± 6.54 mg/L). The lowest concentrations were recorded at P16 (May) and P14 (September), while the highest occurred at P52 (Erenciuc Lake) in May and P36 in September (Figure 6).

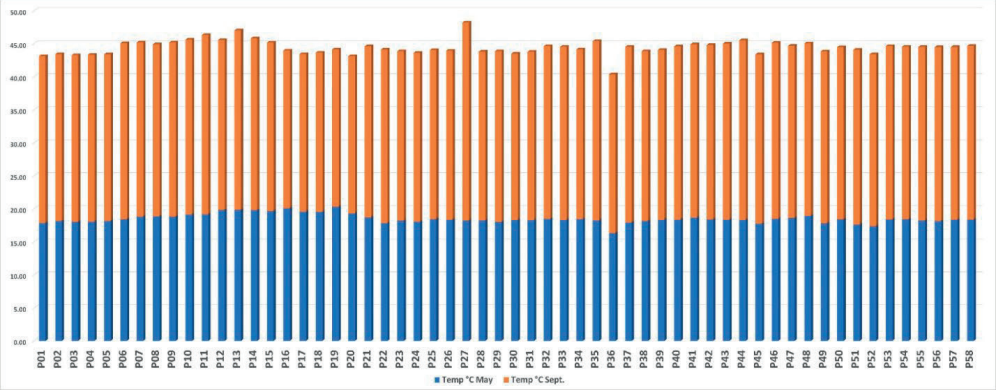

Figure 3. Evolution of the Temperature indicator in the investigated surface water samples

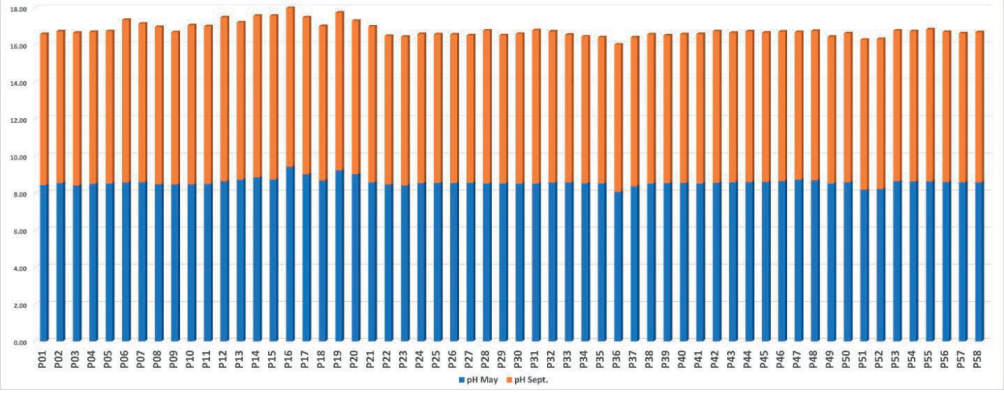

Figure 4. Evolution of the pH indicator in the investigated surface water samples

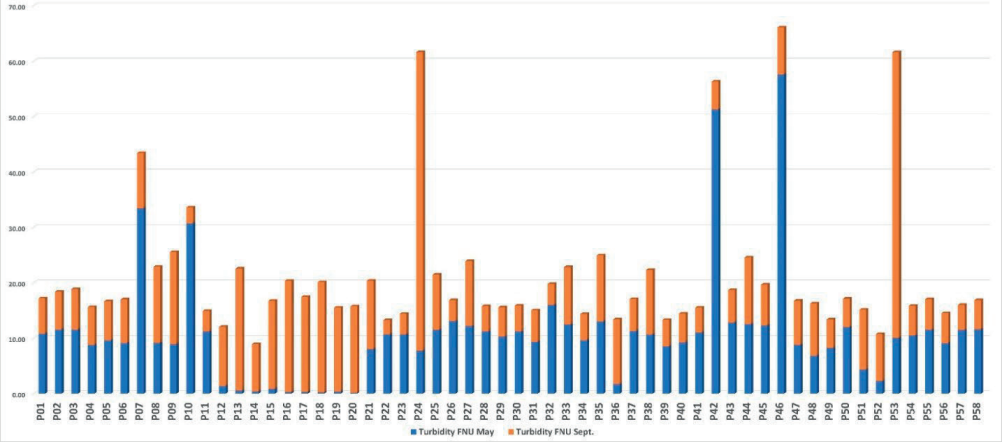

Figure 5. Evolution of the Turbidity FNU indicator in the investigated surface water

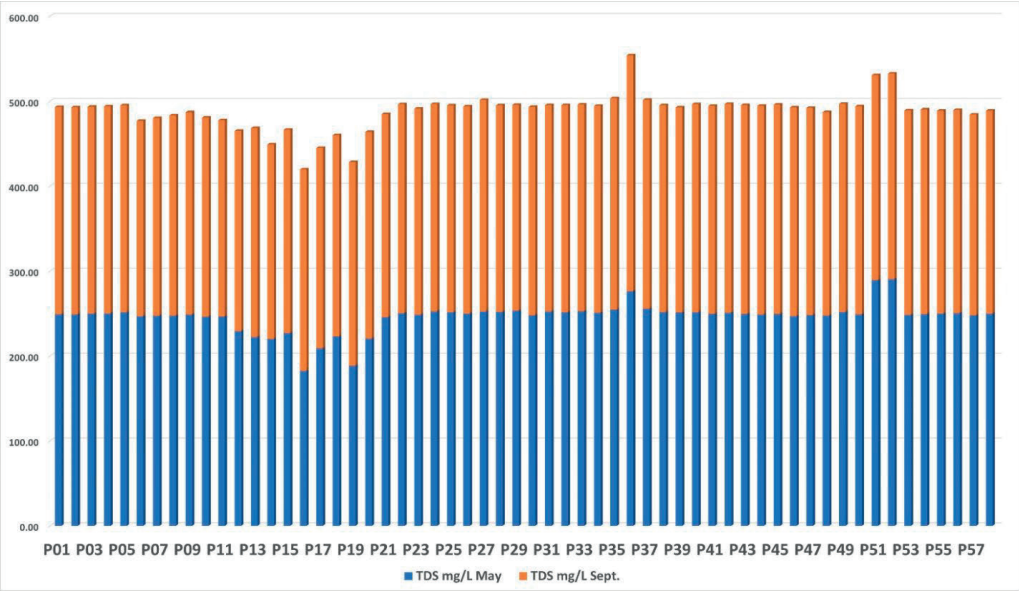

Figure 6. Evolution of the TDS mg/L indicator in the investigated surface water samples

Electrical conductivity (µS/cm). All measured conductivity values classified the water samples in quality class I (≤500 µS/cm, Order 161/2006). In May, conductivity values ranged from 254.11 to 382.14 µS/cm (mean: 331.19 ± 19.75 µS/cm), increasing slightly in September, with values between 354.47 and 419.30 µS/cm (mean: 378.83 ± 11.97 µS/cm). The highest readings were recorded at P51 (May) and P36 (September) (Figure 7).

Dissolved Oxygen (mg/L). Dissolved oxygen concentrations indicate that all water samples tested fall into the well-oxygenated surface water category (quality class I, ≥9 mg/L, Order 161/2006), with all values exceeding the recommended minimum level of 5 mg/L required to support aquatic life (www.niwa.co.nz). Dissolved oxygen varied significantly in May, from 6.82 to 14.81 mg/L, with an average of 10.67 mg/L. In September, values ranged from 3.44 to 14.57 mg/L, with an average of 7.84 mg/L. The lowest values in both May and September were recorded at station P36 (Gârla Perivolovca), while the highest concentrations were observed at station P19 (Isacova Lake) in May and at station P12 in September (Figure 8).

Oxidation-Reduction Potential (ORP, mV). ORP values serve as an indicator of the oxidation state of the water body and its potential to support aerobic processes. In both sampling periods, values fell within the typical range for natural waters (–500 to +700 mV) (Chapman, 1996; Sigg, 2000), suggesting stable redox conditions. In May, ORP values ranged from 1.74 to 100.96 mV (mean: 41.04 ± 20.79 mV), while in September, values ranged from 14.60 to 66.09 mV (mean: 48.70 ± 12.18 mV). The lowest ORP was observed at P19 (Isacova Lake) in May and at P55 in September. The highest values were recorded at P58 (Ivancea Meander – confluence) in May and P35 in September (Figure 9).

Salinity (‰). Salinity levels remained low and consistent throughout the monitoring period, reflecting the freshwater character of the Danube Delta system. All values were well below the 0.5 PSU threshold commonly used to define freshwater ecosystems (Montagna et al., 2013). In May, salinity ranged from 0.13 to 0.22 PSU (mean: 0.18 ± 0.01 PSU), and in September, from 0.17 to 0.21 PSU (mean: 0.18 ± 0.01 PSU), confirming minimal marine influence and dominance of fluvial inputs.

Distribution of nitrate concentrations. Nitrate concentrations (NitraLED, mg/L) showed significant spatial variability between measurement stations. In May, values ranged from 0.01 to 16.28 mg/L (mean: 1.49 ± 2.24 mg/L), with the highest value at P42

(Dranov – bifurcation) and the lowest at P54. In September, concentrations ranged from 0.04 to 9.34 mg/L (mean: 1.70 ± 1.87 mg/L), peaking at P24 and reaching a minimum at P12 (Figure 10). While most values remained within acceptable ecological thresholds, elevated readings at isolated sites may indicate localized nutrient enrichment.

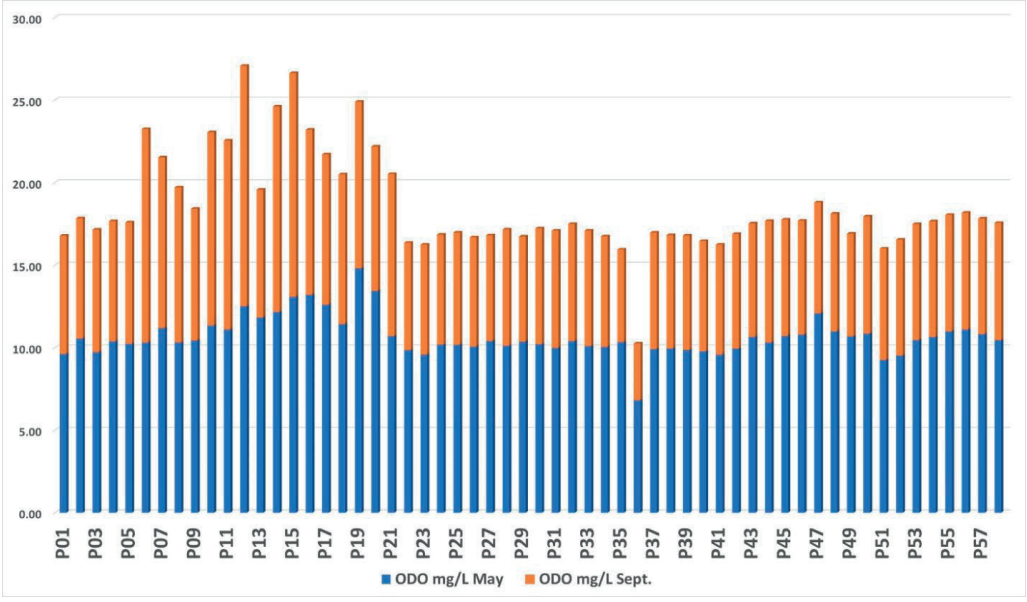

Figure 8. Evolution of the ODO mg/L indicator in the investigated surface water samples

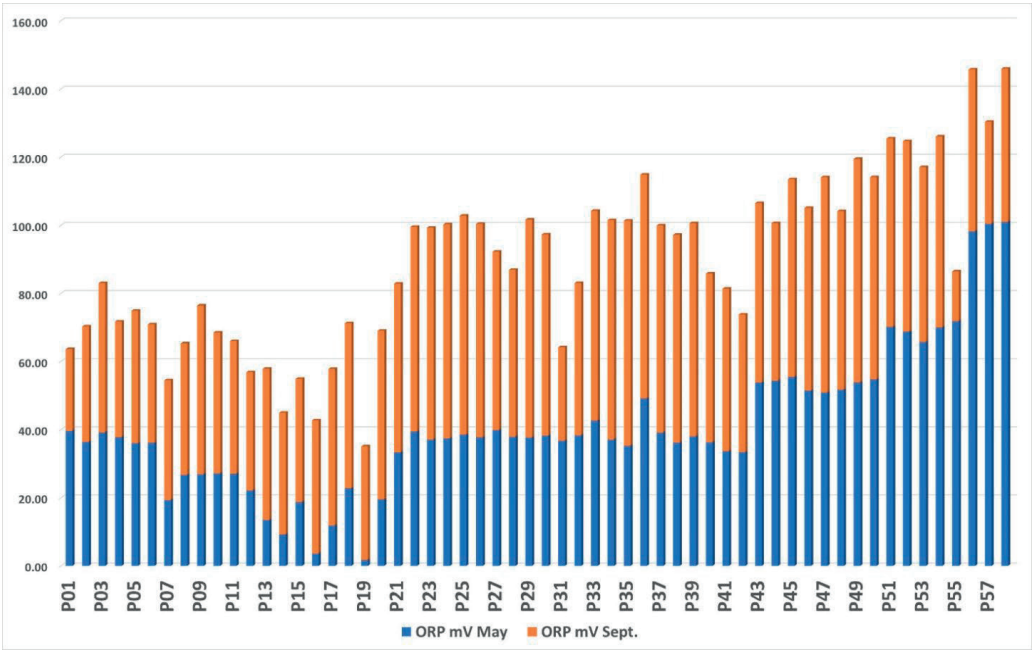

Figure 9. Evolution of the ORP mV indicator in the investigated surface water samples

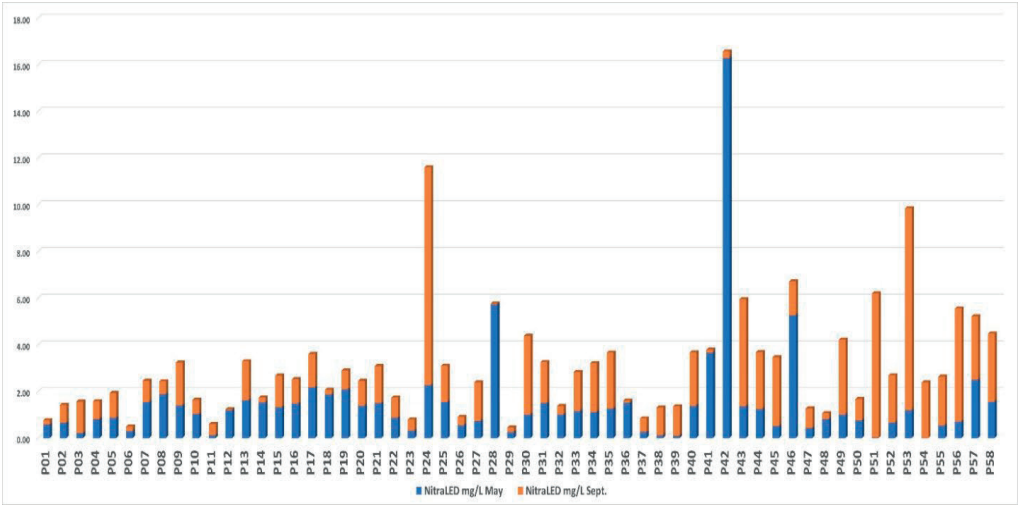

Figure 10. Evolution of the NitraLED mg/L indicator in the investigated surface water samples

Chlorophyll a (µg/L). The concentrations of chlorophyll *a* in the water samples from the investigated sections showed considerable variability. In May, values ranged from 0.26 to 8.57 µg/L (mean: 3.93 ± 2.06 µg/L), while in September, they varied more widely—from 0.27 to 12.65 µg/L (mean: 2.55 ± 3.78 µg/L). Lowest concentrations were found at P20 (May) and P22 (September), while the highest were measured at P46 (May) and P19 (September). All recorded values remained below the class I threshold of 25 µg/L (Order 161/2006), indicating low-to-moderate algal productivity and absence of eutrophic conditions (Figure 11).

Total Algae Content (TAL - PC RFU). TAL values, indicative of overall algal abundance (including cyanobacteria), showed greater variability in September compared to May. In May, TAL ranged from 0.05 to 1.83 RFU (mean: 0.70 ± 0.41 RFU), while in September, values spanned from 0.01 to 14.62 RFU (mean: 2.13 ± 3.85 RFU). Minimal algal content was recorded at P20 (May) and P27 (September), while peak values were observed at P30 (May) and P17 (September) (Figure 12). The overall range suggests a localized increase in algal activity toward the end of the warm season, potentially linked to temperature and nutrient availability

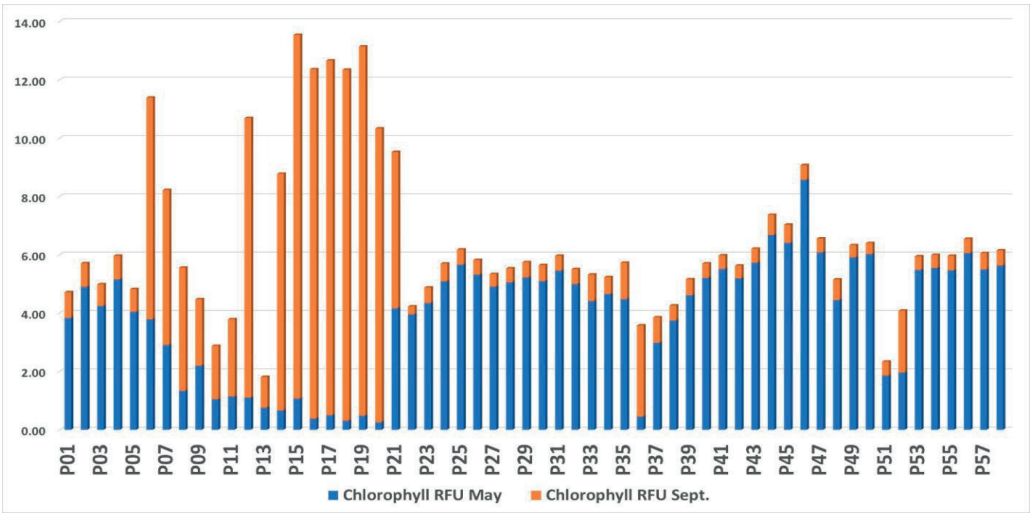

Figure 11. Evolution of the chlorophyll *a* RFU indicator in the investigated surface water samples

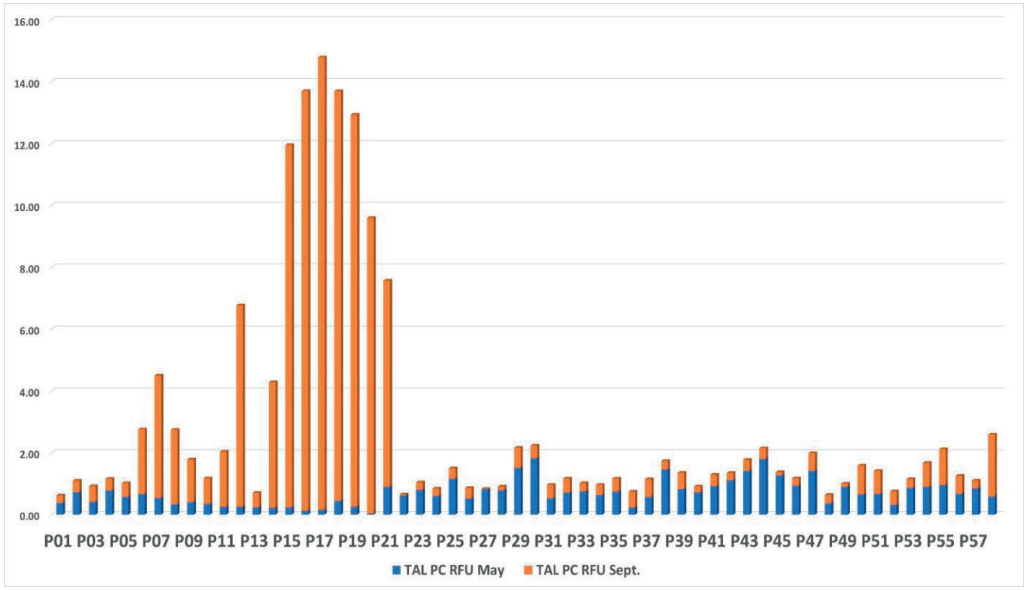

Figure 12. Evolution of the Total Algal Content (TAL - PC RFU) indicator in the investigated surface water samples

Interpretation of seasonal and spatial variability

The seasonal increase in Temperature in September is expected due to higher solar radiation and air temperatures in late summer. Water temperature plays a crucial role in biochemical reactions, dissolved oxygen levels, and biological activity. Higher temperatures generally correlate with lower dissolved oxygen concentrations, as observed in September. Localized differences in temperature values may indicate areas of variable flow dynamics, depth variations, or thermal influences from adjacent land areas. The relatively stable range suggests that there have been no extreme temperature fluctuations that would otherwise indicate thermal pollution or abrupt environmental changes.

Slightly *alkaline conditions*, particularly in stations such as Isacova Lake, indicate biological influences, notably the photosynthetic activity of aquatic plants and phytoplankton. In May, elevated pH levels may result from increased photosynthesis, which reduces CO_2 concentrations and shifts water chemistry toward alkalinity. In contrast, the slight decline in *pH* observed in September could be linked to enhanced respiration and decomposition of organic matter, which releases CO_2 into the water. Nonetheless, all values remained within the acceptable range for freshwater ecosystems, suggesting no immediate risk of acidification or excessive alkalinity.

Turbidity is influenced by sediment transport, organic matter and the presence of phytoplankton. Recent studies, such as Sandu et al. (2023), have reinforced this perspective by demonstrating how elevated turbidity levels in freshwater systems can be linked to nutrient input, sediment resuspension, and decreased water transparency, particularly in areas affected by anthropogenic influence. Higher values at certain stations suggest localized resuspension of sediments or particle growth due to water flow dynamics, bank erosion or anthropogenic influences. The slight decrease in mean turbidity from May to September suggests potential settling of suspended particles as the water flow stabilizes. The high turbidity values at P42 (May) and P24 (September) could be related to increased sediment input from channels or main arm, algal blooms or stormwater runoff. Excessively high values could have a negative impact on submerged vegetation and aquatic organisms by reducing photosynthetic efficiency. Comparisons with standard limits (SR ISO 5667-5:2017: 5 NTU permitted, 10 NTU exceptionally permitted) indicate that some samples exceed these thresholds, indicating localized deterioration of water quality.

Total Dissolved Solids (TDS) values remained within the normal range for freshwater systems (0-1000 mg/L, Lehr, 1980; De Zuane, 1997), indicating good water quality. Seasonal variations were minimal, suggesting that the system maintains stable ion concentrations, without significant dilution or concentration effects. The higher TDS values at P52 (May) and P36 (September) could be due to localized groundwater influence, mineral dissolution, or reduced flushing rates.

Electrical conductivity, closely linked to TDS, increased slightly from May to September, likely due to ion accumulation driven by reduced flow rates and evaporation during late summer. Spatial variation suggests that areas such as the Erenciuc Canal may experience greater mineralization, potentially due to limited water exchange or specific geochemical conditions.

Dissolved oxygen levels were sufficient to support aquatic life during both campaigns, although a noticeable decline from May to September points to temperature-driven oxygen depletion and increased organic matter decomposition. The lowest DO values at P36 may reflect slow circulation, organic accumulation, or microbial respiration. Despite this, most values exceeded the 5 mg/L threshold required for aquatic fauna (NIWA, 2024), indicating overall good oxygenation.

Oxidation-Reduction Potential (ORP) values suggest that the water body remains well oxygenated and capable of supporting aerobic biochemical processes. The slight variations in ORP values between May and September could be attributed to fluctuations in microbial activity, decomposition of organic matter and seasonal variations in dissolved oxygen levels. The highest ORP values at the confluence points probably indicate higher oxygenation due to increased water mixing.

Salinity remained low across all stations, reinforcing the freshwater character of the Sfântu Gheorghe Branch. Minor variations between May and September can be attributed to precipitation, evaporation, and localized mineral input. The consistently low salinity values indicate hydrological stability with minimal marine influence.

Nitrate levels in freshwater systems are influenced by agricultural runoff, wastewater discharge and natural biological processes. The increase in the average nitrate concentration from May to September suggests a seasonal accumulation of nutrients, potentially due to lower dilution rates, organic matter decomposition or anthropogenic inputs. The high values at P42 and P24 warrant closer monitoring as they could indicate localized pollution sources or increased nitrogen inputs from surrounding land use activities.

Chlorophyll a serves as an indicator of phytoplankton biomass and primary productivity. The results suggest a moderate algal growth, with some seasonal and spatial variation. The decrease in mean values from May to September could reflect nutritional limitations or grazing pressures from zooplankton. However, localized peaks (e.g. at P46 and P19) may indicate areas of higher nutrient availability or reduced water flow, favouring phytoplankton accumulation.

The increase in *Total Algal Content (TAL)* values from May to September suggests that phytoplankton biomass was higher in late summer, possibly due to increased water residence time, higher temperatures, and nutrient availability. The peaks observed at P30 and P17 may indicate localized eutrophic conditions where algal growth is enhanced. Further investigation is needed to determine whether these fluctuations are natural seasonal trends or signs of nutrient enrichment from external sources.

Correlation analysis and interpretation - Pearson Correlation – May 2024

Based on the Pearson correlation matrix for May (Table 2, Figure 13), several strong and statistically significant relationships were identified ($\alpha = 0.05$)

1. *Strong positive correlations (directly proportional)*

- ODO % sat and ODO mg/L (r = 0.998): a near-perfect correlation, indicating the expected interdependence between oxygen concentration and its saturation in water.
- Conductivity, TDS, and Salinity: very strong positive correlations were found among Conductivity (µS/cm) and TDS (mg/L) (r = 0.990), Conductivity and Salinity (r = 0.960), and Salinity and TDS (r = 0.978), confirming their shared dependence on dissolved ion concentrations.
- pH and DO (r ≈ 0.881-0.877): higher pH is positively associated with higher dissolved oxygen and percent saturation.
- Temperature and DO (r ≈ 0.895-0.869): increasing temperature is strongly positively associated with higher dissolved oxygen levels.
- Chlorophyll and TAL (r = 0.713): increased chlorophyll concentration (an indicator of primary productivity) is positively correlated with TAL PC RFU, suggesting a link between chlorophyll and other fluorescent particles or phytoplankton.
- Turbidity and Nitrate (r = 0.589): suggests that higher nitrate concentrations are associated with increased turbidity, potentially due to suspended organic material or nutrient-rich runoff.

2. *Strong negative correlations (inversely proportional)*

- pH vs Conductivity, Salinity, TDS (r ≈ -0.914 to -0.923): lower pH is associated with increased values of conductivity, salinity and total dissolved substances, which indicates acidification in more mineralized waters.
- Temperature vs Conductivity, Salinity, TDS (r ≈ -0.783 to -0.870): higher temperatures are associated with lower conductivity and lower salinity, suggesting dilution or the influence of other processes that reduce ion concentration with warming.
- Conductivity vs DO (r ≈ -0.809 to -0.794): higher conductivity correlates negatively with dissolved oxygen, suggesting that waters with more dissolved substances have lower dissolved oxygen levels.
- Chlorophyll (May) vs Chlorophyll (September): a previously observed strong negative correlation (r = -0.732) highlights significant seasonal variability in primary productivity.

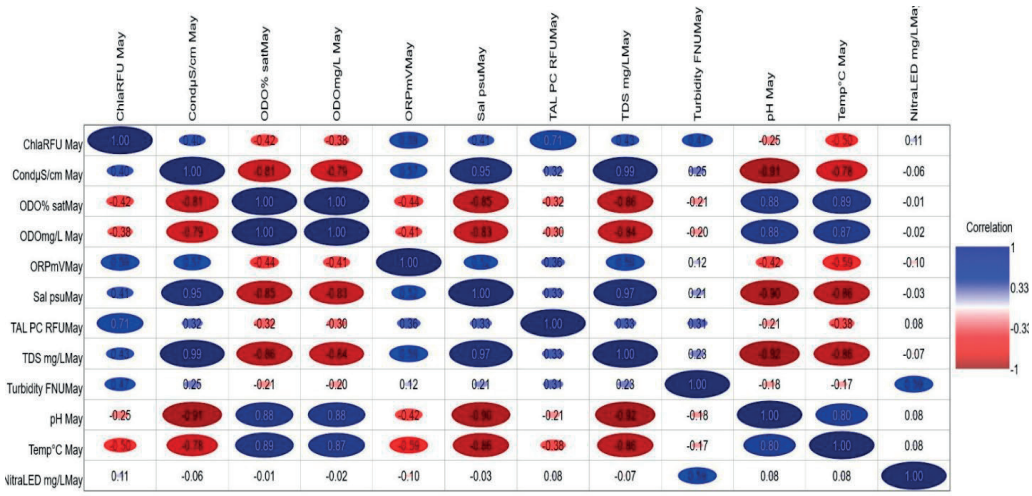

Figure 13. Correlation matrix (Pearson), in May 2024

Pearson Correlation – September 2024

In September (Table 3, Figure 14), the correlation matrix also revealed several statistically significant relationships

1. *Significant positive correlations (directly proportional):*

- ODO % sat and ODO mg/L (r = 0.998). Strongly positive and almost perfect relationship, demonstrating that oxygen saturation and its concentration are directly related and interdependent.
- Chlorophyll and TAL (r = 0.950): An extremely strong correlation indicating that the presence of chlorophyll (an indicator of algal activity) is directly related to the fluorescence of other organic or biological substances.
- Salinity and TDS (r = 0.928): Reflects the direct relationship between salinity and total dissolved solids, being indicators that vary simultaneously.
- pH and ODO mg/L (r = 0.932), ODO % sat (r = 0.923), Chlorophyll (r = 0.739). High pH is associated with increased dissolved oxygen levels and increased chlorophyll concentrations, suggesting high photosynthetic activity, which generates oxygen and raises the pH of the water.
- Turbidity and NitraLED (r = 0.633): Indicates that higher nitrates are related to

increased turbidity, possibly due to organic loading or nutrient input.

- TDS and Conductivity (r = 0.807): Increased conductivity indicates increased ions and dissolved substances, explaining the positive relationship with TDS.

2. *Significant negative correlations (inversely proportional):*

- Conductivity and Chlorophyll (r = -0.612): Suggests that high conductivity is associated with lower chlorophyll values, possibly indicating the negative influence of high salinity on algae growth.
- DO vs TDS (r = -0.711) and Conductivity (r = -0.653): High dissolved solids and high conductivity are negatively associated with dissolved oxygen, indicating that waters with high salt and other substances are poorer in dissolved oxygen.
- pH vs ORP (r = -0.639) and Conductivity (r = -0.618): Higher pH (basic) is associated with lower ORP and conductivity values, suggesting that alkaline water has a lower redox potential and lower mineralization.
- Temperature vs Chlorophyll (r = -0.517) and TAL (r = -0.568): Higher temperatures are associated with decreases in chlorophyll concentration and fluorescence of other organic substances, possibly due to thermal stress on photosynthetic organisms.

General observations on specific parameters

Chlorophyll (May) have moderate positive relationships with Turbidity, ORP, and TAL, suggesting the influence of biological activity (algae and phytoplankton) on physicochemical parameters.

Nitrates (NitraLED) did not show strong correlations with most variables, except Turbidity, possibly indicating its association with suspended particles or runoff rather than in situ biological processes.

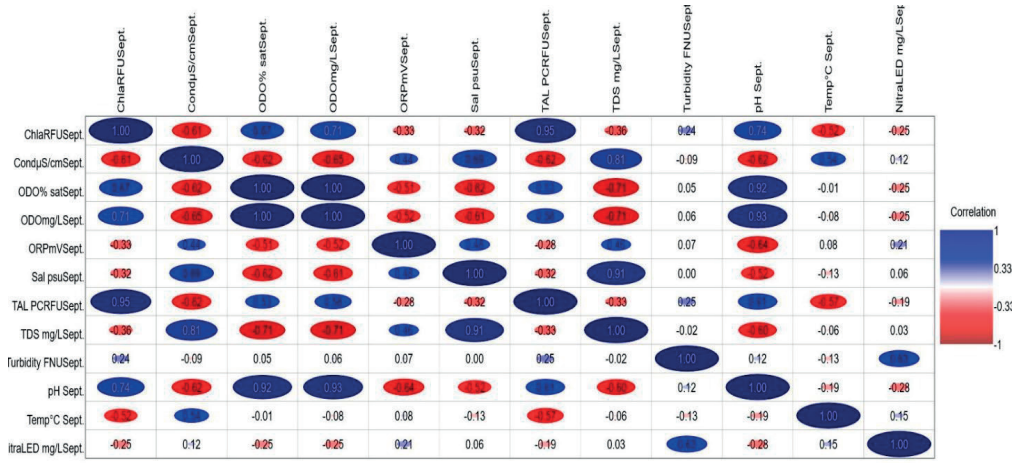

Figure 14. Correlation matrix (Pearson), in September 2024

Practical significance of the results

Conductivity and salinity are inversely related to oxygen availability and pH, emphasizing the impact of mineralization on water quality.

Temperature plays a pivotal role in modulating *DO, pH,* and *ion concentration*, reinforcing its importance in ecosystem metabolism and management.

Chlorophyll correlates with biological productivity and responds to both physicochemical conditions and seasonal shifts.

The *strong link between nitrates and turbidity* suggests external nutrient inputs that may degrade water transparency and stimulate eutrophication.

Comparison with previous studies

The results of this study are consistent with previous findings reported for the Danube Delta and lower Danube River, including those by Calmuc et al. (2021), Catianis et al. (2024), Isvoranu (1979), Iticescu et al. (2014), Najamuddin et al. (2016), Bashir et al. 2020, Teodorof et al. (2021), Ene et al. (2024), and Podlasek et al. 2024.

These studies also highlighted the influence of seasonal dynamics, hydrological variation, and anthropogenic factors such as sediment input and nutrient loading.

The current findings support these trends and contribute additional spatial and seasonal resolution to the understanding of ecological variability in the Danube Delta.

CONCLUSIONS

This study highlights the influence of *seasonal dynamics* - particularly temperature, hydrological conditions, and biological activity - on the water quality of the Sfântu Gheorghe Arm. Observed variations in *temperature, dissolved oxygen,* and *oxidation-reduction potential (ORP)* are consistent with expected physicochemical responses to seasonal change, especially the inverse relationship between temperature and dissolved oxygen driven by thermal stratification and increased biological oxygen demand in late summer.

Turbidity and *nitrate* concentrations exhibited localized fluctuations, likely influenced by sediment resuspension, surface runoff, and biological productivity. Although certain stations (e.g., P42, P24, and P53) recorded nitrate peaks exceeding recommended thresholds, the overall water quality remained within acceptable ranges for freshwater ecosystems. These sites may be subject to nutrient enrichment, warranting further investigation into potential agricultural or wastewater inputs.

The stability of *pH, salinity,* and *TDS* across the sampling campaigns indicates a well-buffered system with consistent hydrological conditions and no significant signs of acidification or salinity stress.

Meanwhile, moderate values of *Chlorophyll a* and *total algal content (TAL-PC)* suggest ongoing primary production, with spatial

variation likely influenced by nutrient levels and local hydrodynamic conditions.

RECOMMENDATIONS

Regular Monitoring
Continuous assessment of turbidity, nitrate concentrations and dissolved oxygen levels is essential to detect potential changes in water quality.
Nutrient Management
High nitrate concentrations at P42, P24 and P53 may indicate agricultural runoff or wastewater inputs; further analysis is needed to identify sources and mitigate impacts.
Erosion and Sediment Control
Elevated turbidity values suggest possible sediment transport issues; implementing land use management and erosion control measures could reduce sediment input.
Ecological Risk Assessment
The decrease in dissolved oxygen in September indicates a risk of hypoxic conditions, which should be further examined to assess potential effects on aquatic life.
Hydrodynamic Investigation
Investigation of flow dynamics and mixing processes could provide insights into localized variations in water quality and help optimize water management strategies.
By integrating these findings with long-term monitoring and cross-seasonal studies, a more comprehensive understanding of the ecological functioning of the Sfântu Gheorghe Arm can be achieved. This knowledge is crucial for the development of effective conservation, restoration, and sustainable water resource management practices in the Danube Delta.

PHYSICO-CHEMICAL CHARACTERISTICS OF SURFACE WATER SAMPLES FROM THE GORGOVA-UZLINA DEPRESSION AND THE IZMAIL AND SF. GHEORGHE CONFLUENCES (SEPTEMBER–OCTOBER 2024)

Abstract

The Danube Delta's ecosystems, encompassing riverine branches, lakes, and wetlands, face ecological pressures driven by natural and anthropogenic factors. This study evaluates the physico-chemical characteristics of surface water samples collected in September and October 2024 from 25 locations in the Gorgova-Uzlina Depression and 32 sites near the Izmail and Sf. Gheorghe confluences. Measurements were performed in situ using the EXO2 multiparameter probe (YSI, USA), which recorded parameters including temperature, pH, dissolved oxygen, chlorophyll "a," turbidity, electrical conductivity, and oxidation-reduction potential. Results indicate that most water samples fall within Class I and II of the Romanian water quality classification (Order 161/2006), reflecting good ecological status. Local variations in dissolved oxygen, turbidity, and chlorophyll "a" suggest potential ecological vulnerabilities, particularly in areas with elevated sediment loads. Conductivity and salinity values confirm the freshwater nature of the investigated sites. The findings highlight the importance of continuous monitoring to assess seasonal and anthropogenic influences on water quality and maintain the ecological integrity of the Danube Delta's aquatic ecosystems.

Key words: *Danube Delta; surface water quality; physico-chemical parameters.*

INTRODUCTION

The Danube Delta, located in the southeastern part of Romania, is one of the most important ecosystems globally, hosting over 3500 plant species and approximately 1800 animal species (Gâștescu, 2009). With an area of approximately 5640 km², it represents a distinct geomorphological unit within the Danube-Danube Delta-Black Sea geosystem, acting as an ecological interface between the Danube River and the Black Sea basin. This strategic position allows the delta to function as a natural filter, influencing sedimentation processes by retaining solid materials and chemical substances transported by the river, either dissolved or associated with suspended particles (Cotet, 1960; Almazov et al., 1963; Oaie et al., 2015).

The complex hydrographic network of the delta includes natural and artificial channels, interconnected lakes and wetlands (Chiriac & Udrescu, 1965), significantly influencing sediment transport, nutrient dynamics, pollutant distribution and general water quality. These processes are determined by both natural factors and extensive anthropogenic interventions, which have substantially modified the hydrological and sedimentological dynamics within the delta (Isvoranu, 1979; Bondar & Panin, 2000; Panin, 2003; Romanescu, 2013). Anthropogenic activities, such as dam construction, hydrotechnical works (grooves, embankments, dikes, meander cuts) and canalization have a significant impact on sediment transport and deposition processes. Specifically, the construction of the Iron Gates I (1973) and Iron Gates II (1984) dams dramatically reduced downstream sediment discharge by approximately 25–30%, consequently affecting environmental conditions (Panin & Jipa, 2002; Habersack et al., 2016; Tiron Duțu et al. 2014; 2019; Kanownik et al., 2019).

Numerous studies have highlighted the importance of analysing water flow regimes, sediment transport, pollutant dynamics, flood impacts, trophic gradients, and nutrient cycling

within the delta, given their profound effects on biodiversity, ecosystem health, navigation, and fishing activities (Calmuc et al., 2021a, 2021b). Accurate hydrochemical analyses require precise topographic data to characterize channel cross-sections and underwater terrain. Modern topographic equipment facilitates the collection of reliable data essential for studying these complex interactions. In addition, geochemical analyses play a crucial role in determining sediment provenance, weathering processes, diagenesis, anthropogenic impacts, and environmental risks (Wu et al., 2013; Najamuddin et al., 2016; Zhang et al., 2017; Bucșe et al., 2020; Teaca et al., 2020).

This study aims to analyse the physicochemical characteristics of surface waters in representative areas such as the Gorgova-Uzlina Depression and the confluence of Izmail and Sfântu Gheorghe during September and October 2024. The research will provide essential insights into the variability of hydrochemical parameters, identifying the influences of both natural factors and human activities on water quality and ecosystem dynamics in the Danube Delta.

The findings of this research have significant relevance for environmental management, conservation efforts, and policy formulation regarding the use and protection of water resources in the Danube Delta. By examining the physicochemical variability of surface waters and the specific impacts of anthropogenic activities, the study contributes crucial data for understanding and mitigating ecological risks (József et al., 2023; Kirschner et al., 2024). These insights can guide targeted interventions and inform sustainable management strategies aimed at conserving biodiversity, maintaining ecosystem functionality, and supporting socio-economic activities such as fishing, navigation, and tourism in this sensitive and internationally recognized region (Frîncu et al., 2021).

MATERIALS AND METHODS

Study area

The Gorgova-Uzlina Depression is located between the Sulina and Sfântu Gheorghe Arms, being influenced by the hydrographic system formed by the Litcov Canal, the Gârla Perivolovca and the Gorgova, Isacova and Uzlina Lakes. This region is characterized by variations in the hydrological regime, determined by morphological and hydrotechnical changes, which influence water circulation, sediment transport and water chemical quality. The closure and reopening of some channels (e.g. Gârla Filatului, Uzlina Canal) have modified the water and sediment supply over time, affecting the ecological balance of the lakes (Antipa, 1937; Driga, 2004). The confluences at Izmail and Sfântu Gheorghe are critical points for assessing water quality, being areas of mixing between river and lake waters, with intense sedimentation processes and changes in physico-chemical parameters (Poonam et al., 2013; Paun et al., 2017). These interactions are relevant for understanding the impact of the Danube on deltaic and coastal ecosystems (Gastescu & Stiuca, 2008; Dutu et al., 2023).

Methodology

The assessment of surface water quality in the Gorgova-Uzlina lake complex was carried out through in situ measurements of key physicochemical parameters at 25 stations in lakes Uzlina, Isacova, Durnoliatca, Isaccel, Gorgova, Potcoava, Gorgovăț, Rădăcinoș and Rotund and in 32 stations from Ceatal Izmail bifurcation (Danube-Mm 43.5, Chilia-Km 115, Tulcea-Mm 42.5) and Ceatal Sf. Gheorghe bifurcation (Tulcea-Mm 34, Sulina-Mm 33, Sf. Gheorghe-Km 108) in September and October 2024 (Figures 1 and 2).

Field analyses were performed using the multiparameter probe EXO 2 (YSI – USA) (Figure 3), equipped with sensors that collect water quality data through physical, optical and electrochemical detection methods (STAS 6323).

The determined parameters included:

Temperature (°C), pH (pH units), Turbidity (FNU), Total Dissolved Solids (TDS) (mg/L), Conductivity (µS/cm), Dissolved Oxygen (ODO mg/L), Oxygen Saturation (ODO%), Oxidation-Reduction Potential (ORP, mV), Salinity (PSU), Nitrate (NitraLED mg/L), Chlorophyll (RFU), Total Algal Content (TAL) – PC RFU.

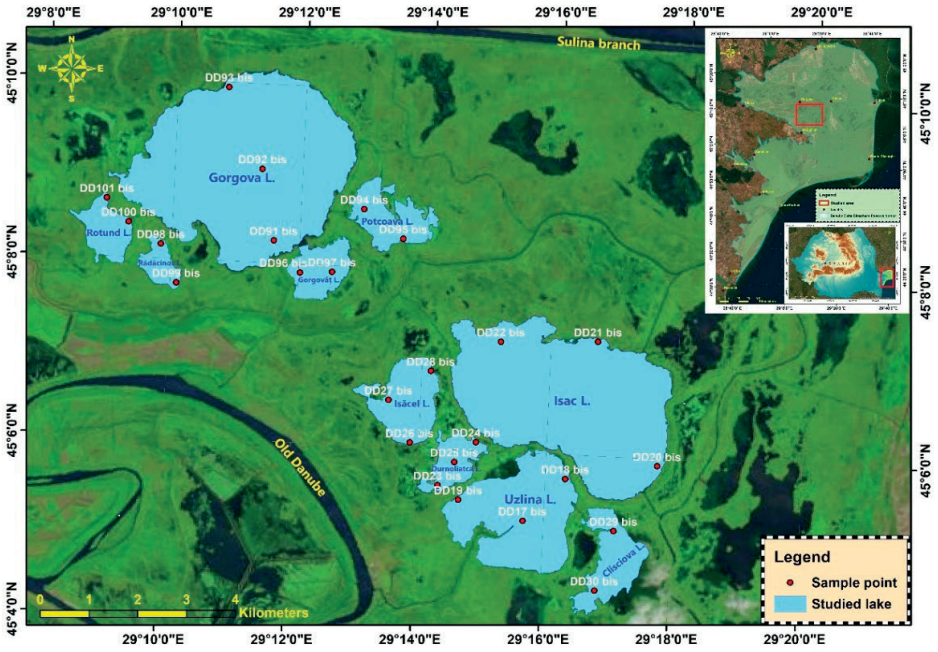

Figure 1. Sampling stations from Gorgova – Uzlina Complex

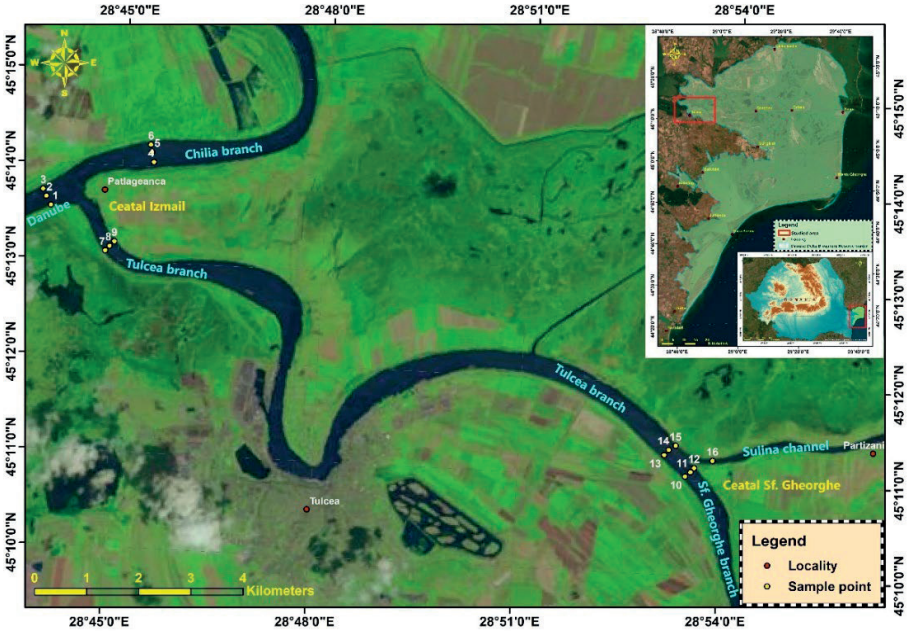

Figure 2. Sampling stations from the Ceatal Izmail and Ceatal Sf. Gheorghe

The water quality assessment was performed based on the classification provided by Order 161/2006, which defines five quality classes:

- Class I – Very good;
- Class II – Good;
- Class III – Moderate;
- Class IV – Poor;
- Class V – Bad.

In addition, reference standards from both national and international regulatory frameworks were considered to ensure a comprehensive assessment of water quality.

Figure 3. Multiparameter probe, model EX02

For a detailed analysis, both national and international water quality standards were applied. The assessment followed the European Union Water Framework Directive (WFD, 2000/60/EC), which sets requirements for managing aquatic resources to ensure a 'good' water quality status. In Romania, the evaluation was based on Regulation no. 161/2006 (Official Monitor of Romania, Part I, no. 511 bis), which outlines criteria for classifying surface water quality and ecological status, using parameters such as total dissolved solids (TDS) and turbidity (ISO 5667-5:2017). Physicochemical analyses were conducted in accordance with international standards, including SR EN ISO 5667-1:2023, SR EN ISO 10523:2012 (pH determination), and SR EN ISO 5814:2013 (dissolved oxygen measurement).

Statistical analysis

All statistical analyses were conducted using xlSTAT 7.5.2 software (Addinsoft, 2020) and Past 4 (https://past.en.lo4d.com/download). Pearson correlation was used to examine relationships between parameters.

RESULTS AND DISCUSSIONS

The ecosystems of the Danube Delta – including the branches of the Danube River, channels, lakes, ponds and coastal ecosystems – are subject to ecological pressures resulting from natural factors such as hydrological fluctuations, sedimentation processes and climate variability, as well as anthropogenic activities, including agriculture, navigation, water pollution, fishing and infrastructure development (Cazacu & Adamescu, 2017; Chapter 10 Nutrients, 2025).

According to Annex XI of the WFD, the complexes of lotic ecosystems, represented by the Danube River and the Danube Delta, are part of the Pontic Ecoregion (12).

Based on to the updated Management Plan for the Danube River, the Danube Delta, the Dobrogea River Basin and Coastal Waters (2021), in conjunction with the details provided in sub-chapter 6.3, a total of 112 surface water bodies have been identified and classified into:

- 92 natural water bodies, including 20 rivers, 68 lakes, 2 transitional water bodies and 2 coastal water bodies;
- 15 heavily modified water bodies, comprising 3 rivers, 4 reservoirs, 6 heavily modified natural lakes and 2 coastal water bodies;
- 5 artificial water bodies (mainly river-type channels).

Of these 112 surface water bodies, 2 (approximately 1.78%) are classified as non-permanent, both belonging to the river category. The specific area of this study falls within the category RO15 (Danube – Isaccea – Danube Delta). Within the current management plan, natural water bodies have been identified for types RO15, RO19, RO06* and RO08*, while types RO13 and RO14 consist exclusively of heavily modified water bodies:

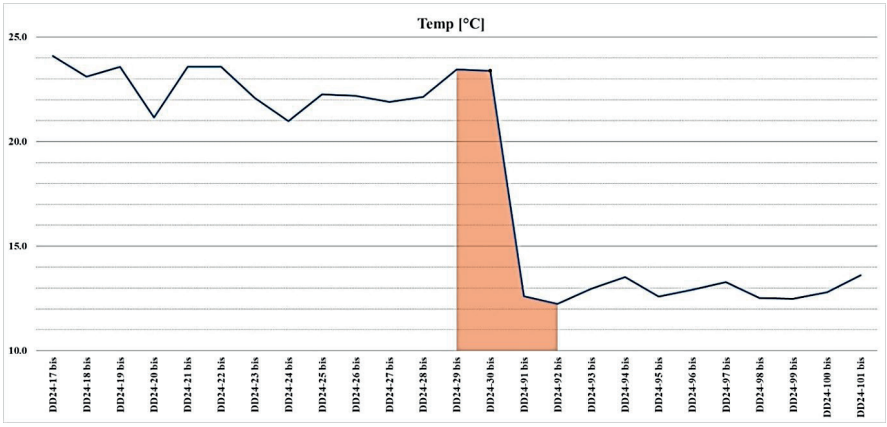
- RO06*: Lowland streams naturally devoid of fish fauna, usually characterised by intermittent flows, shallow depths and limited ecological complexity.
- RO08*: Similar to RO06*, these are also lowland streams without naturally occurring fish populations, frequently subject to dry periods and minimum water flow.
- RO13 (Danube River - Cazane - Călărași): A heavily modified river sector, significantly influenced by human activities such as navigation, river training and infrastructure development.
- RO14 (Danube River - Călărași - Isaccea): Another extensively modified section

of the Danube River, shaped by navigation channels, hydraulic engineering works and associated anthropogenic pressures.

- RO15 (Danube River - Isaccea - Danube Delta): Represents the lower section of the Danube, characterized by complex hydrological dynamics, high ecological diversity, significant sediment transport and natural interactions between fluvial and deltaic ecosystems.
- RO19: Non-permanent lowland streams, characterized by seasonal or intermittent flow regimes, which usually dry up periodically.

The values of the physicochemical parameters generally varied within the limits set by environmental standards, in particular national standards set by Romanian legislation (such as Order 161/2006), international guidelines and the criteria highlighted by the European Union Water Framework Directive (EU-WFD, 2000). The results obtained in this study contribute to improving the existing database on water quality by providing relevant and detailed information, aligned with the EU-WFD guidelines. The integration of data from multiple authorized sources, including national monitoring programmes, scientific studies and regulatory frameworks, ensures a complete and robust assessment of water quality. According to the EU-WFD provisions, European Union Member States must ensure that rivers, lakes, groundwater, estuaries and coastal waters achieve at least a "good" ecological status by 2027 at the latest. The results of the physicochemical determinations obtained at the sampling points are presented in Tables 1 and 2, indicating the minimum, maximum and average values (±standard deviation) for each analysed parameter.

Table 1. A synopsis of the physico-chemical parameters of water surface samples from Izmail and Sf. Gheorghe confluences



Parameter	**Min.**	**Max.**	**Mean ± SD**

Total Algal Content (TAL - PC RFU)	0.44	12.47	2.78±3.17

Water temperature (°C). Water temperature generally follows the trend of autumn air temperatures (https://www.accuweather.com). Recorded values fell within the natural variability of the study areas. In the Gorgova-Uzlina Complex, temperatures ranged from 12.24 to 24.09 °C (average 18.36 °C), while in Ceatal Izmail and Sf. Gheorghe, they ranged from 14.46 to 25.11 °C (average 19.60 °C). The lowest temperature was recorded at station DD24-92 bis (Gorgova Lake), and the highest at station DD24-11 (Ceatal Izmail) (Figure 4a, b). These results reflect typical seasonal fluctuations, with temperature variation mainly influenced by air temperature dynamics during the sampling period.

Water pH (pH units). The values of the results obtained place the tested water from most of the investigated samples within the pH range of normal values (6.5-8.5 pH units), which is considered optimal for aquatic life. The range of variation of the values was relatively narrow (7.77-8.98, average = 8.20) for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 8.05-8.33, average 8.16, so that the lowest value was found in station DD24-26 bis (Lake Isaccel), and the highest value was measured in station DD24-21 bis (Lake Isacova) (Figure 5 a, b). These pH values indicate that the water quality at the sampled sites is generally within a range favourable for the sustainability of aquatic ecosystems.

Turbidity (NTU). The turbidity values measured in the water samples taken from the study lakes show a series of variations that fall within the normal range of surface waters (1-1000 NTU) (Chapman, 1996). The range of values was relatively wide (1.14-91.60, average = 14.59) for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 2.46-58.26, average 9.96, so that the lowest value was recorded in station DD24-30 bis, Clisciova Lake, and the highest value was measured in station DD24-28 bis, Isaccel Lake (Figure 6 a, b). several samples exhibited relatively high turbidity values compared to the limits stipulated in SR ISO 5667-5:2017, which sets 5 NTU as the allowed value and 10 NTU as the exceptionally allowed value~~), indicating a deterioration in water quality. In general, increased turbidity levels can be attributed to the Danube's fluvial input, which carries water and sediments loaded with dissolved or suspended organic/inorganic substances.

The TDS concentration (total dissolved organic and inorganic substances) places the tested water in a good condition (values corresponding to fresh waters = 0 – 1000 mg/L TDS), (Lehr, 1980; De Zuane, 1997). The range of variation of the values was relatively narrow (212.05-273.74; average = 251.33) for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 228.14-256.00, average – 250.56, so that the lowest

value was found in station DD24-19 bis, Lake Uzlina, and the highest value was measured in station DD24-25 bis, Lake Durnoliatca (Figure 7 a, b). These results indicate that the investigated lakes are in good condition in terms of the concentration of dissolved inorganic and organic substances and that the water is not excessively influenced by external sources of pollution.

a

b

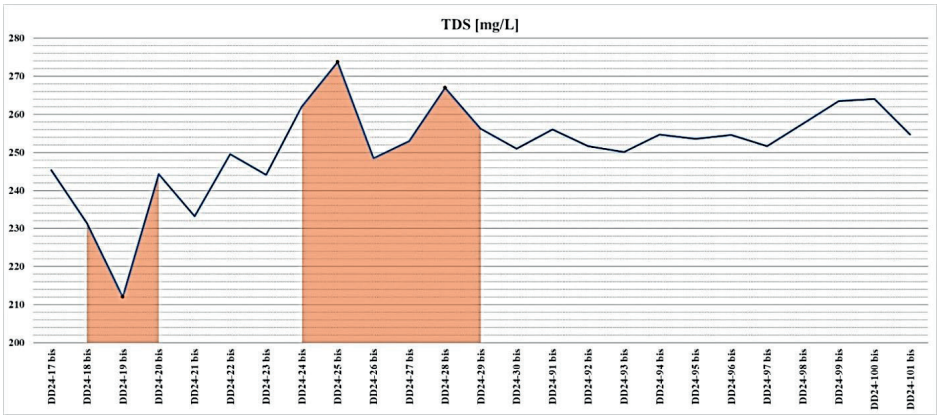

Figure 6 a) Evolution of the Turbidity FNU indicator in the investigated surface water samples for Gorgova-Uzlina Complex; b) Evolution of the Turbidity FNU indicator in the investigated surface water samples for Izmail and Sf. Gheorghe Confluences

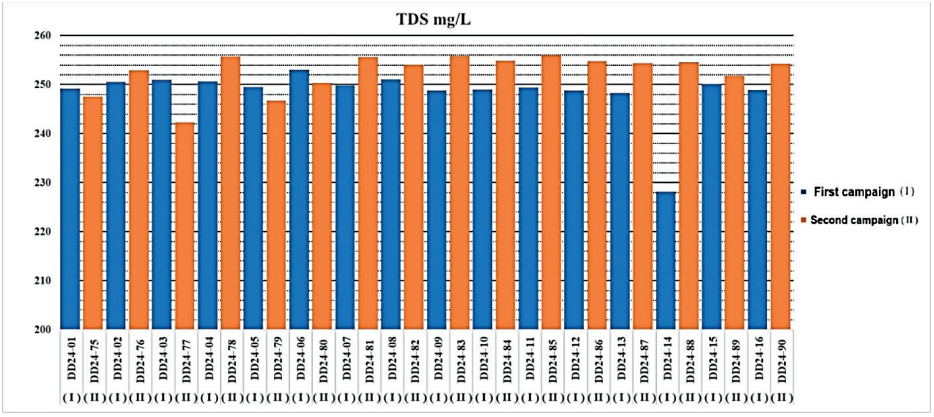
The level of electrical conductivity places the tested water from all investigated samples in the category of quality class I (500 µS/cm) (Order 161/2006). The range of variation of the values was relatively narrow (292.84-399.04, average = 336.99) for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 300.82-385.10, average = 345.38, so that the lowest value was found in station DD24-92 bis, Lake Gorgova, and the highest value was measured in station DD24-25 bis, Lake Durnoliatca (Figure 8 a, b). These values are typical of freshwaters with low mineralization, which is characteristic of the studied lakes, indicating that the water chemistry is consistent with a good ecological status.



The dissolved oxygen regime (mg/l) ranged from quality class I - 9 mg/L to quality class IV - 4 mg/L (Order 161/2006). The dissolved oxygen

concentrations (measured in all evaluated water samples) were also below the value of 5 mg/L. A minimum concentration of 5 mg/L dissolved oxygen is recommended to adequately support aquatic life (www.niwa.co.nz). The range of values includes a relatively wide gap (4.67-14.13, average = 9.14) for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 7.14 and 9.93, average = 8.54, so that the lowest value was found in station DD24-23 bis, Durnoliatca Lake, and the highest value was measured in station DD24-21 bis, Isacova Lake (Figure 9 a, b). These variations suggest that oxygen levels in water are influenced by a variety of factors, including water temperature, biological activity and hydrodynamic conditions.

The oxidation-reduction potential (ORP) (mV) places the tested water in a good condition. The values obtained for the tested water samples fall within the ORP range of natural waters (with values in the range -500 to + 700 mV) (Chapman, 1996; Sigg, 2000). The range of variation was included in both the positive and negative spectrum (-22.37-254.70; average = 75.25) for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 49.93-107.14, average 84.00, so that the lowest value was found in station DD24-17 bis, Uzlina Lake, and the highest value was measured in station DD24-27 bis, Isaccel Lake (Figure 10 a, b). These results suggest that water quality is generally good and that the investigated lakes maintain a healthy balance of redox reactions.

b

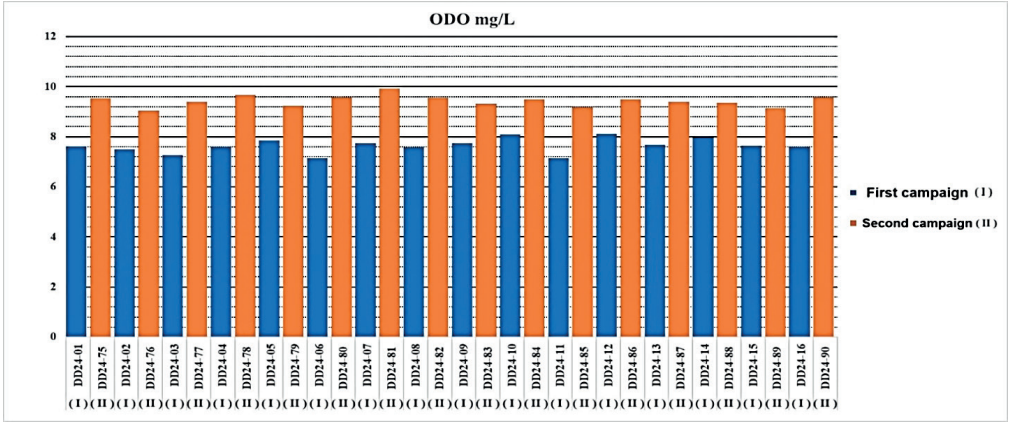
Figure 8 a) Evolution of the Cond µS/cm indicator in the investigated surface water samples for Gorgova-Uzlina Complex; b) Evolution of the Cond µS/cm indicator in the investigated surface water samples for Izmail and Sf. Gheorghe Confluences



Salinity level (‰). The investigated water samples showed salinity values ranging between 0.16-0.20‰ (average = 0.19) for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 0.17-0.19, average = 0.18. These values indicate fresh surface waters, with low salinity (salinity below 0.5‰) (Montagna et al., 2013) characteristic of the fluvial and lacustrine domain.

These low salinity values confirm that the lakes are characteristic of freshwater environments, typically found in fluvial and lacustrine settings, and are minimally influenced by marine waters.

Distribution of nitrate concentrations. Measurements made with the NitraLED sensor indicated significant variations in nitrate concentration (mg/L) at different sampling stations. The recorded values range from 0.10 mg/L to 10.46 mg/L, for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 0.11-18.36, average = 5.78, suggesting notable differences in the chemical composition of the water depending on location (Figure 11 a, b).

Grouping of stations by nitrate concentration

- *Low concentrations (≤1 mg/L)*

Stations such as DD24-03 – Ceatal Izmail (0.1108 mg/L), DD24-26 bis – Isaccel lake (0.095 mg/L) and DD24-21 bis – Isacova lake (0.144 mg/L) indicate very low nitrate presence. These values may reflect areas with low anthropogenic impact or geochemical conditions that limit nitrate accumulation.

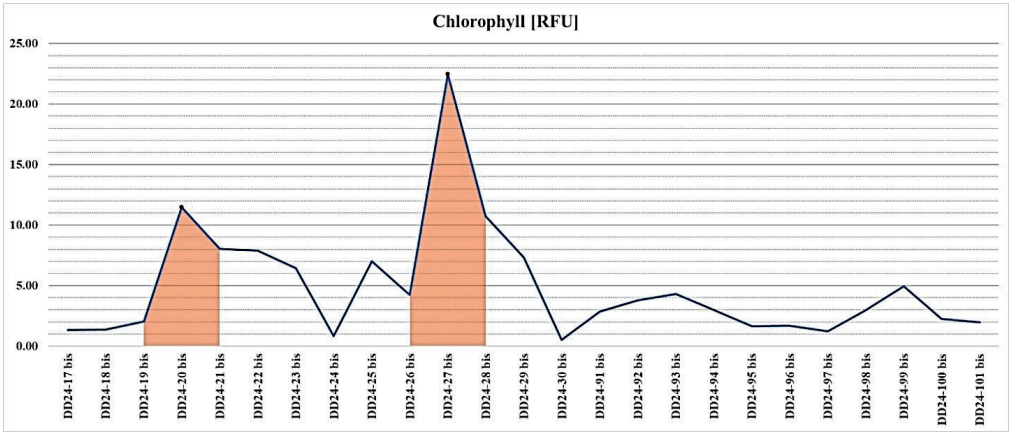
- *Moderate concentrations (1 – 5 mg/L)*

This range includes most of the stations in the first sets of measurements (e.g. DD24-02, DD24-04, DD24-15) – Ceatal Izmail and Ceatal Sf. Gheorghe in September, and the stations (e.g. DD24-17 bis, DD24-19 bis, DD24-22 bis) – Uzlina and Isacova Lakes.

Moderate values may indicate a natural influence or a limited source of pollution.

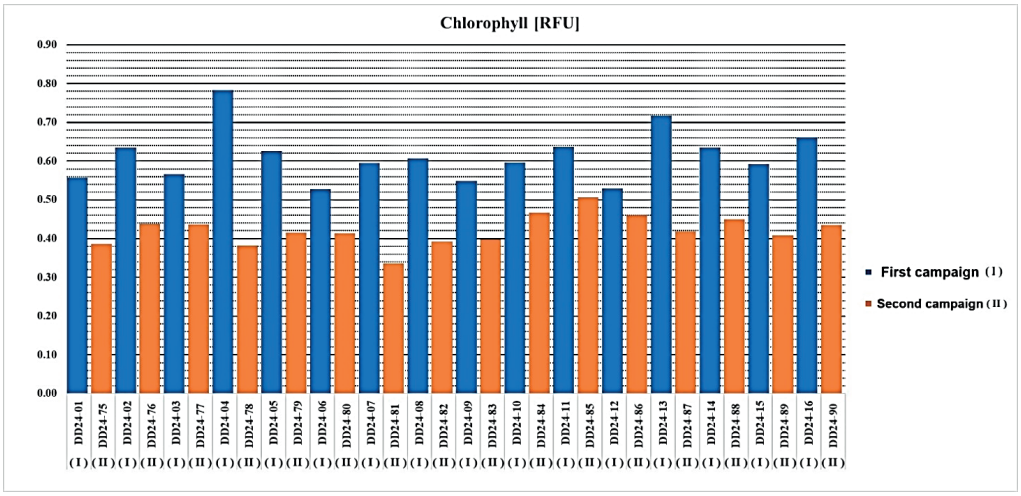
- *High concentrations (>5 mg/L)*

The highest values occur at stations DD24-75, DD24-76, DD24-81, DD24-85 – Ceatal Izmail in October, with a maximum concentration of 18.362 mg/L.



These concentrations are significantly higher and may indicate either a point source of contamination (e.g. anthropogenic activities, domestic effluents, agricultural inputs, industrial waste) or specific geological and hydrological factors, in the upstream urban section of the Danube River.

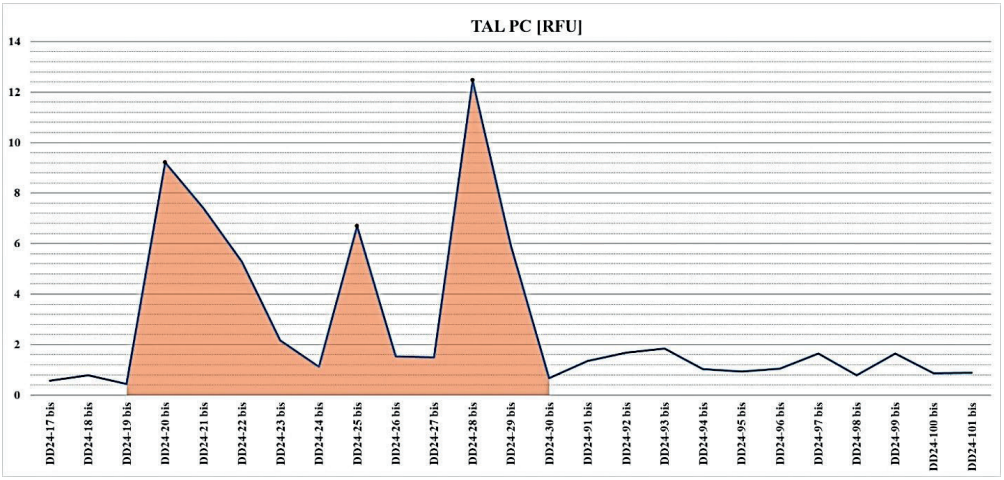
The concentration of chlorophyll a RFU concentration measured in the samples from the investigated lakes showed significant variability. Specifically, the values ranged broadly from 0.51 to 22.48 (mean = 4.89) in the Gorgova-Uzlina Complex and from 0.34 to 0.78 (mean = 0.52) in the Ceatal Izmail and Sf. Gheorghe areas. The lowest concentration was recorded at station DD24-81 (Ceatal Izmail), while the highest was observed at station DD24-27 bis (Isaccel Lake) (Figure 12 a, b).



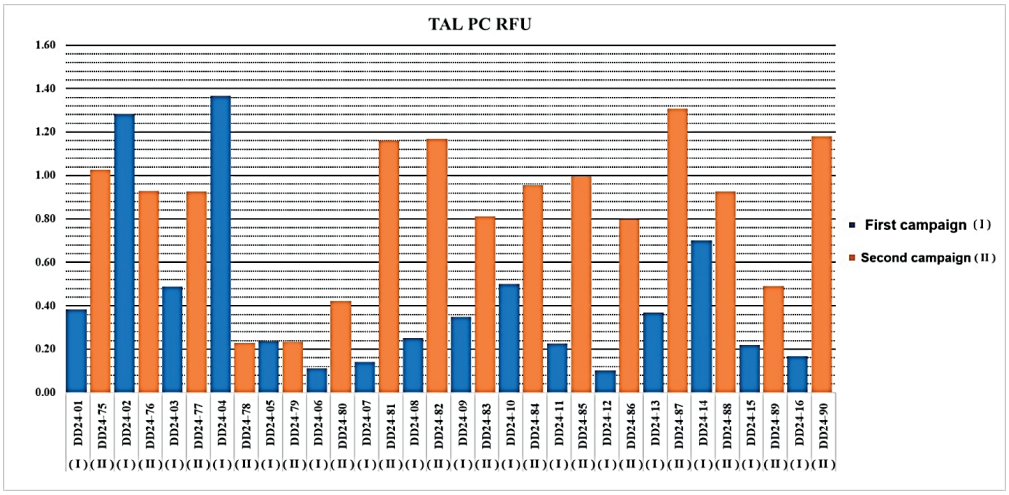
Several factors contribute to this variability:

- *Nutrient availability*: the main cause of variations in chlorophyll "a" concentration is the differences in nutrient availability (especially nitrogen and phosphorus) between lakes. High nutrient levels can stimulate algal growth, leading to increased chlorophyll concentrations.
- *Hydrological conditions*: Lakes differ in water renewal rates, connectivity to major channels, and water residence time. Lakes with slower water exchange rates or limited flushing often accumulate nutrients, promoting higher algal productivity.
- *Biological activity*: Differences in algal community composition and the presence or absence of macrophytes or other aquatic vegetation can significantly influence chlorophyll levels. Lakes with abundant aquatic vegetation may have lower chlorophyll concentrations due to competition for nutrients.
- *Anthropogenic influence*: Human activities, such as agricultural runoff, wastewater discharge, or fish farming operations, can lead to increased nutrient inputs, stimulating algal growth and chlorophyll concentration.
- *Physical factors*: Light availability, temperature variations and mixing conditions in lakes can also affect algal growth rates and therefore chlorophyll concentrations.

Most samples showed chlorophyll values below the threshold of 25 µg/l established for water quality class I (very good status) according to Order 161/2006, suggesting that the lakes generally have a good ecological status in terms of primary productivity. However, the wide range of chlorophyll values clearly indicates variability driven by the interaction between nutrient dynamics, hydrological conditions, biological communities, anthropogenic pressures and physical environmental factors.



a



b

Figure 12 a) Evolution of the chlorophyll a RFU indicator in the investigated surface water samples for Gorgova-Uzlina Complex; b) Evolution of the chlorophyll a RFU indicator in the investigated surface water samples for Izmail and Sf. Gheorghe Confluences

Total Algal Content (TAL - PC RFU). The TAL PC values show significant variations between stations, ranging from a minimum of 0.44 µg/L to a maximum of 12.47 µg/L, average = 2.78, for Gorgova-Uzlina Complex and for Ceatal Izmail and Sf. Gheorghe, the values varied between 0.10-1.37, average = 0.64 (Figure 13, a b). The lowest concentration values (below 0.5 µg/L) occur at stations DD24-78, DD24-79 and DD24-80, indicating reduced contamination or better water quality conditions at these points. In contrast, the highest concentrations (above 1.5 µg/L) are observed at stations DD24-92 bis, DD24-93 bis, DD24-97 bis and DD24-99 bis, suggesting possible local sources of pollution or increased accumulation of the analysed compounds. Most values are around the range of 0.8-1.2 µg/L, indicating a moderate concentration, possibly reflecting a relatively balanced state of the waters at most of the investigated points. The distribution of the data may suggest differences in the intensity of anthropogenic or natural factors influencing each sampling point, reflecting specific local impacts.

b

Figure 13 a) Evolution of the Total Algal Content (TAL - PC RFU) indicator in the investigated surface water samples for Gorgova-Uzlina Complex; b) Evolution of the Total Algal Content (TAL - PC RFU) indicator in the investigated surface water samples for Izmail and Sf. Gheorghe Confluences

Based on Pearson correlation for all the samples, a strong positive correlation was found between (Table 3, Figure 14):

Strong positive correlations:

- ODO % sat and ODO mg/L (0.803): As expected, the percentage of dissolved oxygen saturation and its concentration measured in mg/L are strongly correlated. This is because both measure oxygen, but in different units, influenced by temperature and pressure.
- Salinity and TDS (0.937): Total dissolved solids (TDS) concentration is closely related to salinity, as dissolved salts contribute significantly to TDS.
- Conductivity and temperature (0.936): As temperature increases, the conductivity of water increases significantly, as ions in the water become more mobile.

Strong negative correlations:

- Temperature and TAL PC ug/L (-0.892): As temperature increases, the concentration of algal pigments decreases significantly, suggesting a decrease in phytoplankton biomass under warmer conditions.

- Temperature and NitraLED mg/L (-0.838): Higher temperatures are associated with lower nitrate levels, likely due to increased biological consumption in the ecosystem.
- Temperature and ODO mg/L (-0.498): While there is a negative relationship between temperature and dissolved oxygen, the correlation is moderate. In general, warmer water holds less oxygen.

Moderate correlations:

- pH and ODO % sat (0.811): higher pH is correlated with higher oxygen saturation, likely due to photosynthetic activity.
- pH and ORP (-0.420): There are a moderately negative relationship between pH and redox potential (ORP), suggesting that at higher pH, the environment becomes more reductive.
- TAL PC ug/L vs. NitraLED mg/L (0.748) → The number of algal pigments is correlated with the concentration of nitrates, suggesting that nitrates are an important source of nutrients for phytoplankton.

Weak correlations:

- Chlorophyll RFU and turbidity (0.191): The relationship between chlorophyll levels measured by fluorescence and turbidity is weak. Therefore, algae growth does not fully explain water turbidity.
- Chlorophyll ug/L and temperature (-0.676): Chlorophyll measured as actual concentration is negatively influenced by temperature, but to a moderate to strong extent.

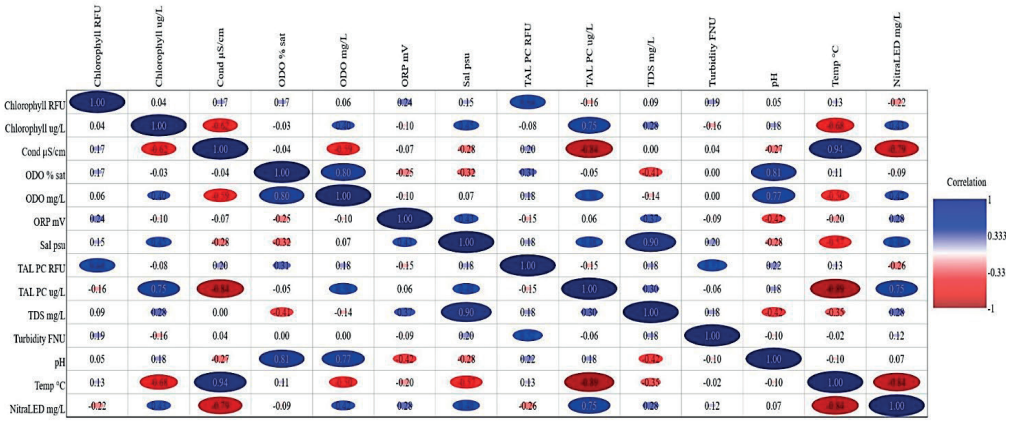

Figure 14. Pearson correlation

The physico-chemical parameters measured in this study varied within ranges compatible with natural seasonal fluctuations and environmental standards. Water temperature closely followed air temperature trends, reflecting typical autumn conditions. pH values consistently indicated optimal conditions for aquatic life, demonstrating stability in the ecosystem. Turbidity levels showed a wide range, with some stations showing high values, probably influenced by sediment inputs from the Danube River. Electrical conductivity and total dissolved solids (TDS) values demonstrated typical freshwater conditions with low mineralization, indicating minimal impacts of external pollution. Similarly, low salinity values confirmed the predominantly freshwater nature of the lakes.

Dissolved oxygen levels showed significant variability, with some sites recording concentrations below the recommended minimum of 5 mg/L, potentially influenced by biological activity and hydrodynamic conditions. Oxidation-reduction potential (ORP) values fell within natural limits, indicating healthy redox conditions in the water bodies. Nitrate concentrations varied significantly, highlighting areas with potential anthropogenic impact. Chlorophyll "a" concentration generally indicated very good ecological conditions, although some sites displayed higher values, suggesting localized variations in nutrient availability and primary productivity. In addition, the total algal content (TAL - PC RFU) reflects variations in primary productivity and algal biomass between sampling points, highlighting potential eutrophication patterns. The observed variability in TAL PC values could thus be related to differences in nutrient availability, water circulation or local anthropogenic inputs influencing algal growth.

The results obtained in this study on the physicochemical parameters of the Danube Delta waters closely align with the findings of previous research conducted in the same region and in similar environments. Studies focused on areas such as the Gorgova-Uzlina Depression, the Somova-Parches area and the Matita-Merhei Complex have similarly reported good overall ecosystem conditions (Botnariuc, 1985). Furthermore, the measured values are consistent with those documented in other recent water quality assessments for the Sfântu Gheorghe and Chilia branches (Sener et al., 2016; Oz et al., 2019; Teodorof et al., 2021) and the predeltaic area near Galați (Iticescu et al., 2014). Collectively, these studies suggest a medium-term stability of the hydrochemical characteristics in the Danube Delta region (Karabulut et al., 2014).

Pearson correlation analysis revealed strong relationships between parameters such as dissolved oxygen and oxygen saturation, salinity and TDS, as well as conductivity and temperature. These correlations indicate interdependencies between physicochemical factors and underline the importance of integrated monitoring approaches for managing the ecological health of the Danube Delta.

CONCLUSIONS

To determine the water quality status of the studied areas of the Izmail and Sf. Gheorghe Rivers and the Danube Delta, several physicochemical parameters were evaluated, including temperature, pH, turbidity, total dissolved solids (TDS), conductivity, dissolved oxygen, oxygen saturation, oxidation-reduction potential (ORP), salinity, nitrate concentration, chlorophyll and total algae content (RFU-PC). The measurements and interpretations followed the established reference standards and methods.

• *Water quality in the investigated ecosystems of the confluence areas and lakes of the Gorgova Uzlina Lake Complex*.

According to the analysed parameters, most of the water samples from the studied lakes and canals fell predominantly into quality classes I and II according to Order 161/2006, indicating a generally good ecological status. However, localized variations were identified, reflecting specific environmental conditions or pressures.

• *Ecological vulnerabilities and anthropogenic pressures*

Ecosystems remain vulnerable to fluvial inputs of organic and inorganic substances, influencing turbidity and dissolved substance concentrations. Elevated turbidity values recorded in certain locations, such as Lake Isaccel, highlight potential negative impacts on aquatic organisms and overall water quality, requiring continuous monitoring.

• *Physico-chemical water parameters*

Temperature (°C): the values recorded were characteristic of the autumn season, showing minimal variability and remaining within natural limits.

pH (pH units): most samples indicated values within the normal range (6.5–8.5), suggesting a chemically stable aquatic environment.

Turbidity (FNU): localised increased turbidity was observed, indicating variations due to sediment influx or anthropogenic impact, which may negatively affect aquatic life.

Total Dissolved Solids (TDS) (mg/L): values were consistent with freshwater systems, reflecting limited dissolved salt content.

Conductivity (µS/cm): all measurements are aligned with quality class I, confirming the minimal presence of dissolved salts and indicating low contamination.

Dissolved Oxygen (ODO mg/L) and Oxygen Saturation (ODO%): although generally reflecting good ecological status, certain locations (e.g. Durnoliatca Lake) showed lower dissolved oxygen values (below 5 mg/L), posing risks to aquatic biota.

Oxidation-Reduction Potential (ORP, mV): ORP values indicate favourable oxidative conditions in most locations, leading to a balanced ecological environment.

Salinity (PSU): the recorded values affirmed the freshwater nature of the studied aquatic environments, with no significant saline influence.

Nitrate (NitraLED mg/L): concentrations were within acceptable limits, with no significant indication of nutrient pollution in the studied areas.

Chlorophyll (RFU): Chlorophyll values remained generally low, suggesting minimal risks of eutrophication and reduction of algal biomass.

Total Algal Content (TAL-PC RFU): significant variations were identified between stations, reflecting differences in nutrient availability or localized anthropogenic influences affecting algal biomass.

• *Risk factors and recommendations*

Sediment and organic matter inputs from the Danube significantly influence water quality. Continuous monitoring is essential to detect and mitigate potential deterioration, especially in areas with high turbidity and low dissolved oxygen levels.

Future monitoring efforts should correlate physicochemical data with meteorological and hydrological conditions of the Danube – Danube Delta lakes, improving the understanding of seasonal and anthropogenic impacts on these sensitive ecosystems.

Abstract

This study evaluated the surface water quality of selected Danube River sectors (km 549-990) in the RO13 Cazane-Călărași area using direct field measurements. A multiparameter EXO 2 probe (YSI, USA) was used to analyze key physico-chemical parameters, while hydrocarbon concentrations (Oil in Water and HC micro-g/L) were assessed using PAH probes. Results indicate that most water quality parameters remain within environmental standards, classifying the waters as either "Very Good" or "Good." Temperature (15.03-24.40°C) and pH (7.92-8.36) remained stable, while dissolved oxygen levels (7.01-9.43 mg/L) and chlorophyll concentrations (0.27–1.49 RFU) suggested low risk of eutrophication. Conductivity (262.53-411.56 µS/cm), TDS (207.56-280.80 mg/L), and salinity (0.15-0.21 psu) confirmed freshwater conditions. Turbidity values (2.44-28.75 FNU) and oxidation-reduction potential (-26.59 to 238.79 mV) indicated relatively stable conditions. Hydrocarbon levels (0.03-1.46 mg/L) were within acceptable environmental limits, though localized variations suggested potential pollution sources. These findings emphasize the need for long-term monitoring and transboundary collaboration to address localized pollution concerns and ensure sustainable water management in the Danube Basin.

Key words*: Danube River, surface water quality, hydrocarbon pollution, ecosystem monitoring, environmental assessment.*

INTRODUCTION

The Danube, the second longest river in Europe, crosses ten countries and plays a key role in the economy, biodiversity and hydrological dynamics of the region (Banu, 1967; Panin, 2003). The lower Danube, between Drobeta-Turnu Severin and the Black Sea, is characterized by a complex hydrographic network, fed by tributaries such as the Siret, Olt, Prut and Jiu. In this area, hydromorphological diversity determines significant variations in the flow regime, sediment transport and distribution of aquatic habitats (Călinescu & Iana, 1967; Bușniță et al., 1970; Cioboiu & Brezeanu, 2017; Nike et al., 2022). Assessing water quality in this sector is essential for monitoring the impact of anthropogenic pressures and climate change on the river ecosystem (Calmuc et al., 2020; Radu et al., 2022). The main threats to water quality include pollution with nutrients, hazardous substances, hydromorphological changes and organic pollution (Gasparotti, 2014). These problems are aggravated by industrial, agricultural and urban activities in the Danube basin, which influence the physico-chemical parameters of the water and, implicitly, the ecological status of the river (Rico et al., 2016).
This research aims to answer the question: How do natural and anthropogenic factors influence water quality in the Lower Danube? To address this, the study assesses spatial and temporal variations in key physicochemical water parameters, including temperature, pH, dissolved oxygen (DO), chlorophyll, turbidity, salinity, total dissolved solids (TDS), oxidation-reduction potential (ORP), and hydrocarbon contamination.
By identifying potential pollution sources and assessing deviations from reference standards, this research provides insights into both natural variability and human-induced impacts on Danube water quality. The findings contribute to ongoing monitoring efforts and serve as a reference for future water management and conservation strategies in the region.

Relevance and impact of the study

By analyzing water quality and hydromorphological pressures in detail, this research contributes to sustainable management strategies and the implementation of the Water Framework Directive (WFD). The results will support the development of effective measures to reduce pollution, protect aquatic biodiversity and improve navigation, providing a solid scientific basis for conservation policies and sustainable use of Danube River resources.

According to Annex XI of the Water Framework Directive (WFD), the Danube is classified within the Pontic Ecoregion. Based on the hydromorphological and physico-chemical characteristics outlined in the River Basin Management Plans, 19 distinct natural river types have been identified for the Danube and its delta. These classifications play a crucial role in assessing water quality, monitoring ecosystem health, and guiding conservation strategies.

MATERIALS AND METHODS

Study sectors

The selection and delimitation of key monitoring sectors in the Lower Danube were based on hydromorphological characteristics and anthropogenic pressures.

The primary investigated sectors included Calnovat (km 604-616; D2_24_01 - D2_24_39), Corabia (km 626-631), Bechet (km 674-678; D2_24_40 - D2_24_54), Pisculet Desa (km 760-631; D2_24_26_; D2_24_72), and Bogdan Seclan (km 781-786; D2_24_73 - D2_24_90). These locations were chosen based on their hydromorphological diversity and potential exposure to anthropogenic influences.

In addition to these core sectors, supplementary sampling points were distributed in key areas to capture a comprehensive picture of spatial variations in water quality. These included sites downstream (km 594) and upstream (km 599) of Zimnicea, upstream of the Iskar River (km 638), as well as both downstream (km 689) and upstream (km 696) of the Jiu River. Further sampling was carried out upstream of Kozloduy (km 705 and 407), at the Lom River, upstream of Vidin/downstream of Calafat (km 794), upstream of Calafat (km 798) and near the Timok River, both downstream (km 844) and upstream (km 847). Additional sites were surveyed around the Iron Gates II Dam (km 860-878), a critical hydropower infrastructure that influences the hydrodynamics of the Danube.

Further upstream, monitoring was conducted at strategic locations, including downstream (km 882) and upstream (km 885) of Brza Palanka, downstream (km 925) and upstream (km 934) of Drobeta-Turnu Severin, and several locations in the Orșova region. These included downstream (km 951), Orșova Bay (km 954), and upstream of Orșova (km 954). Additional sites were examined in Eșelnița (km 963), downstream (km 968) and upstream (km 971) of Dubova, as well as downstream (km 986) and upstream (km 990) of the Poreka River.

These study sites are part of the RO13 Danube – Cazane - Călărași sector, ensuring a comprehensive assessment of hydromorphological conditions, pollution sources and ecosystem health in the lower Danube (Figure 1).

Methodology for analyzing physico-chemical parameters of water

The assessment of surface water quality in selected Danube sectors was conducted through in situ measurements of key physico-chemical parameters across 201 monitoring stations.

Field analyses were performed using the EXO 2 multiparameter probe (YSI - USA) (Figure 2), which utilizes physical, optical, and electrochemical detection methods to collect water quality data through a variety of sensors.

Measured parameters: Temperature (°C), pH (pH units), Turbidity (FNU), Total Dissolved Solids (TDS) (mg/L), Conductivity (µS/cm), Dissolved Oxygen (ODO mg/L), Oxygen Saturation (ODO%), Oxidation-Reduction Potential (ORP, mV), Salinity (PSU), Nitrate (NitraLED mg/L), Chlorophyll (RFU), Total Algal Content (TAL) - PC RFU.

Additionally, Polycyclic Aromatic Hydrocarbon (PAH) levels were monitored using PAH probes (microFlu oil sensors) for real-time hydrocarbon detection in water (Figure 2).

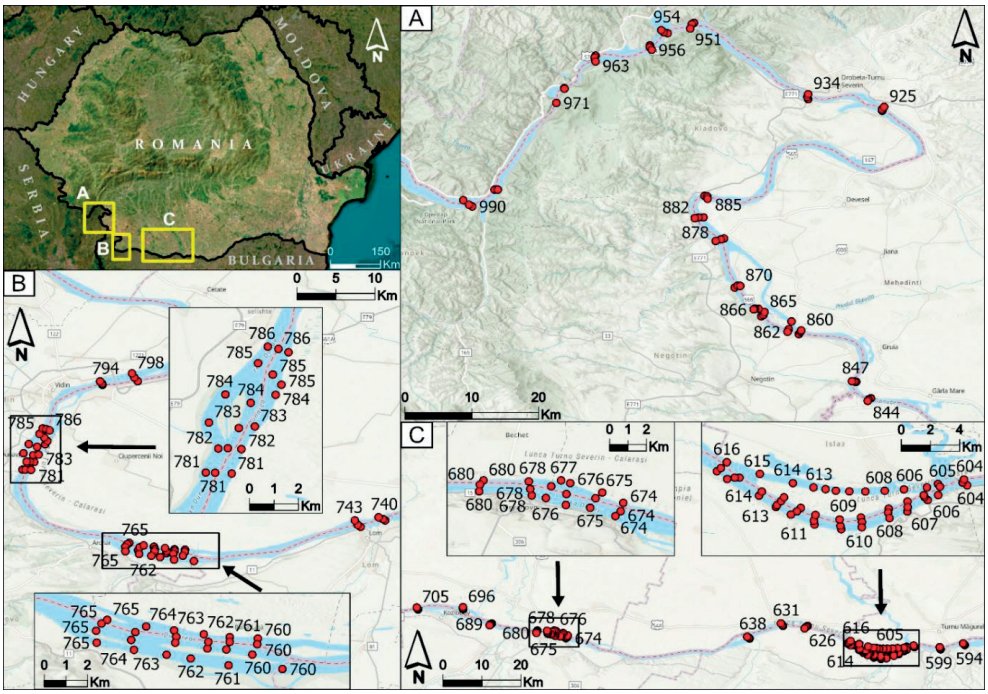

Figure 1. Sampling stations on the Danube River

The water quality assessment was carried out mainly based on the classification provided for in Order 161/2006, which defines five quality classes:

- Class I – Very good;
- Class II – Good;
- Class III – Moderate;
- Class IV – Poor;
- Class V – Bad.

For comprehensive analysis, both national and international standards regulating water quality were taken into account. The EU Water Framework Directive (WFD, 2000/60/EC) requires qualitative and quantitative management of water resources, with the objective of maintaining healthy aquatic ecosystems and achieving "good status" of water quality. In this regard, the assessment of surface water quality was carried out in accordance with the Romanian National Environmental Standards, in particular Regulation no. 161/2006 (on the approval of reference objectives for the classification of surface water quality, Official Gazette of Romania, Part I, no. 511 bis). This regulation establishes the criteria for the classification of surface waters and the assessment of ecological status, using environmental parameters such as total dissolved solids (TDS) and turbidity (ISO 5667-5:2017).

The physicochemical determinations were carried out in accordance with applicable international standards, including SR ISO 5667/2007 (General Guide for the Establishment of Sampling Programs and Techniques), SR EN ISO 10523:2012 for the determination of pH and SR ISO 5814:1984 for the measurement of dissolved oxygen (DO). The data obtained for the physicochemical parameters of water at the sampling points are presented in Table 1, highlighting the minimum, maximum and average values (± standard deviation) for each parameter.

Methodology for hydrodynamic measurements (velocities, currents, and water discharges)

Hydrodynamic measurements, including current velocity, flow rate and direction, are essential for understanding the distribution and transport of pollutants in the aquatic environment. They influence both chemical dispersion and oxygenation and sedimentation processes,

having a direct impact on water quality (Kern et al., 2014; Teodorof et al., 2015; Iticescu et al., 2016; Catianis et al., 2024).
To determine the hydrodynamic parameters, a high-precision system based on the Doppler effect was used - Acoustic Doppler Current Profiler (ADCP), model River Ray 600 kHz, produced by Teledyne RD Instruments. The measurements were carried out exclusively in the sectors Calnovat, Corabia, Bechet, Pisculet Desa and Bogdan Seclan (Figure 2).

Statistical analysis
All statistical analyses were performed using xlSTAT 7.5.2 software (Addinsoft, 2020) and Past 4 (https://past.en.lo4d.com/download). Correlation between parameters were analysed using the Pearson correlation.

Figure 2. Multiparameter probe, model EX02 and the PAH probes, microFlu from Aquams and ADCP River Ray 600 kHz

RESULTS AND DISCUSSIONS

Water is a central element in the integration of various environmental concerns and strategies, playing an essential role in multiple human activities, such as agriculture, economy, transport, energy, industry and environmental protection (Podlasek et al., 2024). It is a determining factor in development, being indispensable both for maintaining the balance of aquatic ecosystems and for human health and well-being, ensuring fundamental needs such as food, hygiene, comfort and health (Gasparotti, 2014). Water quality is significantly influenced by industrial and agricultural activities, energy production and domestic activities (Banaduc et al., 2016). In the context of climate change, a resilient and integrated approach to water resources management is required (Poff et al., 2002; Capon et al., 2013).

Water quality parameters analysis
The values of the physicochemical parameters generally varied within the limits established by environmental standards (Table 1).
Rapid and persistent increases in global temperatures are expected in the coming decades (Diop et al., 2018). Global warming does not only affect the atmosphere, but also significantly influences aquatic environments (Hannesson, 2007). This phenomenon has led to an increase in the global average temperature of between 1.8 and 4.0°C, changes in climatic and hydrodynamic patterns, and rising sea levels (Madeira et al., 2016; Simionov et al. 2020).
Water temperature is closely linked to seasonal air temperature variations, particularly in autumn (https://www.accuweather.com). The recorded values ranged from 15.03°C to 24.40°C (mean 18.55°C), aligning with natural seasonal fluctuations. The lowest temperature was measured at km 968 (left bank), while the highest was recorded at km 631 (center). These variations can influence biological activity, affecting metabolic rates of aquatic organisms and oxygen solubility (Figure 3).
Water pH (pH units). The measured pH values ranged from 7.92 to 8.36 (mean 8.10), staying within the expected range for freshwater systems (6.5-8.5). These stable conditions indicate no significant acidification or alkalization events. The lowest pH was observed

at km 860 center, while the highest was recorded at km 605 right bank. The slight alkalinity corresponds to the buffering capacity of the Danube, primarily influenced by the carbonate-bicarbonate balance (Figure 4).

Turbidity (NTU). The turbidity values measured in the investigated water samples exhibited variations within the normal range for surface waters (1-1000 NTU) (Chapman, 1996). Turbidity ranged from 2.44 to 28.75 FNU, with a mean of 11.02 FNU, the highest value recorded at km 762 right bank, and the lowest at km 611 bis left bank. Although turbidity fluctuated widely, several values exceeded the 10 NTU limit specified in ISO 5667-5:2017. Increased turbidity at km 762 right bank was likely caused by sediment resuspension or an increased particle load from the upstream fluvial inlet. In contrast, the lowest turbidity recorded at km 611 Bis left bank may be attributed to reduced sediment influx or localized settling processes that contributed to water clarification. Overall, turbidity variations were primarily influenced by the Danube's fluvial input, which transports water and sediments loaded with dissolved and suspended organic/inorganic substances (Figure 5).

The *TDS concentration (*representing total dissolved organic and inorganic substances) indicates that the tested water is in good condition, with values consistent with freshwater standards (0-1000 mg/L TDS) (Lehr, 1980; De Zuane, 1997). The TDS concentration ranged from 207.56 to 280.80 mg/L, with a mean of 249.47 mg/L, the lowest value recorded at km 762 Bis right bank, and the highest at km 740 (right bank). These values suggest limited influence of dissolved salts or pollutants from upstream sources (Figure 6).

The *electrical conductivity* values ranged from 262.53 to 411.56 µS/cm, with a mean of 337.56 µS/cm (Figure 7). Electrical conductivity and TDS values confirm the freshwater characteristics of the investigated sectors, with no significant deviations that would indicate excessive mineralization or contamination.

Table 1. Synopsis of physico-chemical parameters in surface water samples

Parameter	Min.	Max.	Mean ± SD
Temperature (°C)	15.03	24.40	18.55 ± 2.65
pH	7.92	8.36	8.10 ± 0.07
Turbidity (FNU)	2.44	28.75	11.02 ± 4.72
Total Dissolved Solids (TDS mg/L)	207.56	280.80	249.47 ± 19.02
Conductivity (µS/cm)	262.53	411.56	337.56±41.75
Dissolved Oxygen (ODO mg/L)	7.01	9.43	8.06 ± 0.55
Oxygen Saturation (ODO % sat)	78.94	94.91	85.93 ± 3.09
Oxidation-Reduction Potential (ORP mV)	-26.59	238.79	122.69 ± 59.28
Salinity (PSU)	0.15	0.21	0.18 ± 0.01
Nitrate (NitraLED mg/L)	2.67	101.82	12.80 ± 12.71
Chlorophyll (RFU)	0.27	1.49	0.48 ± 0.16
Total Algal Content (TAL - PC RFU)	0.01	1.91	0.69 ± 0.41
Total Flow Rate (m^3/s)	1368.31	7750.719	6196.83 ± 1339.17

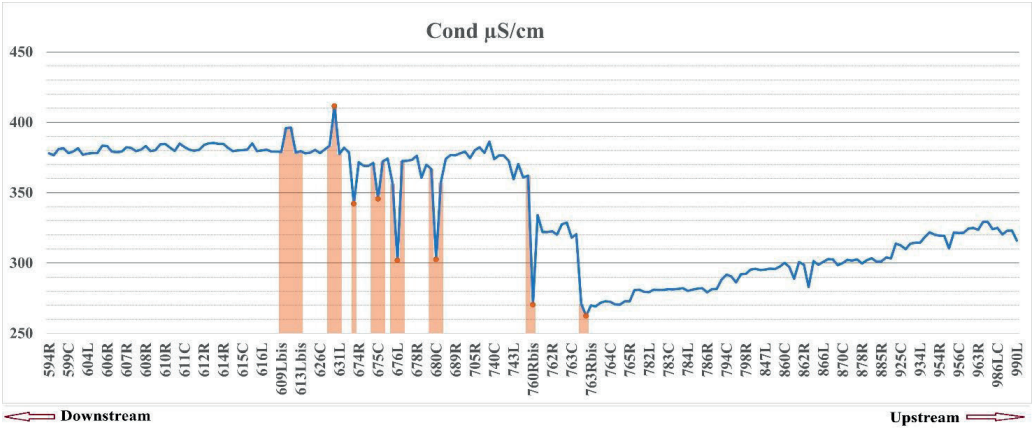

Figure 7. Evolution of the Conductivity (µS/cm) indicator in the investigated surface water samples

The dissolved oxygen regime (mg/l). The dissolved oxygen (DO) concentrations confirmed that the investigated waters belong to the well-oxygenated surface water category (quality class I, ≥9 mg/L), as defined by Order 161/2006. All measured values were above the 5 mg/L threshold, which is the minimum recommended concentration to support aquatic life (www.niwa.co.nz). Measured DO concentrations ranged from 7.01 to 9.43 mg/L, with an average of 8.06 mg/L. The lowest concentration was recorded at km 610 Bis left bank, while the highest was observed at km 762 Bis right bank. Oxygen saturation levels ranged from 78.94% to 94.91%, confirming good aeration and the absence of significant hypoxic conditions (Figure 8). These findings highlight stable oxygen levels, ensuring adequate conditions for aquatic ecosystems.

The *oxidation-reduction potential* (ORP) values indicate that the tested water is in good condition, falling within the typical range for natural waters (-500 to +700 mV) (Chapman, 1996; Sigg, 2000). The oxidation-reduction potential (ORP) ranged from -26.59 to 238.79 mV, with a mean of 122.69 mV, the lowest value recorded at km 674 center, and the highest at km 763 center. The presence of both positive and negative values suggests dynamic redox conditions influenced by organic matter decomposition, microbial activity, and oxygen availability. These variations reflect localized environmental factors that regulate oxidation-

reduction processes in the Danube's aquatic system (Figure 9).

Salinity values (0.15-0.21 PSU, mean 0.18) confirm the freshwater nature of the Danube, in agreement with previous studies. Low salinity levels reflect limited seawater intrusion or evaporative concentration effects. These values indicate fresh surface waters, with low salinity (salinity below 0.5‰), (Montagna et al., 2013) characteristic of the fluvial and lacustrine domain.

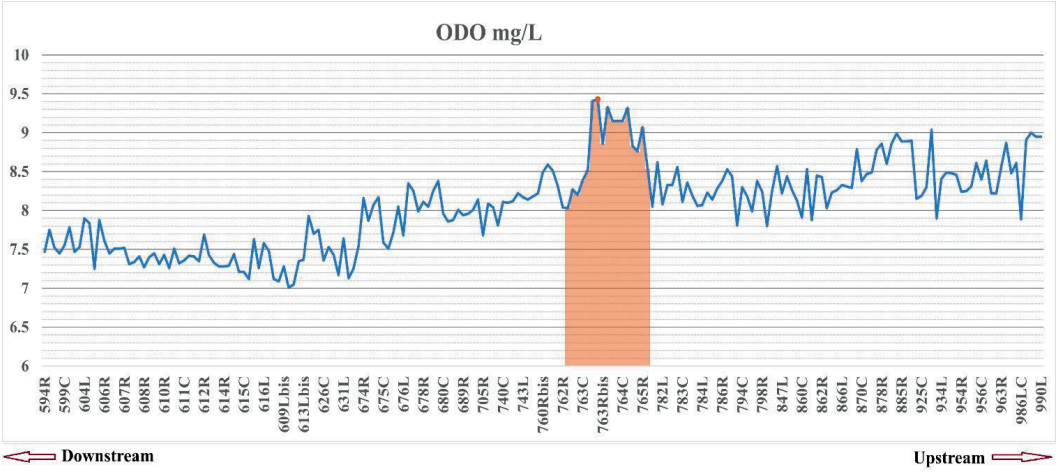

Figure 8. Evolution of the ODO (mg/L) indicator in the investigated surface water samples

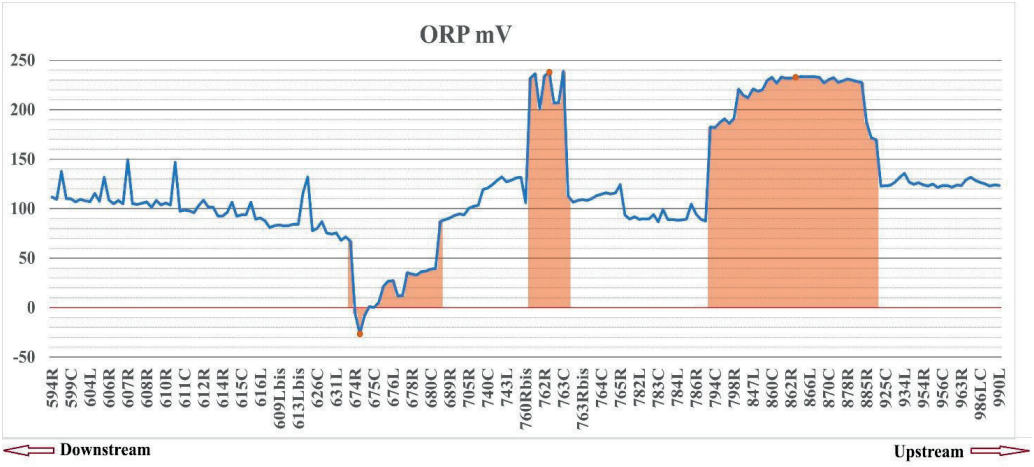

Figure 9. Evolution of the ORP (mV) indicator in the investigated surface water samples

The *NitraLED (mg/L)* values indicate significant variations in nitrate concentrations at different measurement points. The Nitrate concentrations (mg/L) ranged from 2.67 to 101.82 mg/L, with a mean of 12.80 mg/L. The highest value recorded was 101.82 mg/L at km 956 right bank, followed by 92.56 mg/L at km 925 central and 80.45 mg/L at km 677 right bank. These levels are significantly higher than the rest of the measurements and may indicate local sources of nitrate pollution. Other significantly elevated values include 74.19 mg/L (km 866 left bank), 53.69 mg/L (km 608 left bank), and 52.73 mg/L (km 638 central).

Most measurements range between 10 and 20 mg/L, which is relatively common for surface waters affected by anthropogenic activities. For example, at km 594, concentrations are relatively constant between 14.8 and 15.54 mg/L, suggesting a stable source of nitrates in this area. The lowest concentrations are found in the range of 4 to 7 mg/L, such as km 844 central (4.29 mg/L), km 798 right bank (4.07 mg/L) and km 794 central (4.32 mg/L). These values may indicate areas less affected by agricultural activities or industrial discharges (Figure 10).

High nitrate levels may be associated with agricultural discharges (fertilizers), wastewater or natural sources (organic remineralization).

Sudden increases in certain locations (e.g. km 956 md) suggest localized contamination.

Chlorophyll RFU values ranged from 0.27 to 1.49 (mean 0.48), remaining well below the 25 µg/L threshold for quality class I, which indicates low phytoplankton biomass and minimal risk of eutrophication. The lowest value was recorded at km 762 left bis. The highest value was observed at km 638 (left bank). These results suggest stable trophic conditions, with no significant algal blooms detected, supporting a balanced aquatic ecosystem (Figure 11).

Total Algal Content (TAL - PC RFU) values ranged from 0.01 to 1.91 (mean 0.69). High values (RFU > 1.0) were recorded in the Calnovat areas (km 604-616): km 609 center (1.46), km 609 right bank (1.33); Corabia (km 631 left bank): 1.58 (strong local input from the grain port); Bogdan Seclan (km 781-786): km 783 center (1.91); Drobeta Turnu-Severin (km 925-934): km 934 left bank (1.39), km 935 center (1.37); Orșova and surroundings (km 951-954): km 951 center (1.37), km 954 left bank (1.54); Iron Gates II area (km 860-878): km 878 center (1.5); Eșelnița–Dubova: km 971 center (1.1) (Figure 12). These values suggest intense anthropogenic influences, particularly related to port, industrial, urban and tourist activities.

Medium values (RFU between 0.3 and 1.0) were recorded in the areas such as Zimnicea (km 594): 0.58 (moderate urban impact); Bechet (km 674-678): 0.13-0.55 (low to moderate impact); Pisculet Desa (km 760 center): 0.97 (significant local variation, local moderate influences);

Bogdan Seclan (km 781-786): most values between 0.3 and 0.9, reflecting local moderate to high impact. Instead, low values (RFU < 0.3) were recorded at Zimnicea (km 599 upstream): 0.08-0.13 (low anthropogenic influence); Corabia (km 626-631 centru/right bank): 0.01-0.06 (clean, uncontaminated areas); Pisculet Desa (km 760 left bank): 0.1 (minimal local impact). These values indicate relatively clean areas, with little or no anthropogenic impact.

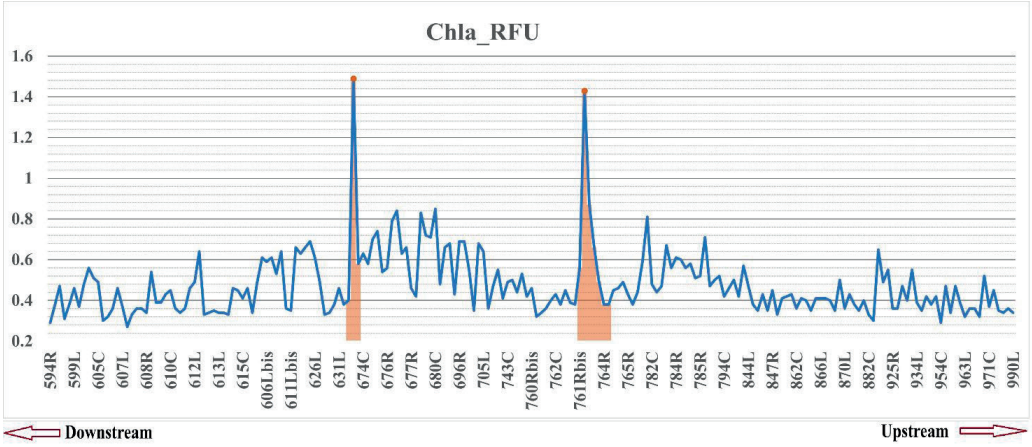

Figure 11. Evolution of the Chlorophyll RFU indicator in the investigated surface water samples

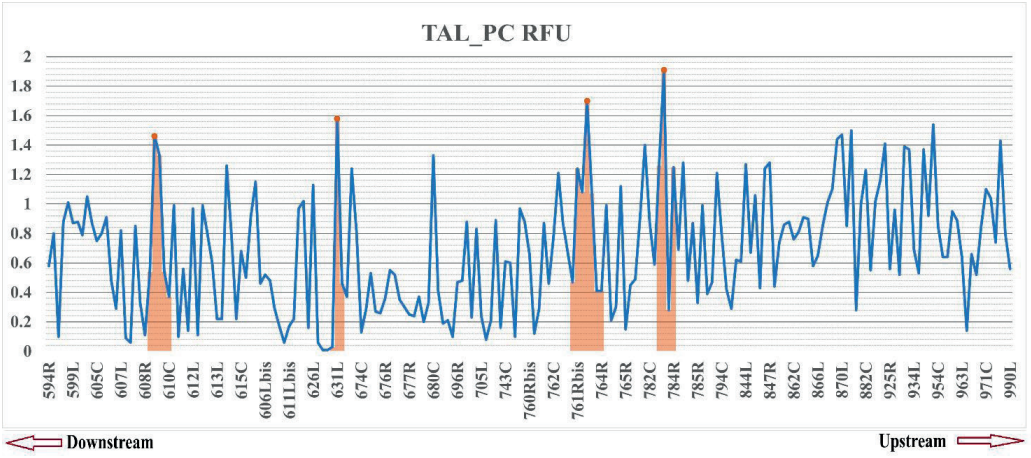

Figure 12. Evolution of the TAL_PC RFU indicator in the investigated surface water samples

Hydrocarbon contamination levels remained relatively low, with oil-in-water concentrations ranging from 0.03 to 1.46 mg/L (mean 0.44 mg/L) and hydrocarbon (HC) concentrations between 0.89 and 48.70 µg/L (mean 14.74 µg/L). The highest hydrocarbon levels were detected at km 675 (right bank) in the Bechet Sector, suggesting possible localized sources of pollution. However, despite these findings, overall concentrations remained below critical thresholds for significant environmental risk, indicating no immediate threat to water quality (Table 2, Figures 13 and 14).

Table 2. Hydrocarbon concentrations of water surface samples

Parameter	Oil in Water (mg/L)	Hydrocarbons (HC) (µg/L)	Custom#3 (mg/L)
Minimum	0.03	0.89	0.41
Maximum	1.46	48.70	48.70
Mean ± SD	0.44 ± 0.17	14.74 ± 5.67	14.27 ± 6.14

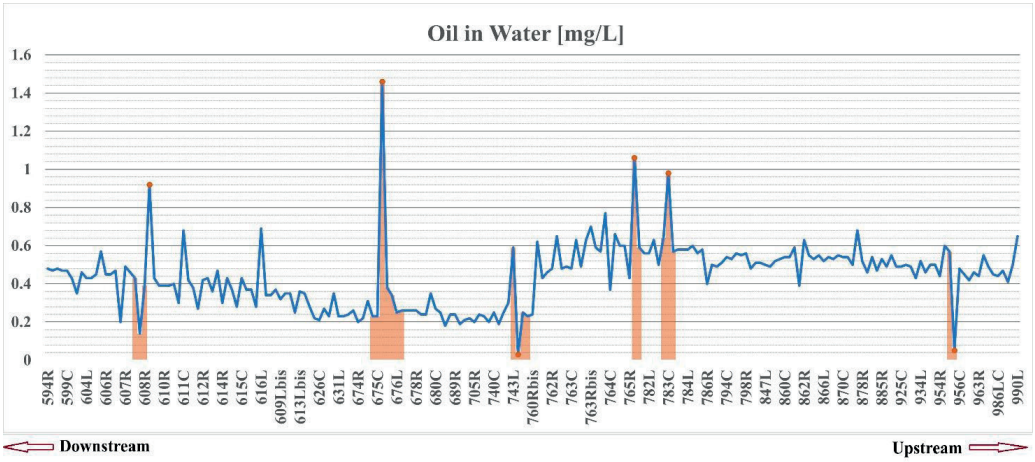

Figure 13. Evolution of the Oil in water (mg/l) indicator in the investigated surface water samples

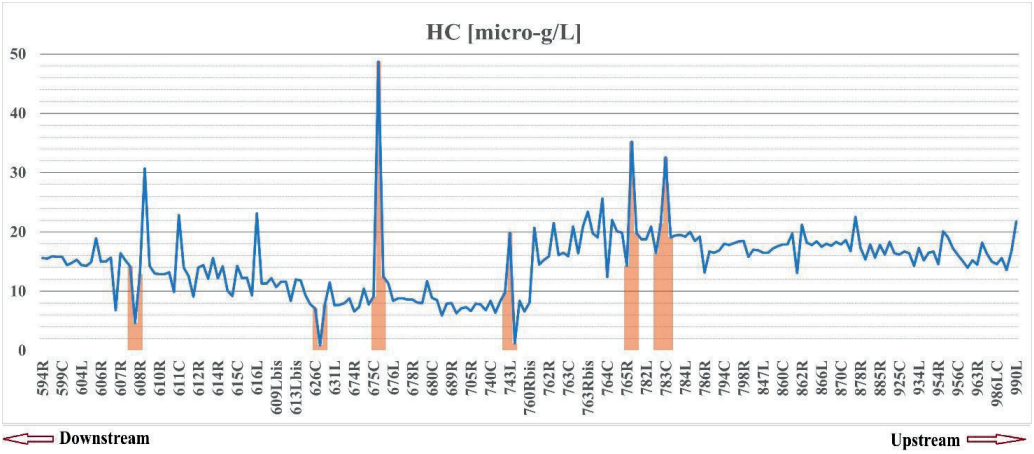

Figure 14. Evolution of the HC (micro-g/l) indicator in the investigated surface water samples

The values of the monitored physicochemical parameters were generally within the limits allowed by environmental standards, reflecting a good state of water quality in the analyzed sectors of the Danube (Pavlović et al., 2016; Calmuc et al., 2018; Radu et al., 2022).

The *water temperature* varied between 15.03°C (km 968, left bank) and 24.40°C (km 631, center), with an overall average of 18.55°C, reflecting natural seasonal influences specific to autumn. These variations can influence biological activity, metabolism of aquatic organisms and solubility of dissolved oxygen in water.

pH values ranging from 7.92 (km 860 center) to 8.36 (km 605 right bank), with an average of 8.10, indicate a slightly alkaline state of the water, characteristic of aquatic systems with high buffer capacity, due to the carbonate-bicarbonate balance present in the Danube River. No significant acidification or alkalization events were identified.

Water turbidity showed significant variations, with values between 2.44 FNU (Km 610, left bank, Calnovăț sector) and 28.75 FNU (km 762 right bank Pisculet-Desa Sector), with an average of 11.02 FNU. Values exceeding the standard limit of 10 NTU (ISO 5667-5:2017) indicate increased local sediment input or intense resuspension processes, especially at km 762 right bank, while low turbidity (km 610 left bank) reflects areas with increased

sedimentation or reduced suspended sediment flux.

TDS concentration values ranged between 207.56 mg/L (km 762 right bank) and 280.80 mg/L (km 740, right bank), with an average of 249.47 mg/L. These values reflect a moderate influence of dissolved salts, indicating good quality water, without significant contamination from upstream.

The *water conductivity* had values between 262.53 µS/cm and 411.56 µS/cm (km 631 center), with an average of 337.56 µS/cm. The higher conductivity in the km 631 - Upstream Corabia/Downstream River Isker, area suggests local influences, possibly geological or anthropogenic, but generally confirms the typical characteristics of freshwaters, with moderate mineralization.

Dissolved oxygen concentration ranged from 7.01 mg/L (km 610 bis left bank) to 9.43 mg/L (km 762 right bank), with an overall average of 8.06 mg/L, above the recommended minimum limit (5 mg/L) for aquatic life support. However, some points with lower values suggest intense biological activity or localized organic matter input.

Oxygen saturation levels ranged from 78.94% to 94.91%, indicating good overall water aeration and the absence of extensive hypoxic conditions. Lower values may indicate point sources of organic pollution or active local microbial processes.

The measured *ORP values* ranged from -26.59 mV (km 674 center) to 238.79 mV (km 763 center), with an average of 122.69 mV. The presence of both positive and negative values suggests complex dynamics of the redox environment, influenced by organic matter decomposition, microbial activity and oxygen availability. The negative values observed in the Bechet sector (km 674 right bank to km 674 left bank) indicate possible local anoxic conditions, related to organic matter decomposition or reducing groundwater inputs.

The *water salinity* remained low (between 0.15 and 0.21 PSU, average 0.18 PSU), confirming the freshwater characteristics of the Danube and indicating the lack of significant influences from seawater or intense evaporative processes.

Nitrate concentrations varied significantly (between 2.67 and 101.82 mg/L), with an average of 12.80 mg/L. Very high values were identified at km 956 (101.82 mg/L), km 925 center (92.56 mg/L) and Km 677, Bechet Sector (80.45 mg/L), indicating possible local sources of contamination (agricultural runoff, urban wastewater). Most of the average values (10-20 mg/L) suggest moderate anthropogenic influences, while low values (4-7 mg/L) indicate areas with low impact.

Chlorophyll values were low (0.27-1.49 RFU, mean 0.48 RFU), reflecting a low phytoplankton biomass and minimal risk of eutrophication. Moderate peaks (km 638, left bank, (Upstream of Isker River) suggest local algal blooms caused by nutrient inputs.

Total Algae Content (TAL-PC RFU). Algal indicators showed significant variations (between 0.01-1.91 RFU, average 0.69 RFU). High values (>1.0 RFU) indicate significant anthropogenic influences in the areas of Calnovăț, Corabia, Bogdan Seclan, Drobeta-Turnu Severin, Orșova and the area of Iron Gate Dam II. Medium values (0.3-1.0 RFU) reflect moderate impacts in other urban and port areas, and low values (<0.3 RFU) suggest clean areas, without notable anthropogenic influences.

Polycyclic aromatic hydrocarbons and total hydrocarbons. The level of hydrocarbons (0.89-48.70 µg/L HC and 0.03-1.46 mg/L Oil in Water) was relatively low, with moderate peaks in the Bechet sector (km 675). Although indicating the presence of local sources of contamination, the values are below the critical thresholds, suggesting the absence of an immediate ecological risk.

Data analysis using the Pearson correlation matrix indicates statistically significant relationships at a significant level of $\alpha = 0.05$, as shown in Table 3 and Figure 15.

Positive correlations:

- Electrical conductivity (Cond µS/cm) and total dissolved solids (TDS mg/L): Strong positive correlation (r=0.943), confirming that TDS directly depends on the ionic concentration of water, reflected by conductivity.
- Hydrocarbons (HC µg/L) and oil concentration in water (Oil in Water mg/L): Very strong positive correlation (r=0.974), suggesting that hydrocarbons contribute significantly to the total oil concentration in water, indicating common sources, possibly local oil pollution.
- Conductivity and Salinity (Sal psu): Significant positive correlation (r=0.911),

indicating a clear link between the total dissolved salt concentration and water conductivity.

- Conductivity and Water Temperature: Positive correlation (r=0.694), which may indicate that temperature variations significantly influence ionic concentrations and implicitly water conductivity.
- Oxygen Saturation (ODO % sat and ODO mg/L): Moderate to high positive correlation (r=0.632), signaling the consistency of these measurements in reflecting the concentration of dissolved oxygen in water.

Negative correlations:

- Temperature and Dissolved Oxygen (ODO mg/L): Strong negative correlation (r=-0.847), indicating that higher temperatures lead to lower concentrations of dissolved oxygen, a common fact in aquatic systems.
- Temperature and Redox Potential (ORP mV): Significant negative correlation (r=-0.517), with higher temperatures being associated with reduced redox conditions, reflecting a change in chemical conditions due to temperature.
- Electrical Conductivity and Dissolved Oxygen (ODO mg/L): Strong negative correlation (r=-0.764), indicating that waters with high conductivity (possibly with inputs of inorganic pollutants or salts) have low dissolved oxygen concentrations.

Based on the Euclidian similarity index (Figure 16), it can be observed that as the total flow rate increases, the percentage of oxygen saturation tends to decrease moderately, while the concentration of dissolved oxygen in mg/L is almost unaffected. In stations km 761 bis right bank and km 762 bis right bank, where a very low flow was recorded, due to their location after the ostrov, in an area with weaker currents and reduced depth, high dissolved oxygen concentrations, low TDS values and lower water temperatures were recorded.

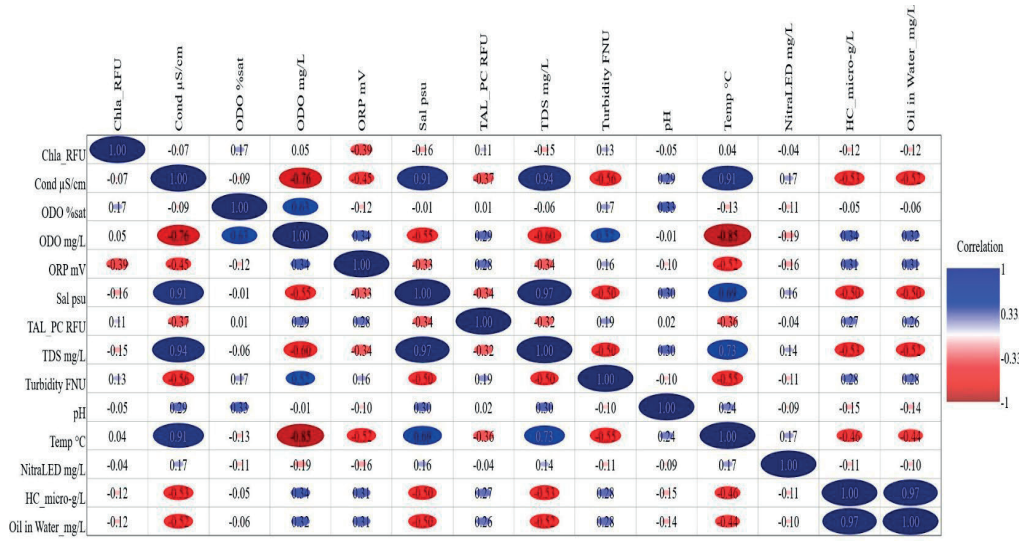

Figure 15. Correlation matrix (Pearson)

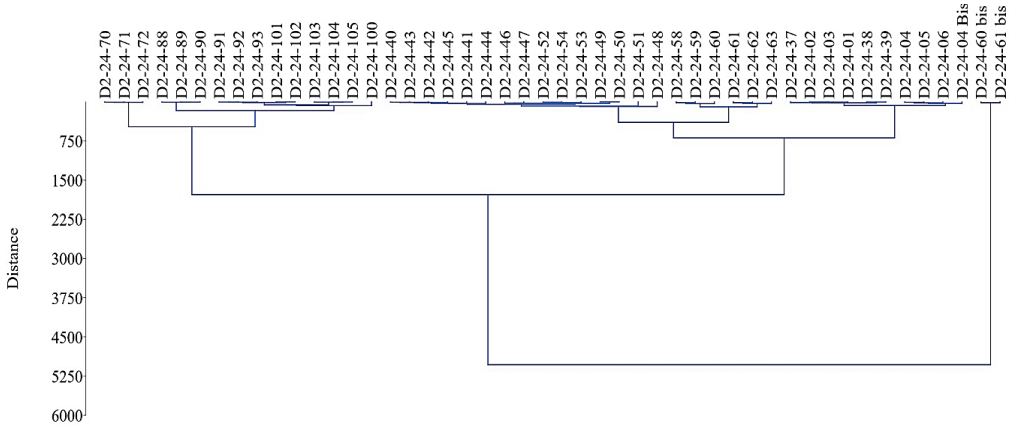

Figure 16. Similarity index based on Euclidian transformed data

Possible causes and ecological implications

Agricultural runoff: high nitrate and turbidity levels suggest significant inputs of fertilizers or animal manure.

Urban/industrial pollution: atypical values of conductivity, TDS and ORP may indicate anthropogenic influences, such as wastewater discharges.

Geological factors: variability of TDS, conductivity and ORP could be influenced by inputs of mineralized groundwater.

The results indicate that the investigated Danube River sectors generally maintain good water quality, parameters that fall within regulatory standards. However, localized variations in turbidity, dissolved oxygen and hydrocarbon levels highlight the importance of continuous monitoring to detect potential environmental stressors and anthropogenic impacts (Chitescu et al., 2021; Halder et al., 2022).

In order to determine the water quality status of the investigated control sections, a series of physicochemical parameters were taken into account (water temperature, pH, dissolved oxygen chlorophyll *a*, electrical conductivity, total dissolved solids, salinity, turbidity and oxidation-reduction potential).

The determination and interpretation of the results obtained was carried out using the methods provided in the reference standards.
In general, no significant increases/decreases were recorded, except for some specific cases, which can be attributed mainly to the local conditions of the fluvial environment.
Overall, the results obtained are within the limits provided for the first quality classes (Very good status and good status).

CONCLUSIONS

Comprehensive analysis of water quality parameters - temperature, pH, turbidity, total dissolved solids (TDS), conductivity, dissolved oxygen (ODO), oxygen saturation, oxidation-reduction potential (ORP), salinity, nitrates, chlorophyll levels, total algal content and hydrocarbons - indicates generally favorable conditions in the investigated areas of the lower Danube, though localized areas of concern have been identified.
These localized problems, such as high nitrate concentrations, increased turbidity, occasional anoxic conditions and high algal fluorescence, highlight critical anthropogenic pressures mainly related to agricultural runoff, urban wastewater discharges, port operations and other local sources. Although current concentrations remain largely below critical ecological thresholds, persistent anthropogenic pressures may compromise water quality and ecosystem stability if not managed.
Therefore, these findings highlight the need for targeted monitoring and mitigation actions, especially around urban centers, the port and agricultural areas, to prevent long-term deterioration of water quality. Ensuring consistent and high-quality water in the Danube basin is vital for supporting biodiversity, preserving ecological balance and supporting the socioeconomic well-being of riparian communities dependent on river resources. These insights highlight the need for proactive environmental management strategies, targeted pollution control and continuous monitoring to protect the health of the Danube ecosystem and its resilience against future anthropogenic pressures.

Abstract

Gorj County is located in the south-west of Romania with a predominantly mountainous relief, and the main economic activities are specific to the exploitation of natural resources, agriculture and tourism. As a result of the lack of sewerage systems in most of the villages in Gorj County and the uncontrolled storage of manure resulting from animal husbandry activities, the groundwater has suffered significant microbiological contamination. This paper describes the investigations carried out to determine the degree of microbiological contamination of groundwater in the northern part of Gorj County, in one of the most attractive tourist localities. The investigations consisted of taking 45 water samples from public and private wells in the villages of Gureni and Frâncești, in the commune of Peștișani. The most important microbiological indicators for determining water quality were determined from samples: the number of bacterial colonies, the number of coliform bacteria, the number of Escherichia coli and the number of intestinal enterococci.

Key words*: Evaluation, groundwater, contamination, microbiologic, bacteria.*

INTRODUCTION

Romania, situated in South-Eastern Europe at the crossroads of Central Europe and the Balkans, covers about 238,397 km², ranking as the 12th largest country in Europe. Its landscape features diverse relief - mountains, hills, and plains - and a rich hydrographic network of rivers, lakes, and groundwater.

Gorj County, in southwestern Romania, is known for its mountainous landscapes and cultural heritage. Traversed by the Southern Carpathians and near Retezat National Park, its capital, Târgu Jiu, hosts the iconic works of sculptor Constantin Brâncuși. Rich in forests and minerals, Gorj is a key energy hub, with an economy driven by industry, agriculture, and tourism.

Peștișani commune, located in Gorj County, is a picturesque locality near the city of Târgu Jiu, which stands out for its mountain landscapes and folk traditions. The commune is known for its agricultural activities and local crafts, and among the attractions are the old churches and specific customs, which reflect the culture of the area. The commune of Peștișani is associated with the life and activity of the artist Constantin Brâncuși, having links with the cultural heritage of the county and offering opportunities for rural tourism and nature exploration. The villages that make up the commune of Peştişani are: Boroşteni, Brădiceni, Frâncești, Gureni, Hobiţa, Peştişani and Seuca (Puianu, 2019)

The main source of water in Peștișani commune is groundwater from public and private wells, because not all the inhabitants of the commune have access to the public drinking water network. Given the characteristics of groundwater, it is a very convenient source of drinking water, provided that the reserves are large enough and the quality indicators regulated by the legislation in force are respected. Groundwater composition can be significantly altered by human activities such as improper fertilizer use, household waste disposal, and the infiltration of wastewater or fuels (Begea et al., 2024)

Due to the multiple possibilities of pollution of water sources, it is necessary to establish the sanitary conditions that drinking water must meet. The drinking conditions of the water are the organoleptic characteristics (taste, smell, color), as well as the physical, chemical and biological indicators within the maximum allowed limits and the normal values provided in the national and international legislation in force. The relationship of water with infectious diseases has led to the development of bacteriological

conditions for drinking water. The first bacterial conditions appeared in 1904 and are due to Christiaan Eijkman, being perfected later.

The drinking conditions of the water are divided into four groups:

- organoleptic (taste, smell, coloured);
- (temperature, pH, turbidity, conductivity, radioactivity);
- chemical (fluorine, heavy metals, nitrites, nitrates, ammonia nitrogen);
- microbiological (mesophilic germs, coliform germs, enterococci) (Masciopinto et al., 2021; Cirtină & Căpățână 2017).

The most important bacteriological condition of potability is the total lack of pathogenic germs in the water:

- **Mesophilic germs** bacteria that grow at 37°C, typically originating from humans and warm-blooded animals; higher counts indicate a greater presence of potentially pathogenic microorganisms.
- **Coliform germs** (relatively heterogeneous group, found in large numbers in the feces of humans and warm-blooded animals)
- **Enteric virus** (germs that are found in feces, but in smaller numbers than coliforms, which makes them more difficult to determine; they are more resistant in water than fecal coliforms and do not suffer from the phenomenon of microbial variability; they have types characteristic for humans and animals, which allows differentiation of the type of water pollution) (Cheong et al., 2009)

The presence and intensity of fecal pollution is an important factor in assessing water quality and the infectious risk posed to human health. Examination of water samples for the presence of *Escherichia coli*, which normally populates the intestines of humans and other warm-blooded animals, provides an indication of water pollution (Kampouris et al., 2022).

Analyzing the latest statistical information provided by the National Institute of Statistics in 2022, the population connected to the public water supply system was 14,277,262 people, representing 74.9% of Romania's resident population. At the level of the development regions, the lowest degree of connection to the public water supply system was recorded in the North-East region (50.7%), followed by the South-West Oltenia region (63.4%), a region to which Gorj county, the area taken in the study belongs (Figure 1).

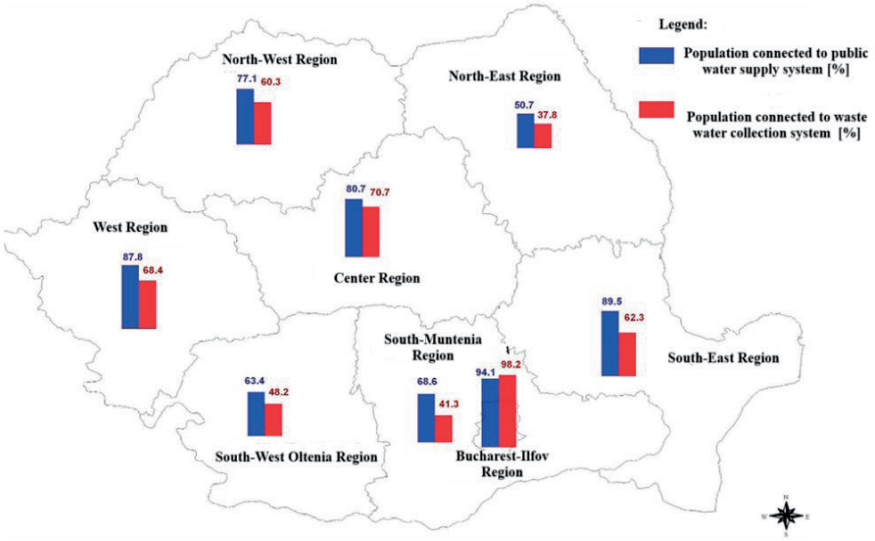

Figure 1. Romania's population connected to the public drinking water supply and sanitation system, by development regions, in 2022 (National Institute of Statistics of Romania, 2022)

Regarding wastewater treatment, 11,062,432 people - 58.1% of Romania's resident population - were connected to sewerage systems with treatment plants. The lowest

connection rates were in the North-East (37.8%), South-Muntenia (41.3%), and South-West Oltenia (48.2%) regions.

MATERIALS AND METHODS

To assess groundwater microbiological contamination in Gorj County, a case study was conducted in the Gureni and Frâncești villages of Peștișani commune.

A total of 45 water samples were collected from public and private wells - 19 from Gureni village and 26 from Frâncești village - as shown in Figure 2.

Figure 2. Distribution of the sampling points of the 45 water samples in the area of Gureni and Frâncești villages

The microbiological quality indicators determined from the collected groundwater samples, as well as the methods of analysis were:

- *The number of colonies at 22^{0}C*, by counting the cultures formed in a nutrient agar culture medium, after incubation in aerobiosis at a temperature of 22^{0}C, in accordance with the international technical provisions referred to in SR EN ISO 6222:2004.
- *Number of colonies at 37^{0}C*, by counting cultures formed in a nutrient agar culture medium, after incubation in aerobiosis at a temperature of 37 ^{0}C, in accordance with the international technical provisions referred to in SR EN ISO 6222:2004.
- *Coliform bacteria*, by filtering the analysis water sample through the membrane, followed by chromogenic agar culture and counting the coliform bacteria in the sample, in accordance with the international technical provisions mentioned in SR EN ISO 9308:2015.
- *Escherichia coli,* by filtering the analysis water sample through the membrane, followed by chromogenic agar culture and counting the coliform bacteria in the sample, in accordance with the international technical provisions referred to in SR EN ISO 9308:2015.
- *Intestinal enterococci,* by filtering the analysis water sample through the membrane, followed by chromogenic agar culture and counting the coliform bacteria in the sample, in accordance with the international technical provisions mentioned in SR EN ISO 9308:2015.

The permissible limits for microbiological indicators in groundwater taken from wells are regulated by Ordinance no. 7/2023 on the quality of water intended for human consumption, which transposes Directive (EU) 2020/2.184 of the European Parliament and of the Council of 16 December 2020 on the quality of water intended for human consumption, published in the Official Journal of the European Union, series L, no. 435 of 23 December 2020 and which provides that for the indicators: number of colonies at 22 ^{0}C, Number of colonies at 37^{0}C, coliform bacteria, *Escherichia coli* and intestinal *Enterococci,* the permissible value is 0 Cfu/ml.

Thus, for the evaluation of the level of microbiological pollution, the values obtained

were compared with the allowed value 0 Cfu/ml and graphically represented. (Popa et al., 2022)

RESULTS AND DISCUSSIONS

The evolution of colony counts at 22°C for water samples from Gureni and Frâncești villages is presented in Figures 3 and 4.

According to Figure 3, 17 out of 19 water samples from Gureni village exceeded the permitted limit, representing 89.47%. Similarly, Figure 4 shows that 19 out of 26 samples from Frâncești village were above the allowed limit, accounting for 73.07% (Șchiopu, 2023). The evolution of colony counts at 37°C for samples from both villages is shown in Figures 5 and 6.

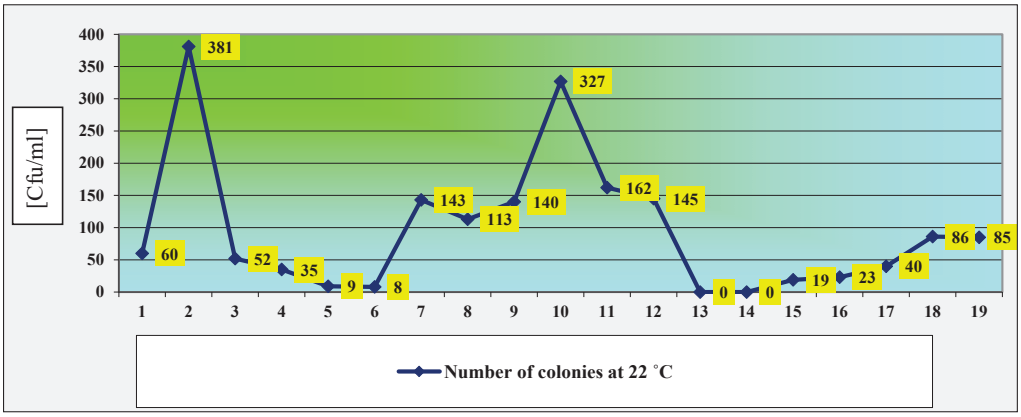

Figure 3. Number of colonies at 22^{0}C from groundwater samples taken on 22.02.2023 from Gureni village, Gorj county, South-West region Romania

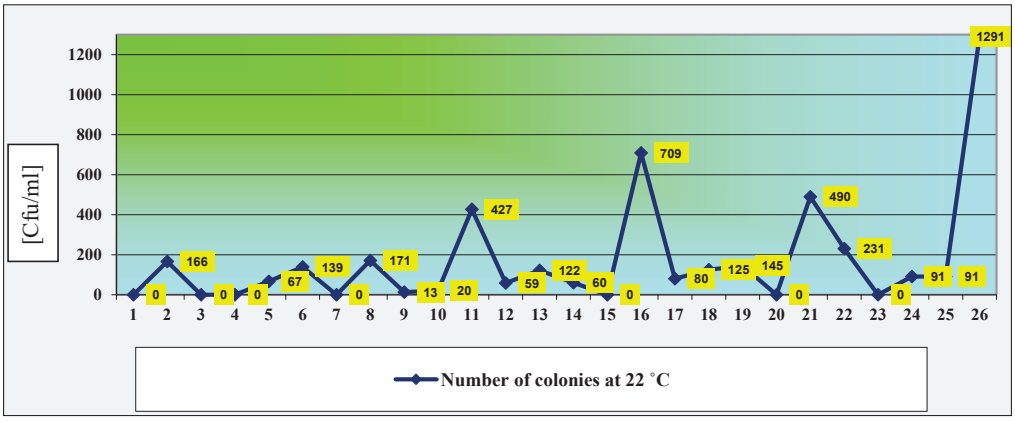

Figure 4. Number of colonies at 22^{0}C from groundwater samples taken on 22.02.2023 from Frâncești village, Gorj County, South-West region Romania

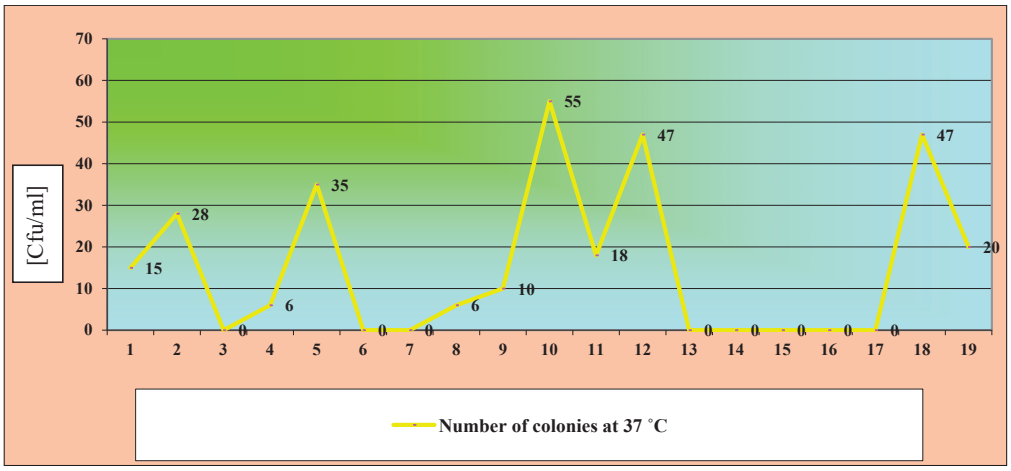

Figure 5. Number of colonies at 37^{0}C in groundwater samples taken on 22.02.2023 from Gureni village, Gorj County, South-West region Romania

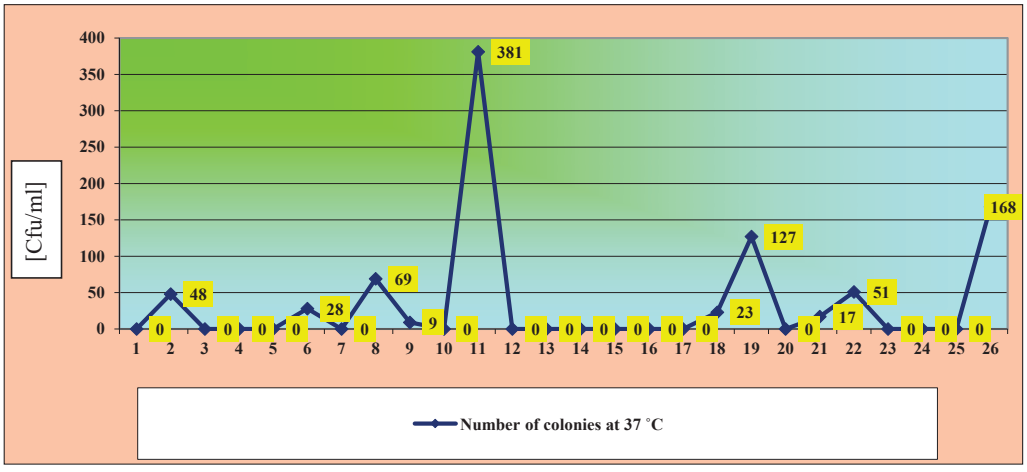

Figure 6. Number of colonies at 37^{0}C from groundwater samples taken on 22.02.2023 from Frâncești village, Gorj County, South-West region Romania

Figure 5 shows that 11 of the 19 water samples from Gureni village exceeded the maximum limit, representing 57.89%. In Figures 6-10 of the 26 samples from Frâncești village also surpassed the limit, accounting for 38.46%. The evolution of coliform bacteria in samples from Gureni and Frâncești villages is illustrated in Figures 7 and 8, respectively.

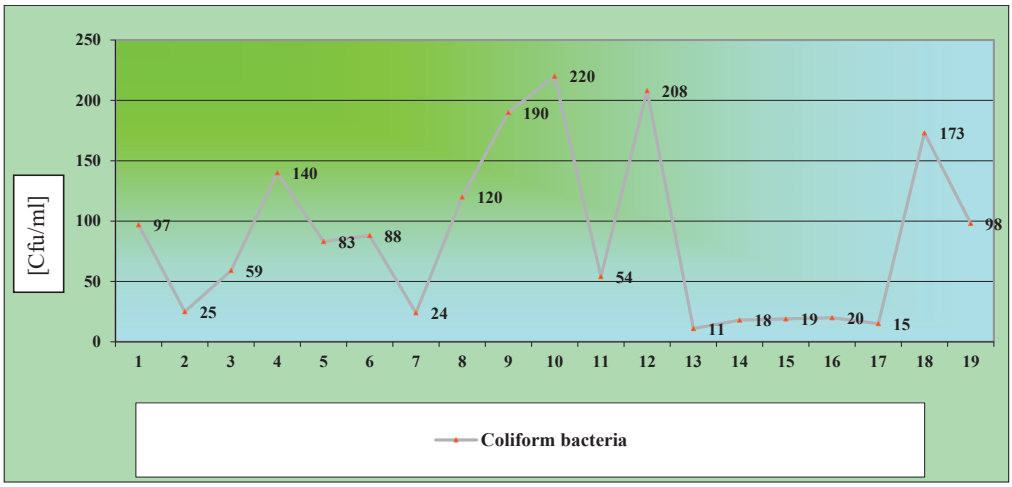

Figure 7. Concentration of coliform bacteria in groundwater samples taken on 22.02.2023 from Gureni village, Gorj County, South-West region Romania

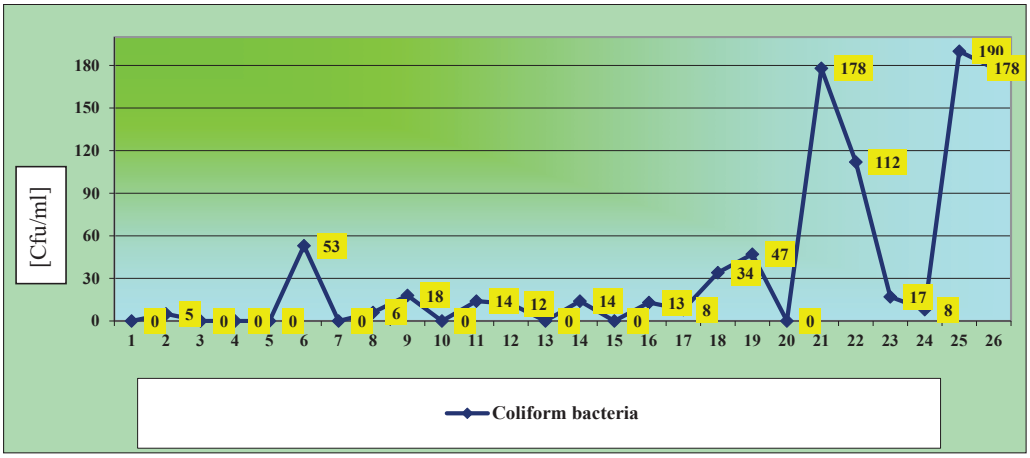

Figure 8. Concentration of coliform bacteria in groundwater samples taken on 22.02.2023 from Gureni village, Gorj County, South-West region Romania

As shown in Figure 7, all water samples from Gureni village exceeded the maximum limit for coliform bacteria, representing 100%. Figure 8 indicates that 17 of the 26 samples from Frâncești village also surpassed the limit, accounting for 65.38%. Figures 9 and 10 present the evolution of *Escherichia coli* levels in water samples from Gureni and Frâncești villages, respectively.

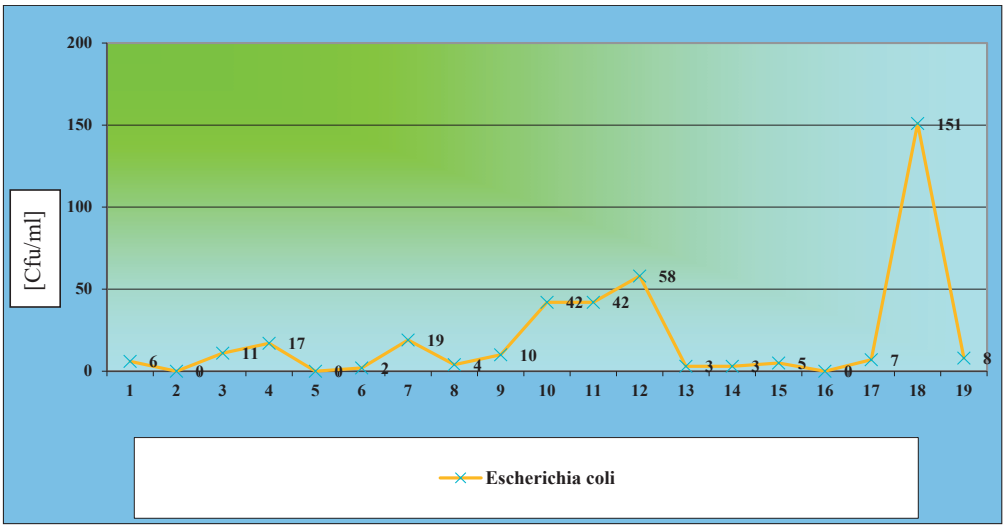

Figure 9. The number of *Escherichia coli* in groundwater samples taken on 22.02.2023 from Gureni village, Gorj County, South-West region Romania

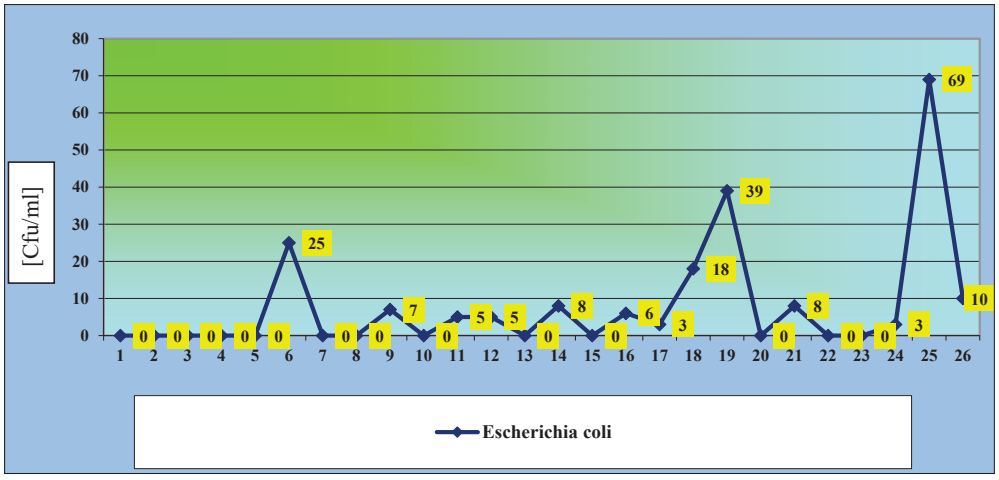

Figure 10. The number of *Escherichia coli* in groundwater samples taken on 22.02.2023 from Frâncești village, Gorj County, South-West region Romania

Figure 9 shows that 16 of the 19 water samples from Gureni village exceeded the maximum limit for *Escherichia coli*, representing 84.21%. According to Figure 10, 13 of the 26 samples from Frâncești village also exceeded the limit, accounting for 50%.

Figures 11 and 12 illustrate the evolution of intestinal Enterococci levels in water samples from Gureni and Frâncești villages, respectively.

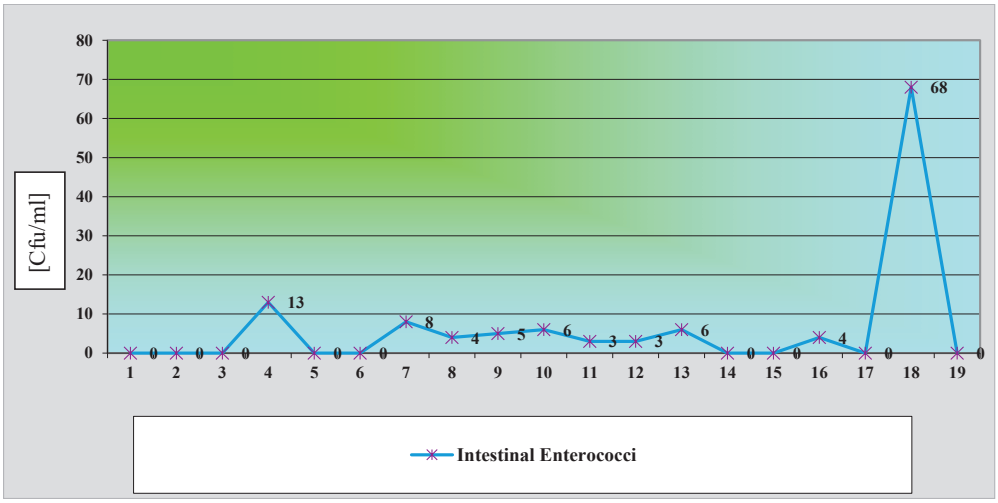

Figure 11. The number of intestinal *Enterococci* in groundwater samples taken on 22.02.2023 from Gureni village, Gorj County, South-West region Romania

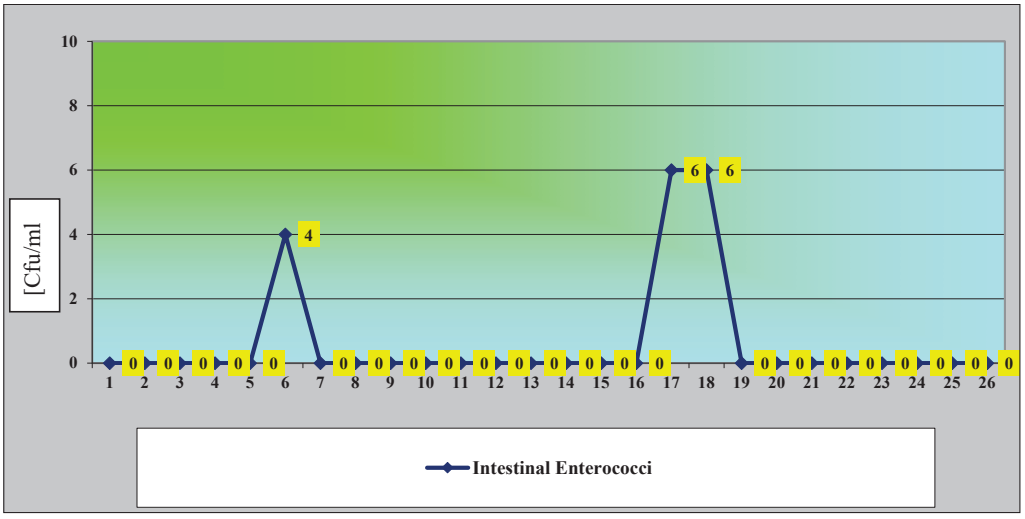

Figure 12. The number of intestinal *Enterococci* in groundwater samples taken on 22.02.2023 from Gureni village, Gorj County, South-West region Romania

Figure 11 shows that 10 of the 19 water samples from Gureni village exceeded the maximum limit for intestinal Enterococci, representing 52.63%. In Figure 12, only 3 of the 26 samples from Frâncești exceeded the limit, accounting for 11.53%.

Overall, analysis of all microbiological indicators confirmed that all 19 samples from public and private wells in Gureni exceeded at least one microbiological parameter, rendering them unfit for human consumption. Specifically, 7 samples exceeded the limit for all five indicators, 3 samples for four indicators, 8 for three indicators, and 1 sample for two indicators. The primary cause of contamination is the proximity of animal shelters and manure storage areas to the wells.

The sample with exceedances for only two of the five indicators came from a public well located at a relatively greater distance from known pollution sources. In Frâncești village, 6 of the 26 analyzed wells (codes: 1, 3, 4, 7, 15, and 20)

were free of exceedances for all five microbiological indicators and are considered safe for drinking. These samples were collected from public wells near roads or institutions (e.g., schools, cultural centers, and stores) where no animal waste was stored and septic tanks are regularly emptied.

Among the remaining 20 samples, 3 exceeded all five indicators, 5 exceeded four, 8 exceeded three, and 4 exceeded only one. The primary cause of microbiological contamination in both villages is the absence of a sewerage system and the uncontrolled storage of animal manure.

For consumption, contaminated water from wells must be applied by one of the following methods:

1. Treatment with chlorine solution, going through the steps mentioned in Order 119/2014 for the approval of Rules of hygiene and public health regarding the living environment of the population, applicable on the territory of Romania, namely:

Calculating the volume of water in the well:

$$V = 3.14r\ x\ rH$$

where:

V = volume of water (m^3);

r = 1/2 of the diameter of the well (m);

H = the height of the water column in the well (m);

Choosing a substance with a chlorine concentration of 15 – 25%;

Calculation of the quantity of chlorine substance according to the concentration of free residual chlorine to be obtained, according to the following example:

0.5 mg Residual Cl ..... 1 l water

X mg Residual Cl ..... 1,000 l water

X = 0.5 g residual chlorine/m^3 water

100 g chlorine ..... 25 g active chlorine

X ..... 0.5 g active chlorine

X = 2 g chlorine/m^3 water

For a water column height of 7 m and a well tube diameter of 1 m, the volume of water is determined as follows:

$$V = 3.14 \cdot 0.5\ x\ 0.5 \cdot 7$$

$$V = 11.02\ m^3 \text{ water}$$

The amount of chlorine required to disinfect the volume of water is calculated as follows:

2 g chlorine/m^3 water x 11.02 m^3 = 22.04 g chlorine of concentration 25%

2. Boil water before consumption for at least 1-3 minutes, to destroy pathogenic microorganisms.

CONCLUSIONS

Human activities, such as: uncontrolled and improper use of fertilizers, disposal of household waste, infiltration of wastewater or fuels, carried out in the South-West area of Romania, Gorj County, Peștișani commune are sources of groundwater pollution, and it is necessary to establish the sanitary conditions that must meet the drinking water.

The bacteriological condition of potability of the water in the wells is the total absence of pathogenic germs (mesophils, coliforms and enterococci). In this regard, this study provided for the collection of groundwater samples and microbiological analysis, according to international standards, of five microbiological indicators of drinking water quality (Number of colonies at 22^0C, Number of colonies at 37^0C, coliform bacteria, *Escherichia coli* and intestinal *Enterococci).*

Following the analysis of the 45 water samples collected from public and private wells and the comparison of the results obtained with the admitted value 0 Cf/ml, it was shown that for most of them there were exceedances of the analyzed microbiological indicators, the main cause being the lack of a centralized sewerage system and the uncontrolled storage of animal manure.

It is recommended that drinking water extracted from wells be treated with chlorine solution or boiled.

Abstract

This study assesses the ecological state of the surface water of the Mechka River from the Maritsa River Basin usingthe biological quality element macrozoobenthos. Four sampling sites (biotopes) were investigated in autumn 2024 along the Mechka River - 1) near the village of Lenovo; 2) near the village of Poroyna; 3) between the town of Parvomay and the village of Poroyna and 4) before the town of Parvomay. A total of 772 specimens of macrozoobenthos from 36 taxa were identified. The highest number of macroinvertebrate taxa was identified in the second biotope (21 taxa) and the lowest - in the first (14 taxa). The study shows that in three of the four biotopes, macroinvertebrates of Group C (relatively tolerant forms) dominate, whereas in Biotope 3) Mechka River between the town of Parvomay and the village of Poroyna, Group D (tolerant forms) dominates. Basic indices and metrics were calculated according to an established methodology.

Key words*: biological monitoring, ecological status, macrozoobenthos, Mechka River, water quality.*

INTRODUCTION

The Maritsa River originates in the Rila Mountains, Mancho Peak, at 2,378 m above sea level. The river's catchment area on Bulgarian territory is 21,084 km^2. The Maritsa River flows into the Aegean Sea. The catchment area of the Maritsa River falls into Ecoregion 7: Eastern Balkans. It includes numerous tributaries, the largest of which are the Topolnitsa River, the Luda Yana River, the Stryama River, the Sazliyka River, the Tundzha River, the Arda River and others (Belkinova et al., 2013; Kiradzhiev, 2013).

The Mechka River (43 km) is a right tributary of the Maritsa River. The river originates in the Western Rhodopes, entering the Upper Thracian Lowland in the village of Poroyna and flowing into the Maritsa River near the town of Parvomay. The river's waters are used for irrigation (Kiradzhiev, 2013). A significant part of the country's territory is occupied by agricultural lands, of which approximately 30% is irrigated (Metodieva et al., 2024; Kilifarska et al., 2025).

According to the typology of rivers in Bulgaria, the Mechka River is of type R5 "Semi-mountainous rivers" (East Aegean River Basin Directorate, 2018). The largest tributary of the river is the Chinardere River (left tributary; 31 km) (Kiradzhiev, 2013).

According to the Water Framework Directive (Directive 2000/60/EU), in the assessment of the state of surface water, biological elements (listed in Annex V) play a leading role, while physicochemical and hydromorphological elements have a complementary role.

Studies concerning the assessment of the ecological state of the water of the Maritsa River have been conducted by Vidinova et al. (2008), Park et al. (2022a), Varadinova et al. (2022). At present, no studies have been established on the ecological state of the water of the Mechka River based on the biological quality element macrozoobenthos. Park et al. (2022b) and Park et al. (2023) provide data on the taxonomic composition and structure of the macrozoobenthos from the Maritsa River. Georgiev (2012) studied the freshwater malacofauna of rivers from the Upper Thracian Lowland, including the Mechka River.

The present study aims to assess the ecological state of the surface water of the Mechka River from the Maritsa River basin based on the

biological quality element (BQE) macrozoobenthos.

MATERIALS AND METHODS

Macrozoobenthos sampling was carried out in the autumn of 2024 from four locations (biotopes) along the Mechka River - 1) near the village of Lenovo (41°57'05.7"N 25°05'48.1"E); 2) near the village of Poroyna (42°02'19.9"N 25°08'42.8"E); 3) between the town of Parvomay and the village of Poroyna (42°03'11.7"N 25°09'08.3"E) and 4) before the town of Parvomay, Debar district (42°04'27.7"N 25°11'49.1"E) (Figure 1).

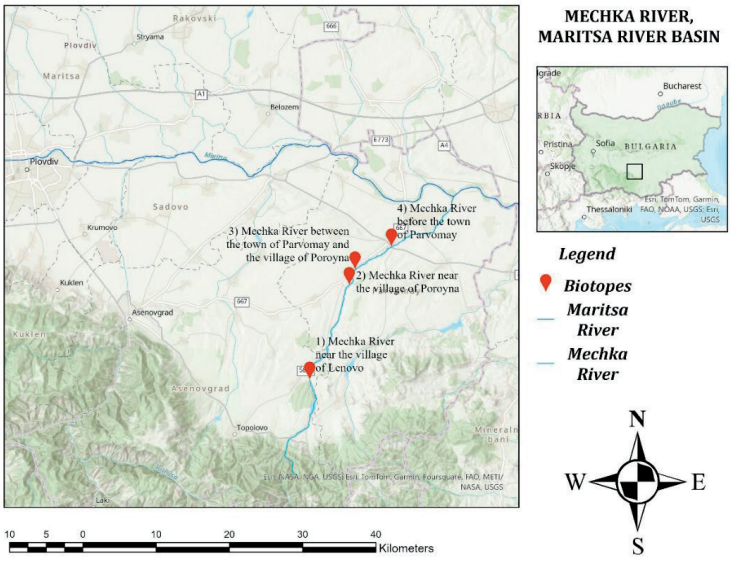

Figure 1. Map of the studied biotopes of the Mechka River

Biotope 1 is located along the Mechka River, northwest of the village of Lenovo (300 m above sea level), downstream of the Mechka Dam. The current is moderate to fast. Biotope 2 is located along the Mechka River, west of the village of Poroyna (215 m above sea level), upstream of the confluence with the Chinardere River. The current is moderate to fast. Biotope 3 is located along the Mechka River, between the village of Poroyna and the town of Parvomay (202 m above sea level), downstream of the confluence of the Chinardere River. The current is slow. Biotope 4 is located along the Mechka River, west of the Debar district, in the town of Parvomay (185 m above sea level). The current is moderate to fast. The river bed in all studied biotopes is sandy and rocky (Figure 2).

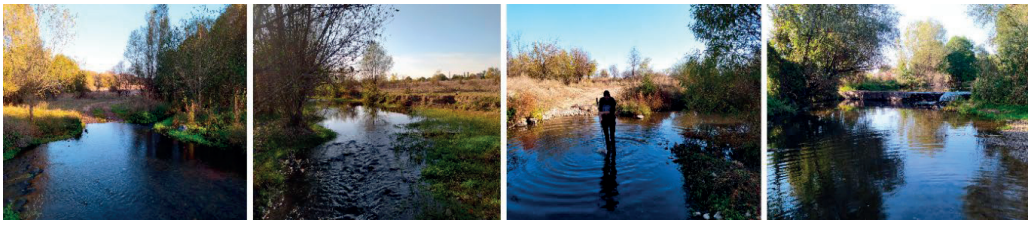

Figure 2. Views of the studied biotopes from the Mechka River (from left to right: 1) near the village of Lenovo; 2) near the village of Poroyna; 3) between the town of Parvomay and the village of Poroyna and 4) before the town of Parvomay)

Macrozoobenthos samples were collected in accordance with European and national water legislation and established methodologies (Cheshmedjiev et al., 2011; EN ISO 10870:2012; EN 16150:2012; Regulation No. H-4 of 14.09.2012; Belkinova et al., 2013). The taxonomic composition and abundance of macrozoobenthos from all biotopes were determined.

The ecological state of the Mechka River was assessed based on the following metrics: total number of taxa; number of Ephemeroptera, Plecoptera and Trichoptera (EPT) taxa; metrics for abundance of benthic macroinvertebrate fauna; Margalef species richness index (Dmg); Shannon-Weaver species diversity index (H'); Pielou's evenness index (E); Simpson's dominance index (C); saprobic index (SPUB); trophic index (RETI) and biotic index (BI) according to Flanagan & Toner (1972), modified by Clabby & Bowman (1979), Clabby (1982) (Belkinova et al., 2013).

RESULTS AND DISCUSSIONS

In this study, 772 specimens of macrozoobenthos belonging to 36 taxa and 15 orders (Allogastropoda, Amphipoda, Arhynchobdellida, Coleoptera, Diptera, Ephemeroptera, Hemiptera, Hygrophila, Isopoda, Odonata, Plecoptera, Sphaeriida, Trichoptera, Tricladida, Tubificida) were identified.

In the study of the macroinvertebrate fauna from the four biotopes along the Mechka River, the largest number of taxa was found in Biotope 2 (21 taxa) and the smallest – in Biotope 1 (14 taxa). The highest number of specimens was recordedin Biotope 3 (273 specimens) and the lowest – in Biotope 4 (Figure 3).

In the four biotopes, different macroinvertebrate taxa dominated: *Simulium* sp., larva (221 specimens; order Diptera) in Biotope 1; *Baetis* sp., nymph (64 specimens; order Ephemeroptera) in Biotope 2; *Asellus* (*Asellus*) *aquaticus* (Linnaeus, 1758) (128 specimens; order Isopoda) in Biotope 3; *Gammarus pulex* (Linnaeus, 1758) (11 specimens; order Amphipoda) in Biotope 4.

Only in Biotope 2 is the ecological state of the river according to the metric "total number of taxa" assessed as very good. In contrast, it is assessed as good in the other three biotopes.

Georgiev (2012) studied the freshwater malacofauna of the Mechka River (at the bridge of Parvomay town) and reported the species *Planorbis planorbis* (Linnaeus 1758) and *Anodonta cygnaea* (Linnaeus 1758). These two species were not found in any of the studied biotopes in the present study.

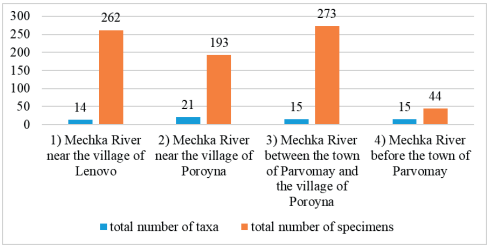

Figure 3. Taxonomic composition and abundance of macrozoobenthos in the studied biotopes

The highest number of EPT taxa was found in Biotope 2 (6 taxa with 105 specimens), followed by Biotope 1 (5 taxa with 20 specimens). An equal number of EPT taxa were found in biotope 3 (4 taxa with 53 specimens) and Biotope 4 (4 taxa with eight specimens) (Figure 4). Taxa from the orders Ephemeroptera, Plecoptera and Trichoptera are known to be sensitive to pollution. Therefore, their higher abundance in the Mechka River, Biotope 2, indicates a better ecological state of the water in this section. According to this metric, the Mechka River's ecological state ranges from good in Biotope 2 to moderate in the remaining three biotopes.

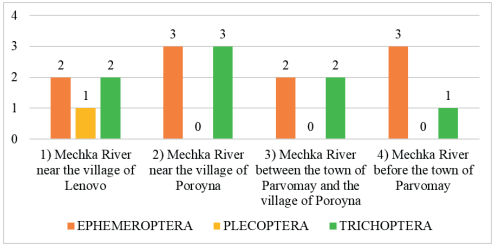

Figure 4. Number of EPT taxa in the studied biotopes

The obtained values for the Margalef species richness index (Dmg) indicate conditions that are suboptimal in all biotopes. The Shannon-Weaver species diversity index (H') indicates

better conditions in Biotopes 2 and 4 (β-mesosaprobic) compared to Biotope 1 (p-saprobic conditions) and Biotope 3 (α-mesosaprobic conditions). The Pielou's evenness index (E) and Simpson dominance index (C) indicate the most favourable conditions in Biotopes 2 and 4 and the most unfavourable in Biotope 1 (Table 1).

The highest percentage of Oligochaeta and Diptera, as well as the highest percentage of filtering feeders in total abundance was found for Biotope 1, where the percentage of EPT taxa was also the lowest. In Biotope 1, two Diptera taxa (*Simulium* sp., larva and *Chironomus plumosus* (Linnaeus, 1758), larva) represented by 234 specimens, and two filtering feeders taxa (*Simulium* sp., larva and *Pisidium* sp.) represented by 222 specimens were identified. The highest percentage of EPT taxa was recorded in Biotope 2 (Table 2).

Table 1. Species diversity indices

	Species richness index of Margalef (Dmg)	**Shannon-Weaver species diversity index (H')**	**Pielou's evenness index (E)**	**Simpson's dominance index (C)**
1) Mechka River near the village of Lenovo	2.33	0.763	0.289	0.716
2) Mechka River near the village of Poroyna	3.8	2.17	0.714	0.174
3) Mechka River between the town of Parvomay and the village of Poroyna	2.5	1.8	0.665	0.266
4) Mechka River before the town of Parvomay	3.46	2.34	0.888	0.124

Table 2. Abundance of macroinvertebrate fauna from the studied biotopes of the Mechka River

	% (Oligochaeta & Diptera)	**% Filtering feeders**	**% EPT taxa**
1) Mechka River near the village of Lenovo	89.31 %	84.73 %	7.63 %
2) Mechka River near the village of Poroyna	23.32 %	18.65 %	54.40 %
3) Mechka River between the town of Parvomay and the village of Poroyna	9.52 %	1.1 %	19.41 %
4) Mechka River before the town of Parvomay	15.91 %	4.55 %	18.18 %

To assess the ecological state of the Mechka River, the German trophic index RETI was calculated, which reflects varying levels of trophic impact across the studied sites. The index has the lowest value in biotope 1 ($RETI_{Biotope1}$ = 0.08), indicating a significant imbalance in the river ecosystem at this site. According to this index, the ecological state of the Mechka River varies from very bad in Biotope 1 to very good in Biotope 3 ($RETI_{Biotope3}$ = 0.8). The ecological state is good in the remaining two studied biotopes ($RETI_{Biotope2}$ = 0.74; $RETI_{Biotope4}$ = 0.59).

In Biotope 1, macrozoobenthos typical of 0-β-mesosaprobic conditions predominate (4 taxa). In Biotope 2, taxa indicative of β-mesosaprobic conditions predominate (4 taxa). In Biotopes 3 and 4, macroinvertebrates characteristic for β to β-α-mesosaprobic (3 taxa each) and 0-β to β-mesosaprobic conditions (3 taxa each), respectively, dominate (Figure 5).

The saprobic index (SPUB) was calculated based on the bioindicator potential of the macrozoobenthos from each biotope. A moderate ecological state was established in Biotope 3 ($SPUB_{Biotope3}$ = 2.43); good in Biotope 4 ($SPUB_{Biotope4}$ = 2.09) and very good ecological state in the remaining two biotopes ($SPUB_{Biotope1}$ = 1.68; $SPUB_{Biotope2}$ = 1.9).

The macroinvertebrate organisms found in this study belong to four groups of sensitivity: Group B (less sensitive forms), Group C (relatively tolerant forms), Group D (tolerant forms) and Group E (the most tolerant forms).

In three of the studied biotopes, the highest number of taxa and specimens belong to Group C. Only in Biotope 3 did the highest number of taxa belong to Group C, while the highest number of specimens belonged to Group D (Figure 6).

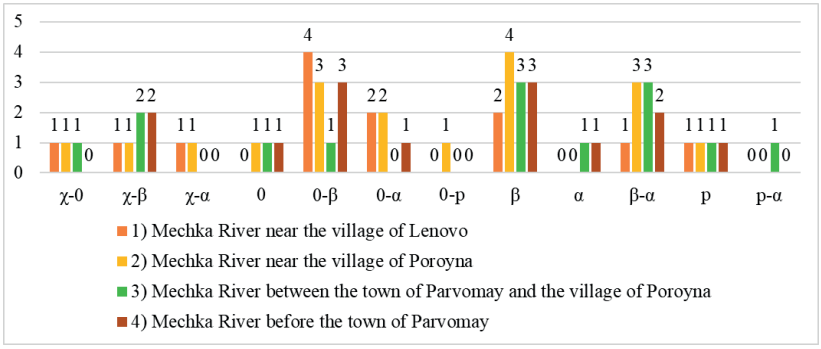

Figure 5. Distribution of macroinvertebrate taxa from the studied biotopes of the Mechka River by saprobity groups

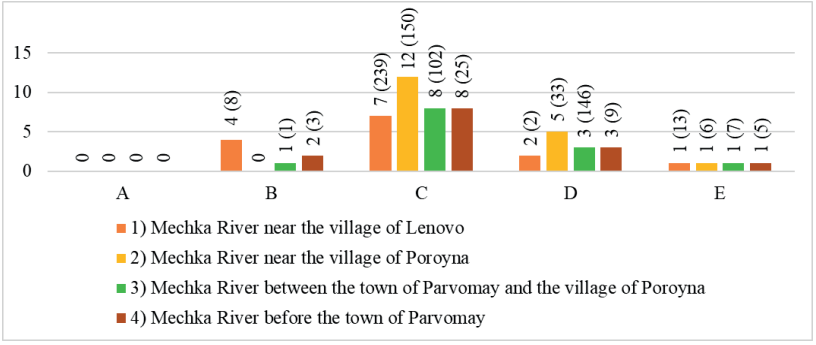

Figure 6. Distribution of macroinvertebrate taxa from the studied biotopes of the Mechka River by sensitivity groups

To determine the ecological state of the river, the biotic index (BI) was calculated, indicating a moderate ecological state in Biotopes 1 and 2 (BI (nEQR) = 2.5 (0.5)) and a bad ecological state in Biotopes 3 and 4 (BI (nEQR) = 2 (0.4)). During the period of this study, according to data from the East Aegean River Basin Directorate (2018) on deviations in the quality of surface water of the Mechka River, an exceedance of total nitrogen (2.5 mg/l at environmental quality standards (EQSs) set at 1.5 mg/l) was recorded on 12.11.2024 in the area of the town of Parvomay, Lyubenovo district. From September to November 2024, no other excesses of basic physicochemical elements and specific substances were established in the water of the Mechka River. According to the 2023 Report on the State of Water in the East Aegean Region, the ecological state of the upper section of the Mechka River (up to the confluence of Chinardere River), based on biological quality elements (BQEs), is unknown, while the ecological status of the lower reaches and tributary sections is assessed as moderate (East Aegean River Basin Directorate, 2018).

CONCLUSIONS

In the present study, 772 specimens of macrozoobenthos belonging to 36 taxa were identified. The highest number of taxa was identified in Biotope 2 near the village of Poroyna (21 taxa), and the lowest in Biotope 1) near the village of Lenovo (14 taxa). Based on the calculated metrics, the ecological state of the Mechka River is assessed as very bad in Biotope 1) near the village of Lenovo; bad in Biotopes 3 (between the town of Parvomay and the village of Poroyna), and 4 (before the town

of Parvomay, Debar district); and moderate in Biotope 2 near the village of Poroyna.

These findings indicate varying levels of ecological degradation along the river, with Biotope 1 showing the most critical conditions. We recommend that Biotope 1 be prioritized for inclusion in long-term monitoring programs to support targeted river management and conservation efforts.

Abstract

The study aims to conduct hydrobiological monitoring of the Kayaliika River (Maritsa River watershed) based on the biological quality element macrozoobenthos. The monitoring was performed following methodologies approved by the European Union and Bulgaria. Macrozoobenthos samples were collected in the autumn of 2024 from four locations (biotopes) along the Kayaliika River near the village of Ezerovo, Bodrovo, Varbitsa and Skobelevo. The number and taxonomic composition of the macrozoobenthos were determined, with the highest number of taxa found in the Kayaliika River biotope near the village of Skobelevo – 28 taxa, and the lowest – in the Kayaliika River biotope near the village of Varbitsa – 12 taxa. Basic indices for species diversity and abundance were calculated. The number of macrozoobenthos taxa by saprobity groups and sensitivity groups from the four biotopes of the studied river ecosystem was presented and compared. The results provide valuable insights into the ecological status of the Kayaliika River and contribute to regional water quality assessments.

Key words*: biological quality elements (BQE), ecological assessment, Kayaliika River, macrozoobenthos, water quality.*

INTRODUCTION

The territory of Bulgaria covers an area of 110,994 km^2 (Metodieva et al., 2024; Kilifarska et al., 2025), characterized by a complex hydrogeographic network (Belkinova et al., 2013). The countryis divided into four river basin management regions: Danube, Black Sea, East Aegean and West Aegean (Cheshmedjiev et al., 2010). The East Aegean region covers 31% of Bulgaria's territory and encompasses the catchments of four rivers (Maritsa, Tundzha, Arda and Byala). The Maritsa River is the largest river on the Balkan Peninsula and has over 100 tributaries (Belkinova et al., 2013), one of which is the Kayaliika River.

The Kayaliika River originatesin the Rhodope Mountains near the village of Zhalt Kamak. It flows for 39 km, passing through the villages of Iskra, Bregovo, Dragoynovo, Ezerovo, Bodrovo, Varbitsa and the village of Skobelevo, before discharging into the Maritsa River (Kiradzhiev, 2013). According to the East Aegean River Basin Directorate (2018), the Kayaliika River is classified as type R5 ("Semi-mountainous river").

Water is a valuable natural resource. River waters are used for irrigation and domestic and industrial needs. However, various anthropogenic activities contribute to water pollution (Gartsiyanova et al., 2022; Gartsiyanova et al., 2024). Benthic macroinvertebrates a key component of aquatic ecosystems, are widely used as bioindicators due to their low mobility, long life cycles, and sensitivity to pollution. Their abundance and diversity depend on the physicochemical properties of the water and substrate. Any environmental changes directly influence macrozoobenthos communities, making them essential for biological monitoring (Rashid & Pandit, 2014). According to the Water Framework Directive (Directive 2000/60/EU), the leading role in assessing the ecological state of surface water is played by the biological quality elements (BQEs) (algae, macrophytes, benthic macroinvertebrates, fish) listed in Annex V of the Directive. Physicochemical and

hydromorphological quality elements have a complementary role and provide information about the causes that led to the deterioration of the ecological state. The final ecological state assessment is determined according to the "one out – all out" rule (Belkinova et al., 2013). Despite extensive hydrobiological studies in Bulgaria, no prior research has assessed the ecological state of the Kayaliika River using biological quality elements.

This study aims conduct hydrobiological monitoring of the Kayaliika River using macrozoobenthos as a biological quality element, contributing to regional water quality assessments and ecological status evaluation.

MATERIALS AND METHODS

Hydrobiological monitoring of the Kayaliika River was carried out in the autumn of 2024. Four biotopes located along the Kayaliika River were selected and surveyed: the Ezerovo biotope (42°00'49.0"N 25°17'24.2"E); the Bodrovo biotope (42°01'41.6"N 25°18'54.6"E); the Varbitsa biotope (42°03'07.8"N 25°20'40.2"E) and the Skobelovo biotope (42°05'35.4"N 25°22'33.8"E) (Figures 1-2; Table 1).

Macrozoobenthos samples were collected using standardized methods (Cheshmedjiev et al. 2011; EN ISO 10870:2012; EN 16150:2012; Regulation No. H-4 of 14.09.2012; Belkinova et al., 2013). Sampling was conducted using a kick net sampler. The collected material was preserved in 70% ethyl alcohol until subsequent laboratory processing. In laboratory conditions, the taxonomic affiliation of the macrozoobenthos was determined using a Micros Austria MZ 1240 stereomicroscope. The following metrics were calculated:

- The total number of taxa;
- The number of taxa from the orders Ephemeroptera, Plecoptera and Trichoptera (EPT);
- Margalef species richness index (Dmg);
- Shannon-Weaver species diversity index (H');
- Pielou's evenness index (E);
- Simpson's dominance index (C);
- Abundance metrics (% (Oligochaeta & Diptera), % Filtering feeders, % EPT taxa);
- Saprobic index (SPUB), trophic index (RETI) and
- Adapted Biotic Index (BI) according to Regulation No. H-4 of 14.09.2012 and Belkinova et al. (2013).

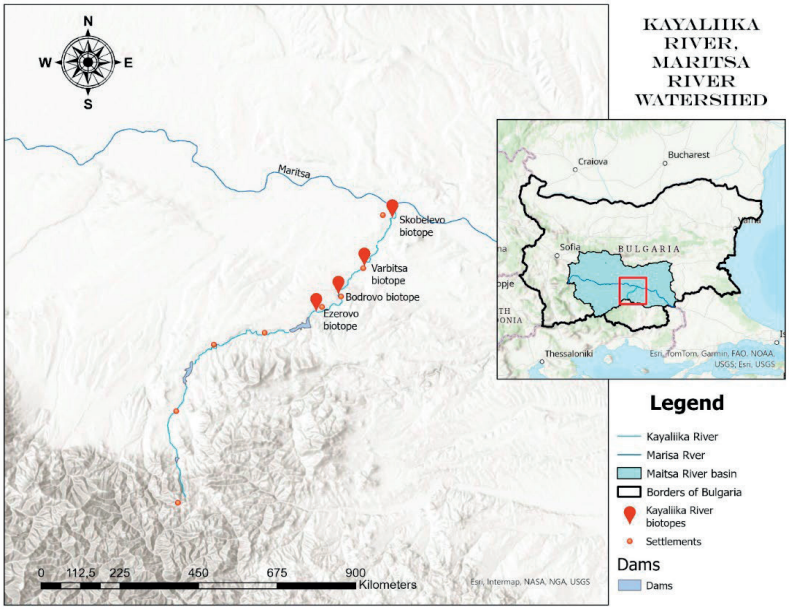

Figure 1. Researched biotopes along the Kayaliika River, Maritsa River watershed

Figure 2. Views of the studied biotopes from the Kayaliika River (from left to right: 1) near the village of Ezerovo; 2) near the village of Bodrovo; 3) near the village of Varbitsa and 4) near the village of Skobelevo)

Table 1. Characteristics of the studied biotopes from the Kayaliika River

Biotopes	Altitude	Location	Bottom substrate and current speed
Ezerovo	197 м	Along the Kayaliika River, southwest of the village of Ezerovo, after the Ezerovo Dam	Sandy/muddy bottom and slow current
Bodrovo	180 м	Along the Kayaliika River, northwest of the village of Bodrovo	Sandy/muddy bottom and slow current
Varbitsa	173 м	Along the Kayaliika River, within the borders of the village of Varbitsa	Sandy/rocky bottom and slow current
Skobelevo	148 м	Along the Kayaliika River, east of the village of Skobelevo, before flowing into the Maritsa River	Sandy/rocky bottom and slow current

RESULTS AND DISCUSSIONS

During the hydrobiological monitoring of the Kayaliika River, a total of 970 specimens of 42 taxa were identified. These taxa included: (*Asellus (Asellus) aquaticus* (Linnaeus, 1758); *Anodonta cygnea* (Linnaeus, 1758); *Atherix ibis* (Fabricius, 1798), larva; *Baetis* sp., nymph; *Bithynia tentaculata* (Linnaeus, 1758); *Caenis horaria* (Linnaeus, 1758), nymph; Ceratopogonidae; Chironomidae, larva and pupa; *Chironomus plumosus* (Linnaeus, 1758), larva; *Cloeon* sp., nymph; *Corixa* sp., nymph; *Culex* sp., larva; *Dytiscus* sp., larva; *Enallagma cyathigerum* (Charpentier, 1840), larva; *Gammarus pulex* (Linnaeus, 1758); *Gerris* sp., nymph; *Glossiphonia* sp.; *Gomphus* sp., larva; *Gyraulus (Gyraulus) albus* (O.F.Müller, 1774); *Gyrinus substriatus* Stephens, 1829; *Haemopis sanguisuga* (Linnaeus, 1758); *Hydropsyche ornatula* McLachlan, 1878, larva; *Hydroporus* sp.; *Hydroptila* sp., larva; *Hyphydrus ovatus* (Linnaeus, 1761); *Ilyocoris cimicoides* (Linnaeus, 1758), nymph; *Lethocerus patruelis* (Stål, 1854); *Limnodrilus hoffmeisteri* Claparède, 1862; *Lumbricus rubellus* Hoffmeister, 1843; *Notonecta* sp., nymph; *Peregriana peregra* (O.F.Müller, 1774) (syn. *Radix peregra*); *Physella acuta* (Draparnaud, 1805); *Platambus maculatus* (Linnaeus, 1758); *Plea minutissima* Leach, 1818; *Radix (Radix) auricularia* (Linnaeus, 1758); *Rhantus frontalis* (Marsham, 1802); *Schmidtea polychroa* (Schmidt, 1861); *Sialis lutaria* (Linnaeus, 1758); *Simulium* sp., larva; *Sphaerium (Sphaerium) corneum* (Linnaeus, 1758); *Tipula* sp., larva; *Valvata (Cincinna) piscinalis* (O.F.Müller, 1774)). These taxa belonged to 18 orders and were found in the four studied biotopes, including: Amphipoda, Arhynchobdellida, Coleoptera, Crassiclitellata, Diptera, Ephemeroptera, Gastropoda, Hemiptera, Isopoda, Littorinimorpha, Megaloptera, Odonata, Rhynchobdellida, Sphaeriida, Trichoptera, Tricladida, Tubificida, Unionida. Insects in the order Hemiptera do not undergo a larval and pupal stage; instead, they develop through several nymph stages or "instars". The highestnumber of macrozoobenthos taxa was found in the Skobelevo biotope, and the lowest– in the Varbitsa biotope (Figure 3). The dominant macrozoobenthos taxon in the Ezerovo and Varbitsa biotopes is *En. cyathigerum*, larva (order Odonata), with 103 and 40 specimens, respectively. Dominant in the Bodrovo biotope

is *G. pulex* (order Amphipoda) with 40 specimens, and in the Skobelevo biotope – *Cloeon* sp., nymph (order Ephemeroptera) with 141 specimens. According to the total number of taxa metric, the ecological state of the Kayaliika River was classified as very good in three of the studied biotopes and good in the Varbitsa biotope.

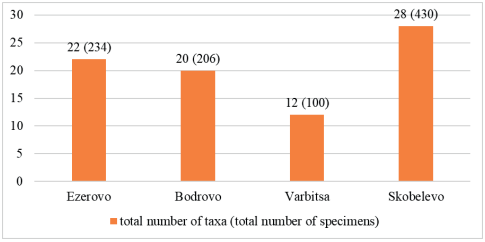

Figure 3. Total number of macrozoobenthos taxa by biotope

In general, acrossall four studied biotopes, there were few representatives of the Ephemeroptera and Trichoptera. Plecoptera taxa were absent, which contribute to the classification of a moderate ecological state for Ezerovo, Bodrovo and Skobelevo biotopes and a bad ecological state for the Varbitsa biotope (Figure 4).

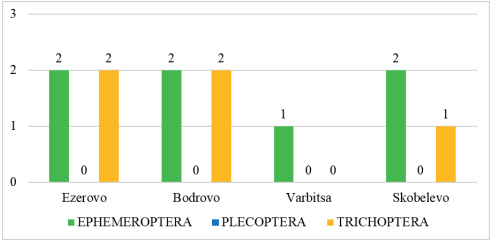

Figure 4. Number of taxa from the orders Ephemeroptera, Plecoptera and Trichoptera by biotope

The percentage of Oligochaeta and Diptera, as well as the percentage of Filtering feeders, is lowest in the Ezerovo biotope, while the percentage of EPT taxa is relatively high, indicating a weakly influenced river ecosystem. In contrast, the Varbitsa biotope shows the highest percentage of Oligochaeta and Diptera and the lowest percentage of EPT taxa, suggesting anthropogenic pressure on the aquatic environment in this section of the river (Figure 5).

The value of the German trophic index RETI increases downstream along the Kayaliika River, with the highest value observed in the Skobelevo biotope ($RETI_{Skobelevo}$ = 0.79), indicating a stable and undisturbed river ecosystem in this biotope. According to the RETI index, the ecological state of the Kayaliika River is classified as good across all four biotopes ($RETI_{Ezerovo}$ = 0.51; $RETI_{Bodrovo}$ = 0.62; $RETI_{Varbitsa}$ = 0.67).

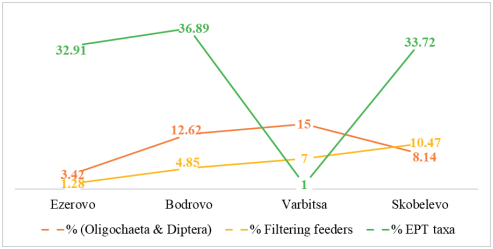

Figure 5. Macrozoobenthos abundance metrics by biotopes

The macrozoobenthos identified in this study belong to 4 sensitivity groups –: Group B (less sensitive forms), Group C (relatively tolerant forms), Group D (tolerant forms) and Group E (the most tolerant forms). No taxa were identified from Group A (sensitive forms). In three of the studied biotopes (Ezerovo, Bodrovo and Skobelevo), the majority ofmacrozoobenthos taxa belonged to Group C. In the Varbitsa biotope, an equal number of taxa for Groups C and D were identified (Figure 6).

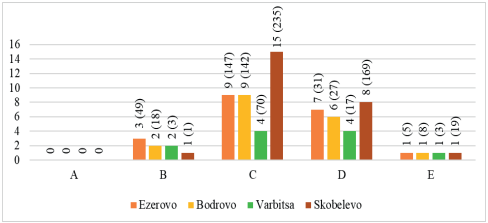

Figure 6. Distribution of macrozoobenthos taxa by sensitivity groups

In the Ezerovo biotope, indicator macrozoobenthos for β and β-α-mesosaprobic conditions prevails (6 taxa each). In the Bodrovo biotope, taxa indicating β-mesosaprobic conditions were dominant (6 taxa), while in the Varbitsa biotope taxa

indicating for 0-β and β-α-mesosaprobic conditions (3 taxa each). In the Skobelevo biotope taxa characteristic of 0-β and β-mesosaprobic conditions dominated (6 taxa each) (Figure 7).

According to the obtained values of the saprobic index (SPUB), the ecological state of the Ezerovo, Bodrovo and Varbitsa biotopes was classified as very good ($SPUB_{Ezerovo}$ = 1.89; $SPUB_{Bodrovo}$ = 1.69; $SPUB_{Varbitsa}$ = 1.80), while in the Skobelevo biotope the ecological state was assessed as good ($SPUB_{Skobelevo}$ = 2.07).

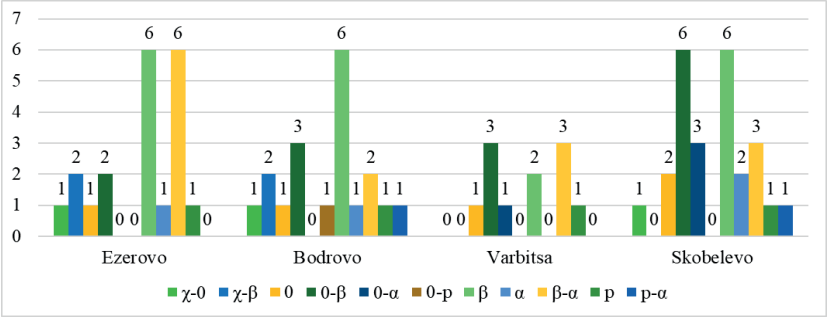

Figure 7. Distribution of macrozoobenthos taxa by saprobity groups

The Margalef species richness index (Dmg) in all studied biotopes was below 8, indicating that the environmental conditions in the studied river ecosystem are not optimal. The Shannon-Weaver species diversity index (H') indicated β-mesosaprobic conditions in three of the studied biotopes (Ezerovo, Bodrovo and Skobelevo) and α-mesosaprobic conditions in the Varbitsa biotope. The calculated Pielou's evenness index (E) and Simpson's dominance index (C) showed the most favorable conditions in the Bodrovo biotope (E = 0.845; C = 0.106) (Figure 8).

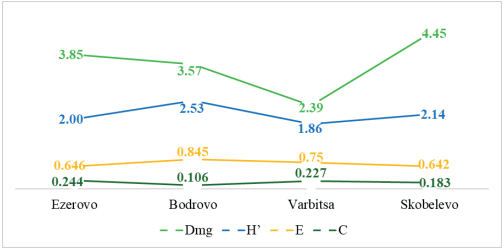

Figure 8. Species diversity indices (Margalef species richness index (Dmg), Shannon-Weaver species diversity index (H'), Pielou's evenness index (E), Simpson's dominance index (C)) by biotope

The biotic index (BI) indicates a bad ecological state in the Varbitsa biotope – BI (nEQR) = 2 (0.4) and a moderate state in the other three biotopes – BI (nEQR) = 2.5 (0.5).

CONCLUSIONS

During the hydrobiological monitoring of the Kayaliika River, a total of 42 taxa of macroinvertebrate organisms were identified, represented by 970 specimens, from the four studied biotopes. The highest number of macrozoobenthos taxa was recorded in the Skobelevo biotope (28 taxa), while the lowest number was observed in the Varbitsa biotope (12 taxa). Based on the assessment of biological quality elements (BQE), particularly macrozoobenthos, the ecological state of the river was classified as moderate in the Ezerovo, Bodrovo, and Skobelevo biotopes, and bad in the Varbitsa biotope, reflecting potential anthropogenic pressures.

These findings underscore the importance of regular biological monitoring to detect early signs of ecological degradation and guide targeted conservation measures. Further research integrating physicochemical parameters and land-use impacts is recommended to support comprehensive water management strategies for the Kayaliika River.

ACKNOWLEDGEMENTS

This research is supported by the Bulgarian Ministry of Education and Science under the national Program "Young Scientists and

Postdoctoral Students-2". The study results have been published with financial support (project No. 17-12) of the Centre of Research, Technology Transfer and Protection of Intellectual Property Rights at the Agricultural University-Plovdiv.

Abstract

Starting from the statement "A good cadastre of the parcels will be the complement of my civil code," the fundamental importance of the cadastre in the management of land and real estate properties becomes evident. It provides a detailed and up-to-date record of land parcels, including their owners, describing the boundaries and characteristics of each property. Through this, the cadastre facilitates the implementation and adherence to legal norms regarding property rights and their transfer. In the context of societal development and evolution, a well-maintained cadastre becomes an essential tool for urban planning, natural resource management, and infrastructure project implementation. Furthermore, a modern cadastre system can help prevent legal disputes related to property and serve as a crucial instrument in urbanization and economic development processes. An efficient cadastre is not only a technical necessity but also a fundamental element for the functioning of a coherent legal system and for responsible real estate management, contributing to the establishment and maintenance of a cohesive societal structure.

Key words*: property rights, legislative changes, real estate, collectivization, possession.*

INTRODUCTION

The study of the effects of applying the law in cadastre activity, through a comparative analysis of the resolutions adopted for the registration of real estate properties in the land registry, represents a research endeavor that warrants the attention and careful analysis of the academic community and decision-makers. This complex and current topic is essential for the preservation and efficiency of land and real estate management systems.

The evolution of legislation in the field of cadastre and real estate is inevitable in a continuously changing society. In this context, the current law regulating the cadastre and real estate publicity in Romania, Law no. 7/1996, represents a crucial pillar in defining the legal framework for land and property management (Badea & Badea, 2015 a).

The year 2023 brought significant legislative changes, highlighted by the modification of Order 700/2014 into the new reception and registration order 600/2023. This legislative change was subsequently adjusted by Decision no. 6 of 13.04.2021 regarding Minute no. 16893/2753 of 13.04.2021 of the Director of the Real Estate Publicity Directorate and Decision 1255 of 17 July 2023, reflecting the necessary adaptations to the continuously changing societal requirements. Through these changes, the legislation aims to streamline cadastral processes, provide a clear and updated framework for owners, and facilitate the implementation of new technologies within cadastre and real estate publicity activities. It is essential to evaluate and understand these legislative changes to appreciate how they might influence research and practice in the field of cadastre.

A well-defined and clear legal framework regarding the cadastre offers owners confidence in the management system of their properties. By adopting effective resolutions, property rights can be protected, and real estate transactions facilitated, contributing to the stimulation of the real estate market and economic growth.

MATERIALS AND METHODS

Technical and cadastral documentation is prepared based on Law 7/1996 on cadastre and real estate publicity and Order of the General Director no. 600/2023 with subsequent amendments and completions. The technical documentation for initial registration is categorized into the following main types (Badea & Badea, 2015 b; Pădure et al., 2006):

- Initial registration in the integrated cadastre and land registry system; This involves preparing technical documentation for initial registration in the integrated cadastre and land registry system, with the allocation of a cadastral number for:

1. The registration of property rights acquired under property laws:

Law 18/1991	Law 123/2023	Law 15/1990	Law 1/2000	Law 247/2005
Land Fund	For the amendment and completion of Law 18/1991	Regarding the reorganization of state economic units as autonomous regies and commercial companies	Reconstitution of property rights over agricultural and forest lands	Regarding the reform in property and justice domains, as well as some adjacent measures

2. Technical documentation for initial registration – possession notation (Art. 41, para. (8) of Law no. 7/1996 on Cadastre and Real Estate Publicity, Art. 119 ODG 600/2023, for which no registrations have been made in the last 30 years prior to the coming into force of Law 287/2009 regarding the Civil Code). For preparing the documentation, after measurements are completed, land registry identification will be necessary (required both if the property is located within and outside the built-up area of a locality).

3. Technical documentation for initial registration based on a civil judgment; Given that the judgment noted in the land registry, it must be final, irrevocable, and enforceable.

4. Technical documentation for initial registration – identification of the property located in a different administrative territorial unit (UAT) than the one recorded in the land registry (Art. 120-122 of ODG 600/2023). In fact, this is an update of the old land registry with current attributes and the registration of the correct UAT. The particularity of this documentation is represented by the "report of finding and cancellation of cadastral number, prepared by the cadastral inspector and approved by the chief engineer, which is registered ex officio in the General Entry Register, based on which the old land registry is terminated".

5. Consolidation of properties registered in the land registry opened according to Decree-Law no. 115/1938, which were not the subject of registration in the land registry by allocating a cadastral number with the appearance of Law 7/1996 on Cadastre and Real Estate Publicity, but have always been part of the same property body; If only part of the property registered in a land registry based on Decree-Law no. 115/1938 was the subject of one of the aforementioned normative acts, it is necessary to detach that part by forming a new property for which a new land registry will be prepared. This procedure will be mentioned in the existing land registry. The unaffected part will be re-registered in favor of the old owners from the old land registry, while the detached part will have a new land registry created. The existing land registry will mention the cadastral number and the land registry number in which the property has been transcribed. Regarding the opening of the new land registry, if the property is assigned a cadastral number, the area and categories of use will be assimilated according to the cadastral documentation, and for the second and third parts of the land registry, the information will be taken. Thus, a land registry decision will be generated, which will be communicated to all interested parts.

Registration in a new land registry is carried out by preparing initial cadastral documentation for the actual measured area of the property, based on the provisions of Art. 41 of Law 7/1996 on Cadastre and Real Estate Publicity and Art. 72, para. (1) of ODG 600/2023.

When referring to the area where the property is located, we will consider the built-up area and outside built-up area of the administrative territorial unit within which it is classified. Thus, concerning these areas, both in terms of address and the choice of suitable and correct documentation type, we will refer.

This refers to the initial registration in the integrated cadastre and land registry system of a property located in the built-up area, where the area determined from measurements may be up to 15% larger and in the outside built-up area up to 5%, otherwise, registration is not permitted.
Regarding the categories and subcategories of land use, these are determined based on observations made in the field and the documents proving the legality of the changes made.
In other words, for registration, we distinguish the following cases:

Urban land	Rural land	
	Cooperativism area	**Uncooperative area**
The categories of use will be entered according to the actual use (of the cadastral documentation). The deviation from the rule is made in the case of vineyards with an area greater than 200 sq m, which will not be able to be modified. Equally, the categories of use will be those in the sentence, if it exists.	The categories of use of the property do not change unless it is removed from agricultural use.	The categories of use will be recorded according to the cadastral documentation (with the updated fiscal attestation certificate according to the location and delimitation plan) or based on a civil sentence, where applicable.

- Registration in the cadastral plan of real estate located in the land registry regions subject to Decree-Law 115/1938.

This type of documentation applies if the real estate has not been the subject of registration in the land registry by allocating a cadastral number since the advent of Law 7/1996 on the cadastre and real estate advertising, but it was registered based on Decree-Law 115/1938, in other words in the situation where the land has never been the subject of cadastral documentation. This case should not be confused with the situation in which the real estate comes from the same old land registry, being registered under the title of reconstitution by tabulation of some plots of a property title, in which case correction of the error by conversion is requested.
This will result in a single land registry which will subsequently be subject to the cadastral data update offer.

RESULTS AND DISCUSSIONS

This study refers to the Land Registry of identifying a property, with records dating before 1st of October 1981. It is important to note that the registered owner in the document is not in the direct line of descent of the benefiting family. According to the documentation, the nominal area of the property is 462 m², while actual measurements indicate an area of 528 m². In fact, the property is owned by Mr. Nicolae Popescu, who is also the seller in the transaction that constitutes the subject of this study. It is noted that the real estate transaction will occur between the father and his son, Marcu Popescu.
Since the property is located in a cooperative area, as certified by the Cugir City Hall, the following resolutions can be adopted for the property under study:

- Technical and Cadastral Documentation for Issuance of the Property Title Based on the Provisions of Law No. 18/1991 on the Land Fund and Law No. 1/2000 for the Restoration of Property Rights on Agricultural and Forest Land. The property title will be issued in favor of Mr. Nicolae Popescu, who is registered in the agricultural register for which a tax certificate can be issued. The technical documentation will be delivered in 3 copies (one copy for the beneficiary, one copy for the municipality, and one copy for the Local Land Fund Commission, which will be forwarded to the Cadastre and Real Estate Publicity Office for verification and approval). Following the issuance of the property title, it will be registered in the land register as the first entry based on the property title. Subsequently, based on the land registry extract and the sale-purchase contract, the notary will submit the registration request to the Cadastre and Real Estate Publicity Office for registration in favor of the new owner.
- Technical Documentation for the First Registration Based on Article 41 (10) of Law No. 7/1996, Republished with Subsequent Amendments and Additions. In this case, the atypical document required is the certificate according to Annex 1.51/1 of Order No. 3442/2019, which demonstrates that the owner was a cooperative member, thus enabling him to obtain registration in his favor. For this property, until April 13, 2021, possession could have been noted in favor of the actual possessor. However,

according to Decision No. 6/April 16, 2021, and Minute No. 16983/2753 dated April 13, 2021, attached to it, point b) states that possession "is not possible for properties located in former cooperative zones, regardless of whether property titles have been issued under Law No. 18/1991 on the Land Fund".

➢ Extra-Tabulary Adverse Possession: First Registration Based on a Civil Judgment. Extratabular adverse possession is defined as the situation where the adverse possessor is not registered as the owner in the land register (even though the property has a land register) or the property does not even have a land register. The adverse possessor can claim adverse possession as an exception if sued by the rightful owner or can file a request with the court to definitively consolidate his ownership right. The conditions that must be met by the beneficiary of our work are as follows:

1. Possession of 10 Years: This period can be interrupted due to defects in possession; however, these defects only suspend the process of adverse possession (if they occur). Overall, the possessor must hold the property as a true owner for a period of 10 years. It is possible to combine (junction) possessions when multiple possessors use the property successively. To prove this union or accumulation of possessions, especially regarding the peaceful transfer of possession from one possessor to another, appropriate evidence is needed. The 10-year period refers to the possession of the property, not to the possessors themselves. During these 10 years, there can be 2-3-4 possessors, and the last possessor who completes the legal 10-year period can benefit from adverse possession if he can demonstrate the connection between his possession and previous possessions.

2. A useful Possession: The possession must be unblemished, public/non-secretive, and peaceful.

3. No Land Register or Deceased/Removed Registered Owner: The property must not have a land register, or if there is one, the registered owner in the land register has died or is no longer alive (being removed/dissolved in the case of legal entities), or he has submitted a declaration of renunciation of ownership in the land register. In the case of death or removal/dissolution of the registered owner, the 10-year term begins at the earliest from the date of death/removal/dissolution, even if the possession began before this event. In the case of a declaration of renunciation of ownership, the 10-year term begins at the earliest from the date of registration of that declaration in the land register.

Once the above conditions are met, based on the technical judicial expertise report prepared by an authorized physical/legal person, a definitive, irrevocable, and enforceable civil judgment will be issued, which will grant ownership that will subsequently be registered.

➢ First Registration Based on the Property Title + Other Successive Documents of the Property. This possibility is viable based on successive documents issued up to January 1, 2005. The explanation for this is that, until this date, extratabulary sales and transfers of rights were conducted. Since then, any authentic transaction (carried out through a notary), except for inheritance, could no longer be performed. However, a transaction can be carried out through a handwritten document, regardless of the number of transactions. The documents are registered and recorded in chronological order, and their history is detailed in section B of the land register, which contains information regarding owners and documents.

The accelerated digital transformation of cadastral operations, spurred by the integration of GIS technologies, poses notable adaptation challenges for professionals, particularly in terms of aligning with continuously evolving procedural and legislative frameworks (Tereşneu & Tereşneu, 2023).

From an engineering perspective, the imperative to translate conceptual work into tangible, measurable outcomes is a defining professional attribute. In this sense, for easier evidence of cadastral documentation and resolutions that can be adopted we propose an interactive cadastral WEB Page.

This WEB page is designed as an interface between the contractor and beneficiaries and could provide support for all those interested in cadastral operations in the field of cadastre and land registry (employees of cadastral companies, beneficiaries of works, as well as other interested parts from related fields, students, etc.).

The graphical interface of the WEB Page is presented in Figure 1.

Figure 1. Graphical interface of the WEB Page

The WEB Page presented in Figure 1 has the following structure:
- Theoretical concepts;
- Types of documentation;
- Property location;
- Equipment and working methods;
- Resolutions that can be adopted.

The developed WEB Page includes all types of cadastral documentation that can be elaborated according to Order 600/2023 (Figure 2).

Figure 2. The Cadastral Documentation Menu of the WEB page

By selecting a certain type of cadastral documentation from Cadastral Documentation Menu, is shown a list with all cadastral documentation, of that type, elaborated within the company.

By selecting one type of cadastral documentations from the list, the cadastral documentation is displayed as well as all the information regarding that documentation (Figure 3).

Figure 3. Information regarding cadastral documentation

Property location menu - provides information about property localization and help users to locate their properties using cadastral maps and geographic tools.

Also, for each cadastral documentation elaborated, the WEB Page provides information about the topographic equipment used for measurements, the working methods, the solutions adopted and about the resolution that can be adopted.

The WEB Page incorporates current legislation and explains relevant laws, regulations and procedures related to property registration into the Land Registry.

It includes contact forms, chat support or FAQs for user assistance, which allow users to request or submit cadastral documents online and check the status of their cadastral documentation.

CONCLUSIONS

In the context of globalization, adapting to international standards becomes a priority. Comparative studies provide relevant information regarding the need or advantages of complying with these standards, which can contribute to increasing competitiveness at the national or even international level.

Moreover, the results of such a study can serve as a significant contribution to discussions on the legislative reforms needed in the field of cadastre and real estate publicity. This can guide legislative decisions towards optimizing and improving existing processes, ensuring that the legislation reflects current needs and challenges.

In conclusion, the examination of the effects of applying the law in cadastre activities is not just

an academic concern but a vital step for ensuring effective and transparent management of real estate properties. It not only reflects but actively contributes to the evolution and efficiency of the legal and administrative system in the field.

Abstract

This study examines the geomorphological conditions of representative gravel extraction sites along the Moldova River and assesses the impact of riverbed material extraction on the stability of the riverbed and the sediment regeneration rate. The analyzed sector spans approximately 26 km, encompassing the stretch of the Moldova River between Păltinoasa and Cornu Luncii in Suceava County, with a particular focus on the Capu Câmpului extraction site. The intensity of gravel extraction activities is reflected in the variations of suspended sediment hydrographs, which exhibit an increasing trend over time in the Moldova River, contrasting with the general decreasing trend observed in other rivers of the Siret Basin. Utilizing GIS techniques, including orthophotoplans and ArcGIS 9.2 software (via Digital Elevation Model creation), calculations were made for the volumes of mineral aggregates potentially extractable between 2017 and 2021. Previous studies have demonstrated that riverbed material extraction can lead to significant modifications in river morphology, including channel erosion and changes in hydraulic regimes, with effects on aquatic biodiversity and water quality. In conclusion, the research underscores the importance of detailed evaluation of the impact of riverbed material extraction on the geomorphological and ecological stability of the Moldova River, to support the development of sustainable management practices for fluvial resources.

Key words*: GIS techniques, riverbed, extraction.*

INTRODUCTION

Before 1990, Romania's construction materials industry faced a significant annual demand of approximately 80 million cubic meters of sorted sands and gravels (Călinoiu et al., 1988). These natural resources were regularly extracted from riverbeds and surrounding lands, playing a crucial role in supporting infrastructure development. However, ballast extraction was insufficiently regulated, leading to considerable environmental impacts, especially concerning alterations to watercourses and degradation of adjacent soils.
Following a period of economic decline, the demand for ballast increased again, reflecting a revitalization of the construction industry and, implicitly, greater pressure on natural resources. Currently, the requirements are much higher, placing considerable strain on riverbeds and the lands of major riverbeds, which are used for extracting sand and gravel. Romanescu (2009) observed this trend and emphasized that despite increased demand, there is a lack of detailed assessments of these activities' effects on riverbeds.
One of the main constraints regarding sand and gravel extraction is the imposition of quality conditions and strict environmental regulations. Consequently, the extraction area has significantly narrowed, and extraction activities are mainly concentrated in the middle and lower sectors of the minor riverbeds of major rivers, where there is greater resource availability and more flexibility in managing environmental impact. Thus, in the case of the Siret River, for example, approximately 230 gravel pits operate, with an annual production of about 2 million cubic meters of ballast, representing a considerable potential for transforming minor riverbeds (Călinoiu et al., 1988). This constitutes an important resource but poses a significant challenge for the sustainable management of river ecosystems (Gâștescu 2014). Despite this high ballast extraction potential, studies on the ecological impact of gravel pits on riverbeds are relatively limited. Romanescu (2009) observes that

comprehensive or detailed evaluations of how these gravel pits contribute to modifying riverbeds or changing river landscapes are lacking. Instead, most research focuses on isolated observations and case studies of individual rivers, limiting the general understanding of the phenomenon. This highlights the critical need for comprehensive research to systematically evaluate the effects of ballast extraction on river morphology and adjacent ecosystems. Such studies are essential for developing informed and sustainable resource management strategies. Additionally, it's important to note that changes in riverbeds resulting from ballast extraction activities can have profound effects on their biodiversity and ecological stability (Bătucă et al., 1992). For example, the disappearance of natural habitats for aquatic species and soil erosion can lead to a significant decline in biological diversity. Therefore, ballast extraction must be conducted within a regulated framework that minimizes environmental harm.

In conclusion, extracting sand and gravel from riverbeds represents a vital resource for the construction industry, but also poses major challenges for environmental conservation.

GIS technology enables the integration of various data sources, such as satellite imagery, aerial photographs, topographic maps, and remote sensing data, to provide a detailed and updated view of riverbed changes. This spatial data integration is essential for long-term monitoring, helping to document erosion, sedimentation, and channel migration processes.

Thorne et al. (2012) demonstrated that remote sensing and GIS technologies facilitate the rapid detection of river morphology changes, including erosion and channel shifts, which are often challenging to observe using conventional methods. Similarly, Goss et al. (2004) showed that GIS-based analysis of multi-temporal georeferenced data enables the monitoring of sequential riverbed changes following human interventions, such as dam construction or water diversion, revealing trends in channel migration and their ecological impacts.A relevant example highlighting the effectiveness of these tools is the study by Zhang et al. (2017), which applied GIS to assess channel changes in the Yangtze River, successfully identifying areas prone to erosion and flooding. Such spatial analyses are essential for flood disaster prevention and infrastructure protection in vulnerable regions (Vlad, 2017; Moldovan et al., 2023).

This study aims to enhance our understanding of the long-term effects of gravel pit operations on riverbeds and aquatic ecosystems (Cercel, 2019). The findings highlight the necessity for comprehensive research to systematically evaluate the impact of ballast extraction on river morphology and surrounding ecosystems. Such studies are essential for developing and implementing more effective resource management strategies that balance development with environmental conservation.

MATERIALS AND METHODS

This study employs ArcGIS 9.2 technology, encompassing: (i) the development of a Digital Elevation Model (DEM) through triangulation techniques and delineation of the study area's boundaries; and (ii) the computation of aggregate volumes resulting from both extraction and alluvial transport processes, as illustrated in Figure 1.

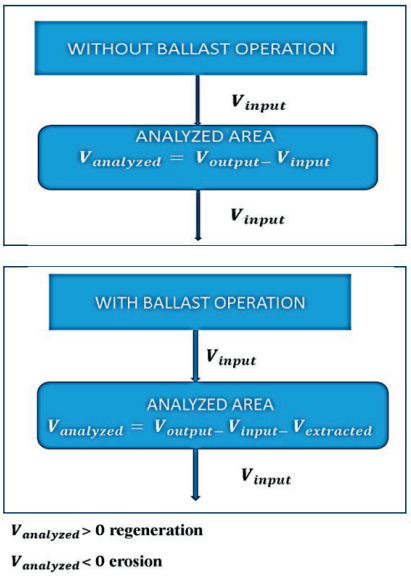

Figure 1. Calculation of aggregate volume

This methodology is applied to the profiles situated on the middle course of the Moldova

River, between Păltinoasa and Cornu Luncii localities. The research is conducted for the period 2017-2021.

Study Area

The study area is situated on the Moldova River, which is located in the northeastern part of the Eastern Carpathians and the northwestern part of the Moldavian Plateau (Figure 2).

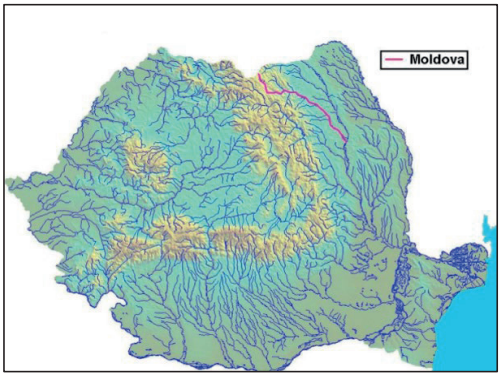

Figure 2. Location of the Moldova River on the hydrographic map of Romania (source: Wikipedia)

The Moldova Valley forms a depression between the Subcarpathians of Moldova and the Suceava Plateau, shaped by the Moldova River. Originating in the Obcina Feredeu Mountains (Suceava County), the river flows through Suceava and Neamț counties before joining the Siret River near Roman. As a right tributary of the Siret, the Moldova River features a broad and low floodplain up to Ciumulești, with its widest floodplain and terrace development observed at Baia, where the landscape adopts a depression-like character (Bartha et al., 2014; Bălan et al., 2016). The floodplain hosts a single, highly productive aquifer (yielding over 10 l/s), representing a key high-quality water reserve for eastern Romania (Cercel, 2018). The alluvial plain of the Moldova River, characterized by a grain size distribution well-suited for construction aggregates, represents one of the most significant exploitable sources in the Moldova region (Amăriucăi, 2000; Marcoie et al., 2023). This renewable resource is continuously replenished due to the river's mountainous hydrological regime, which alternates with plateau influences, and notably due to the absence of hydroelectric infrastructure in the Moldova River basin (Ichim et al., 1989). The analyzed extraction sites are located along the middle course of the Moldova River, between Păltinoasa and Cornu Luncii, entirely within the Subcarpathian sector of the Moldavian Plateau. This region is defined by hilly terrain with altitudes ranging from 400 to 600 meters, gradually decreasing from north to south.

According to detailed geomorphological mapping by Rădoane (2007), the middle sector of the Moldova River in Suceava County, between Păltinoasa and Cornu Luncii, features a well-developed alluvial plain with alluvial terraces rising 4-5 meters above the current riverbed. Key extraction perimeters within this area include Pod Izvor, Capu Câmpului, and Cornu Luncii (Figure 3).

The Capu Câmpului extraction site is located outside the built-up area (extravilan) of Capu Câmpului village, Suceava County, along the riverbed of the Moldova River, just downstream of the confluence with the Isachia stream. The operational perimeter lies between cadastral markers C.S.A. 116 and C.S.A. 117 (Figure 4).

Figure 3. Plan with the location of the three exploitation perimeters. Source: Google maps

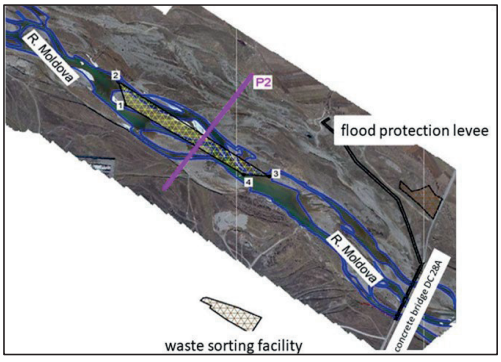
Figure 4. Plan with the location of the Capu Câmpului exploitation perimeters. Source: Google maps

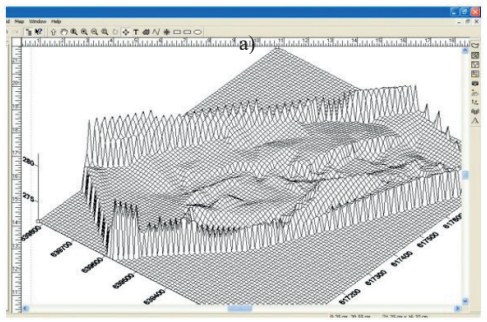
The following data sets were used in this study: updated situation plans with contour lines at a scale of 1:5000 and orthophotoplans. The contour lines were vectorized and together with the measured points on the situation plans allowed the creation of a Digital Elevation Model (Biali, 2013). The interpolation method chosen was TIN (Triangulated Irregular Network). TIN interpolation is another popular tool in GIS. A common TIN algorithm is called Delaunay triangulation.

The updated situation plans and orthophotoplans used to represent the study sectors are documents provided and authorized by ANCPI Suceava. Over these orthophotoplans, the Modova riverbed was vectorized and the positions of the transversal profiles were drawn. These profiles tracking the riverbed that frames the exploitation perimeter were maintained in the same place year after year (by means of field markers) so that the measurement results are correct and consistent in accordance with the initiated study.

RESULTS AND DISCUSSIONS

The study commenced in 2017 with field measurements conducted across five cross-sections (P1-P5). Figure 5 shows the 2017 boundary of the mineral aggregate extraction perimeter (points 1–2–3–4) along the Moldova River bed.





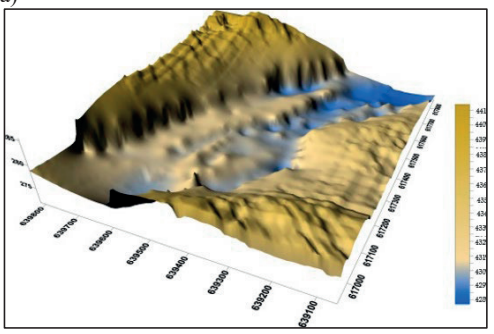


Figure 5. Orthophotomap of the Capu Câmpului perimeter from 2017

The Numerical Terrain Model in Figure 6 represents the studied Capu Câmpului sector. The hypsometry is in the range of 428 (thalweg) 441 m (left slope).

The Numerical Terrain Model served as the foundation for calculating the volumes of mineral aggregates present within the riverbed.

a)

b)

Figure 6. 3D representation of the Numerical Terrain Model for the studied perimeter (a. wireframe; b. grid fill)

This study employs two complementary research methods: profile-based approaches and Digital Terrain Model (DTM)-based analyses. Transversal profile measurements, conducted annually within the same cross-section, yield direct and reliable results. These measurements are processed using ArcGIS 9.2 software to model the riverbed of the Moldova River. The DTM results are utilized for both aggregate volume calculations and monitoring the morphological evolution of the riverbed over time. Field measurements were performed using the Trimble® R780 GNSS receiver, an advanced geospatial instrument. The R780 features a 9 GB internal memory and operates with Trimble Access software. It incorporates Trimble Inertial Platform™ (TIP) technology, providing tilt compensation based on an Inertial Measurement Unit (IMU), ensuring resistance to magnetic interference. This system is designed to withstand harsh environmental

conditions, offering high precision and reliability for geospatial data collection.

Tables 1 and 2 show the calculation of the volumes of mineral aggregates potentially exploitable in the Capu Câmpului perimeter for the year 2017 and year 2018 (without lowering below the current riverbed thalweg elevation).

Table 1. Estimated volumes of mineral aggregates exploitable in the Capu Câmpului perimeter (2017), without lowering below the current thalweg elevation

Profile	Surface	Average surface area	Partial distance	Partial volume	Total volume
P1	17.243	8.622	0.000	0.000	0.000
P2	66,628	41.936	164.548	6,900.365	6,900.365
P3	28.504	47.566	175.540	8,349.746	15,250.111
P4	13.688	21.096	112.957	2,382.950	17,633.061
P5	0.000	6.844	141.931	971.374	18,604.435
Total			**595**		**18,604.435**

The total length of the exploitation perimeter is approximately 595 meters, with a maximum extractable volume (V_{max}) of 18,600 m³. Based on the 2017 volume calculations, the sand and gravel reserve within the analyzed section - spanning approximately 595 meters of the riverbed - was estimated at V_i = 18,600 m³ per gravel bar. Figure 7 shows the 2019 boundary of the mineral aggregate extraction perimeter along the Moldova River bed.

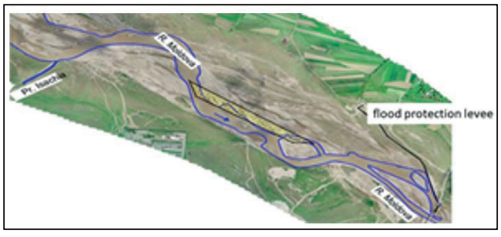

Figure 7. Orthophotomap of the Capu Câmpului perimeter from 2019

The 2019 volume calculations, based on a current measured riverbed length of 460 meters, indicate an updated reserve of V_{actual} = 20,387 m³ per gravel bar. Furthermore, a volume of V_e = 15,000 m³ of gravel was extracted from the analyzed section between 2017 and 2019, according to data reported by the operating extraction company. Based on these figures, the following resource balance equation can be established to quantify the reserve dynamics over the evaluation period:

$$V_{actual} = V_i + V_e + V_{regeneration} \quad (1)$$

The regeneration volume $V_{regeneration}$ is calculated as:

$$V_{regeneration} = V_{actual} - V_i + V_e \quad (2)$$

Applying the provided data, the regeneration volume is:

$V_{regeneration}$ = 20,387 - 18,600 + 15,000 = 16,787 mc/year.

Considering the current reserve volume of V_{actual} = 1,787,486 mc, the percentage variation in reserve volume is:

$$P_{regeneration} = 100 \cdot (V_{regeneration} / V_{actual}) \quad (3)$$

$P_{regeneration}$ = 82.34%

Note: Volume calculations can be performed using either the cross-sectional profile method or by creating a Digital Terrain Model (DTM), with the latter providing greater precision.

Table 2. Volumes of mineral aggregates potentially exploitable in the Capu Câmpului perimeter in 2019, without lowering below the existing riverbed thalweg elevation

Profile	Surface	Average surface area	Partial distance	Partial volume	Total volume
P1	0.000	0.000	0.000	0.000	0.000
P2	47.632	23.816	172.641	4,111.584	4,111.584
P3	53.561	50.597	174.732	8,840.811	12,952.395
P4	78.634	66.098	112.484	7,434.910	20,387.305
P5	0.000	39.317	0.000	0.000	20,387.305
Total			460		20,387.305

The total length of the exploitation perimeter is 460 meters, with a maximum extractable volume (V_{max}) of 20,387 m³.

Figure 8 shows the 2021 boundary of the mineral aggregate extraction perimeter (points 1–2–3–4) along the Moldova River bed.

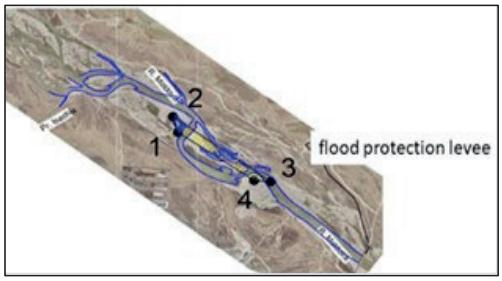

Figure 8. Orthophotomap of the Capu Câmpului perimeter from 2021

Table 3. Estimated volumes of mineral aggregates exploitable in the Capu Câmpului perimeter (2021), without lowering below the current thalweg elevation

Profile	Surface (m²)	Average Surface Area (m²)	Partial Distance (m)	Partial Volume (m³)	Total Volume (m³)
P1	3.912	1.956	0.000	0.000	0.000
P2	83.535	43.724	0.000	0.000	0.000
P3	30.655	57.095	174.636	9,970.823	9,970.823
P4	32.222	31.439	113.304	3,562.129	13,532.952
P5	0.000	16.111	140.379	2,261.643	15,794.595
Total			428		15,795.000

The total length of the exploitation perimeter is 428 meters, with a maximum extractable volume (V_{max}) of 15,795 m³.

According to the volume calculations performed in 2019, the reserve of sand and gravel within the approved exploitation perimeter - spanning approximately 460 meters of riverbed - was estimated at V_i = 20,387 m³ of ballast. Updated measurements in 2021 for the same perimeter, adjusted to a current riverbed length of 428 meters, indicate a revised reserve of V_{actual} = 15,795 m³. Additionally, the volume extracted from the area between 2019 and 2021 was reported as V_e = 15,000 m³, based on operator records.

Using the resource balance equation:

$V_{regeneration} = V_{actual} - V_i + V_e$,

we obtain:

$V_{regeneration}$ = 15,795 – 20,387 + 15,000 = 10,408 m³,

representing the net accumulation or loss in the riverbed over the period.

The regeneration percentage is calculated as:

$P_{regeneration} = 100 \times (V_{regeneration} / V_{actual})$ = 65.89%

Interpretation:

- $V_{regeneration} > 0$: indicates an aggradation process (material accumulation);
- $V_{regeneration} < 0$: indicates a degradation process (erosion or material loss).

An analysis of overlapping cross-sections from the years 2017, 2019, and 2021 reveals a relatively stable riverbed, with elevation fluctuations ranging from +0.12 m to –0.29 m (Figure 9). These variations are within acceptable limits and do not necessitate additional stabilization measures for the riverbed at this time.

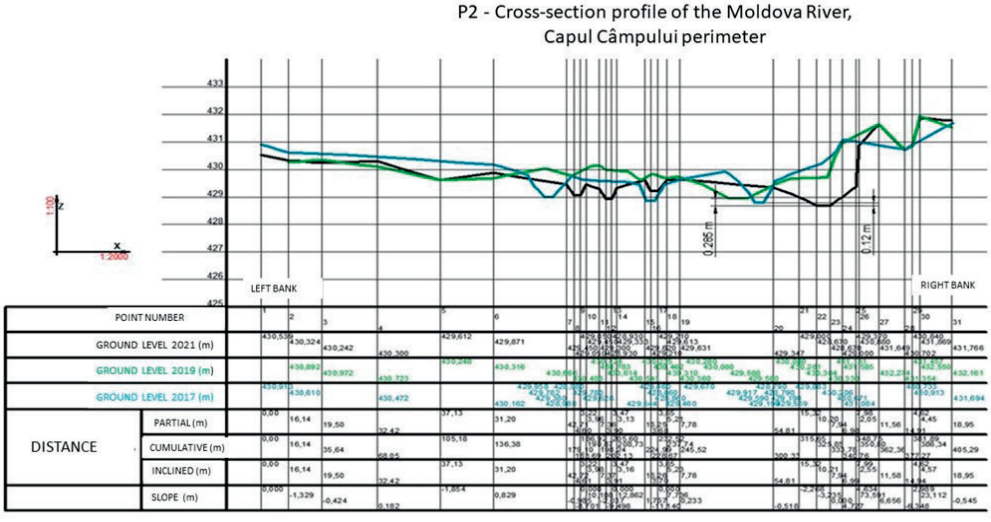

Figure 9. Cross-section of the Moldova River in the Capu Câmpului extraction perimeter area

CONCLUSIONS

Our analysis reveals that the Moldova River channel undergoes ongoing horizontal shifts, with lateral erosion occurring at an average rate of 4-5 meters per year. These processes are mainly confined to the active river corridor, which ranges in width from 500 to 800 meters.

Before 2010, approximately 15 extraction perimeters were active along the analyzed river

section. Currently, this number has significantly decreased, indicating a corresponding reduction in the volume of extracted mineral aggregates. The intensity of gravel mining activities is further evidenced by variations in suspended sediment hydrographs, which, in the case of the Moldova River, show an increasing trend over time. This contrasts with other rivers in the Siret Basin, where the general tendency is a reduction in sediment load. One plausible explanation for this divergence is the mobilization of sediments resulting from gravel extraction, a process that increases water turbidity.

The mobile riverbed depth along this section of the Moldova River has been measured at 2-3 meters, increasing to over 4 meters near the confluence with the Siret River, close to the Roman city. Cross-sectional analyses and measurements reveal a significant deepening of the riverbed in the Pod Izvor area. Long-term monitoring confirms the Moldova River's high sensitivity to two main categories of controlling factors: the natural variability of hydrological flow and anthropogenic influences. While natural factors were predominant before 1978, post-1978 observations indicate a marked dominance of human activities, particularly through an accelerated trend of riverbed incision.

In light of these findings, the following hydrotechnical interventions are proposed:

- *Channel development* through localized excavation, reprofiling of consolidated banks, and desilting, without altering the channel's width or depth.
- *Bank stabilization* in areas affected by active erosion poses risks to nearby infrastructure, using gabion walls or riprap with stone revetments.
- *Flood protection measures,* including embankments made from local materials, concrete parapets, elevation of riverbanks through reinforcement works, or the raising of existing access roads.
- *Longitudinal stabilization* through the construction of grade control structures using raw stone or gabions.

Recalibration of the channel is recommended in areas where sediment deposits or islands have formed, in order to improve flow capacity during medium and high discharge events and to restore the riverbed to dimensions derived from hydraulic modeling.

As demonstrated in this study - and supported by other research such as that conducted by Hooke (2004) - the use of GIS for monitoring land and land-use changes provides critical insights into the impact of human activities on river morphology, particularly in the context of land-use transformations.

In conclusion, GIS technology proves to be an indispensable tool for the monitoring and management of riverbed dynamics. It offers a robust and efficient methodology for spatial data collection and analysis. The application of GIS enables a comprehensive understanding of both natural and anthropogenic processes influencing river systems and facilitates the development of effective strategies for environmental protection, water resource management, and disaster risk reduction. The present study, alongside existing literature, reinforces the importance of GIS in fluvial geomorphology research and highlights its relevance in environmental policy and climate change adaptation.

Abstract

The paper presents a case study in which the application of a modern aerial scanning technology with the help of drones is carried out through a specific method, for the creation of a multifunctional database, with a wide applicability in several fields of economic activity and production specific to rural areas, as well as in cadastre real estate advertising works and rural tourism. The choice of the study topic is justified by actuality and necessity, as it contributes significantly to increasing the degree of predictability of the management as a result of the real-time collection of a very large number of data and information, the processing in a short time in order to identify vulnerabilities and their quick and efficient solution, as a result of the increase in knowledge, respectively of minimizing situations of risk and uncertainty. The use of aerial scanning equipment in cadastral works, agriculture, forestry, rural tourism and other important areas for rural development is an activity of great interest and allows to obtain in a short time a large volume of data used for the sustainable development of the community.

Key words*: aerial scanning, drone, multifunctional database, tourism promotion*

INTRODUCTION

The development of unmanned aircraft systems is a certainty of the present in which society shows increased interest. If at the time of their appearance they were intended and used in various military applications, we have gradually witnessed their adoption by civil society where there is a rapid increase in interest in their use in various civilian applications. They target multiple services that have as a common point the technique of terrestrial measurements using emerging technologies. The use of aerial scanning equipment with the help of drones is based on photogrammetry and remote sensing. The high capacity to collect data and information naturally leads to the design, development, and implementation of a geographic information system, a tool that allows for easy analysis of the collected data (Călina et al., 2022).

Unmanned aircraft systems comprise different components (unmanned aerial vehicle, launch and recovery station, data network, technical support systems, control station, human interface, etc.) whose complexity configures different classes among which the mini UAS is considered the fastest growing class (Iagăru et al., 2022). The growth is due to recognized characteristics such as: low costs, implementability directly from the field, accessibility of technologies (Iagăru et al., 2021), flexibility, etc., which give it advantages and ensure a dominant presence in civil applications in all fields of activity (Aswini et al., 2018; Barbedo, 2019; Călina et al., 2020; Wang et al., 2015; Borra-Serrano et al., 2022; Parraga-Alava et al., 2021).

The first uses of drones in civil applications were made by Yamaha Motor Company (Japan, 1987) through the RMAX-R50 concept dedicated to spraying pesticides on rice crops. Cisneros (2013) proposed the low-cost concept for use in emerging countries in South America (especially Peru). Later, Glen (2015) anticipated the downsizing effect and showed a possible market entry of medium and small UAV robotic systems that take advantage of the size reduction of specific multispectral sensor systems (Iagăru et al., 2022). Regarding drones for precision agriculture/horticulture (aircraft or multicopter type), there are very few bibliographic references (Krishna, 2016). In this case, the elements of interest (performance, flight qualities, specific transport aspects) refer to semi-autonomous flight

capabilities, initial acquisition cost, level of complexity of possible missions, maintenance costs (including periodic corrections specific to small drones).

Information collection takes place using sensors mounted on mini UAV. There are four types of sensors that cover almost all research applications in UAV remote sensing in precision agriculture: RGB, multispectral, hyperspectral and thermal sensors (Kovanič et al., 2023). The first three categories contribute to the creation of georeferenced reflectance maps, and the last category to the creation of temperature maps (Maes & Steppe, 2019).

The choice of the study topic is justified by its topicality and necessity, as it significantly contributes to increasing the degree of predictability of management based on the real-time collection of a very large number of data and information, processing in a short time in order to identify vulnerabilities and their rapid and efficient resolution, as a result of increasing the degree of knowledge, respectively minimizing risk and uncertainty situations.

The use of aerial scanning equipment in cadastral works and agriculture for rural development is an area of interest and allows obtaining in a short time a large volume of data that, when properly processed, provides a realistic overview, which leads to the development of relevant strategic options for sustainable community development (Călina et al., 2020).

The concretization of aerial monitoring takes place by carrying out flight missions at certain heights (for example, 100 m), according to a flight plan made by selecting a land area on a Google Earth or Map support. Approvals from the Aeronautical Authority and the Ministry of National Defense for flying over a land area at this height with the specification of take-off and landing points follow; creating the flight plan, aiming first of all to cover the area of interest, then generating the flight paths that the drone must cover, so that the photos taken have an overlap of 70% and the flight times are supported by the battery power (about 25 min for one battery); preparing for the drone take off (favorable weather conditions - clear sky and wind below 7 m/s, telephone network coverage necessary for data transmissions, adequate GPS signal); carefully following the trajectories travelled (Sălăgean et al., 2016).

The images obtained during aerial monitoring of ecosystems are processed with the help of dedicated software leading to the early detection of diseases and pests in the crop; precise mapping of weeds; precision in forecasting; precise application and reduced volume of pesticide solution; optimization of nutrient management; monitoring plant growth (Achtilik, 2015; Zhang et al., 2014). Mini UAVs for disease and pest control manage to maintain their control in identified areas, by applying variable doses of pesticides (Filho et al., 2020).

MATERIALS AND METHODS

The purpose of the work is represented by the study of aerial scanning equipment and UAV systems, respectively by its use in the data collection process in order to create a multifunctional database corresponding to the current requirements for sustainable development of the territory.

The achievement of the purpose is mediated by the establishment of objectives that represent stages in its achievement. These are:

- geographical and socio-economic characterization of the Cârțișoara locality,
- knowledge of aerial scanning equipment and traffic vectors;
- presentation of the research methodology;
- carrying out a study on the scanning of the Cârțișoara locality in order to create a GIS database.

The research methodology employed is the case study approach, as it allows for a comprehensive examination of the rural economy within the natural environment of Cârțișoara commune, viewed from various perspectives.

This study represents a detailed analysis method applied to complex scenarios and provides an in-depth view of the phenomenon being analysed “in a real-life context and using multiple sources of information (interviews, questionnaires, testimonies, evidence, documents, direct observation, participant observation)” (Glen, B., 2015). In particular, the research methodology utilized both quantitative and qualitative methods in parallel

and complementary ways (Upadhyaya et al., 2022), including secondary analysis of specialized literature and documentation from the Cârțișoara city hall to identify the object of interest, as well as from the Cadastre and Real Estate Advertising Office in Sibiu.

To achieve the established objectives, the research was structured and carried out in four stages, as shown in Figure 1. In stage 1, data and information were collected in accordance with the research purpose using the questionnaire applied at the level of administrative-territorial unit (ATU), secondary analysis of statistical data and relevant specialized literature, and observation for qualitative improvement of information. As a result, an accurate representation was achieved, highlighting critical factors and identifying best practices.

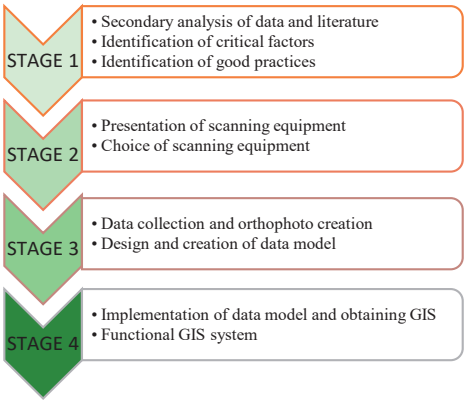

Figure 1. Schematic structure of the research

Case study

The study was conducted in the locality of Cârțișoara, Sibiu County, located at coordinates 45°43′34″N and 24°34′28″E. The primary objective of this research is to examine aerial scanning equipment and UAV systems and their application in the data collection process. The collected data will be used to design and develop a database aligned with current requirements for the sustainable development of the territory.

Cârțișoara commune is situated in the southeastern part of Sibiu County, in the central region of Țara Oltului, at the base of the Arpășel, Bâlea, Valea Doamnei, and Laița Mountains. To the east, it borders the village of Arpașul de Sus (part of Arpașu de Jos commune); to the west, it is adjacent to Scorei village (belonging to Porumbacu de Jos commune); to the south, it borders Argeș County; and to the north, it neighbors the commune of Cârța.

Documentarily, the commune is attested since the 13th century (yearbook of the Institute of History of Cluj-Napoca, volume VII-1964, page 317). The total area of the commune is 8.576 hectares. The commune of Cârțișoara presents a number of 4 main relief elements with their own specificity in terms of geomorphology. Geology, hydrology, climatology, lora and fauna, as follows: a) the Bâlii plain area; b) the hilly area; c) the pre-alpine area; d) the alpine area.

Stages of the research

To ensure the successful achievement of the project objectives, the research activities - both fieldwork and office-based - were structured into specific stages, as outlined in Table 1.

Table 1. Stages of carrying out activities

Activity type	Activity type	Activity type
Office	Establishing the work stages and inventorying the resources to be used (equipment, software products, documents, data, human resources, etc.)	01.08.2023 – 30.09.2023
Field	Obtaining raw data through aerial photography	01.10.2023– 15.10.2023
Field	Carrying out the analysis stage to identify the needs, requirements, and methods for obtaining the data of interest.	16.10.2023 – 30.10.2023
Office	Validating the raw data collected and performing photogrammetric processing in order to obtain an orthophoto map.	01.11.2023 – 15.11.2023
Office	Designing, testing, validating, and implementing a specific data model (database).	16.11.2023 - 30.11.2023
Office	Writing the technical specifications to be used for the administration and operation of the database.	01.12.2023 – 15.01.2024

Raw data collection by aerial photography

The data collection required the following activities:

• marking (materializing) on the ground of known coordinate points that will be used to georeference the obtained orthophoto map;

• using a GNSS receiver to determine the coordinates of the ground control points (GCP);
• planning and conducting the flight to acquire the photogrammetric data, from which the necessary orthophoto map will be generated.
• marking the ground points using FENO topographic markers.

For easy recognition on the photograms of the points marked on the ground, 50x50 cm marking panels were made and used (by positioning centered on the ground markings) painted in two colors (white/red). At the same time, for the areas that allowed, the marking was done directly on the ground, by applying a layer of paint (white, red).

The GCP coordinates were determined in the Stereo 70 reference system, by using GNSS equipment using the RTK method. Considering that the goal is to achieve a pixel size of 3 cm/pixel, we deemed the use of the RTK measurement method sufficient, as it ensures the required accuracy.

The coordinates were determined for 18 points marked or identified on the ground and which ensure visibility on the acquired photograms. In Table 2 are presented coordinates for 12 marked points.

Table 2.GPS coordinates inventory

Point no.	X	Y	Z
1	467013.193	470317.381	494.870
2	466953.872	469902.502	494.900
3	466731.680	469672.695	494.950
4	466914.265	469494.041	495.101
5	466768.974	469154.739	495.205
6	467204.136	469931.276	494.400
7	467338.487	469895.056	494.381
8	467525.948	470182.443	495.501
9	467744.810	470118.427	495.602
10	467515.69	469716.783	495.750
11	467593.025	469534.312	495.859
12	467661.940	469164.808	496.050

Planning and execution of the flight

The proposed goal of the graphic data acquisition flight was to obtain data that met certain minimum requirements from a technical and functional (content) point of view, such as:

- ensuring an orthophoto resolution of approximately 3cm/pixel;
- respecting the degree of lateral and longitudinal overlap (60°/85°);
- ensuring ground visibility.

The Matrice 300 RTK UAV was used for aerial scanning and DJI Zenmuse P1 (35 mm) sensor. The construction parameters of the DJI Zenmuse P1 (35 mm) are shown in Figure 2.

Figure 2. DJI Zenmuse P1 (35 mm) parameters

For flight planning, UgCS Drone flight planning software was used. This software includes background maps on which the area for the photogrammetric flight was identified and marked. Then, the other necessary flight planning parameters were entered: the type and model of the drone used, the specifications of the camera used, pixel size, flight speed, lateral and longitudinal overlap, etc. (Figure 3 and 4, Table 3).

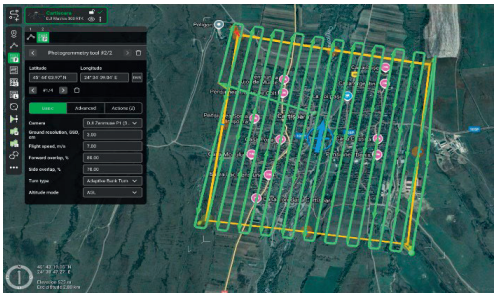

Figure 3. Flight planning and flight parameters

Figure 4. Elevation profile and flight details (area, size of footprint, no. of waypoints, camera triggering details)

Table 3. Presentation of the field book - photogram acquisition

# Label	X/East	Y/North	Z/Altitude

DJI_0123.JPG	23.786468	44.319000	221.874000
Due to volume considerations, only 10 positions from the field notebook are presented for illustration purposes.			

Processing raw data and obtaining an orthophoto map

The raw data collected was processed to produce a high-resolution orthophoto map (Table 4). The following activities were conducted during this stage:

- processing the raw data acquired in the field (1,172 photograms);
- generating the primary output: a digital 2D orthophoto map;
- producing secondary outputs, including: Digital Elevation Model (DEM); 3D Digital Surface Model; Point cloud; KMZ map format compatible with Google Earth.

Table 4. Resources required and used for processing raw data (photograms)

Resource type	Name	Features
Hardware	Workstation Fujitsu Siemens Celsius R570-2	Processor: 2 x Intel Xeon Six Core X5650, 2.66 GHz, 12M Cache, 6.40 GT/s Intel QPI, 12 Cores, 24 Logical processors Video card: NVIDIA Quadro FX1700, 512 MB GDDR2 128-Bit, 2 x DVI Network: integrated 10/100/1000 Mbps Chipset: Intel 5520 RAM: 48 GB DDR3 ECC Storage: HDD 2 x 320 GB 7200 rpm (RAID 1 - mirror) SSD 1 x 500 GB Samsung 850 EVO Optical drive: DVD-RW Operating system: Windows 8.1 Pro 64-bit Monitor: LCD Acer B243HL, 24 inch, 1920 x 1080, VGA, DVI Keyboard, Mouse
Software	ZwCAD Professional	ZwCAD offers performance in CAD design and significantly increased work speed, works with files up to DWG 2018 inclusive, includes 3D editing mode. It has efficient functions for 2D drafting and 3D modeling, ZwCAD offers perfect DWG compatibility
Software	Agisoft Metashape Professional	Agisoft Metashape Professional is a software product for advanced image processing and generation of 3D models based on static images. This software product is based on 3D reconstruction technology and can process images both under certain predefined conditions and in an unconstrained environment.
Software	ArcGIS Desktop	ArcGIS is a software product used for managing various datasets (both geographic and descriptive) and facilitating their manipulation. It allows working with maps and geospatial information and is mainly used for: creating and using maps, analyzing recorded data, sharing information, organizing and managing geographic information within databases, etc. During this stage of the project, ArcGIS was used to georeference the previously obtained orthophoto map.

The main steps involved in raw data processing using Agisoft Metashape Professional are illustrated in Figure 5. Following the completion of the data processing workflow, a 2D orthophoto map was generated (Figure 6), already georeferenced in the Stereo70 coordinate system.

Point cloud generation was the next step, during which a dense point cloud was created and visualized (Figure 7). This was achieved by aligning the photograms using the estimated camera positions recorded at the time of image capture. The resulting point cloud can be further refined or exported for additional use.

Subsequently, a 3D polygonal model was constructed using processed data and pre-defined parameters.

As shown in Figure 8, ground control points (GCPs) were identified, marked, and integrated into the processing workflow to enhance spatial accuracy.

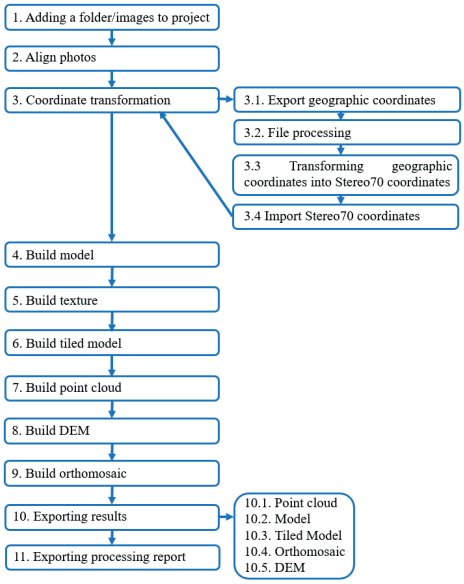

Figure 5. Workflow and results

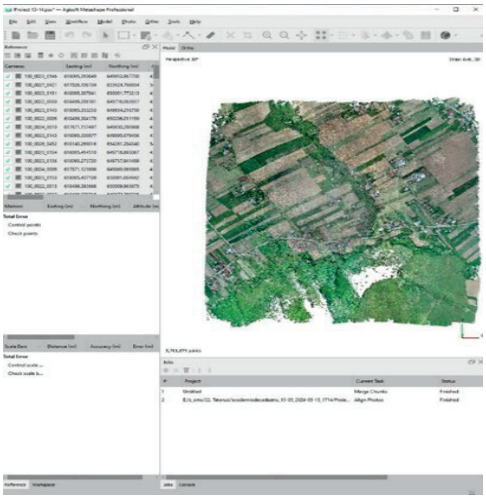

Figure 6. Orthophoto map

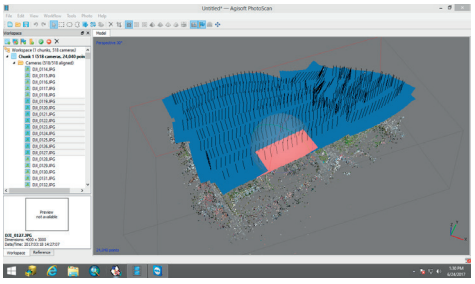

Figure 7. Point cloud generation

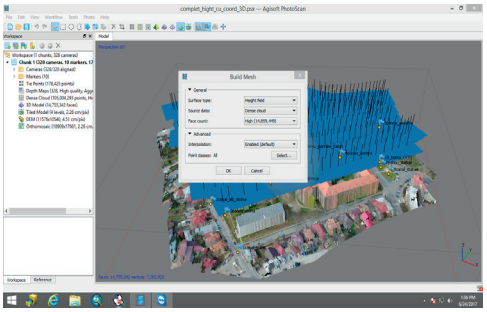

Figure 8. Parameters for generating 3D polygon model

• Surface type: height field – is the specific setting for wide planes (especially in the case of aerial photography);
• Source data: dense cloud – the dense point cloud was utilized as the source, as the goal is to generate a high-resolution orthophoto map;
• Face count: high – specifies the maximum number of facets of the generated model;
• Interpolation: enabled – this allows areas not covered by photograms to be generated through interpolation, based on data from surrounding areas; it is possible that uncovered areas will still remain.

Structure generation – proper structure generation determines the manner and quality of subsequent visualization of the generated model.

Therefore, the structure generation was carried out with the proper configuration of the generation parameters:
• The adaptive orthophoto mode was selected for mapping mode, so objects are segmented into flat/smooth areas and vertical parts. This ensures processing quality for both smooth areas and vertical surfaces (such as buildings, walls, etc.);
• Blending mode: defines how pixels with different values (from various photograms) will be merged in the final structure; According to the user manual, the mosaic value was used for the blending mode.
• Enable color correction: true - a helpful option when there are significant brightness variations (though it can be time-consuming and resource-intensive).

After processing, a ground resolution of 2,256 cm/pixel is obtained.

DEM creation - the DEM will be generated based on the processing parameters selected:
• reference system: Stereo 70;

• DEM is build using the existing dense point cloud;
• Interpolation mode: active.
After processing, the obtained DEM resolution is 4.51 cm/pixel. All the obtained results can be saved/exported. Thus, it is possible to export both the main result sought (orthophoto map) and other obtained products such as: point cloud, DEM, etc. (Figure 9).

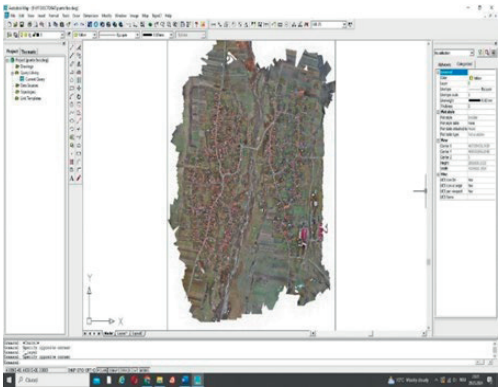

Figure 9. Export results

Design of the data model (database)
In general terms, a database is a collection of information that can be accessed and used as needed. Databases, as organized data structures, are present in all fields of activity. If we consider the users of the data and the need to organize it, the concept can be defined more broadly as follows: a database represents a structured collection of logically interconnected information, which can be shared and includes both the relationships between the data and their descriptions. The database design is carried out in such a way as to meet the specific requirements of the users it serves.
Any database must fulfil the basic functions, which are: storing and organizing data, ensuring data accuracy, easy exploitation, non-redundant data recording, ensuring data retrieval and extraction, and updating through CRUD operations (create, read, update, delete).
Database design is a complex process that includes several working phases, from planning the process to maintenance during operation. The main stages of database architecture design are shown in Figure 10.

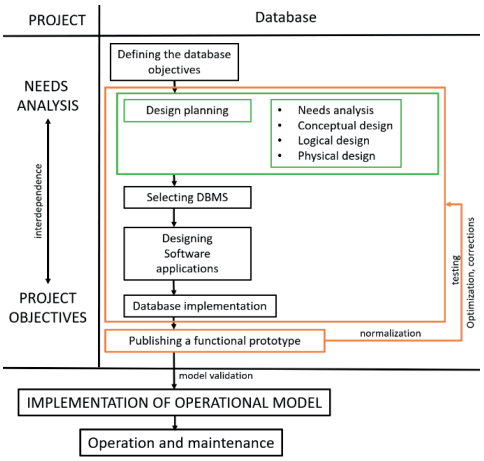

Figure 10. The logical flow for designing a database. Source: Own elaboration, adapted from (Vangu et al., 2023)

GIS systems use spatial databases, which ensure their scalability, allowing them to be used at local, regional, national, or global levels. From an IT perspective, the process of designing, developing, and implementing the database is the same, but the structure and content of the database must be adapted and aligned with the requirements of each project.
The database designing, testing, validating, and implementing is mainly based on the results of the analysis stage. Starting from these results, a structuring and filtering of the data of interest was carried out.

RESULTS AND DISCUSSIONS

As a result of the case study, the orthophoto map obtained through the application of photogrammetric techniques has multiple uses and can provide valuable data for various applications. Below are the main ways to exploit it.

Mapping and updating maps: the orthophoto map can be used to update the digital maps of the area, providing a detailed and up-to-date image of the terrain (Vangu et al., 2025).
Urban planning and rural development: local authorities can use the orthophoto map to analyze existing infrastructure, plan expansions, and identify areas for development.

Tourism promotion: the orthophoto map can be used to create interactive maps and tourist guides based on real images, enhancing the tourist experience (Chen et al., 2017).

Land use analysis: it can be used to assess land use (built-up areas, agricultural land, forests, watercourses) (Budiharto et al., 2021).

Environmental monitoring: the orthophoto map allows the analysis of the impact of human activities on the environment and the identification of potential issues (deforestation, erosion, pollution).

Based on the orthophoto map, information can be extracted regarding: the exact boundaries of land and properties, with direct benefits in real estate management; infrastructure and transport networks; the typology of buildings and their use (guesthouses, traditional houses, tourist attractions, etc. can be classified and analyzed); vegetation and natural resources studies; 3D modeling and topographic and spatial analyses (Sedano-Cibrian et al., 2023).

Considering the touristic nature of the Cârțișoara commune, we focused on the possibilities of exploiting the orthophoto map for tourism purposes.

As mentioned before, the most important stage in database design is the needs analysis, which is the stage where a detailed analysis of the requirements and expectations of the end users is carried out. Any aspect overlooked during this stage can compromise the final results.

As a result of the needs analysis stage (through consulting specialized literature and discussions with local authorities and tourism operators), we found that a well-structured local tourism development plan should contain both information about attractions and infrastructure, as well as promotion strategies, services offered, and statistical data about tourists. By using the orthophoto map, we can create interactive maps, optimize routes, and plan sustainable tourism development.

An orthophoto map of a rural tourist locality can significantly contribute to the development and promotion of tourism by providing accurate and up-to-date. Below are the main ways it can be used for promoting and developing local tourism.

Creating interactive tourist maps: the orthophoto map can be used to develop interactive digital maps integrated into mobile apps or web platforms; based on it, tourist attractions such as historical monuments, old churches, hiking trails, guesthouses, traditional restaurants, etc., can be marked (Quamar et al., 2023). Tourists can explore the locality virtually before visiting, with access to detailed information about the attractions in the area.

Planning tourist routes: the orthophoto map helps in identifying and optimizing tourist routes, whether for hiking, cycling, or car tours. Trails through forests, access roads to lesser-known attractions, or scenic routes for spectacular photos can be marked. Rural tourism organizers can create thematic routes, such as gastronomic, eco-tourism, or historical routes (Hognogi et al., 2021).

Promoting guesthouses and other accommodation units: guesthouse and agro-tourism owners can use the orthophoto map to showcase the exact location of their units along with the surrounding landscapes. Maps based on the orthophoto map can help tourists visualize the distances between accommodation locations and main attractions, highlighting nearby facilities like local restaurants, shops, or cultural points of interest.

Monitoring and developing tourism infrastructure: local authorities and tourism entrepreneurs can analyze the existing infrastructure and plan the development of new facilities, such as parking lots, camping areas, or viewpoints. Areas with untapped tourism potential can be identified, where recreational activities (e.g., equestrian centers, off-road trails, water sports) can be developed. Issues related to accessibility, such as deteriorated roads or the lack of tourist signs, can be highlighted.

Analyzing the impact of tourism on the environment: by comparing orthophoto maps made at different time intervals, the impact of tourism on the environment can be monitored. Areas affected by deforestation, erosion, waste accumulation, or other issues requiring intervention can be identified. This helps promote sustainable tourism by establishing nature protection rules and conserving ecologically valuable areas.

Creating virtual tours and online promotion: using the orthophoto map together with high-resolution aerial images, virtual tours can be created for promoting the locality. These can be

integrated into tourism websites, online booking platforms, or tourism apps. Tourists can have an immersive experience, exploring the area before deciding to visit.

Support for tour guides and travel agencies: Tour guides can use maps derived from the orthophoto map to provide detailed explanations about the relief and history of the locality. Travel agencies can use this data to personalize tourism experiences, offering routes and activities tailored to each visitor type. The orthophoto map can also help organize local events, such as festivals, traditional fairs, or sports competitions.

Therefore, the orthophoto map provides a valuable tool for planning, promoting, and managing local tourism. From creating interactive maps and optimizing tourist routes to developing infrastructure and protecting the environment, this type of data contributes to increasing the attractiveness of a destination and improving visitors' experiences.

Specifically, the orthophoto map can be integrated into GIS, websites, or various tourist applications where a multitude of tourist information can be marked and published, and which can be structured as shown in Table 5.

Table 5. Structuring of the main information that can be included in databases specific to tourist areas.

Type	Category	Details
General information about the locality	Geographical location	coordinates, county, distance from major cities
	Type of tourism practiced	rural tourism, ecotourism, cultural tourism, agrotourism, etc
	Climate and seasonality	optimal periods for visiting
	Accessibility	access routes: roads, public transport, nearby airports
Tourist infrastructure	Accommodation units	Guesthouses, agrotourism guesthouses, hotels, cabins Accommodation capacity (number of rooms, room types) Facilities (restaurant, swimming pool, accessibility, WiFi, parking) Classification and average prices
	Restaurants and local cuisine	Restaurants, inns, traditional wineries Specific regional menus (traditional dishes, local products) Local culinary events (gastronomy festivals)
	Tourist routes and trails	Hiking trails, cycling, equestrian routes Difficulty and estimated duration Viewpoints and rest areas Accessibility (for families, athletes, elderly tourists)
	Other tourist facilities	Tourist information centers Equipment rentals (bicycles, ATVs, horses, boats) Local transport (taxis, buses, transfers)
Tourist and cultural attractions	Natural landmarks	Mountains, lakes, rivers, forests Nature reserves and protected areas Wildlife and flora observation points
	Cultural and historical landmarks	Old churches, monasteries, castles Museums and memorial houses Historical monuments and archaeological sites
	Traditions and crafts	Pottery workshops, weaving, wood carving Cultural events and traditional fairs Folk music and dances
Tourist services and local experiences	Recreational and adventure activities	Guided tours (cultural, gastronomic, ecotourism) Sports activities (mountaineering, skiing, fishing, hunting) Nature-guided excursions Workshops (traditional cooking, basket weaving, cheese making)
	Other services	Spa and wellness centers Camping and glamping sites Tour guide services and equipment rentals
Statistical data and tourism demand analysis	Annual number of tourists and seasonality Tourist typology (families, adventurers, weekend tourists) Tourist preferences (preferred activities, average budget, length of stay) Assessment of the impact of tourism on the community (economic, social, environmental)	
Tourism promotion strategies	Digital marketing platforms (websites, social media, Google Maps, TripAdvisor) Events and fairs (tourism exhibitions, themed festivals) Collaborations with travel agencies and industry influencers Sustainable tourism (environmental protection strategies, local community involvement)	

Both the previously mentioned datasets and other relevant information can be structured into relational or non-relational data models (databases), as determined by database design

specialists. Relational databases operate with lower hardware resource consumption but may be more challenging to use for inexperienced personnel. Non-relational models require higher hardware resources but can be much easier to use for basic operations.

Figure 11 illustrates a partial relational model of a database in the tourism domain, which structures and organizes information regarding the types of tourism available in the area, accommodation units and their capacities, types of facilities and their locations, tourist attractions, and transportation capacities to these attractions. The presented model can be completed and extended to include additional relevant information, depending on the beneficiaries (tourists, tourism operators, local authorities, etc.).

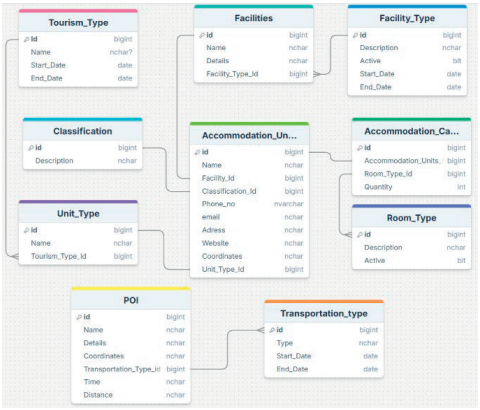

Figure 11. Basic database model for tourism

UAV systems contain a series of emerging technologies that have different levels of evolution and progress, bringing an accelerating role of innovation in a complex mechanism in which those who adopt this innovation early can influence the processes of evolution of technological capacity, with an impact on investments in subsequent stages. The adoption rate of innovation is known to be 20-30%, but taking into account the specific particularities and conditions in Romania, it was found that there is a particularly uneven distribution by age, but it is based on trust in young people who adapt much more easily to new technologies. The proposed topic also has the role of creating a unique integrated framework for analyzing the opportunities, expectations and restrictions of the scalable implementation of UAV systems in the context of the fruition of innovations specific to this emerging field, in the context of the area. The possibility of analyzing different paths of progress at different stages was also pursued, which is why it is valid to apply a quantitative and qualitative analysis to present the opportunities and restrictions of UAV implementation and relevant factors that contribute to or inhibit the technological diffusion specific to UAV missions in the different fields. From the work with students, specialists in the field of terrestrial measurements and farmers, it was observed that in terms of innovation, the use of UAVs is at an early stage because, despite the technological progress at the level of UAV system components, the development of batteries does not yet allow increases in maximum take-off weight, with implications on the maximum payload, specifically affecting active work in precision missions in the different fields of activity. However, there are future expectations of increased performance of propulsion systems and batteries, with an impact on payloads. This aspect is, however, compensated by the advantage of increasing the accuracy of UAV drones and data quality. Innovation is at a level that allows for further growth.

Difficulties in applying this technology also arise due to some operational bottlenecks at the institutional and legislative levels, where transformations are still needed. This leads us to discuss the emergence of signs of scepticism or disappointment given the existence of restrictions on use and safety issues. Legitimizing the use of UAVs is essential in a rather confusing legislative context, but the benefits of previous work by specialists on other sets of UAV applications and missions are relevant. The implementation of UAV systems in specific technology in different fields is also restricted by the level of specialized education, entrepreneurial education and the reduced capacity to create partnerships for the joint use of aerial monitoring platforms and the analysis and interpretation of results. All these problems lead to the emergence of skepticism regarding the interest in this technology, especially

among many older people. However, the ambition of those who understood the usefulness of technology for creating sustainable and intelligent ecosystems and their success in implementing UAV systems, was materialized by early detection of vulnerabilities, intervention focused exclusively on them, reducing resource consumption, highlighting the true potential and offering efficient solutions. Agricultural producers and foresters in the future will adopt UAVs in their business portfolios and will better understand the progress they offer in the context of sustainability. Although there are still a number of uncertainties and risks, significant cost reductions and increased performance will favor the recovery phase that will extend sustainably. Users, despite not having specialized education, are surprisingly becoming more sophisticated and demanding superior performance without deeply understanding the aspects of technological leaps.

This study has certain limitations and constraints that should be taken into account in future research. These are related to the following: the goal of offering a comprehensive understanding of the specific processes of innovation transfer in a field characterized by unknown evolutionary dynamics and the lack of relevant data on aerial scanning and precision applications; understanding the capacity of reliability aspects, digital footprint and the influence of innovation dynamics in the field on the performance of aerial scanning and precision applications in the different domains. The motivation to continue this research is also determined by the fact that the proposed systems work very well from a technical point of view and have the advantage of being easy to use by inexperienced end users. Also, the challenges related to the digital footprint will be further addressed to increase competitiveness in the different fields of activity, where it is very well suited.

The development of a territory/zone/area represents the capitalization under superior conditions of endogenous resources that give it specificity, and the creation of a geographic information system at the UAT level is defining. Rural areas have a relevant heritage of resources that give it specificity and lead to the development of a specific economic structure in accordance with the diversity of endogenous resources that, when digitized, accelerate this process.

CONCLUSIONS

The commune of Cîrțișoara has many resources that can act as a generator of local development, by outlining a vision of sustainable development, for which a multifunctional base provides faster, more detailed necessary data that underpins the strategic planning process.

The research methodology adopted is the case study because it involves the in-depth study of the rural economy, in the natural setting of the commune of Cârțișoara, from several perspectives.

The development of unmanned aircraft systems is a certainty of the present towards which society shows increased interest, including in collecting data for the creation of a geographic information system.

The design and implementation of a multifunctional database requires:

- the existence of a team of specialists in various fields (cartography, photogrammetry, informatics, etc.);
- the development of a data model (database structure);
- the existence of a graphic support (raster type);

The stages of acquiring raw data through aerial photography and their graphic processing are resource-intensive (financial, time, technical);

The stage of vectorizing the elements of interest and recording the related attributes is time-consuming;

The success of implementing a multifunctional database depends on the team's ability to collect the necessary data;

The structure and content of a geographic information system can be updated at any time (with greater or lesser efforts and, of course, with awareness of all subsequent implications);

The built multifunctional database system allows:

- displaying and extracting results in various forms: images, graphs, tables, maps, etc.;
- ensures flexibility in the analysis of data of interest.

The integration of UAV-based data acquisition, database development, and GIS systems constitutes a synergistic process that generates significant added value. Each piece of equipment and each technological procedure serves a well-defined purpose, contributing to the achievement of broader spatial planning and development objectives.

The methodology proposed in this study was validated through a case study, during which all the designed stages were implemented and the targeted objectives were successfully met.

The generation of an orthophoto map and its integration into an information system designed to support local development represent a multi-stage and complex workflow, where technical operations and data modeling are coherently combined. The first essential stage involves the execution of a photogrammetric flight using an UAV, with the main objective of acquiring primary data in the form of overlapping aerial images (photograms) at a spatial resolution tailored to the project requirements. The flight planning process - including the determination of flight altitude, image overlap, and flight path - plays a decisive role in ensuring the quality and accuracy of the subsequent photogrammetric products.

Following data acquisition, a rigorous photogrammetric processing workflow is applied using specialized software. This involves the alignment of photograms, generation of a dense point cloud, construction of a digital terrain model (DTM), and ultimately, the creation of the orthophoto map. The resulting orthophoto map, which is both georeferenced and highly accurate, serves as a fundamental spatial dataset for thematic data extraction and the development of derived cartographic products.

In parallel with these technical activities, an analysis of user requirements is conducted to design a database tailored to the specific needs of the local community or the field of application. In the present study, considering the predominantly rural tourism profile of the investigated area, the proposed data model was specifically developed to meet the requirements of the tourism sector. Accordingly, the conceptual database schema incorporates relevant entities such as accommodation facilities, tourist trails, cultural landmarks, protected areas, infrastructure networks, and tourist amenities. Performing this analysis concurrently with the orthophoto map generation facilitated the optimization of the subsequent data integration stages.

Although the case study focused on supporting tourism-related activities, the validated methodology is adaptable and transferable to a variety of domains, including environmental protection, territorial planning, urban and rural development, the updating of local cartographic products, and utility and infrastructure management.

Once both the orthophoto map and the database structure were finalized, the database population stage was initiated, with the orthophoto map serving as the primary support for the identification, digitization, and recording of spatial features. The collected data were then integrated into a Geographic Information System, enabling efficient spatial analysis, visualization, and data exploitation.

The final outcome of this workflow is a geospatial database integrated within a GIS environment, with direct applicability for local and central authorities, economic operators - particularly those in the tourism sector - and for the general public, facilitating access to relevant spatial information. The integrated use of these data provides a robust foundation for the development of sustainable development strategies, territorial planning, and the promotion of the region's touristic potential.

The study undertaken is oriented towards the use of modern methods, means and tools of analysis carried out within the framework of the case study methodology and represents a contribution to the management of strategic orientation activities of sustainable development in the Cârțișoara ATU model, by using modern aerial scanning techniques, creating a GIS database and integrating information for the development of relevant strategic options for sustainable development.

Further research will refer to the establishment of partnerships, entrepreneurial education and specialized education. These, together with the innovative management framework adopted at the level of agricultural and non-agricultural enterprises, are capable of accelerating the implementation and future development of UAV systems.

Abstract

The work was carried out based on the experience of over 30 years of study of the authors' team in the field of land measurements, during which, throughout the specific activities of topography and cadastre, they worked with both classic equipment and high-performance, modern equipment. Based on this, we thought of presenting in this short work, the essence of the experience, which aims to target the impact of modern information systems on all aspects related to topo-cadastral works. A case study was presented for the technical documentation necessary for the tabulation of a road in a locality in Dolj County. As a result, all the advantages and novelties related to the application in topo-cadastral works of the complex information system, consisting of high-performance modern equipment used to collect data from the field, combined with automatic data processing, with a high-performance specialized program, with wide applicability in several fields in Romania. The results were very relevant and significant in terms of their impact on the efficiency, cost-effectiveness and accuracy of the terrestrial measurement work carried out in the presented case study.

Key words*: information systems, topographic measurements, documentation, AutoCAD, road registration, geospatial accuracy*

INTRODUCTION

It is widely recognized that for an organization to succeed and remain competitive in a dynamic economic environment, managers must identify optimal solutions and drive radical innovations despite uncertainty. To support this, organizations need to invest in information systems that add value to business processes. These systems are primarily designed to automate information processing, which serves as the foundation for informed decision-making (Furby & Akhavian, 2024).

Information systems play a crucial role in enhancing the flow of information between tools, equipment, and work methods. This integration leads to the automation of processes and improved efficiency in topo-cadastral measurement activities (Călina et al., 2018; https://gisgeography.com/trilateration-triangulation-gps).

Studies show that, in order to complete tasks on time and make accurate decisions, professionals in the field must rely on high-performance information systems that align with the core requirements of their activities. All data and information collected from the field and processed through various activities or procedures can be easily accessed by users of information systems, while also offering a unified and integrated perspective. These systems provide a range of advantages for their users, facilitating not only the sharing and transfer of data and information but also supporting the optimization and automation of work processes (Sestras et al., 2022). Efficient data exchange can accelerate the achievement of objectives and reduce the time required to complete specific tasks. The implementation of such systems often results in improved data quality, reduced working time, enhanced communication between operators, more accurate decision-making, and significantly increased productivity (Doneus & Neubauer, 2005; https://rompos.ro/index.php/informatii-tehnice/sisteme-gnss). In the domain of land surveying, automation has substantially improved the quality of topo-cadastral data, particularly through enhanced positional accuracy and resolution. These systems integrate a wide range of technical tools with varying levels of automation, with the electronic

computer at the core. Minimizing manual operations reduces the risk of errors. The integration of real-time position determination using global positioning systems (GPS) and automated data processing contributes to increased accuracy and uniformity across all digital and analog products (Păunescu et al., 2020).

New knowledge in the field of land surveying is already being applied to address both local and global challenges. However, specific issues often arise with certain techniques and technologies - likely due to the absence of well-defined methodologies for designing and utilizing information systems (Stöcker et al., 2020). Numerous studies highlight the growing need for practical geospatial solutions to address social, environmental, and economic problems. One of the most pressing challenges today is balancing the exploitation of natural resources with the preservation of ecological systems. This tension calls for a reevaluation of development strategies at local, regional, and global levels. Information systems will undoubtedly play a critical role in supporting these new directions by providing essential data and tools for managing, analyzing, visualizing, and applying geospatial knowledge (Mihai et al., 2015).

The current development of integrated information systems is characterized by substantial transformations, both in terms of procedures for collecting and processing data and information, and in terms of defining and creating final products, thus analyzing the data collected both as sources and as products. With the launch of the first artificial earth satellites and spacecraft, a new era in the development of topo-cadastral measurements from all points of view opened. Satellite systems have been differentiated from the beginning into: reconnaissance systems; meteorological systems; systems for the study of terrestrial resources; commercial satellite systems. In this field, there have been significant developments in recent decades, which have targeted both theoretical foundations and cartographic technologies, means of representation and equipment for collecting, processing, organizing, storing, retrieving and using topo-cadastral data and information (Longley et al., 2011; https://gisgeography.com/trilateration-triangulationgps).

Among these are: what is the nature of geocoded data (X,Y,Z) at different scales and after different transformations; how does data quality behave at different transformations; how to manage the large volume of data resulting from raster or vector digitization or imported from photogrammetric and remote sensing systems; how to generalize and reduce this amount of data to optimize storage; the criteria to be followed to choose the necessary archives to keep; how to generate missing data, either for the "lost" ones or from those previously compacted; how to choose a national or international standard for data exchange or to collaborate on the creation of maps with continental or global changes (Herbei & Sala, 2020).

In the context of cadastral works, the use of modern technologies plays a crucial role in ensuring the accuracy and efficiency of measurement and recording processes. Among these technologies are GPS systems, modern measurement equipment (total stations), CAD systems, and GIS technology. Each of these tools contributes to the creation of an accurate cadastral framework and proper documentation of land ownership (Dragomir et al., 2025). The technologies serve as tools for primary data collection and processing, while GIS represents an advanced solution that enables the collection, storage, analysis, and visualization of spatial data (Nițu & Tomoioagă, 2015; Roșca et al., 2020).

In cadastral work, GIS proves essential for the integration and efficient management of geographic data. Through GIS, information regarding property boundaries, roads, and existing infrastructure is centralized in a digital system that can be easily accessed and updated. This system allows for precise analysis of land development and changes, which is vital for legal and administrative purposes, including the registration of a road sector in the land registry (Sestras et al., 2025).

One of the key advantages of GIS over other technologies is its ability to manipulate and analyze data within a geographical context. GIS can integrate data from multiple sources (GPS, digital maps, satellite imagery), making it extremely useful for creating a detailed and accurate cadastral framework. Additionally,

through GIS, spatial analyses can be performed to determine risk areas, evaluate the impact of new constructions on existing networks, or optimize land use.

Moreover, it is important to understand the main similarities and differences between CAD products (such as AutoCAD) and GIS products. Both CAD and GIS are essential tools in the field of cadastral work, but each focus on different aspects of the mapping process. AutoCAD is a software primarily dedicated to drafting and creating detailed technical plans, including contours, lines, and geometric shapes. It is frequently used in the design of infrastructure and construction works, and files generated in AutoCAD are often used for cadastral documentation (Akinci et al., 2010).

On the other hand, GIS focuses on managing and analyzing geospatial data. While AutoCAD is geared towards creation and drawing, GIS is concerned with manipulating and interpreting location- and land-related data. GIS allows for advanced analyses such as generating thematic maps, calculating distances, or assessing the impact of various changes on land.

In a complementary manner, AutoCAD can be used to create detailed drawings of an area, which can then be integrated into a GIS system for more detailed geographical analysis and visualization. Data related to a road sector can be created in AutoCAD and then transferred into a GIS to study its impact on the road network in a larger area, considering factors such as topography, land use, or existing infrastructure.

In this study, the use of the AutoCAD work system integrated with field equipment such as total stations and GPS was analyzed. This method was used because AutoCAD represents a standard for design in the fields of mechanics, architecture and geodetic engineering, being very useful for both designers and draftsmen (Becker et al., 2011).

At the same time, this was also due to the advantages obtained by using the AutoCAD program, such as:

- creating 3D (three-dimensional) constructions;
- obtaining virtual images of the designed objects;
- avoiding any routine work, by using the commands that create the required graphic element;
- obtaining drawings of exceptional clarity, due to the fact that the drawing, once created, is printed, and the changes made during the work do not appear on paper;
- perfect quality of the drawing created on the computer;
- its accuracy;
- reduced execution of modification time;
- easy transfer of information (CDs, DVDs, USB Sticks).

This paper aims to evaluate the efficiency and precision of topo-cadastral documentation using modern integrated information systems in a real-world case study.

MATERIALS AND METHODS

Reducing efforts and costs is essential for improving the competitiveness and long-term sustainability of any company. Geodetic engineering activities involve complex processes that require significant time and labor resources, and optimizing these processes can bring major benefits. Automation and digitalization are key solutions for minimizing manual intervention, eliminating errors, and enhancing the precision and speed of operations. Implementing advanced software solutions can significantly reduce the time needed for processing documentation and fieldwork, thus contributing to lower operational costs (Carrera-Hernández et al., 2020).

The applied methodology is presented in Figure 1, with the stages of the applied case study being presented and detailed further.

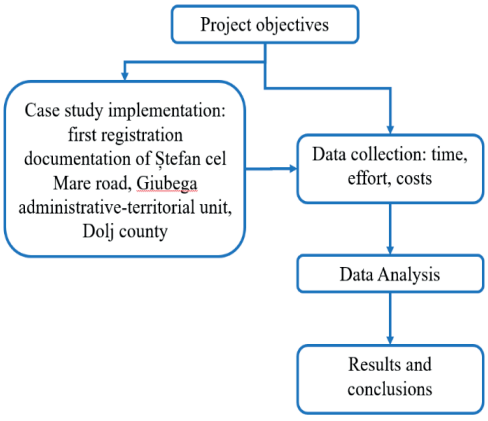

Figure 1. Applied methodology

To analyze efficiency and identify potential areas for improvement, we have conductes a detailed case study. This includes collecting and analyzing data on the time spent, efforts made, and costs involved in carrying out various cadastral activities. The aim of this study is to better understand workflows and discover optimization opportunities. The results obtained will be used to identify solutions that reduce the resources needed to complete projects, thus contributing to the streamlining of the cadastral firm's activities and increasing its profitability.

The case study presents a first registration documentation of the Ștefan cel Mare Street, ATU Giubega, Dolj County.

The process of preparing the cadastral documentation for the first registration of a road sector in the Land Register involves a series of methodical and sequential operations, carried out in accordance with national legislation and technical norms in force. The methodology adopted in this study ensures the acquisition of accurate spatial data, the legal identification of the land parcel, and the formalization of the necessary cadastral documents for submission to the competent cadastral and land registration office.

Field measurements were performed using high-precision GNSS equipment in RTK (Real Time Kinematic) mode, specifically a GPS Hi-Target V200 GNSS receiver and iHand55 controller, with RTK correction through the ROMPOS network, using the Stereo 70 projection system. Coordinates were exported in CSV format and processed in AutoCAD using the TopoLT plugin. To complement the geodetic data, a total station Leica TCA 1205 was used for areas with limited satellite signal reception or for detailing specific construction elements (e.g., curbs, culverts, or road infrastructure boundaries). For data processing, the AutoCAD Civil 3D platform (and TopoLT plugin) was employed for drafting the technical plans, while the geospatial database was managed and analyzed using QGIS 3.28. The final cadastral documentation was structured according to the requirements of the National Agency for Cadastre and Land Registration (ANCPI), using the specialized software e-Terra.

Figure 2 illustrates the main working stages, as well as their logical sequence within the framework of the present project. As shown, the entire workflow is illustrated, starting from equipment preparation and document analysis, all the way to final processing, printing, and exporting the cadastral plan for the measured road sector.

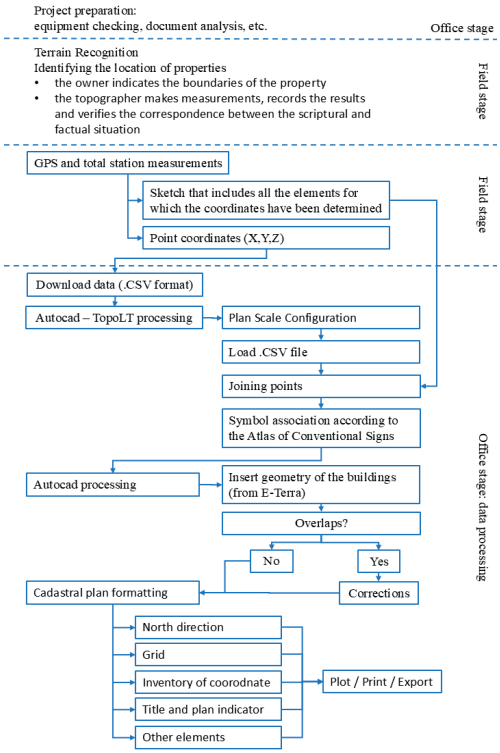

Figure 2. Workflow for measurements and data processing

The cadastral works were executed by a multidisciplinary team consisting of: a certified geodetic engineer (responsible for field measurements and technical verification), a legal consultant (responsible for verifying property rights, administrative boundaries, and legal acts), and a technician (responsible for assisting in field operations and document preparation).

Measurements for the Ștefan cel Mare Road were taken over a distance of about 430 meters and an area of about 6050 sqm. The field data were collected in a single day, in September 2023.

In this case study, a complex work system was used in which modern and high-performance equipment was used for field work, such as

global positioning systems (GPS) for collecting the main data, and total stations with high precision were used to complete the details. After collecting the data with high precision and high efficiency, they were processed with an older specialized program but widely used in several fields of activity in Romania, namely AutoCAD.

Working with this integrated computer system allows the total replacement of the pencil, the drawing board, the ruler, the square, the compass and the eraser. However, this program does not eliminate the need to pay increased attention to details, to thoroughly analyze the project. Emphasis must be placed on accuracy in drawing, as these drawings often go directly to numerically controlled machining machines (Pop et al., 2019).

Considering that the purpose of this article is to study the effectiveness of applying modern data acquisition and processing techniques, in addition to the technical data collected, details regarding execution time, efforts, and costs required to achieve the expected results were also recorded.

RESULTS AND DISCUSSIONS

The case study presents a First Registration Documentation of the Ștefan cel Mare Road, ATU Giubega, Dolj County. For the first registration documentation, the cadastral work was carried out based on field measurements, using the data processing method using the Auto-CAD program and drawing up the plan of this work.

The preparation of cadastral documentation involves the following stages (Sălăgean et al., 2016; Călina et al., 2022):

- identification of the location of the property and technical documentation;
- execution of field and office work;
- preparation of documentation.

This approach was chosen because it was concluded that it is very important and interesting how Auto-CAD has become an essential tool in cadastral works, offering the possibility of creating detailed plans of real estate. By using this complex information system GPS-Total Stations - Auto-CAD, it is possible to create and manage all the information regarding the lands registered in the cadastre, thus facilitating the process of recording and monitoring them. This system ensures precision and efficiency in the creation of cadastral plans, representing a crucial component in cadastral activity.

As is known, the owner is responsible for knowing, indicating the boundaries of the property and preserving them, as well as for making available to the authorized person all the acts/documents he holds regarding the property. The authorized person is responsible for measuring the property indicated by the owner, for the correctness of the documentation and its correspondence with the reality on the ground and with the documents proving the ownership right made available by the owner. In the case of tracings, the authorized person is responsible for materializing the boundaries of the property in accordance with the up-to-date geometry of the property in the database of the territorial office.

The road subject to modernization is located in the village of Giubega, a village located in the immediate vicinity of the city of Băilești. The Ștefan cel Mare Road is a road of national interest connecting the European road DN 56 and the city of Calafat. With the completion of the project for the modernization of the road, traffic in the area will increase, leading to the development and economic growth of the commune.

Before starting the measurement, the team moves into the field to reconnoiter the terrain. In this process, the area to be measured, the length of the route and the fixed elements are checked. Depending on the complexity of the details, the scale at which the documentation will be drawn up is established.

As shown in Figure 3, the survey team used a GPS receiver connected to ROMPOS for real-time measurements and a Leica TCA 1205 total station in the Giubega area.

Figure 3. Taking field measurements

The field trip was carried out with representatives of the Giubega Commune City Hall, who identify the neighborhoods of the building. A person who is part of the measurement team draws up a sketch of the building, respecting the numbering of the points in the GPS and representing all the measured elements.

As a result of the case study, the following concrete outcomes were obtained for Ștefan cel Mare Street, which has a length of approximately 430 meters and a surface area of 6,055 square meters:

- a coordinate inventory consisting of 104 points, for which coordinates were determined in the Stereo 70 reference system, as presented in Table 1;
- the cadastral documentation required for the first registration of this road sector in the land register;
- the site location map at a 1:2000 scale, as shown in Figure 4;
- used resources, as presented in Table 2.

Table 1 presents the inventory of coordinates for the surveyed points, and the publication of this table contributes to the methodological transparency of the study, providing a verifiable and useful database for researchers, professionals in engineering and surveying, as well as cadastral authorities. Thus, the obtained coordinates can serve as a concrete example of the application of advanced geodetic techniques in road infrastructure projects and in the process of updating cadastral data. At the same time, they are essential for the correct integration of the rehabilitated road section into the land registry, a process that guarantees the legal validity of the work.

Including these coordination points in this article not only supports the scientific validity of the research but also adds practical value, contributing to the improvement of precision standards in infrastructure projects and cadastral data management.

Table 1. Inventory of road coordinates for Ștefan cel Mare Street, Giubega, Dolj county

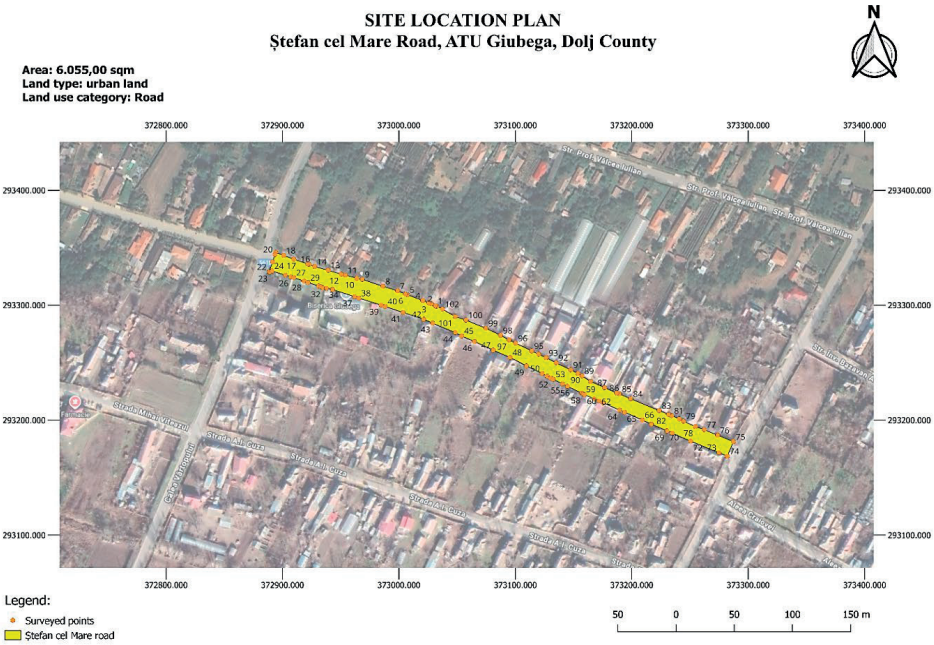

Figure 4. Site location plan

Table 2. Resources used in the case study implementation

No.	Type	Resource	Measuring units	Quantity
1	Personnel	Geodetic engineer	Minutes	530
2	Personnel	Legal consultant	Minutes	45
3	Personnel	Technician	Minutes	305
4	Material	Hi-Target V200 GNSS receiver	Units	1
5	Material	Leica TCA 1205 total station	Units	1
6	Software	AutoCAD, TopoLT plugin	Units	1
7	Software	QGIS v.3.28	Units	1
8	Other	Consumable materials		
9	Other	Transportation expenses		
10	Other	Indirect costs		

In any company, efficient cost management is essential to ensuring profitability and maintaining competitiveness in the market.

A company's efficiency cannot be measured solely by the volume of activities carried out, but also by the ratio between the costs incurred and the results achieved. A company can only be considered efficient when it manages to intelligently reduce costs without compromising the quality of the services or products offered, while simultaneously increasing profitability. This objective can be achieved by adopting modern technological solutions which, although requiring initial investments, bring considerable long-term savings (Šafář et al., 2021).

Therefore, only through constant cost analysis and the identification of optimization opportunities can a company ensure its financial stability and remain relevant in an increasingly competitive economic environment. Cost reduction should not be seen as a crisis measure, but as a strategic practice, integrated into the organizational culture, focused on performance and sustainable development.

It is important to note that the cost structure of a company differs from the cost structure associated with a project. Thus, in order to identify opportunities for reducing efforts and costs, and for optimizing activity, cost analysis must be conducted from at least three

perspectives: the type of expenses, the elements that generate them, and the stage at which they occur. Table 3 presents the main cost structure associated with a project and assesses the impact that each type of cost may have on the total cost of the project.

Table 3. Project cost structure and its impact

Expense type	Generated by:	Details	Impact on the project	Can be optimized	Remarks
Direct	Involved personnel	Primarily includes personnel costs associated with the project.	High	Yes	The personnel can work more accurately and efficiently. The personnel can use optimal solutions to achieve objectives, depending on the field conditions.
	Material consumption	Includes the consumption of materials within the project: survey markers, spray paint, etc.	Low	No	Modifying these cannot have a significant impact.
	Transport expenses	Includes transport expenses within the project.	Low	No	
	Other expenses	Other unforeseen expenses initially not anticipated.	Low	No	
Indirect	Uninvolved personnel	Includes the costs associated with administrative personnel and the costs for the professional training of the staff.	Low	No	
	Equipment	Includes the costs for the depreciation and insurance of the equipment.	High	Yes	They can vary by acquiring more efficient equipment that reduces execution times.
	Licenses	Includes the costs for licensing the software products used.	High	Yes	They can vary by licensing more efficient solutions that reduce processing times.
Administrative	General costs	Includes costs for rent, utilities, etc.	Low	No	

Therefore, it can be observed that the elements with the greatest impact on a project's costs are: the personnel directly involved, the equipment, and the software solutions used. At the same time, these are also the main elements that can be optimized within the context of a project.

The directly involved personnel can contribute to cost reduction through continuous professional development, which enables them to work more efficiently and accurately. Additionally, they can help lower expenses and increase efficiency by using appropriate technologies (best suited to field conditions) and software products that automate data processing. The “high” impact attributed to the equipment and software solutions used does not refer to their depreciation or insurance costs, but to the benefits that can be generated by using optimal equipment and software in the context of a project.

For example, in the case study carried out, measurements could have been performed using either a total station or a GNSS receiver. However, the surveyor chose to use the GNSS receiver because field conditions were favorable, and the execution time was significantly shorter than when using the total station.

Moreover, during the office phase, the surveyor used both TopoLT and AutoCAD to process the data, which reduced the time needed for processing and preparing the required documentation. Table 4 presents the possibilities

for optimizing activities and reducing costs depending on the project phase.

Table 4. Optimization opportunities according to project phase

	Personnel	Equipment	Software
Project preparation	No	No	No
Terrain recognition	No	No	No
Measurements	Yes	Yes	Yes
Data processing	Yes	No	Yes
Cadastral plan formatting and export	Yes	No	Yes

Considering the aspects mentioned above, the equipment and software solutions used, as well as the measurement methods applied, we can conclude that the case study was carried out under optimal conditions. This assessment is based on the following considerations:

- The personnel had access to all necessary resources (equipment, software licenses);
- The participants were properly trained and used the best methods and techniques suited to the field conditions;
- During the office phase, the personnel used all available software solutions (including the TopoLT plugin) to automate data processing;
- Field conditions (absence of interference and good visibility) allowed the use of a GNSS receiver for determining point coordinates. The surveyor also had access to a total station, but its use would have required more time for measurements;
- Data recorded by the GNSS receiver is easier to process compared to data collected by total stations;
- The use of the TopoLT plugin facilitated data processing;
- Predefined templates were used in AutoCAD, which reduced the time required for preparing the necessary documentation.

CONCLUSIONS

From the beginning, great importance was given to the accuracy of the data and products of the complex information system. A good treatment of this problem allowed the choice of the best data sources, the choice of the most correct methods of data collection and the choice of the most correct procedures for processing and creating the final products. Considering the various types of data and procedures for collection, validation and processing, it can be shown that:

- data have different measures and methods of assessing accuracy;
- the required level of accuracy specific to different types of applications varies greatly;
- data accuracy is strictly related to the collection methods, the equipment used, the data sources, the processing procedures, etc.;
- as a result of the above, data accuracy also depends on the costs of the information systems and vice versa.

By strictly respecting all the requirements listed above, the study team achieved much greater precision through this modern method of combining data collection with modern equipment and their automated processing with specialized programs, compared to the classic methods used over time in cadastral works. The classic equipment had a very low precision by construction, little or no possibility of collecting and storing data and a cumbersome maneuverability, aspects that led to the recording of very large total errors, which ultimately resulted in low precisions, which were difficult to achieve within the tolerance limits allowed in the case of such works and especially in the case of engineering works such as those presented in this case study. It was also found that technological and scientific progress led in the field of terrestrial measurements to the emergence of new methods and techniques necessary for the proper conduct of the activity, the computer offering greater precision compared to traditional drawing and design methods. Precision, accuracy, flexibility, ease of manipulation and modification are attributes of graphic representations created with specialized programs.

With the help of computer systems, which have a friendly, easy-to-use interface, the tedious tasks of drawing and detailing are greatly simplified by using geometric construction tools, such as: grid, snap, auto-quotation senders. The dimensions and technical notes are always legible on the drawings made, and the paper drawings produced by these systems are of a much higher quality than drawings made by hand. These performances obtained are

undoubtedly related to the qualities of the programs, but they depend mainly on the way in which their capabilities are exploited. A detailed knowledge of these modern computer capabilities and tools represents the basic premise of a high-performance activity, being at the same time powerful tools that can help, but cannot replace, the experience and knowledge of the specialist or user in a certain field.

In terms of the efficiency and profitability of specific land surveying and cadastral works, these have increased considerably, as modern computer systems represent essential tools, which offer the possibility of creating detailed, faithful and highly accurate plans of real estate properties, in a much shorter time and with a much-reduced volume of personnel and material expenses. By using these new systems, it is possible to create and manage all the information relating to real estate registered in the cadastre, thus facilitating the process of recording and monitoring properties, while they also become an essential component in the cadastre and real estate advertising activity.

Abstract

The realization of the cadastral plan for administrative territorial units, involves as field activities, the identification of owners and neighbors, the identification and spatial positioning of plots, and the verification of the category of use. The case study was carried out within the administrative territorial unit Pietroasa, Bihor County, and aims to analyze the technical aspects related to the realization of the cadastral plan of cadastral sector 31. For the identification of the cadastral sector and the plots, a drone flight was carried out, thus obtaining an orthophotogram of the respective location. The spatial positioning of the detailed topographic points related to the plots was carried out with GNSS technology, GPS system, using the RTK method, based on the GNSS station Beiuș. The reporting of the coordinates of the characteristic points of detail, and the preparation of the cadastral plan in digital format was done with the program MapSys 9.0. In the end, a total of 652 plots were reported in cadastral sector 31. By using the above-mentioned logistics and working methods, a high degree of automation and superior positioning accuracy was achieved.

Key words: *cadastral plan, cadastral sector, GNSS technology, GPS system,* plots*, land use categories.*

INTRODUCTION

In Romania, the general cadastre is established by Law No. 7/1996 on Real Estate Cadastre and Advertising. It represents a unified, mandatory system for the systematic registration and inventory of real estate assets nationwide, addressing their legal, quantitative, and qualitative aspects (Mihăilă et al., 1995).

The International Federation of Geodesy (FIG) defines cadastre as "an updated land information system based on cadastral parcels and records of land interests" (Ercan, 2023). Cadastre can also be defined as a creation of man, namely "the effect of his relationship with the land" (Comparetti & Raimondi, 2019).

The cadastre plays a fundamental role in identifying, documenting, and graphically representing properties in official registers and cadastral maps, serving as legal proof of ownership (Boș & Iacobescu, 2009; Nistor et al., 2012).

In the European Union (EU), there are currently two original models of cadastral system, related to land registration systems. As a result, there is the central model, in which the cadastre appears as a graphic basis (map) of land registration (land registry), so that physical changes must be reflected in the cadastre, and legal changes in the land registry, by maintaining a perfect parallelism, and respectively a Latin model, in which it appears only as a taxation instrument, useful for collecting land taxes. Knowledge of the cadastral models related to the EU Member States is a fundamental condition for the harmonisation of the land cadastre at EU level, as an inventory for environmental, social, economic, legal and fiscal purposes (Comparetti & Raimondi, 2019).

The National Agency for Cadastre and Real Estate Advertising (A.N.C.P.I.) is responsible for updating the national land fund records. This includes registering real estate transactions, creating new properties, modifying existing ones, and updating cadastral data in collaboration with local authorities, licensed service providers, public notaries, and survey professionals (https://lege5.ro/Gratuit/g44dcmjsge/...).

Accurate records support territorial planning, urban and r ural development, environmental protection, and sustainable natural resource management, while also enhancing land tenure security and investment stability (Boș & Iacobescu, 2009).

Systematic registration of property rights and cadastre in Romania is free of charge for property owners. The financing is full and comes from three different sources: from ANCPI's own revenues worth approximately 900 million euros, non-reimbursable funds from the European Union, worth approximately 312 million euros, and respectively from allocations from the budget of the administrative-territorial units, through co-financing (Bancioiu & Kovacs, 2022).

Systematic registration relies on field measurements using established surveying methods to generate parcel and cadastral plans. These activities are carried out ex officio, free of charge, and apply to both public and private property, irrespective of legal ownership status, as per Article 918 of the Civil Code. All measurements conform to applicable technical norms and legal requirements (https://lege5.ro/Gratuit/g44dcmjsge/...).

As of January 31, 2025, systematic registration had been completed in 298 administrative-territorial units (U.A.T.s), while in 1,773 U.A.T.s - approximately 64% of the national total-work was still underway (https://www.ancpi.ro/pnccf/documente/H3.).

Key elements of the cadastre include (Badea, 2005; Grecea, 2007, Novac, 2006):

- Cadastral sector: a subdivision of a commune or city, encompassing multiple plots, typically 50-200 ha in plains and 20-100 ha in hilly areas;
- Building: one or more adjacent parcels, with or without constructions, under single ownership;
- Parcel: A land area with a single use category;
- Land register: the official document recording ownership, use rights, area, encumbrances, and other legal attributes;
- Agricultural register: contains data on the ownership and use of agricultural lands, supporting land-use planning and agricultural policy;
- Basic cadastral plan: derived from the topographic plan and enhanced with cadastral attributes, showing location, surface, and boundaries of properties;
- Parcel plan: graphical representation of properties within a cadastral sector, verified by the County Cadastre Office and integrated into the cadastral plan (https://topogalati.ro/ce-este-planul-parcelar/).
- Land use category: a coded cadastral attribute used to determine property taxation.

The systematic registration of properties in Romania, within the framework of the National Cadastre and Real Estate Advertising Program, successfully requires the unitary integration of legal, institutional and geospatial components, for the optimal achievement of transparent and responsible land governance, efficient management of all resources and sustainable rural development (Gherheș et al., 2025).

Although a legal and technical framework exists, the lack of standardized software and methods for creating digital cadastral plans has caused inconsistencies in data handling across counties. National norms offer guidance, but their varied implementation reveals a need for unified standards. At present, research on standardizing digital cadastral plans and systematic registration at the ATU level is scarce, highlighting the need for further studies to improve and align cadastral processes nationally.

Registration in the Land Book through the Systematic Cadastre of real estate, although some difficulties have been reported in some areas, represents an efficient solution and an alternative to the Sporadic Cadastre, which was carried out in the past at the national level. Consequently, field work and working time will be optimized, and the determination of the areas of plots in the cadastral sectors will be achieved with high accuracy (Pop et al., 2021).

MATERIALS AND METHODS

Study location

The case study was carried out within the Pietroasa territorial administrative unit (UAT), Bihor County (Figure 1).

The town of Pietroasa is situated in the meadow zone at the point where the Crișul Pietros River emerges between the surrounding hills, partially extending to the base of the slope along the Bălătrucului Valley.

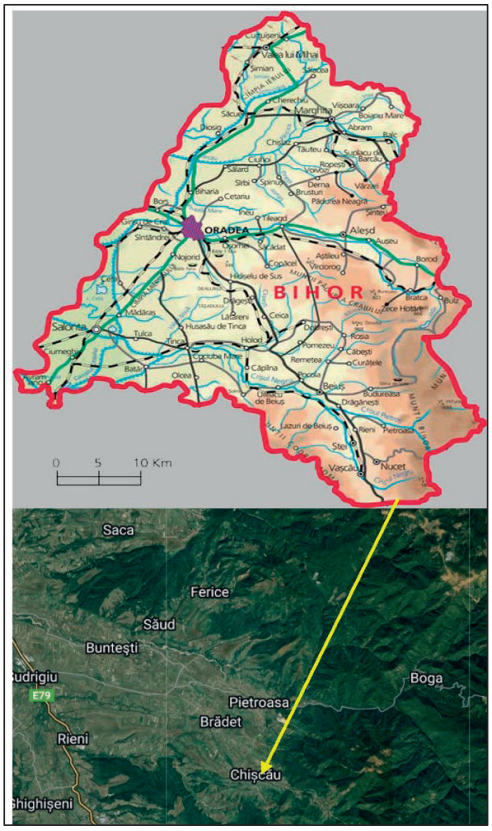

Figure 1. Location of research (https://provinciacrisana.wordpress.com/2017/10/06/scurta-descriere-a-judetului-bihor-provincia-crisana/; http://www.searchromania.net/harta_harti/bihor/pietr./)

The Crișul Pietros flows through the town from east to west, receiving three left-side tributaries - Lazului Valley, Bălătrucului Valley, and Mare Valley. On the right side, within the built-up area, it is joined by the Bălăcel Valley and a smaller, unnamed tributary (General Urban Plan, 2008).

The primary objectives of this case study are to investigate and analyze the specific characteristics and procedural aspects of creating the parcel plan and, subsequently, the cadastral plan for cadastral sector 31 in UAT Pietroasa, Bihor County. This is examined within the broader framework of systematic property registration in the integrated cadastre and land registry system, particularly within the built-up area and non-collectivized zones.

According to data as of January 31, 2025, the process of systematic registration in Bihor County had been completed in six administrative-territorial units (UATs), was ongoing in 49, and had not yet commenced in 46 (Figure 2) (https://www.ancpi.ro/pnccf/documente/H3_Lucrari). This distribution underscores the relevance of the current research in capturing the unique dynamics, implementation challenges, and progression of cadastral registration in the selected study area.

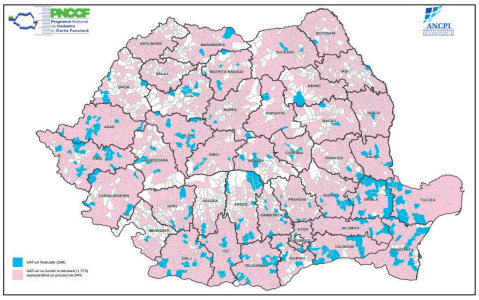

Figure 2. Status of systematic registration works of real estate at the ATU level as of 31 01 2025 (https://www.ancpi.ro/pnccf/documente/H3_Lucrari...)

The research employed a combination of methods, including bibliographic documentation, route and stationary observation, experimentation, simulation, comparison, and analytical techniques.

The bibliographic documentation involved a thorough review of specialized sources such as university courses, technical standards, scientific publications, technical projects in land surveying and cadastre, the General Urban Plan (PUG), and the agricultural register relevant to the case study area.

Field data recording

The experiment consisted of generating GNSS recordings for the spatial positioning of characteristic detail points that define the boundaries of plots and buildings (Crainic, 2024; Pica et al., 2021). This process included data processing, calculation of final coordinates within the national reference system, and the subsequent creation of both the parcel plan and the cadastral plan for cadastral sector 31, located within the Pietroasa administrative-territorial unit (A.T.U.).

To accurately identify the cadastral sector, buildings, and plots included in the plans, reference was made to the General Urban Plan

(PUG) and the coordinate inventory for the boundary points of cadastral sector 31, as provided by the Bihor County Office for Cadastre and Real Estate Advertising (OCPI).

Figure 3. Rebel FAE1718FW drone used for the work (https://fae-drones.com/2023/08/18/drona-fae-1718-fixed-wing-rebel/)

Currently, for the implementation of the National Cadastre and Land Registry Program, for the systematic registration of real estate properties, the recording and processing of the necessary data can be achieved under optimal conditions, through the successful integration of intelligent technologies, namely the Global Navigation Satellite System (GNSS) and Unmanned Aerial Vehicles (UAV) or drones (Ghergar et al., 2023).

To effectively capture, record, and analyze the attributes, features, and specific characteristics of land across different use categories, advanced techniques from geomatics - such as digital photogrammetry and satellite remote sensing - can be employed with high efficiency (Popescu et al., 2024, Tereșneu, & Tereșneu, 2023). Accordingly, an aerial survey was conducted using the Rebel FAE1718FW drone model (Figure 3), resulting in the production of an up-to-date orthophoto map of the targeted area (Figure 4).

The spatial positioning of the characteristic detail points related to the plots was carried out with GNSS technology, the GPS system, with the RTK method, using the Beiuș GNSS station as a base, and the ROMPOS system, respectively. As a result, used as rover GNSS receiver STONEX S900A IMU.

Figure 4. Orthophoto of the work area

Processing of recorded data. Programs used

Real-time data processing was carried out using the STONEX CUBE application, and the transformation of ellipsoidal coordinates into the national reference system STEREO-1970 was carried out using the TransDatRO4.01 application (Bodog et al., 2024; Crainic, 2024).

For reporting the coordinates of the detailed characteristic points, and for drawing up the parcel plan and subsequently the cadastral plan in digital format, the MapSys 10.0 program was used (Marton, 2007).

The simulation was used to obtain the final graphic products in digital format, for all the properties that were positioned and described.

The comparison was carried out at the stage of establishing the attributes of the positioned plots, having the results of the experiment and the records from the property deeds related to them.

The analysis was carried out upon completion of the experiment and the preparation of the plot plan, depending on the specifics and particularities of its elements and those from the property deeds, presented in accordance with the

legislation in force (Law on Cadastre and Real Estate Advertising no. 7/1996 updated in 2025). The case study was carried out according to the steps presented in Figure 5.

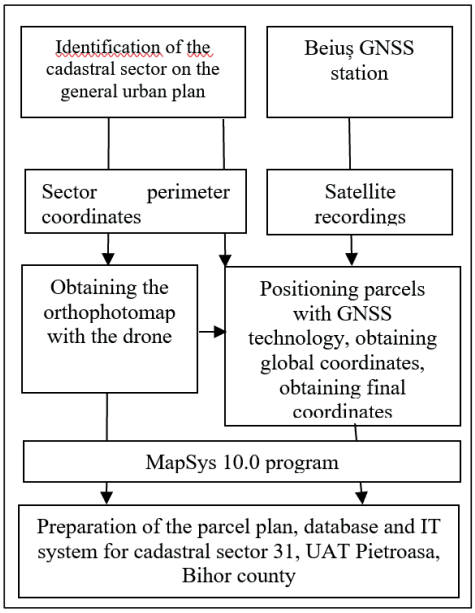

Figure 5. Sequence of stages for carrying out the case study

RESULTS AND DISCUSSIONS

In order to create the parcel plan and implicitly for the systematic registration of real estate at the level of cadastral sector 31, UAT Pietroasa, a number of 658 parcels were identified and verified on the current orthophoto map.

As a result, the use of UAV (Unmanned Aerial Vehicle) technology, by performing multiple flights, optimizes the process of preparing a topographic plan, reducing the time for recording field data and providing various details necessary for architectural planning, both in the studied area and in neighboring areas, compared to other methods, which require more time and provide fewer details, with similar precision (Naș et al., 2023).

As a result, the coordinates for a total of 5404 characteristic topographic points, necessary for the delimitation and positioning of the identified plots, were positioned with GNSS technology and determined in the national reference system STEREO-1970 (in 2D space).

The coordinates of the points are characterized by high precision, since the transformation into the national reference system was performed with the updated transformation parameters for the work area.

The inventory of the coordinates of the detailed characteristic topographic points is presented in a file with the extension txt., configured with four columns, namely the point number, the X coordinate, the Y coordinate and the layer into which it will be imported into the MapSys 10.0 program (Table 1). To obtain the parcel plan and subsequently the cadastral plan, the coordinates of the topographic points were graphically reported with the MapSys 10.0 program.

The way to work with this program is presented suggestively in Figure 6.

Table 1. Extract from the inventory of the coordinates of the detailed topographic points, in the national reference system

No. crt.	X(m)	Y(m)	Layer
1	568496.138	310959.577	1

Analysis of the data presented in Figure 6 reveals that the workflow for generating the cadastral plan using the MapSys 10.0 software follows a logical and well-structured sequence, dictated by the program's internal algorithms and marked by a high degree of automation.

At the initiation of a new project (work-job), the working parameters and necessary metadata were defined to support the specific requirements of the cadastral task. Consequently, the datum elements corresponding to the national land fund were integrated into the system (Figure 7).

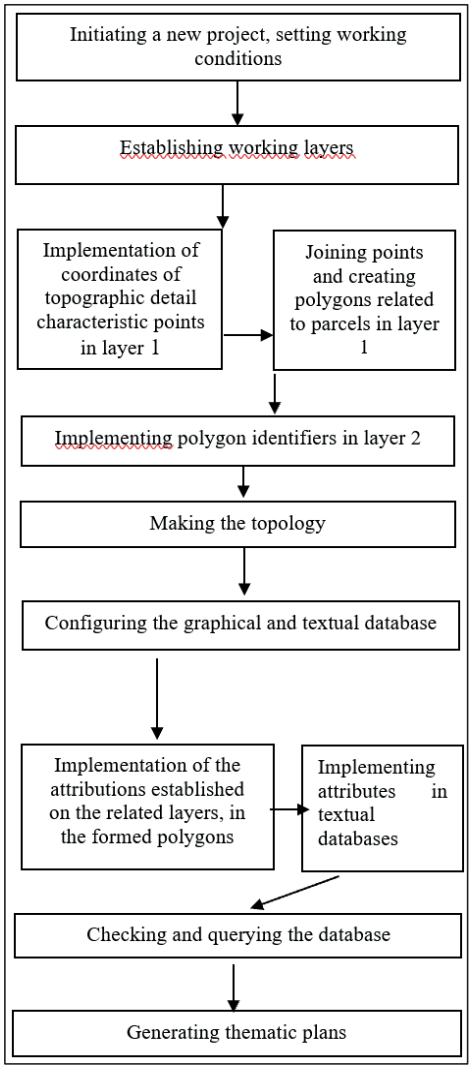

Figure 6. Working steps with the MapSys 10.0 program, to obtain the cadastral plan

The creation and organization of working layers were structured hierarchically, aligned with the operational algorithms of the MapSys software and the logical sequence of inputting collected spatial and attribute data. This hierarchical arrangement ensured consistency in data processing and efficient integration of graphical and textual components.

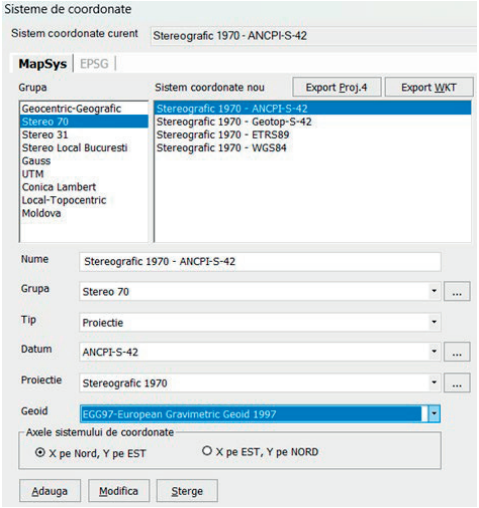

Figure 7. Implementation of the elements of the datum related to the national land fund

The layers were organized as follows:
- Layer 1 - coordinates of detailed topographic points and subsequent creation of plot (real estate) polygons.
- Layer 2 - cadastral identifiers, linking graphical data with the textual database, supporting topology generation and configuration of the primary textual dataset.
- Layer 3 - characteristic points marking the boundaries of cadastral sector 31.
- Layer 4 - text annotation indicating the cadastral sector number under investigation.
- Layer 5 - planimetric coordinates of electric poles located within the plots.
- Layer 6 - textual attributes referencing property deeds and existing topographic numbers associated with positioned plots.
- Layer 7 - records of possession minutes and corresponding property titles.
- Layer 8 - documents confirming possession and actual land use by property holders.
- Layer 9 - land registry extract data available at the time of the study.
- Layer 10 - existing data on newly assigned cadastral numbers as of the study date.
- Layer 11 - data regarding cadastral numbers established by final court decisions.

- Layer 12 - surface discrepancies, where applicable.
- Layer 13 - information on plots with unidentified owners.
- Layer 14 - data concerning areas designated as land reserves.
- Layer 15 - land use categories attributed to the studied plots.
- Layer 16 - coordinates of localities adjacent to cadastral sector 31 in U.A.T. Pietroasa, Bihor County.

The initial stage of the workflow involved importing the planimetric coordinates of the detailed characteristic points corresponding to the parcels within cadastral sector 31 into Layer 1 (Figure 8). Subsequently, within the same layer, a total of 5,404 characteristic topographic points were connected, resulting in the generation of 658 parcel polygons representing the spatial configuration of the positioned plots (Figure 9).

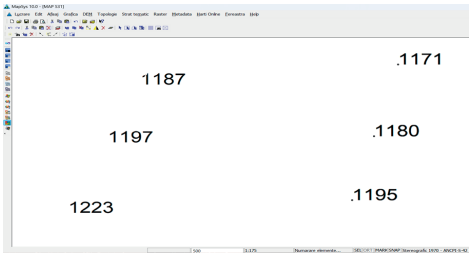

Figure 8. Implementation of feature points

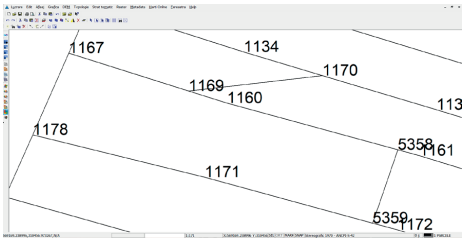

Figure 9. Obtaining polygons

The overlay of the generated parcel polygons onto the newly created orthophotomap enabled optimal verification of the accuracy and precision of the digital graphic representations (Figure 10).

A critical stage in the development of both the parcel plan and the subsequent cadastral plan involved the implementation of cadastral identifiers and the marking of individual parcels. This process commenced in the northwestern part of the locality and progressed toward the southwest, following a systematic spatial logic.

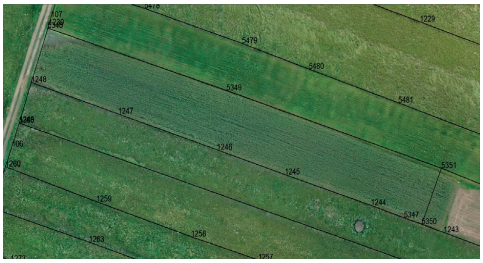

Figure 10. Overlaying polygons on the orthophoto plane

This step was carried out using the cadastral number creation/digitization function, which involved assigning a unique identifier to each polygon (Figure 11). These identifiers establish a direct and exclusive link between each polygon in the graphical database and its corresponding entry in the textual database, ensuring data consistency and integration (Marton, 2007).

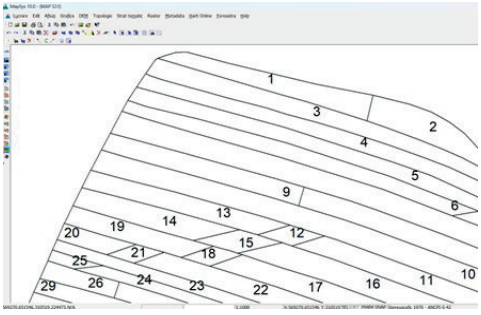

Figure 11. Implementation of cadastral identifiers for each polygon obtained

Verification of non-closure errors in the polygons representing the positioned parcels, the generation of the primary Geographic Information System (GIS) database, and the execution of operations on spatially referenced objects were performed using the Topology menu within the software.

Analysis of the data presented in Figure 12 confirms the absence of non-closure errors in the polygons generated. Additionally, it verifies that the total number of areas computed using the analytical method matches the total number of polygons. The cumulative area of cadastral

sector 31 was determined to be 984,546.153 m², equivalent to 98.45 hectares.

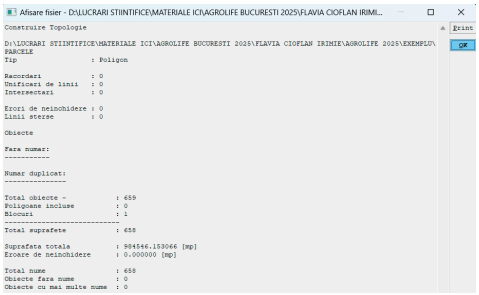

Figure 12. Topology creation

Upon completion of the topology creation process, the primary database (databank) was automatically generated for the polygons (plots) that had been graphically represented in Layer 1 (Figure 13).

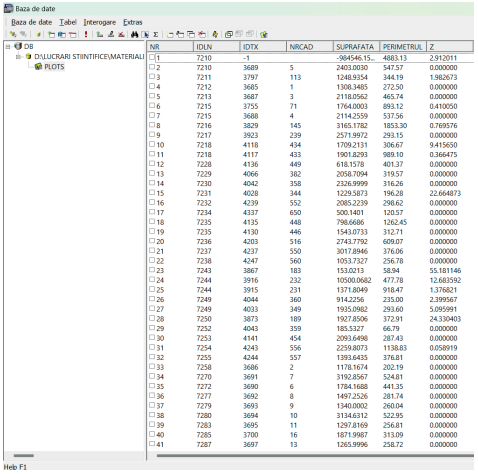

Figure 13. Generation of the primary database related to the polygons (parcels) that were graphically reported in layer 1

To gather all attributes required for the development of the parcel plan and, subsequently, the cadastral plan, the database was modified and configured accordingly (Figure 14). The necessary columns were implemented in alignment with the layer structure defined during the initial project configuration.

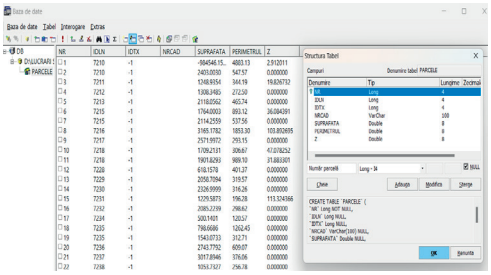

Figure 14. Primary database configuration, depending on the way the layers are organized and the implementation of the established attributes related to the starts

The implemented attributes were assigned to specific layers as follows:
- Layer 3: boundary of the cadastral sector;
- Layer 4: cadastral sector number;
- Layer 5: locations of concrete electric poles;
- Layer 6: property deeds with associated topographic numbers;
- Layer 7: minutes of taking possession, with ownership titles pending issuance as of the study date;
- Layer 8: certificates of actual land use, issued by Pietroasa City Hall based on entries in the agricultural register;
- Layer 9: land register extracts available at the time of the study, confirming property rights based on deeds or converted old registry sheets;
- Layer 10: newly assigned cadastral numbers;
- Layer 11: cadastral numbers granted through final court decisions.

The various documents used to establish ownership or possession rights, which formed the basis for the creation of the parcel plan, are summarized in Figure 15 as percentage distributions. These documents include:
- 254 certificates of actual land use;
- 237 property deeds with topographic numbers;
- 119 land register extracts;
- 30 minutes of taking possession;
- 11 new cadastral numbers.

As illustrated in Figure 15, the largest proportion of documentation consists of certificates of actual use (39%), followed by property deeds with topographic numbers (36%), existing land register extracts (18%), minutes of possession (5%), and new cadastral numbers (2%).

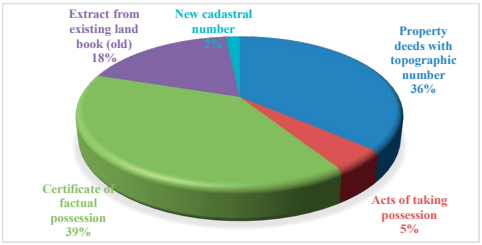

Figure 15. Percentage of documents attesting to the ownership right over the positioned and studied plots

Another important stage was represented by the verification of the areas of the polygons related to the plots, with those in the documents certifying ownership, or with the areas in the official records, respectively with the uses.
Currently, there is a possibility that the changes that are necessary to correct errors in parcels (real estate) can be made efficiently by preparing digital vector parcel plans, only for the respective area, based on accurate measurements, with modern geospatial technologies. As a result, in such situations, it will not be necessary to redo the entire parcel plan and subsequently the cadastral plan, for the entire respective sector (Kyseľ & Hudecová, 2022).
As a result, in layer 12, a number of 13 corrections were implemented for the area of 13 plots, for which it was necessary to reposition the boundaries, due to the differences between the area of the identified and positioned plots and the area in the property documents, respectively.
Also, in layer 13, a number of 6 observations were implemented for 6 plots, with a total area of 6851 m^2, for which the owners were not identified. Finally, in layer 14, a number of 3 plots were implemented, with a total area of 1007 m^2, which were considered as a reserve.
Resolving inconsistencies between the cadastral map in analog format and the cadastral register can be solved by obtaining new parcel plans and cadastral plans, respectively, through vectorization. Consequently, computer processing does not guarantee quality if it is not carried out professionally and conscientiously, and the inadequate maintenance of cadastral maps has facilitated the constant presence of inconsistencies between the two entities mentioned (Roić et al., 2021).
After clarifying the situation of the plots' areas reported graphically, the land use category for the studied buildings was implemented in layer 15. According to the results presented in Figure 16, 651 plots have the arable land use category (A), and 4 plots have the exploitation road use category (Er).

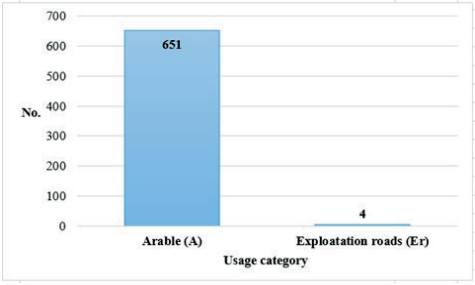

Figure 16. Representation of the number of land use categories for cadastral sector 31 Pietroasa

The land use categories were identified based on ownership documents and official records, with the following distribution:
- 651 parcels classified as arable land (A);
- 4 parcels identified as exploitation roads (Er).

Attributes corresponding to Layers 3 through 16 were incorporated into the database using the Attribute Collection menu. Through this process, the values extracted from text elements located within the topological objects of the active layer were systematically loaded into the respective database fields of the current topological layer.
The updated database containing all necessary attributes for the creation of the parcel plan and, subsequently, the cadastral plan, can be efficiently accessed and managed as needed. A representative extract from the parcel plan and the associated database is presented in Figure 17.

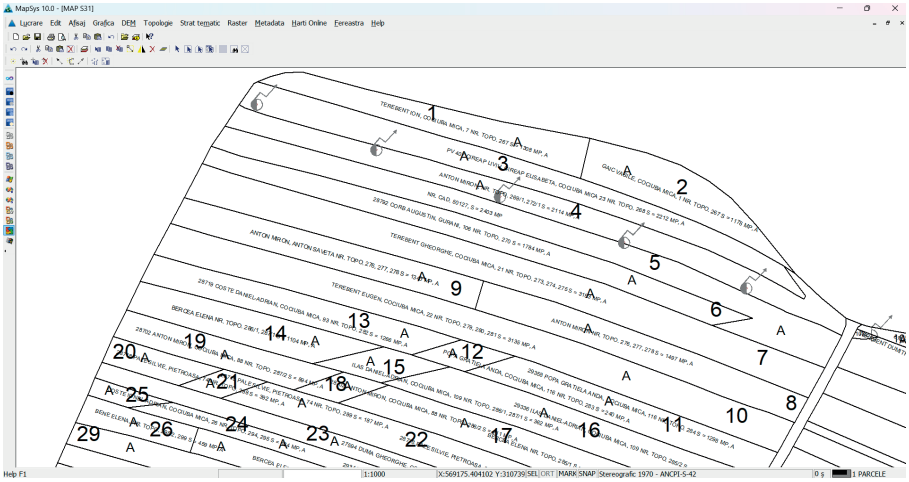

Figure 17. Extract from the parcel plan for cadastral sector 31, UAT Pietroasa, Bihor County with all attributes activated

The MapSys 10.0 software enabled efficient graphical input of contour point coordinates and supported the creation of both the parcel plan and its associated database. The platform allows for direct adjustments based on verified ownership documents. In cases where discrepancies existed between calculated parcel areas and legal records, boundaries were corrected within the software. Revised coordinates were exported as .txt files and transferred to a dual-frequency GNSS receiver for precise field repositioning.

The finalized parcel plan and database were submitted in digital format to the Bihor County Office for Cadastre and Real Estate Advertising (OCPI) for cadastral number assignment and integration into the national land registry system.

The work of registering real estate in the Systematic Cadastre in Romania, performed by the private sector, is perceived as qualitative or predominantly qualitative, based on the verifications carried out by the county Cadastre and Real Estate Advertising Offices (OCPI). Consequently, three elements of the quality of the work carried out by the private sector were highlighted, which need to be optimized, namely credibility, reliability of the service and the level of competence of the human resource (Păunescu et al., 2023).

Field positioning of parcel boundaries is a crucial step requiring the involvement of landowners to ensure spatial and legal accuracy. Recent studies have shown that the success factors in establishing the cadastral boundaries of parcels are the surveyor and the land owner, while paradoxically, land data (cadastral data) is the least important factor (Golob & Lisec, 2022). Consequently, the experienced and well-intentioned surveyor can effectively manage the issues related to cadastral boundaries, especially for lands with unidentified boundaries, which are frequently the subject of possible litigation, which can have a negative impact on cadastral recording activities.

Surveying activities included GNSS-based positioning of characteristic points, enhanced through RTK (Real-Time Kinematic) positioning with data from the Beiuș GNSS permanent station via the ROMPOS service, ensuring high precision.

Final coordinates referenced to the national geodetic system enhanced the accuracy of the digital parcel plan. Legal documents were used to resolve discrepancies between measured and recorded areas.

The cadastral database for Sector 31 was configured under optimal conditions, adapted to the specific requirements of systematic registration. Overall, the use of MapSys 10.0 proved effective in producing high-quality digital outputs - parcel plans, cadastral plans, integrated databases, and thematic maps - critical tools for modern cadastral operations.

From the synthetic analysis of the implementation of the National Systematic Land

Cadastre Program in Romania, by some specialists, it was concluded that it was not designed as an approach fit for purpose. Consequently, there are a number of suggestions that the transition to such a system would optimize the systematic registration process. Also, high standards of precision without flexibility, the use of large-scale field measurements or the lack of provisions for improving and updating the system, are considered factors that significantly delay this process (Păunescu et al., 2022).

Currently, cadastral systems that manage the people-land relationship have evolved into a multifunctional form, supporting various land activities. As a result, it has become necessary to modernize traditional land administration systems and cadastral systems in order to effectively manage the people-land relationship. Consequently, the interest in promoting 3D cadastre is increased, while the cadastre of public right restrictions and the disaster-responsive cadastre are the least promoted (Uşak et al., 2024).

Current research on the possibilities of implementing 3D cadastre shows that the registration of objects for its implementation involves the use of data from various sources, namely laser scanning measurements and technical documentation (Grzelka et al., 2024), as well as other additional data, as appropriate.

CONCLUSIONS

This study highlights the effectiveness of integrating GNSS and UAV technologies with specialized GIS software (MapSys 10.0) in the systematic development of cadastral plans, using Cadastral Sector 31 in Pietroasa, Romania, as a case study. The approach demonstrated high precision in spatial data acquisition and efficient data processing, providing a model for similar cadastral operations in non-collectivized, rural settings.

Key insights include the operational benefits of combining RTK positioning with orthophotomap overlays for boundary verification, and the flexibility of digital workflows in updating parcel attributes based on legal documents. The involvement of landowners verifying plot boundaries was identified as a critical factor for accurate cadastral representation.

Limitations of the study include the reliance on the completeness and accuracy of historical land documents, and challenges in identifying owners for certain plots. Additionally, software-specific constraints in data structuring may affect standardization across regions if not uniformly implemented.

Practical applications of this workflow extend to national cadastral programs, especially in areas undergoing systematic registration. The integration of UAV, GNSS, and GIS technologies offers a scalable, cost-effective solution that can accelerate cadastral mapping efforts and enhance land administration services.

ACKNOWLEDGEMENTS

The research and study were carried out in collaboration with the Local Council of Pietroasa City Hall, Bihor County.

We would like to thank S.C. TOPOGEOTERM S.R.L. Salonta, Bihor County for their logistical support and help in carrying out the experiment related to the case study.

ASSESSMENT OF LAND USE CHANGES IN NON-COLLECTIVIZED AREAS USING GEOMATIC APPLICATIONS: A CASE STUDY IN VÎRFURILE, ROMANIA

Flavia Mălina CIOFLAN

University of Oradea, 1 University Street, 410087, Oradea, Bihor, Romania

Corresponding author email: irimieflavia@gmail.com

Abstract

After 1990, land use categories in non-collectivized hilly and mountainous areas experienced distinct changes, influenced by various socio-economic and environmental factors. This study focuses on cadastral sector 15 within the administrative territorial unit of Vîrfurile, Arad County - an area that was not subjected to collectivization. The objective is to analyze the current state of land use categories using geomatic applications. Plot localization was achieved using orthophotoplans, while spatial positioning was conducted via GNSS technology employing the Real-Time Kinematic (RTK) method, with data transmission between receivers facilitated by internal radio. Base point coordinates were determined using data from the GNSS station in Gurahonț. The coordinates of the characteristic detail points were processed with the MapSys10 software and overlaid onto the orthophotoplan. Analysis of the results reveals that several plots formerly designated for agricultural use are now partially covered by arboreal forest vegetation, indicating a significant process of natural succession and land use transformation.

Key words: *geomatic applications, land use categories, non-collectivized areas, spatial positioning, GNSS technology.*

INTRODUCTION

Land can be classified based on its use and economic designation - criteria that are essential to both general and specialized cadastre activities (Novac, 2007). The land use category serves as the primary basis for this classification and constitutes one of the cadastral attributes of a land parcel. It is codified in accordance with applicable legislation and technical regulations. This classification may reflect natural conditions or result from human intervention (anthropogenic activity). It is documented in the technical component of the general cadastre, primarily to establish tax liabilities associated with real estate (Novac, 2007).

The land use category is a subset of a broader group of uses and can be further divided into subcategories. However, in general cadastre practices, these subcategories are not individually recorded; they are only identified and registered within specialized cadastres (Novac, 2007). Land use monitoring and analysis are effective tools for identifying the most important developments with positive and negative effects on their use categories. Consequently, the need for the immediate implementation of the national general cadastre system, appropriate policies and legislative provisions, with direct implications for optimal management practices of the national land fund, is highlighted (Călina et al., 2025).

The built-up area refers to the densely constructed portion of the territory - essentially the settlement itself. These areas include buildings, yards, roads, socio-cultural facilities, parks, forests, water bodies, and other land uses within the established boundaries of urban or rural localities. They are regulated by specific legal provisions related to construction permits and urban planning (Novac, 2007; Table 1).

Table 1. Land fund of Romania on 1.01.2004 (statistical data, Novac, 2007)

Land use category	**Area (ha)**	**%**
Arable	9,414,341	38.35
Grassland	3,354,970	14.07
Rough	1,490,384	6.25
Vineyards	230,527	0.97
Orchards	227,204	0.95
Agricultural total	**14,717,426**	**61.74**
Private property	14,155,954	59.38
Forestry	6,751,645	28.32
Water	843,710	3.54
Other lands	1,526,290	6.40
Total non-agricultural	**9,121,645**	**38.26**
Total land fund	**23,839,071**	**100.00**

The extra-urban area refers to the territory located between a locality's administrative boundary and the outer limit of its built-up zone. This area encompasses land designated for various uses, including agriculture, forestry, transportation infrastructure (roads and railways), water bodies, yard-buildings, and non-productive functions. In accordance with current legislation, these lands are systematically subdivided into cadastral sectors, fields, plots, and subplots, following specific cadastral rules. The agricultural use group comprises lands utilized for agricultural purposes and includes the following use categories: arable land, pastures, hayfields, vineyards, and orchards (Figure 1).

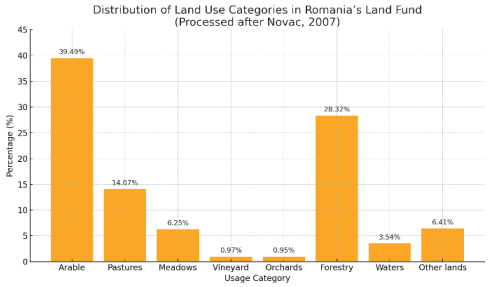

Figure 1. The share of use categories in the agricultural and non-agricultural use group in Romania's land fund (processing after Novac, 2007)

The non-agricultural use group comprises lands not designated for farming, including forests and areas with forest vegetation, water bodies and wetlands (including reed-covered areas), transport infrastructure (roads and railways), lands used for courtyards and other specific purposes, as well as unproductive lands (Novac, 2007; Tămăioagă & Tămăioagă D., 2005).

The credibility of cadastral data on land use and the methodology for their verification and updating. Information on the category of land use is of particular importance in all countries, constituting the basis for taxation and urban planning, directly influencing real estate values and land management procedures. Modern geospatial technologies can facilitate the regular verification of data and information on land use, ensuring future economic benefits for territorial administrative units. As a result, the results of research conducted using unmanned aerial vehicles (UAVs) resulted in obtaining high-resolution orthophotomaps (with a GSD of 3 cm), which provide precise data on the specificity and dynamics of land use at the time of photogrammetric registration (Cienciała et al., 2021).

In conclusion, land use categories are fundamental attributes within the cadastre and real estate registration systems. They play a key role in property classification, taxation, and land management processes.

Land use change has been a major concern for many countries around the world over the years. The main reasons for this situation are: rapid population growth, population migration, the transformation of rural areas into urban areas, changing political systems, and the effect of climate change (Nedd et al., 2021).

Since 1989, uncultivated, hilly, and mountainous regions in Romania have experienced notable shifts in land use categories due to socio-political changes. The declining interest in traditional agricultural activities has led to the abandonment of several arable land subcategories, rendering some parcels unsuitable for conventional crop production.

Currently, obtaining high-precision land use classification can be achieved from high-resolution remote sensing images, using models that can be used as automatic tools for precise land classification and mapping (Kang et al., 2022).

A Western method for recording land use categories, used in Switzerland, is based on two inputs, namely information provided by base topographic maps at a scale of 1:25,000 and national land use statistics, which were obtained from high-precision aerial photointerpretation, performed on a rectangular grid with a side of 100 m. Consequently, the method combines a simple spatial weighting of the inverse distance of information about 36 nearest neighbors and an expert system of correspondence between land use categories on base maps, as input data, and possible land use types obtained by photointerpretation, as output data. This method can be used with high efficiency to transform and use different types of geographic information at scale (Giuliani, 2022).

Additionally, many administrative territorial units (ATUs) in these regions have not updated their agricultural registers, often due to a lack of initiative from landowners. Consequently, the

real land use categories recorded during the systematic property registration and cadastral plan development were based on outdated documents and registry information, rather than on-site verification.

To address these discrepancies, it is essential to conduct field identification, observation, and analysis of plots to accurately determine the productive capacities of the land. In many cases, prolonged abandonment has allowed for the growth of subshrub, shrub, and woody vegetation, obstructing access and complicating evaluation.

Modern geomatic technologies offer effective solutions for analyzing and updating land use categories. These include spatial positioning of cadastral features, data processing, and generation of accurate coordinates through integrated methods. For defining the boundaries of cadastral sectors and individual parcels, tools such as the Global Navigation Satellite System (GNSS), total stations, and other integrated surveying technologies are commonly employed.

Collectively referred to as geomatics, these advanced geospatial technologies ensure accurate acquisition, verification, and processing of spatial data, all referenced to the national coordinate system (Crainic, 2024; Boș, 2003). Their application greatly enhances the efficiency and precision of cadastre-related activities, supporting identification, positioning, area measurement, and classification of land uses across Romania's national land fund.

Geomatics applications are particularly effective for analyzing agricultural land use. They enable the creation of thematic maps that classify agricultural areas by category and subcategory, offering valuable insights into land suitability for various crop types. Furthermore, geomatics tools facilitate spatial analysis and classification of lands for fruit tree cultivation, enhancing land management strategies in agriculture (Roşca et al., 2015).

As a result, space technologies and related applications in the land survey sector support the integrity and record of land, with direct implications for climate change monitoring, disaster risk reduction, land tenure security, land governance, geospatial information management, sustainable land administration and management, spatial planning and land valuation (Upadhyaya, 2024).

MATERIALS AND METHODS

This study was conducted in cadastral sector 15 within the administrative territorial unit (ATU) Vârfurile, located in Arad County, Romania. The region is a rural, non-collectivized area situated at the intersection of Arad, Bihor, and Alba counties, at the foot of the Bihor and Codru-Moma Mountains, within the northwestern part of the Hălmagiu Depression along the Crișul Alb River.

The dominant landforms in the study area are represented by hills, with good accessibility, which in the past were cultivated with potatoes, wheat, oats and corn. There were also lands on which fruit tree orchards were installed, of the apple, plum, pear and cherry species. After 1989, the activities related to the agricultural sector in this location reduced their intensity, because currently they are found only sporadically, due to the lack of adequate equipment and the recent climate changes.

The objectives of the research refer to the study and analysis of the current situation of the categories and subcategories of land use, in cadastral sector 15, which belongs to the territorial administrative unit (UAT) Vârfurile, using geomatic applications. These are necessary due to the current situation of the lands in the mentioned location, in order to establish the necessary strategies for their inclusion in a productive circuit, in correlation with their real use and agricultural production capacity.

This study is conducted as part of a doctoral research program and benefits from the completion of systematic registration works for buildings located outside the built-up area within the targeted cadastral sector. As a result, a parcel plan has been developed and is available in both digital and analog formats (Figure 2).

The primary objective of this research was to analyze the current state of land use categories using geomatic applications. The study benefits from the recent completion of systematic land registration in this area, which resulted in the creation of both digital and analog parcel plans. The research is part of ongoing doctoral studies

and employed a combination of the following methodologies:
- bibliographic analysis of cadastre-related literature, technical norms, cadastral records, agricultural registers, and monographs;
- field observations, both in motion and stationery, for identifying and mapping topographic features;
- experimental measurements using GNSS-based techniques;
- comparative analysis of historical and current land use data;
- simulation and interpretation of land use category transformations.

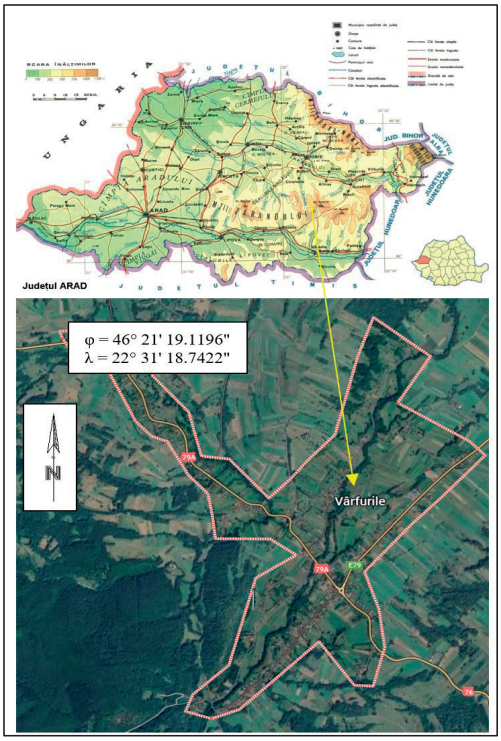

Figure 2. Location of the case study (https://pe harta.ro/judete/Arad.jpg;ttps://www.google.com/maps/place/317390+V%C3%A2rfurile)

To identify and map the characteristic topographic points defining parcel boundaries and land use separations, GNSS positioning was performed. These characteristic detail points delineate the contours of the land plots and subcategories of use.

During the field campaign, GNSS data were collected using the Trimble R8 receiver (with 4W external radio) as the base and the Trimble R10 (with 2W internal radio) as the rover. Positioning was executed using the RTK (Real-Time Kinematic) method. Additionally, remote RTK corrections from the ROMPOS system, using satellite recordings from the Deva GNSS permanent station in Hunedoara County, were integrated to enhance positional accuracy. Five base points were positioned and used as GPS references. The Trimble Access software was employed for field data acquisition and processing, while coordinate transformations into the national reference system were performed using TransDatRO 4.01. Eighteen plots with known use classifications from 1990 were initially surveyed. Subsequently, field validation and digital analysis were expanded to 50 plots, leveraging access to current data from the agricultural register of Vârfurile City Hall and the newly established parcel plan (Figure 3). The recorded coordinates of characteristic point were graphically reported using MapSys 10 software (Marton, 2007).
Digital transformation is vital for modernizing Land Administration Systems (LAS), ensuring efficient, transparent and secure land services. This suggests the implementation of digital workflows, automation services and collaboration with the land survey sector (Chehrehbargh et al., 2024).
Identified subcategories of land use were then compared with historical data from the agricultural register to detect changes and transformations over time.
To further support the interpretation, representative images of selected plots were analyzed, focusing on notable land cover transitions relevant to the case study objectives. These visual and spatial data formed the basis for simulating the evolution of land use subcategories in the studied area.
Also, satellite recordings from the permanent GNSS station Deva, Hunedoara County, were used, with the remote RTK method, using the ROMPOS system. As a result, 18 plots were positioned, where access was allowed and information was held about the categories of use in 1990. After carrying out the systematic registration works of the buildings outside the built-up area and drawing up the plot plan in

digital format, the use categories were analyzed on this plan, superimposed on the orthophoto plan, in parallel with field observations, for a number of 50 plots, where access to the field and to the necessary information was also facilitated.

Figure 3. Location of Cadastral Sector 15, Vârfurile ATU, Arad County

To collect satellite data, the TRIMBLE R8 GNSS receiver with an external 4w radio was used for the base and the TRIMBLE R10 receiver, with an internal 2w radio, as the rover. The Trimble Access program was used to record and process the satellite data. Consequently, rigorously compensated ellipsoidal coordinates were obtained, which were transformed into final coordinates in the national reference system. The coordinates were transformed with the TransDatRO4.01 program, using the updated transformation parameters for Arad County.

This program can be found on the website of the National Agency for Cadastre and Real Estate Advertising (ANCPI) and is used free of charge. As a result, the precision of the coordinates thus obtained is high.

For the graphic reporting of the final coordinates obtained and obtaining the contour of the positioned buildings, the MapSys 10 program was used.

The use subcategories that were identified based on the observations made and the results obtained, for the studied plots, were analyzed and compared with those recorded in the

agricultural register in digital format, related to UAT Vârfurile, Arad County.
Based on the analysis and comparison of the results obtained, a simulation of the current use categories and subcategories was carried out, with the related particularities and occupied areas.

RESULTS AND DISCUSSIONS

The final coordinates of the 307 characteristic points defining the plot boundaries were determined using GNSS technology and are presented in Tables 2 and 3. These coordinates were referenced to the national coordinate system and represent the spatial framework for analyzing current land use categories.
Figure 4 specifically highlights arable land that has undergone natural succession, now being partially or fully covered by forest vegetation, particularly native oak species such as *Quercus cerris* and *Quercus robur*. This transition is indicative of land abandonment and the ongoing ecological succession in previously cultivated areas.
Analysis of field data and imagery (Figures 4 and 5) reveals that portions of the arable plots have undergone natural succession, leading to the establishment of forest vegetation. This transition is characterized by the emergence of biogroups composed of native oak species (*Quercus cerris* and *Quercus robur*) as shown in Figure 4 and pioneer species such *Betula pendula* and *Populus tremula* in Figure 5. These species exhibit clear tendencies toward biological independence and are progressing toward the massif stage of forest development.
A comparative assessment of 50 plots included in the digital parcel plan was conducted, contrasting current land use subcategories (as of 2024) with those recorded in 1989. The synthesized data, grouped by area and category, are presented in Table 2.
Figures 6 and 7 illustrate the spatial positioning of these plots on the orthophoto map of the study area. The positioning method, utilizing base and rover units, allowed for high-precision delineation of parcel boundaries. These boundaries align closely with the current land use categories, as visualized on the orthophoto map.
Proper management of images obtained through remote sensing technologies can facilitate the interpretation and efficient use of spatiotemporal information, which can be used for land use classification. As a result, mapping land use categories, and their changes using, for example, Landsat 5, 7 and 8 images, ensures an optimal investigation of their impact on the environment and implicitly on society (Amini, 2022).
Findings reveal that in 1989, land ownership in the Vârfurile ATU was fragmented, with each plot typically assigned a single use category due to the lack of collectivization.
Today, many plots contain multiple land use subcategories, reflecting shifts in land use driven by reduced agricultural activity - especially potato farming - and widespread abandonment, which has enabled natural ecological succession.
Agricultural land is a basic resource, representative of territorial resilience. In many situations, fertile and relatively accessible soils are subject to pressure caused by urbanization processes, abandonment, the establishment of non-agricultural uses, and due to an agriculture, that is not well adapted to territorial resources. Consequently, the analysis of agricultural land use categories, for the planning of their use, can be carried out according to the properties of the soil and the requirements of society, respectively demographic pressure. Recent studies in the Madrid metropolitan area identified three land use strategies based on suitability: introducing crops in priority zones, designating agricultural protection areas, and promoting ecological regeneration (Morán-Alonso et al., 2025). Declining agricultural activity has led to ecological succession, with spontaneous tree and shrub growth now covering large areas. In addition, climate change - particularly in western Romania - has further contributed to the expansion of areas dominated by native oak species, including holm oak (*Quercus cerris*) and pedunculate oak (*Quercus robur*). These species have regenerated naturally from seed, colonizing many of the abandoned plots
This trend is consistent with findings reported in recent ecological studies. Figure 8 provides a visual summary of the current distribution of land use subcategories across the analyzed plots.

Figure 6. Positioning of plots occupied by forest vegetation using the RTK method, with radio modules

Figure 7. Positioning of characteristic points of parcels by RTK method with internal radio - external radio modules

Analysis of the diagram in Figure 9 shows that 75% of the analyzed plots are currently classified as meadows, while the remaining 25% are categorized as forested meadows.

The tree species identified on the studied plots include a diverse range of native and naturalized species (Stănescu, Șofletea, & Popescu, 1997). These are: *Quercus cerris* L., *Quercus robur* L. (Figure 10), *Carpinus betulus* L., *Tilia tomentosa* Moench., *Robinia pseudoacacia* L., *Populus tremula* L. (Figure 11), *Betula pendula* Roth (Figure 11)., *Fagus sylvatica* L., *Quercus petraea* Matt., *Prunus avium* L., *Salix caprea* L., *Ulmus minor* Mill., *Ulmus laevis*, *Pinus sylvestris* L., *Alnus glutinosa* L., and *Fraxinus excelsior* L.

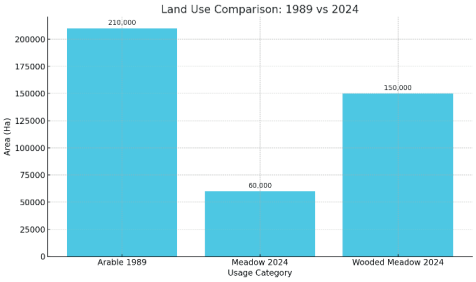

Figure 8. Comparative presentation of use categories for the years 1989 and 2024

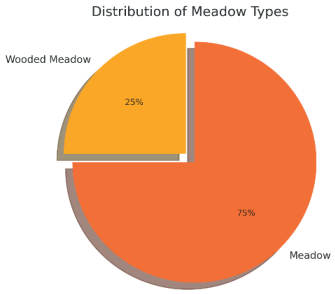

Figure 9. Percentage of subcategories of use, 75% meadow, 25% wooded meadow

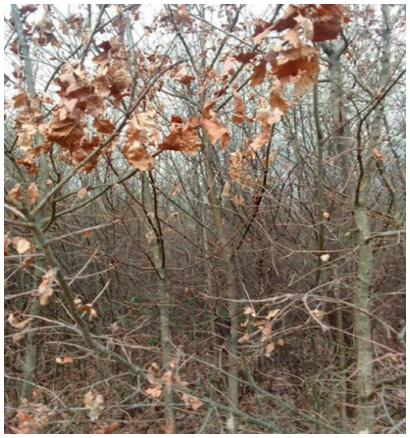

Figure 10. Naturally regenerated forest vegetation of *Quercus robur* (pedunculate oak) established on formerly arable land in Cadastral Sector 15, Vârfurile ATU

Shrub and bush species observed include *Prunus spinosa* L., *Malus sylvestris* Mill., *Pyrus pyraster* L., and *Prunus cerasifera* Ehrh. (Stănescu, Şofletea, & Popescu, 1997).

It is important to note that the maintenance of some plots in good agricultural condition has been supported by financial incentives provided through the Payments and Interventions Agency for Agriculture (PIAA), which encourage landowners to manage and preserve their land use categories effectively.

The changes in land use reported in recent decades are determined by various economic activities carried out in agricultural ecosystems, which have profound implications for society, while also having a major impact on agriculture, the environment, and in the assessment of the sustainability of food and organic products (Barbara et al., 2023).

Figure 11. Biogroups of *Betula Pendula* and *Populus tremula* established through natural succession on former arable land in Cadastral Sector 15, Vârfurile ATU, illustrating the early stages of forest regeneration following land abandonment

CONCLUSIONS

The application of geomatics technologies provides a modern and effective approach for analyzing land use categories and subcategories, particularly in non-collectivized, hilly regions. The integration of GNSS positioning, specifically using RTK methods with dual-frequency receivers and internal/external radio modules, enabled the collection of high-precision spatial data while significantly optimizing fieldwork efforts.

The completion of systematic cadastral registration in Cadastral Sector 15 and the development of parcel plans in both digital and analog formats facilitated a detailed analysis of land use through the MapSys 10 digital cartography program. The overlay of parcel plans onto orthophoto imagery, combined with field observations, allowed for the accurate identification of current land use categories and their spatial distribution.

A comparative analysis revealed that the current land use classifications differ significantly from those recorded in 1990. This shift reflects broader socio-economic changes, particularly the decline in interest in traditional crop cultivation (e.g., potatoes) and the drastic reduction in livestock farming, which has led to widespread abandonment of hayfields and pastures. Consequently, natural ecological succession has occurred, resulting in the

expansion of arboreal and shrub vegetation on previously arable lands. Native deciduous species, especially pedunculate oak (*Quercus robur*) and Turkey oak (*Quercus cerris*), have naturally regenerated and established themselves in biogroups and strips across these abandoned areas. These changes have been further accelerated by evolving climatic conditions in the region.

The land classified under forested and shrub-dominated categories has increased considerably since 1990, often at the expense of arable land and hayfields. Conversely, orchard areas have expanded, supported by the establishment of new plantations financed through European structural funds or private investment.

The continued preservation and productive use of arable land, pastures, and hayfields are largely sustained by financial support provided through the Agricultural Payments and Interventions Agency (APIA). Access to non-reimbursable European development funds has also played a key role in maintaining the viability of traditional land use categories under optimal conditions.

This study highlights significant land use transformations in non-collectivized rural areas, driven by agricultural decline and supported by natural ecological processes. Using modern geomatic tools and precise spatial data, it was found that arable land has increasingly transitioned into meadows and forested areas, reflecting both human inactivity and climate-driven regeneration. Targeted funding - particularly through APIA and European programs - has played a vital role in maintaining productive land use where possible. These insights can inform future land management strategies, support sustainable rural development, and guide the efficient allocation of financial resources.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the Local Council of Vârfurile City Hall (Arad County) and the Arad Cadastre and Real Estate Advertising Office for their valuable support in conducting this research. Special thanks are extended to the landowners in Cadastral Sector 15, UAT Vârfurile, for their cooperation and access to relevant data.

The GNSS equipment and software used for spatial positioning and graphical data processing were kindly provided by S.C. TOPO SISTEM S.R.L. (Oradea, Bihor County) and S.C. ECOPROD FOREST S.R.L. (Paleu, Bihor County).

Abstract

Telecommunications towers are essential infrastructures that serve various functions, including telecommunications, meteorological data collection, and surveillance. Maintaining their structural integrity and accurate vertical alignment is crucial for ensuring operational efficiency, safety, and long-term durability. However, evaluating the verticality of tall structures presents significant challenges, necessitating the use of modern and precise methods. Traditional techniques, such as manual surveys using level instrument, are often limited by human error, environmental factors, and the complexity of the structures involved. This study investigates the use of LiDAR (Light Detection and Ranging) technology as a modern method for assessing verticality. By employing advanced LiDAR scanning techniques, the research establishes a thorough framework for accurate and efficient structural monitoring. The paper highlights how LiDAR technology outperforms traditional methods in accuracy, speed, and flexibility, providing a safer and more dependable solution for managing the vertical alignment of observation towers.

Key words*: 3D scanning, vertical assessment, point cloud, surveying accuracy, LiDAR.*

INTRODUCTION

The rapid expansion of telecommunications infrastructure has necessitated precise and reliable methods for assessing verticality and structural integrity in telecommunication towers. Given the increasing demand for high-speed connectivity and the expansion of cellular networks, ensuring the stability and accuracy of tower installations is essential to maintaining service quality, structural safety, and compliance with regulatory standards. The resistance criteria for these kinds of towers are defined based on the current applicable technical standards and within the framework of the conditions specified in the beneficiary's project requirements (Sîrbu et al., 2023).

Recent advancements in three-dimensional scanning technologies (Kantaros et al., 2023) have revolutionized structural assessment by enabling high-resolution, non-contact measurements with enhanced accuracy and efficiency. 3D laser scanning, photogrammetry, and LiDAR (Light Detection and Ranging) have emerged as powerful tools for capturing detailed spatial data of telecommunications towers. These technologies facilitate the generation of precise digital replica, which allow for comprehensive structural analysis, deformation monitoring, and early detection of anomalies (Kaartinen et al., 2022).

This paper focuses on the use of 3D scanning technologies for the vertical assessment of observation towers, aiming to analyse their stability over time. Observation towers, with their large dimensions and complex structures, require precise measurements to ensure their integrity and safety in the long term. The main goal of this paper is to demonstrate the effectiveness of 3D scanning technologies, especially LiDAR systems and laser scanners, in performing accurate vertical assessments that contribute to monitoring the structural condition of the towers.

Traditional methods of vertical assessment, such as manual plumb-line measurements, total station surveys, and inclinometer readings, often suffer from limitations in precision, efficiency, and accessibility. Compared to traditional surveying methods, 3D scanning provides superior data density, automated processing, and enhanced reproducibility, making it a compelling alternative for vertical assessment in telecommunication infrastructure (El-Tokhey et al., 2019).

In the context of observation towers, maintaining verticality is essential for their structural stability, as significant deviation from verticality can lead to safety risks or deterioration. Thus, by using 3D scanning technologies, extremely high precision can be achieved in measuring angles and tower height, allowing the detection of any deformations or changes that may affect its stability. 3D laser scanners are among the most effective tools for three-dimensional monitoring of various types of constructions, including observation towers, as they provide detailed data such as shape, intensity, and colour, which can be used to study crack growth and detect possible structural weaknesses (Mihai et al., 2014).

A recent study by Wang et al. (2024) introduced an automated 3D reconstruction framework for communication towers using TLS point clouds. Their model-driven approach achieved an average root-mean-square error (RMSE) of 1.3 cm in antenna reconstruction and 1.2 cm in tower body reconstruction, demonstrating high accuracy in capturing complex geometries. This high-precision methodology enables improved structural assessment and facilitates better decision-making in maintenance and design processes.

Figure 1 illustrates the scanned object, a tall telecommunication tower, which has been examined using 3D scanning technology.

Figure 1. The study area

The tower features a cylindrical structure with alternating red and white segments; a typical design used for visibility and aviation safety compliance. It stands on a concrete base, which is slightly elevated from the surrounding ground level. The tower is equipped with antennas and transmission equipment at the top, indicating its function in communication and signal transmission.

The height of the tower necessitates multiple elevation perspectives to accurately capture the structural details. Furthermore, consideration must be given to potential obstacles and reflections from metallic surfaces at the top, as these factors may influence the quality of the scanning process.

MATERIALS AND METHODS

The study utilized the Leica BLK360 G2 laser scanner, a high-precision LiDAR system capable of capturing detailed 3D point clouds with a range accuracy of ±4 mm at 10 meters (ArcTron, n.d.). This scanner operates using a combination of infrared scanning and photogrammetry to generate dense and precise spatial data (ArcTron, n.d.). The determination of control points was carried out using a fully robotic total station to establish 12 ground control points (GCPs) at strategic locations surrounding the telecommunications tower. These GCPs were crucial in georeferencing and validating the accuracy of the scan data (Liu et al., 2022). The total station captured accurate spatial data, ensuring alignment between the scan data and real-world references.

The total station used belongs to the class of high-precision total stations, providing angular accuracy of up to 1” (one second) and distance measurement accuracy of 2 mm + 2 ppm (Stonex, n.d.). The angular measurement system includes a dual-axis compensator, offering stability and an angular accuracy of 1” or 2” with a resolution of 0.1” (Stonex, n.d.). Distance measurements in prism mode reach up to 5000 m with an accuracy of 2 mm + 2 ppm, while reflectorless measurements can extend up to 1000 m with an accuracy of 3 mm + 2 ppm, depending on surface reflectivity (Stonex, n.d.). Initially, the total station was set up at a known reference point or a strategically chosen temporary setup point, with its exact position

pre-established using high-precision GNSS (Global Navigation Satellite System) collected survey data. At the location of the control point, a prism or reflector was positioned to serve as the target for the total station's measurements. The total station employed electromagnetic distance measurement (EDM) technology to precisely calculate the slant distance between the total station and the prism, while simultaneously recording the horizontal and vertical angles to the target. The total station's integration with an Android-based software interface further enhanced this process, enabling real-time data collection, immediate calculations, and seamless display of results either on the instrument itself or through connected devices (Stonex, n.d.). Data processing and analysis were conducted using AutoCAD CIVIL 3D for technical drawing and structural modelling, while CloudCompare was used for point cloud processing, alignment, and accuracy assessment.

Data acquisition involved scanning the telecommunications tower using the Leica BLK360 G2 at 17 scan stations, ensuring full coverage from multiple vantage points. Between these positions, 77 connections were established, each representing an overlap between data acquired from two different perspectives, contributing to the overall coherence of the point cloud. For a detailed evaluation of the coverage and measurement consistency, a data presence matrix was generated (Figure 2).

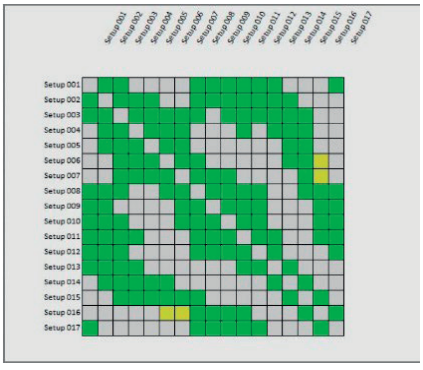

Figure 2. Distribution of overlaps between scanning stations - 3D scan coverage matrix

This matrix indicates the degree of connectivity between scanning stations and helps identify areas where the measurements can be considered reliable for verticality analysis. Cells that are filled indicate the presence of valid data and useful overlaps, while empty or unevenly marked cells point to potential gaps in data capture or regions where accuracy is reduced due to blind spots or obstacles.

The scanning process included pre-scan calibration to ensure measurement precision, positioning the scanner at pre-determined points for optimal visibility of the tower's vertical structure, capturing 3D point clouds using a full panoramic scan, and utilizing the scanner's built-in camera to supplement the LiDAR data with high-resolution images.

Ground control and georeferencing were established by placing GCP markers at fixed, stable locations around the base of the tower, measuring their coordinates using the total station with centimetre-level accuracy, and integrating the GCPs into the point cloud during post-processing to align the scan data with real-world coordinates (Figure 3).

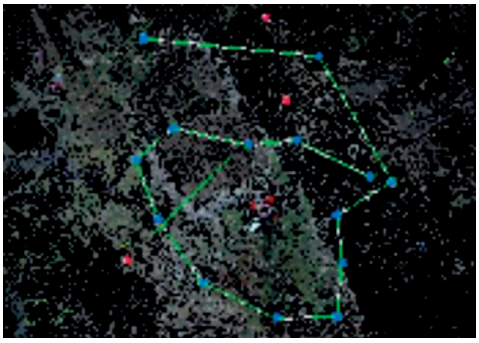

Figure 3. Ground Control and Georeferencing Using GCP Markers

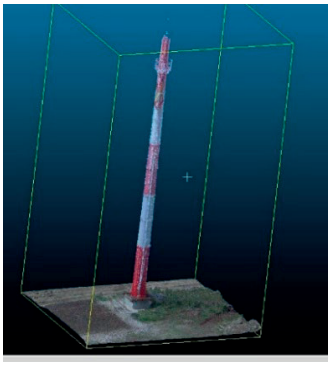
Point cloud processing began with preliminary data cleaning in CloudCompare (Figure 4), where noise reduction and outlier removal were performed to eliminate erroneous data points.

Multi-scan registration was conducted using iterative closest point (ICP) algorithms to align the multiple scan stations into a unified 3D dataset. The total station-derived GCPs were used to refine the spatial accuracy of the point cloud through georeferencing. To determine the vertical accuracy of the telecommunications tower, the central vertical axis of the tower was extracted from the point cloud by identifying key structural elements, followed by a vertical

deviation analysis that compared the actual scanned position of the tower elements with their expected theoretical positions based on the AutoCAD structural model. Statistical assessment was conducted using CloudCompare's cloud-to-cloud distance measurement tool to quantify vertical misalignments.



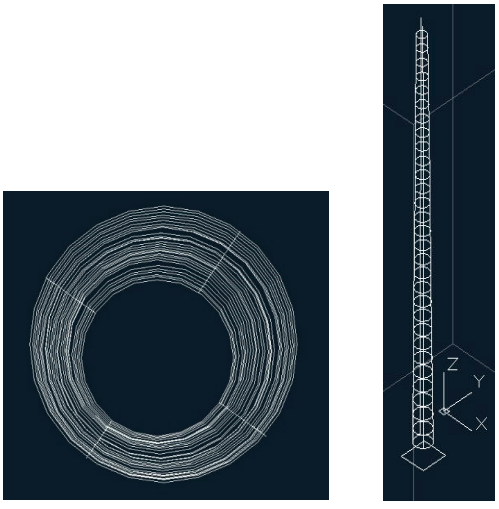


Figure 4. Point Cloud Cleaning and Noise Reduction using CloudCompare

Cross-sections were generated at regular intervals along the height of the tower, providing detailed sectional views that allowed for precise assessment of deviations and misalignments (Figure 5).

a) b)

Figure 5. a) Top-view cross-section b) 3D-view cross-section of the telecommunication tower

These cross-sections were analysed to compare the actual tower profile with its designed specifications. Measurements were taken at multiple points along each section to identify any lateral displacements or distortions in the structure. Additionally, vertical alignment was assessed by projecting reference lines along the tower's intended axis and calculating the deviations at different heights (Figure 6).

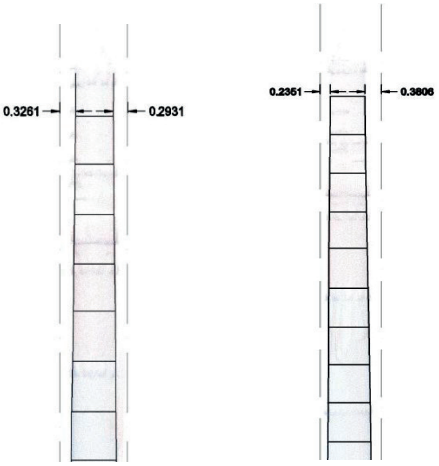

Figure 6. Vertical Alignment Assessment Using Reference Lines

Upon completion of the analysis, final data outputs were generated providing a comprehensive visualization of structural integrity and alignment. Although the overall coverage was 48% and the coherence of the connections between positions was 25%, these values proved sufficient for measuring verticality. The accuracy of the data was confirmed by the very low global errors reported in the technical registration analysis, as follows in Table 1.

Table 1. Summary of mean error values

Type of Error	**Mean Value (m)**
Global bundle adjustment error	0.004
Bundle error	0.006
Cloud-to-cloud error	0.008
Target registration error	0.004

RESULTS AND DISCUSSIONS

The assessment of vertical accuracy in telecommunications towers through 3D scanning provided detailed insights into structural alignment, deviations, and potential deformations. The use of terrestrial laser scanning (TLS) and point cloud analysis allowed for a precise evaluation of the tower's verticality by identifying misalignments and detecting subtle structural shifts that could impact long-term stability. The findings of this study are categorized into different aspects of analysis, including point cloud processing, vertical alignment evaluation, deformation analysis, and implications for structural integrity.

In terms of point cloud processing, advanced computational techniques were employed to generate an accurate 3D representation of the tower. The data was carefully filtered and processed to eliminate noise and ensure precise modelling. This step was crucial in providing a reliable reference for further analysis, particularly in assessing deviations from the ideal structural alignment. However, at the top of the tower, the point cloud was not as dense due to the increased distance from the scanner to the top. Despite the scanner's capability to collect information up to 35 meters, the data density decreased with height, leading to reduced detail in the uppermost sections.

Regarding vertical alignment evaluation, a series of precise measurements were conducted and compared against an ideal perfectly vertical tower. The results indicate that the actual inclination of the structure deviates by approximately ±0.3 meters from the theoretical vertical alignment (Figure 7). This minor deviation is considered negligible in practical terms, as it falls well within acceptable construction tolerances and does not pose any structural or functional risks to the stability of the tower.

Deformation analysis was conducted to identify any structural deformations beyond simple inclinations. The results reveal that while minor deformations exist, they are primarily localized and do not compromise overall structural integrity. Potential causes for these deformations include environmental factors such as wind loads, thermal expansion, and material aging. The findings suggest that these minor deformations are within acceptable engineering limits and do not warrant immediate corrective action. Additionally, the local axis misalignment (Figure 8, Figure 9) was verified, and it was concluded that there are no fabrication or installation irregularities.

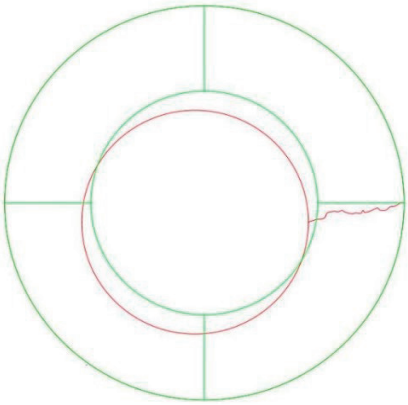

Figure 7. Comparison of Actual (red) and Theoretical (green) Tower Inclination

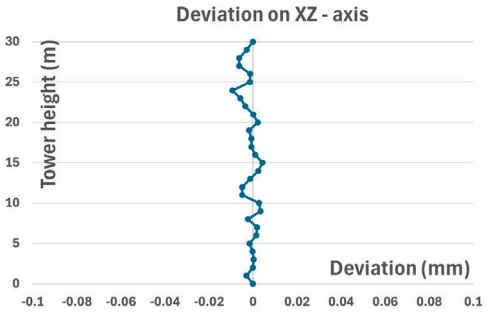

Figure 8. Deviation on XZ axis

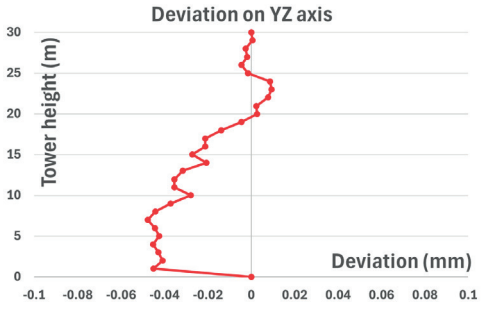

Figure 9. Deviation on YZ axis

Furthermore, deformations might influence long-term stability. The results confirm that the tower maintains a high level of structural reliability and that its slight inclination does not impact on its overall performance or safety. However, the observed deviation may be attributed to minor settlement effects, material deformations, or external environmental influences, all of which remain within industry-accepted limits. These results reinforce the reliability of the construction techniques used and confirm that the tower's alignment remains well within the anticipated engineering standards.

CONCLUSIONS

The assessment of vertical accuracy in telecommunications towers through 3D scanning has proven to be a significant advancement in structural evaluation and maintenance. This study has demonstrated that 3D scanning technology, particularly LiDAR, provides highly precise and reliable data for measuring tower verticality, structural integrity, and component alignment.

A key observation from this research is the detection of slight local axis misalignments that, while measurable, fall within acceptable tolerance limits and are not attributed to fabrication errors. These minor misalignments are typically the result of external factors, such as foundation settlement, small environmental forces or slight variations in installation, which are common in large structures. The environmental factors identified, while seemingly minor at first, have the potential to significantly impact the structural stability of the telecommunication tower over time through cumulative effects, particularly if not consistently and properly monitored. Uneven foundation settlement can lead to a progressive tilting of the structure and the development of additional stresses in load-bearing elements, while repeated environmental actions, such as wind or temperature fluctuations, can induce material ware. Furthermore, even slight deviations in the tower's axis can cause uneven load redistribution, generating unwanted moments and eccentric forces that place extra stress on the structure. In addition, the natural aging of materials, if not countered by proper maintenance, contributes to the decline in overall durability and resistance. Therefore, given that a residential neighbourhood and a public park are planned to be developed in the immediate proximity of the tower, it is essential that comprehensive geodetic measurements and structural evaluations be conducted at intervals of no more than four years, in order to ensure both the integrity of the structure and the safety of the surrounding community. The precision of 3D scanning allows for the identification of these deviations, which, although present, do not pose any immediate structural risk and are well within the industry standards for alignment tolerance.

The ability to quantify such minor misalignments is crucial, as it helps engineers confirm that the tower's alignment remains structurally sound, even when there are small deviations from the ideal vertical. This finding suggests that such misalignments are not a result of poor fabrication or manufacturing defects but rather natural, expected variations that occur during the installation and aging process of the tower.

In conclusion, 3D scanning provides a reliable method for assessing vertical alignment, ensuring that any misalignments are accurately identified, even when they are small and within acceptable limits. This technology allows for proactive monitoring without the need for immediate intervention, promoting the long-term health and operational efficiency of telecommunications towers. As scanning technology continues to improve, future research could focus on further refining the detection of misalignments that could influence tower stability over time, particularly in dynamic environmental conditions.

Abstract

Floods, rapid and destructive phenomena, significantly impact the environment, including agricultural lands. Geospatial methods for analysis, mapping, and monitoring have been developed over time to identify vulnerable areas. In this context, the present study applies a complex GIS model based on geospatial data, remote sensing data and the Analytic Hierarchy Process (AHP) to determine flood susceptibility in the Nera river basin, located in the southwest of Romania (Caraş-Severin County). The analysis includes nine factors: precipitation, drainage density, elevation, slope, distance to rivers, soils, topography, land use and land cover (LULC) and distance to roads. The results are synthesized into a susceptibility map, classified by risk levels and correlated with LULC to evaluate the impact on agriculture. Theoretically and practically, such models are essential for preventing and managing the effects of floods and for implementing optimal measures in line with sustainable development principles

Key words*: GIS models, flood susceptibility, watershed, impact, agricultural land.*

INTRODUCTION

Floods, destructive events with rapid occurrence, are among the most damaging hydro-geomorphological phenomena (Khosh et al., 2022). They result from the complex interaction of natural and anthropogenic factors, affecting the hydrological regime of river basins in various ways and proportions (Papaioannou et al., 2018; Syarifudin et al., 2022). These phenomena have significant effects on both the environment and society, causing loss of human lives, infrastructure damage, and public health issues, including the contamination of drinking water sources (Peker et al., 2024).

The impact of floods on agricultural land manifests through complex abiotic stress, affecting light availability, soil oxygenation, and nutrient cycling (Wang et al., 2022; Barneze et al., 2023). These changes alter soil properties and reduce fertility (Arabameri et al., 2020), negatively impacting plant growth and crop productivity (Bharadwaj et al., 2023).

To better understand and manage the impact of floods on agricultural land, the use of advanced hydrological risk modeling methods is essential. These methods have continuously evolved, enabling more precise identification of flood-prone areas.

Being dynamic and complex phenomena (Swain et al., 2020), floods are most effectively analyzed and mapped using geomatic techniques (Cai et al., 2021; Hagos et al., 2022; Covaci et al., 2023; Copăcean et al., 2025). Methods used for susceptibility assessment include Multi-Criteria Decision Analysis (MCDA) (Souissi et al., 2019) and the Analytic Hierarchy Process (AHP) (Chen et al., 2015), applied globally, including in river basins in Romania (Costache & Zaharia, 2017; Dragomir et al., 2020; Popescu & Bărbulescu, 2023). These methods contribute to identifying vulnerable areas and implementing measures to mitigate the effects on soil and agricultural crops.

In this context, the present study applies a complex spatial analysis model in a GIS environment, based on Multi-Criteria Decision Analysis (MCDA) and the Analytic Hierarchy Process (AHP), to identify flood-prone areas in the Nera River basin and assess their potential impact on agricultural land.

The main objectives include: (1) analyzing the physical-geographical conditions; (2) selecting

and evaluating relevant factors in flood occurrence; (3) creating thematic maps of the involved factors; (4) classifying the basin territory according to flood susceptibility, and (5) analyzing the impact of floods on agricultural land.

MATERIALS AND METHODS

Study area

The Nera River basin, covering 138,084 hectares, is located in southwestern Romania along the Serbian border (Figure 1)

It is bordered by the hydrographic basins of the Caraș, Cerna, and Danube rivers. The hydrographic network is well-defined, with the Nera river having numerous tributaries, whose sources are in the adjacent mountainous area.

The relief varies considerably, with altitudes ranging between 62 m and 1430 m (Figure 1), an aspect that is reflected in the geographical and hydrographic characteristics of the region (Simon et al., 2022) and, further, in hydrogeomorphological phenomena, water resource management strategies, and territorial planning (Posea & Badea, 1984; Rusu, 2007).

The shape of the Nera basin and the varied relief, with significant altitude differences, favor the rapid water concentration downstream, increasing the risk of floods, torrential erosion, and landslides, especially in areas with steep slopes and impermeable soils..

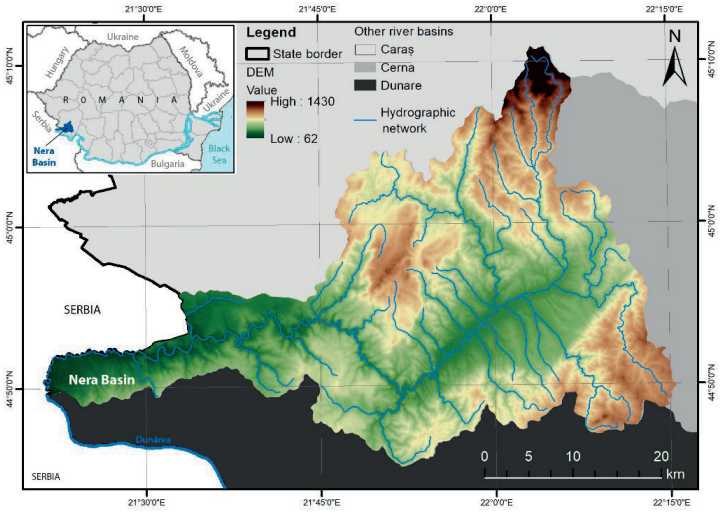

Figure 1. Study area location and Digital Elevation Model (DEM) (processing after EEA-DEM, 2016; Geospatial, 2021)

The working methodology

The methodology for assessing flood susceptibility in the Nera basin was adapted from the MCDA and AHP models applied through GIS, following the research conducted by Hammami et al. (2019), Swain et al. (2020), GIS and RS Solution and Copăcean et al. (2024). The analysis considered nine main factors in triggering and developing floods:

- ***Elevation Factor*** highlights the terrain relief and indicates the altitude and position of the land relative to the water level (Kumar et al., 2023). The Elevation factor map was derived from a Digital Elevation Model (DEM) with a spatial resolution of 25 m (EEA, 2016);

- ***Distance from River Factor*** shows that flood risk is high near rivers and decreases as their distance increases (Vegad et al., 2018). The river distance map was generated in ArcGIS using the Euclidean Distance tool applied to the vector hydrographic network (Geospatial, 2021);

- ***Topographic Wetness Index (TWI) Factor*** estimates soil moisture levels and areas of water accumulation (Kumar et al., 2023). TWI parameters were derived from DEM, and the TWI map was obtained by applying the relation $TWI = \ln(\alpha/\tan\beta)$ (Swain et al., 2020), where α represents the cumulative drainage area per unit contour length, and $\tan\beta$ is the slope at the contact point;

- ***Precipitation Factor***, essential in flood formation (Osman & Das, 2023), influences the susceptibility of the territory by increasing water input and potential runoff (Eriyagama et al., 2017; Kumar et al., 2023). The precipitation factor map was generated based on the amount of rainfall (mm) recorded at meteorological stations near the study area in 2022, a year that experienced significantly higher precipitation than the regional average (Climatic Databases, 2024). Data was integrated into GIS and geostatistically interpolated using the IDW (Inverse Distance Weighting) method;
- ***Slope Factor*** influences water runoff; on steep slopes, water drains quickly, reducing accumulation, whereas on flat or low-slope terrain, runoff is slower, favoring accumulation (Tehrany & Kumar, 2018). The slope map was generated from DEM and expressed in degrees;
- ***Drainage Density Factor*** indicates the development of the hydrographic network and is calculated as the ratio between its length and the drained area (Dube, 2018). Higher density implies a higher flood risk (Mitra & Das, 2022). In this study, the drainage density map (km/km²) was created using the Line Density tool in ArcGIS, based on the vector hydrographic network;
- ***Soil Type Factor*** influences water runoff and infiltration through its structure and texture. Clayey soils retain water on the surface, promoting accumulation, while sandy soils allow its infiltration (Anni et al., 2020). The map for this factor was created based on vector soil types (Geospatial, 2021), classified according to flood susceptibility and converted into raster format for analysis;
- ***Land Use/Land Cover (LULC) Factor*** affects water infiltration, runoff, and flood dynamics (Osman & Das, 2023). In the study area, the LULC map is based on Corine Land Cover 2018 (CLC, 2025) data, classified according to flood susceptibility. Forest areas have the lowest risk, while arable land has the highest. After reclassifying the vector data, the map was rasterized for cumulative analysis;
- ***Distance from Road Factor*** influences infiltration, as land near roads has reduced permeability, favoring water accumulation (Osman & Das, 2023). For the study area, the road distance map (m) was generated in ArcGIS using the Euclidean Distance tool applied to the vector road network (Geospatial, 2021).

The nine factors analyzed for assessing the flood susceptibility of the Nera basin were represented as raster maps with a resolution of 25 m, in the WGS 1984 system. Based on the specific values of the study area, they were reclassified into five susceptibility classes (Swain et al., 2020): very low, low, moderate, high, and very high.

To determine the value classes, the Natural Break method in ArcGIS was used, and the weight of each factor was determined using the AHP method (GIS and RS Solution, 2025). The final flood susceptibility map was obtained using the Weighted Overlay tool in ArcGIS, following specific workflow algorithms (ArcGIS Desktop Documentation, 2022). In the final analysis, the factors were weighted as follows: Elevation (m): 14%; Distance from River (m): 14%; TWI (dimensionless): 14%; Precipitation (mm/year): 13%; Slope (degrees): 12%; Drainage density (km/km²): 11%; Soil type: 8%; LULC: 8% and Distance from Road (m): 6%.

RESULTS AND DISCUSSIONS

A comprehensive assessment of flood susceptibility in the Nera Basin was conducted by analyzing nine key factors that influence hydrological risk. By examining these factors, it is possible to identify vulnerable areas and understand the mechanisms that determine the extent and intensity of floods.

The altitude factor influences the position of the terrain relative to the water level (Kumar et al., 2023), determining the direction of runoff and water accumulation, with low-lying areas, such as plains, being the most vulnerable to flooding (Hammami et al., 2019).

In terms of altitude, low-lying areas (61 - 335 m) along rivers in the Nera Basin (Figure 2) are the most susceptible to flooding, presenting the highest risk. Intermediate altitudes (336 - 550 m) remain vulnerable but with a lower risk, while transition zones (551-781 m) exhibit moderate susceptibility. In contrast, high-altitude regions (782-1430 m) have minimal risk due to rapid water runoff. An inverse relationship is observed between altitude and flood susceptibility, with low-lying terrains being the most exposed.

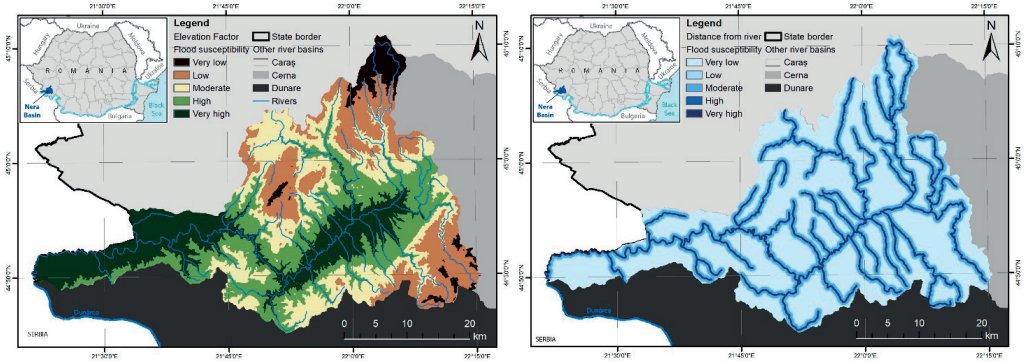

Figure 2. Susceptibility to flooding in the Nera basin based on the Elevation factor - m (left) and the Distance from rivers factor - m (right)

The distance from rivers factor (Figure 2) highlights a direct correlation between proximity to watercourses and flood risk (Vegad et al., 2018). Areas located within 0 - 100 m of rivers exhibit very high susceptibility, frequently experiencing flooding during rainy periods. Regions situated 101 - 150 m away have a high risk, those between 151 - 500 m face a moderate risk, while areas at 501 - 700 m show low susceptibility. Zones beyond 701 m are the least exposed to flooding.

The TWI (Topographic Wetness Index) factor reflects the terrain's tendency to accumulate and retain water (Kumar et al., 2023). In the analyzed area, areas with very high susceptibility (TWI 14.68-28.09) are found in valleys and depressions, where water naturally accumulates, presenting the highest flood risk. High susceptibility (TWI 10.21- 14.67) characterizes low-lying areas near rivers. Moderate susceptibility regions (TWI 7.32-10.20) are located in transitional zones, with partial water accumulation. Low and very low susceptibility (TWI 2.64-7.31) is specific to slopes and higher areas, where natural drainage reduces the flood risk (Figure 3).

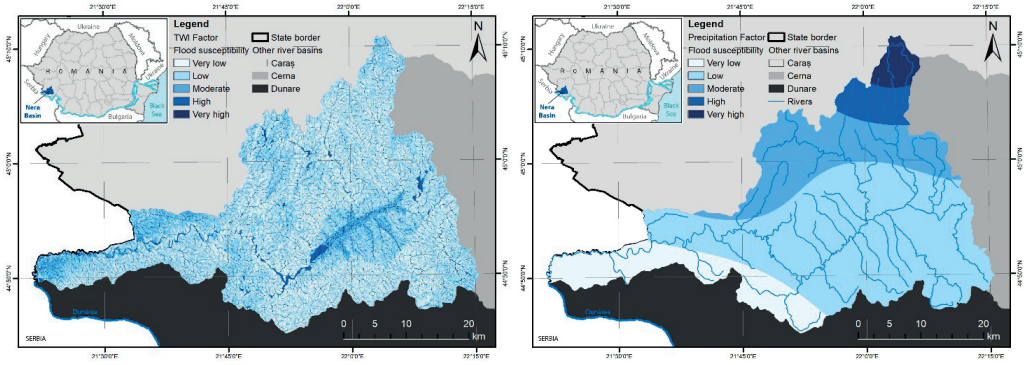

Figure 3. Susceptibility to flooding in the Nera basin based on the TWI factor (left) and the Precipitation factor - mm/year (right)

The precipitation factor plays a crucial role in triggering floods, influencing the land's susceptibility through increased water input and intensified surface runoff (Osman & Das, 2023). In the Nera basin, the distribution of flood risk varies depending on the amount of precipitation (Figure 3). Areas with very high susceptibility (1876-2261 mm) are located in the north, where precipitation is most abundant, significantly increasing flood risk, especially during rainy periods. High susceptibility regions (1562-1875 mm) extend toward the center, indicating a considerable risk. Moderate susceptibility areas (1353-1561 mm) are centrally located, where

precipitation levels are lower, reducing the probability of flooding. In the southern part of the basin, where precipitation is lower, areas with low susceptibility (1221-1352 mm) and very low susceptibility (1098-1220 mm) can be found.

The relationship between **terrain slope** and flood risk is inverse: areas with gentle slopes facilitate water accumulation and present a higher flood risk, whereas regions with steep slopes allow rapid water drainage, reducing vulnerability (Tehrany & Kumar, 2018).

In the Nera basin (Figure 4), areas with very high susceptibility (0-6.50°) are found in river floodplains and depressions, where water drains slowly and can stagnate, favoring floods. High susceptibility (6.51-12.76°) characterizes transitional areas, where the risk remains significant. Moderate susceptibility (12.77- 19.26°) is typical for steeper terrains, where water runoff is more efficient. Areas with low and very low susceptibility (19.27-64.05°) are located in hilly and mountainous regions, where water is rapidly evacuated, reducing the flood risk.

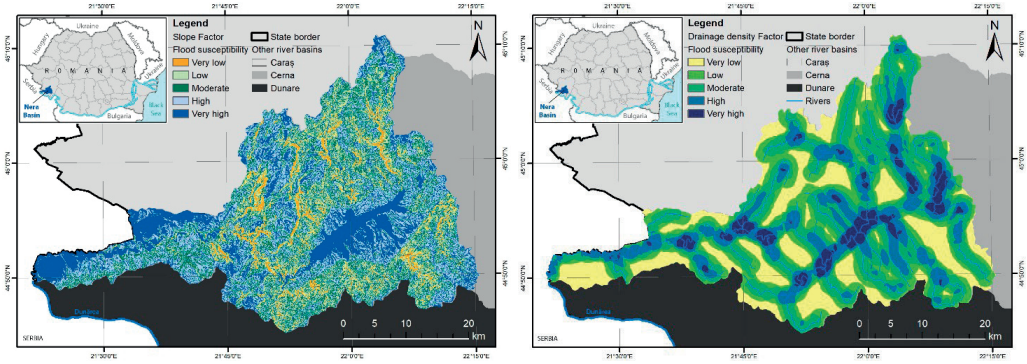

Figure 4. Susceptibility to flooding in the Nera basin based on the Slope factor - degrees (left) and the Drainage density factor - km/km² (right)

The drainage density reflects the degree of fragmentation of the hydrographic network and influences the land's capacity to evacuate water (Mitra & Das, 2022). Areas with high drainage density are more exposed to flooding as they collect and transport a large volume of water. Areas with very high susceptibility (0.78-1.22 km/km²) are located near major rivers and dense secondary watercourses, where water accumulation is frequent. High susceptibility (0.54-0.77 km/km²) extends along watercourses, indicating a significant but lower flood risk. Regions with moderate susceptibility (0.35-0.53 km/km²) are farther from rivers, with a lower risk of water accumulation.

Areas with low susceptibility (0.15-0.34 km/km²) and very low susceptibility (0-0.14 km/km²) are situated in regions with poorly developed drainage, where the probability of flooding is minimal (Figure 4).

The type of soil influences the degree of water infiltration and runoff, determining the flood risk level (Anni et al., 2020). Areas with very high susceptibility correspond to clay soils (Figure 5). These have very low permeability, favoring water accumulation and increasing the flood risk. Such soils are predominant in lowland areas and near rivers.

Regions with moderate susceptibility are associated with medium-textured soils. These allow partial water infiltration, reducing the flood risk compared to clay soils but still having limited drainage capacity. Areas with low susceptibility consist of sandy soils, which have high permeability, allowing rapid water infiltration and thus reducing the flood risk. These regions are less exposed to surface water accumulation.

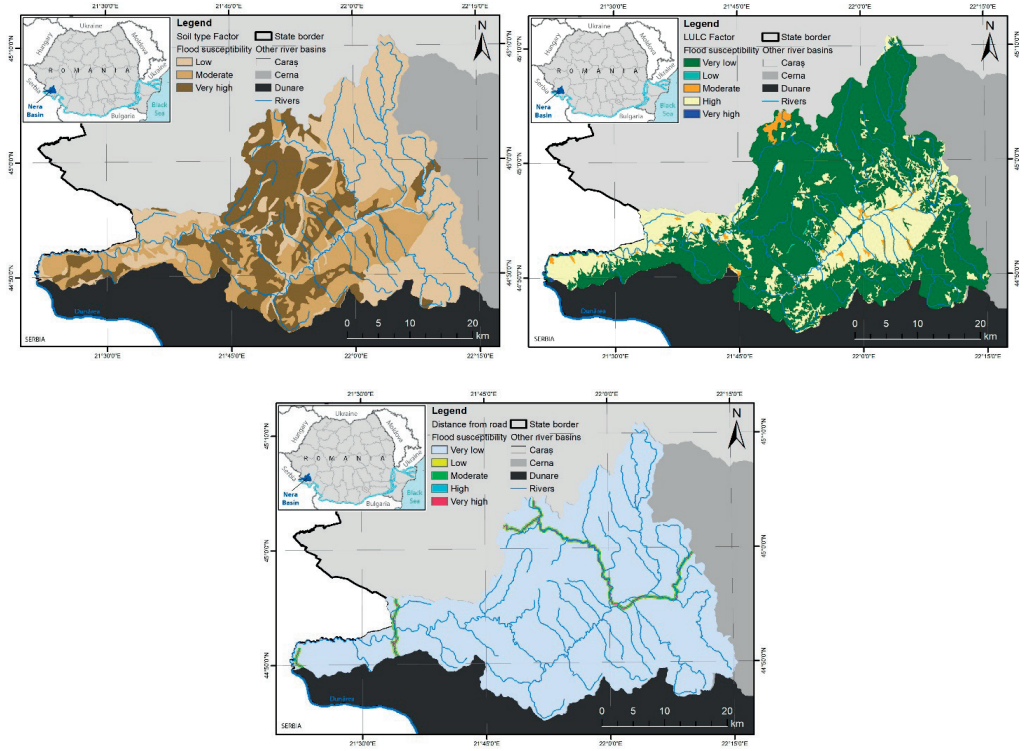

Figure 5. Susceptibility to flooding in the Nera basin based on the Soil Types factor (left), the Land Use/Land Cover factor (right), and the Distance to Roads factor - m (center)

LULC influence the water infiltration capacity, determining the degree of flood vulnerability (Osman & Das, 2023). Areas with very high susceptibility are those covered by water, where accumulation is permanent, presenting the highest flood risk (Figure 5). Agricultural lands, with low permeability, have high susceptibility, being exposed to flooding during periods of heavy rainfall. Built-up areas exhibit moderate susceptibility, as they reduce water infiltration and promote accumulation in the absence of adequate drainage. In contrast, areas covered by dense vegetation, especially forests, have very low susceptibility.

The Distance from Road (m) factor influences the water infiltration and accumulation capacity (Osman & Das, 2023). Areas with very high susceptibility (0-50 m) are located to the near roads (Figure 5). In these areas, the flood risk is at its maximum due to insufficient drainage or obstruction of natural runoff. Regions with high susceptibility (51-100 m) are also near roads, where the effect of water accumulation is significant but slightly less intense. Areas with moderate susceptibility (101-200 m) are situated at greater distances from roads and have a lower flood risk. Regions with low susceptibility (201-300 m) and very low susceptibility (>301 m) are located far from roads, where the terrain allows for better water infiltration and dispersion, reducing flood risk.

Based on the nine factors analyzed previously, a flood susceptibility map was generated, and by applying the Weighted Overlay Analysis (WOA) method, the final distribution of areas with different degrees of vulnerability was obtained (Figure 6).

The area with very low susceptibility represents only 441 ha, equivalent to 0.32% of the basin, indicating a minimal flood risk in these territories. The low susceptibility zone occupies the largest area of the basin, covering 72,356 ha, representing 52.4% of the total. This zone is predominantly located in regions less exposed to water accumulation. The moderate susceptibility zone covers 59,498 ha, or 43.1% of the basin. These regions lie in the transition between lowland and highland areas, presenting

a considerable flood risk. The high susceptibility zone extends over 5,784 ha (4.2%), being concentrated near watercourses, where water accumulation is frequent.

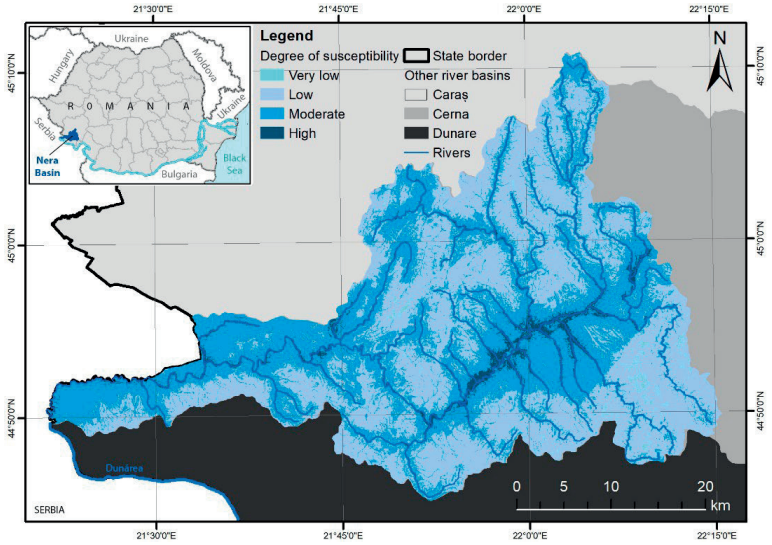

Figure 6. Flood susceptibility map in the Nera basin

The map in Figure 6 indicates a prevalence of low and moderate susceptibility classes, suggesting that most of the basin is not highly exposed to flooding. However, areas located near rivers require special preventive measures. The flood susceptibility analysis in the Nera basin provides a clear picture of the distribution of areas at hydrological risk (Figure 6). However, for a more detailed assessment of the effects of these phenomena, it is essential to examine and analyze the impact of floods, with varying intensities, on different types of LULC. Floods affect soil properties, agricultural fertility, and ecosystem functioning, with a significant impact on land use (Furtak & Wolińska, 2023; Rupngam & Messiga, 2024).

In the analyzed area, forests represent the most extensive type of land cover (Table 1), occupying 97,322 ha. Among these, 30,233 ha (31%) are exposed to moderate risk, while only 794 ha (0.8%) fall into the high-risk category, confirming the role of forests in reducing the impact of floods. Artificial areas (settlements, infrastructure) total 2,213 ha, with 1,954 ha (88.3%) classified under moderate and high susceptibility categories, indicating a significant vulnerability of urban infrastructure to flooding. Bare soils cover a very small area (86 ha) and are mainly affected by low or moderate susceptibility floods.

Table 1 The impact of floods on different types of LULC in the Nera River basin

LULC classes	Flood susceptibility degree (ha)				
	Very low	Low	Moderate	High	Total (ha)
Artificial surfaces	0	293	1543	411	2213
Forest areas	467	65828	30233	794	97322
Agricultural land	1	6087	27704	4635	38426
Bare soil	1	82	2	0	86
Total (ha)	469	72290	59485	5840	138084

Agricultural lands cover a total of 38,426 hectares, of which 32,339 hectares (84.2%) are classified as moderate or high susceptibility to flooding. Only 6,087 hectares (15.8%) are located in a low-risk area, indicating a limited percentage of agricultural land protected from

floods. Following flood events, arable lands are the most vulnerable, as nutrient losses and the accumulation of toxic metabolites reduce crop yields (Rupngam & Messiga, 2024). In the case of grasslands, flooding induces physiological stress on plants, which can lead to biodiversity loss (Căluşeru et al., 2013; Pedersen & Colmer, 2013). Additionally, soils may undergo structural changes, reducing drainage capacity and long-term fertility, which impacts vegetation regeneration and the use of land for agricultural or pastoral activities (Copăcean et al., 2020; Barneze et al., 2023).

CONCLUSIONS

The analysis of factors influencing flood susceptibility in the Nera basin has highlighted that elevation, distance from rivers, Topographic Wetness Index (TWI), precipitation, slope, drainage density, soil type, land use/land cover, and distance from roads play a crucial role in determining vulnerable areas. Factors related to terrain positioning and hydrological characteristics directly influence water accumulation and drainage. Low-lying areas close to watercourses with poorly permeable soils are the most exposed to flood risks.

The flood susceptibility map of the Nera basin, classified based on susceptibility levels, shows that most of the analyzed area falls into low and moderate susceptibility categories, covering over 95% of the total surface. However, approximately 4% of the territory is at high risk, concentrated in lowland areas along rivers where water accumulation is frequent. This underscores the importance of implementing prevention and risk management measures, particularly in regions vulnerable to flooding.

The impact of floods on LULC classes is significant, with agricultural lands being the most affected. Over 84% of these areas are in moderate and high susceptibility zones, making them vulnerable to nutrient loss, decreased productivity, and soil degradation.

Geomatic models, through the integration and analysis of spatial data, have proven to be essential tools in flood susceptibility assessment. These models enable detailed risk mapping and the identification of vulnerable areas, providing scientific support for decision-making regarding territorial planning and prevention measures. The application of GIS techniques and the Weighted Overlay Analysis method demonstrates the importance of multidisciplinary approaches in managing natural hazards, contributing to the development of effective strategies for reducing flood impact.

Abstract

This article explores innovative approaches to improving cadastral systems and utilizing Geographic Information System (GIS) tools for forest management. It emphasizes the importance of accurate and up-to-date cadastral records to support sustainable forest management, land ownership clarity, and environmental preservation. The study outlines methodologies for integrating cadastral updates with advanced GIS spatial analysis techniques, enabling the efficient mapping and monitoring of forested areas. Key applications include assessing land use changes, detecting illegal activities, and planning conservation efforts. The research highlights how GIS tools enhance spatial data visualization, offering insights into forest density, composition, and land-use dynamics. By analysing case studies from forested regions, the article demonstrates practical implementations and benefits, including improved decision-making for policymakers, forest managers and environmental stakeholders. The integration of cadastral updates and GIS-based analysis represents a significant step toward ensuring the sustainable management of forested areas, balancing ecological protection with economic and social considerations.

Key words*: forested area, GIS, cadastral updates.*

INTRODUCTION

Given the rapid growth of the global population, land emerges as a critical resource requiring strategic management. In this context, ensuring legal assessment, clear definition, and accurate registration of real estate is essential - especially when advancing cadastral updates and GIS spatial analysis for forested areas, where precise land delineation supports sustainable planning and resource protection (Chiorean et al., 2024). The Geographic Information System (GIS) is a contemporary tool widely applied across various domains for managing both attribute and spatial data, including demographic information, playing a vital role in advancing cadastral updates and spatial analysis for forested areas by enabling precise mapping, monitoring, and informed decision-making.

The primary objective of this study is to develop updated cadastral documentation for a land parcel within the Administrative-Territorial Unit (ATU) Telciu and to conduct a spatial analysis within a Geographic Information System (GIS) framework. The spatial and raster analyses focus on evaluating the forested area and timber volume, encompassing a precise assessment of forest extent, species composition, and available timber resources. To achieve this, an accurate delineation of property and forest boundaries was performed using advanced measurement techniques and high-precision GPS equipment, ensuring a clear and reliable definition of land contours. Additionally, a photogrammetric flight was conducted to obtain high-resolution imagery of the terrain. The data acquired through photogrammetric processing in Agisoft Metashape has been integrated into ArcGIS Pro for in-depth spatial analysis. The results are to be disseminated via ArcGIS Online, enabling interactive visualization and efficient data sharing with both stakeholders and the broader public. This approach enhances the accessibility and interpretability of geospatial information. Ultimately, the study is set to result in the development of accurate and up-to-date cadastral documentation, incorporating all

analyzed and processed data. This documentation comprises detailed cadastral maps and technical reports, prepared in accordance with current regulations and standards, thereby ensuring precise property registration and long-term availability of data for land management and administrative purposes.

The inherent nature of agricultural activities means that risks and uncertainties are a constant presence in agricultural value chains. Therefore, it is crucial for decision support models in farming to incorporate risk management metrics and strategies. This becomes particularly relevant in the context of advancing cadastral updates and GIS spatial analysis for forested areas, where accurate spatial data and land parcel information can significantly enhance risk assessment and support more resilient decision-making in forest-related agricultural systems.

MATERIALS AND METHODS

Telciu is located in Bistrița-Năsăud County, in the Transylvania region of Romania. The locality is situated at coordinates 47°24'N 24°53'E and covers an area of 291.42 km². It is traversed by two rivers, Sălăuța and Telcișor, which originate from the Rodna and Țibleș Mountains. The commune of Telciu consists of the villages of Telciu, Fiad, Telcișor, and Bichigiu. It borders the localities of Romuli, Dragomirești (Maramureș), Rebra, Rebrișoara, Coșbuc, Runcu Salvei (Salva), Suplai, and Zagra (Figure 1).

The initial phase of the study involved defining the study area, with a specific focus on the targeted forest (Figure 2).

Data processing was conducted using ArcGIS Pro and ArcGIS Online, ensuring the integration and standardization of all raster and vector datasets. These datasets were harmonized in terms of spatial resolution, coordinate reference system (Stereographic 1970, Romania's national projection system), and the extent of the study area. The Digital Elevation Model (DEM) and Digital Surface Model (DSM) were utilized to generate thematic maps representing slope, aspect, curvature, and hill shade, which provided a detailed understanding of the terrain characteristics. The results were synthesized through spatial analysis, facilitating the classification of the study area, forest structure assessment, and the evaluation of tree volume and height.

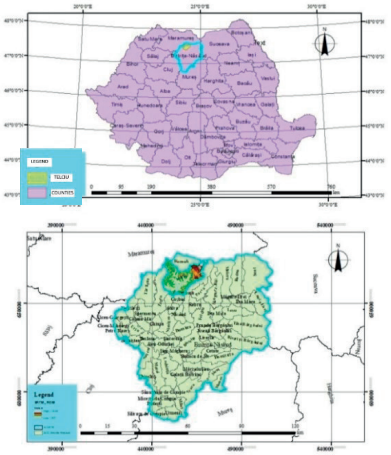

Figure 1. Macrolocalization of Bistrița-Năsăud County

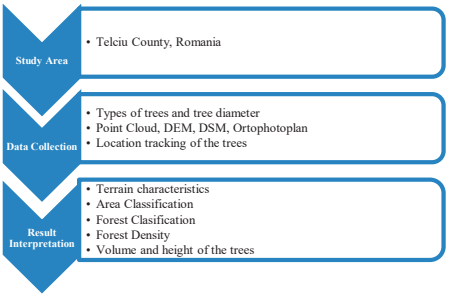

Figure 2. Research methodology

For the study of the proposed objective, the following equipment and instruments were used to conduct field measurements, delineate and map the forest, and inventory the trees: GPS V200, DJI MAVIC 3M drone, forestry calliper, and forestry measuring tape. Additionally, various specialized software tools were employed to ensure the collection, processing, and analysis of the data required for forest evaluation. For effective forest management, ArcGIS Online was utilized: a secure cloud-based platform for mapping and spatial analysis, provided as a software-as-a-service solution. This platform enables organizations to leverage geospatial insights through its scalable and resilient technology, supporting the collection, management, and analysis of geospatial data. By facilitating data-driven decision-making,

ArcGIS Online allows for seamless sharing of maps and applications. With a configurable sharing model and a wide range of integrated applications and analytical tools, the platform enhances collaboration and efficiency among users.

RESULTS AND DISCUSSIONS

As part of the cadastral documentation preparation, a property data update file was compiled, encompassing operations such as boundary and area modifications, land use category updates, and corrections to other critical property information. These procedures require the submission of specific supporting documents and may involve multiple types of technical updates simultaneously. The resolution of such requests is conducted while preserving the area determined through measurements as recorded in the land registers, thereby ensuring the accuracy and currency of cadastral data. The reception and registration request form is intended to facilitate the update of cadastral information, including revisions to land use classifications and parcel identifiers. The approved updates are subsequently integrated into the national cadastral and land registration system. The property is not subject to litigation/is subject to litigation with the property ID [property ID], case number [case number], court [name of the court], subject [subject of the dispute].

After updating the land use categories, the property located in the outskirts of Telciu, Bistrița-Năsăud County, is described as follows: it consists of three distinct parcels. Parcel 1 has an area of 4,944 sqm and is classified as PD (forest). Parcel 2 has an area of 8,027 sqm and is classified as F (hayfield). Parcel 3 has an area of 2,522 sqm and is also classified as PD (forest). Following the update process, the total measured area of the property remains 15,495 square meters, as illustrated in Figure 3. In the absence of leaves, flowers, and fruits, species identification relies primarily on the morphological characteristics of bark and branches. During the winter season, features such as bark texture, color, and pattern serve as key diagnostic traits for differentiating between species (Figure 4; Mikita et al., 2016).

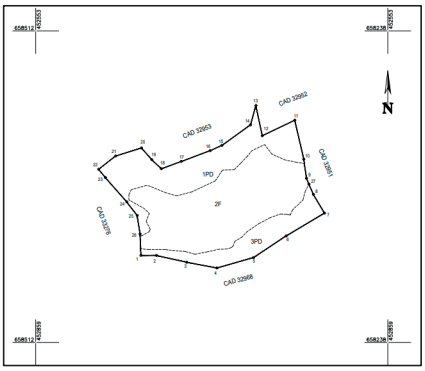

Figure 3. Delimitation Plan after Update

Figure 4. Types of trees

Figure 5. Determination of tree diameter

Figure 5 presents the methodology and equipment utilized for measuring tree diameter, employing the traditional approach. This method involves the use of a specialized forestry instrument, the caliper, to obtain precise diameter measurements. In the context of tree height measurement, the described method utilizing a forestry tape requires ascending the tallest tree to obtain a direct measurement, which serves as a reference for estimating the height of other trees. While this approach can provide practical and accurate results, it presents considerable safety risks due to the necessity of climbing tall trees. To enhance both accuracy and safety, tree height was determined using

data derived from photogrammetric processing (Figure 6) (Meng et al., 2019).

To conduct the planned study, a photogrammetric flight was performed using the DJI Phantom 4 RTK drone. This drone is widely utilized for photogrammetric applications due to its high-resolution camera and integrated sensors, which collectively ensure superior imaging performance. The advanced technology incorporated in this drone enables data acquisition with centimetre-level accuracy, eliminating the necessity for additional ground control points. Equipped with an integrated RTK module, the drone provides real-time positioning data, ensuring absolute geo-tagging of the captured images. Additionally, to optimize flight safety and enhance data precision, the DJI Phantom 4 RTK records satellite observation data, which can be post-processed (PPK) (Risna et al., 2023). The photogrammetric data was processed using Agisoft Metashape software, involving the reconstruction of previously acquired images to generate a dense point cloud (Soubry et al. 2021).

Figure 6 illustrates the resulting 3D model/point cloud, which consists of a set of data points within a three-dimensional coordinate system (X, Y, Z axes). Each point corresponds to a precise spatial measurement on the surface of the object (Coroian et al., 2021).

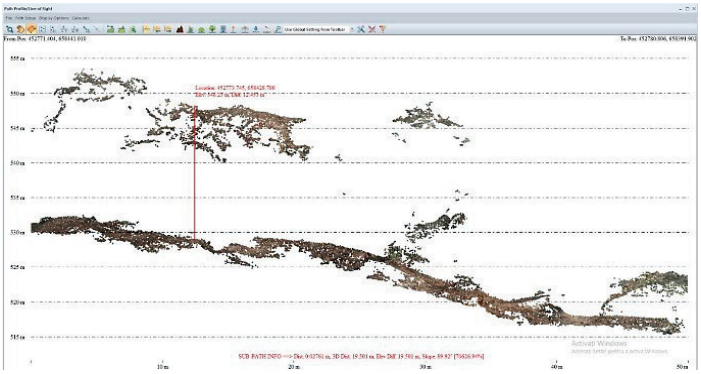

Figure 6. Point Cloud of the terrain

In contrast, Figure 7 illustrates a more efficient and safer approach for measuring tree height by utilizing Point Cloud technology. This method leverages photogrammetrically acquired data to generate an accurate three-dimensional model of the studied area, enabling precise height measurements (Zlinszky et al., 2015).

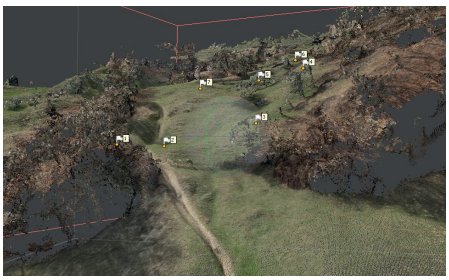

Figure 7. Point Cloud

Figure 8 presents the orthophoto map, an aerial image that has been geometrically corrected to remove distortions caused by aircraft tilt during image acquisition, variations in photogrammetric scale, and topographic relief differences (Qiu et al., 2018).

Figure 8. Ortophotomap

For the forest monitoring system, a technology was employed that enables real-time tree localization and tracking using ArcGis Online (Figure 9) (Boroushaki et al., 2010).
Utilizing a mobile device, the precise position of each tree is determined with centimetre-level accuracy through integrated GPS technology. During field data collection, trees are documented through photographs and videos captured with the mobile device's camera, ensuring a comprehensive visual record for identification and assessment (Brovelli et al., 2016). Additionally, a digital field notebook is used to record essential attributes for each tree, including species, diameter, height, and volume (Li et al., 2011).

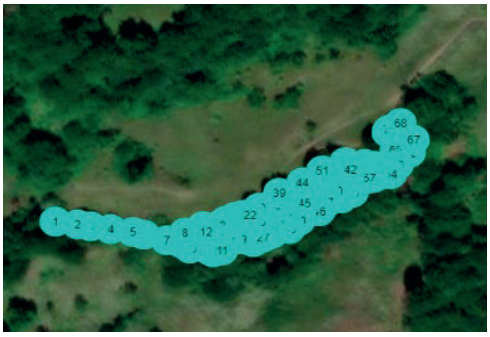

Figure 9. Real-time location tracking

Table 1 presents the classification of the study area, which has been categorized into three distinct land types: Upper Forest, Lower Forest, and Meadow (Figure 10). The Upper Forest covers 4,944.47 square meters, making up 32% of the total land area. The Lower Forest occupies 2,522.89 square meters, which constitutes 16% of the total. The Meadow extends over 8,027.37 square meters, accounting for the remaining 52%. Altogether, these areas sum to a total of 15,495 square meters.

Table 1. The classification of the area

Land use category	**Area**
The Upper Forest	4944 (32%)
The Lower Forest	2523 (16%)
Meadow	8027 (52%)
Total Area	15495

Figure 10. Thematic Map for area classification

Using the data presented in the Tables 2 and 3, a direct comparison can be made between the upper and lower forest in terms of species diversity and tree abundance. The upper forest comprises four tree species beech, hornbeam, maple, and willow while the lower forest contains only three species: beech, maple, and willow. Additionally, differences are observed in the number of trees per species. The upper forest consists of 48 beech trees, 39 hornbeams, 12 maples, and 2 willows, amounting to a total of 101 trees (Table 2). In contrast, the lower forest contains 45 beech trees, 16 maples, and 11 willows, summing up to 72 trees (Table 3) (Cammerino et al., 2023).

Table 2. The Upper Forest Classification

The Upper Forest	**Area**
Beech	48 (48%)
Hornbeam	39 (39%)
Maple	12 (12%)
Willow	2 (2%)
Total	101

Table 3. The Lower Forest Classification

The Lower Forest	**Area**
Beech	45 (63%)
Maple	16 (22%)
Willow	11 (15%)
Total	72

Figure 11 presents the forest classification, in which four tree species have been identified: beech, hornbeam, willow, and maple.

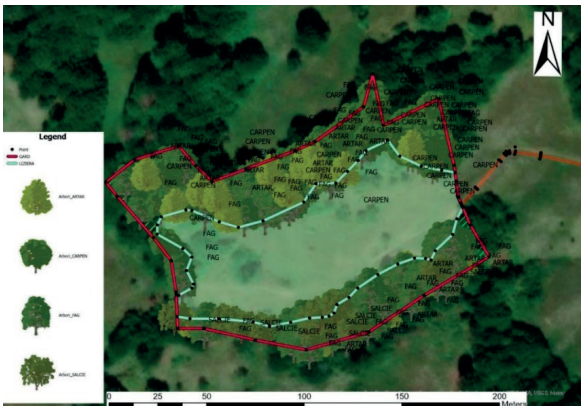

Figure 11. Thematic Map for forest classification

In assessing forest density, the analysis was conducted based on the volume of each tree species. Figure 12 visually represents forest density using a color-coded classification, as indicated in the legend. Areas with high tree density, where trees are closely spaced and create a shaded environment, are depicted in yellow. Conversely, regions with low tree density, characterized by widely spaced trees and a more open landscape, are represented in gray blue. This colour differentiation facilitates a rapid and clear interpretation of the spatial distribution of tree density within the forest. Identifying areas of higher density enables the planning of thinning operations to promote the optimal growth and diameter expansion of the remaining trees (Chakhar et al., 2008).

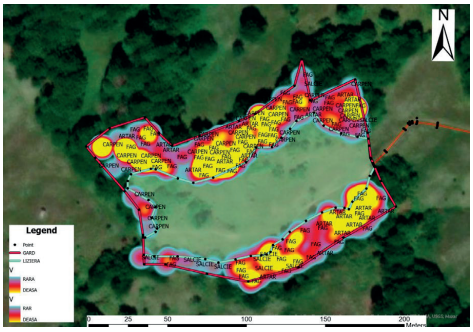

Figure 12. Thematic Map for forest density classification

Using the graphs presented in Figure 13 and Figure 14, a comparative analysis of the timber volume between the Upper Forest and the Lower Forest was conducted. The volume was calculated based on Huber's Theory, allowing for an objective assessment of the differences in timber mass between the two forest areas.

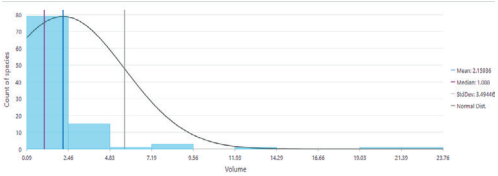

Figure 13. Volume of Upper Forest

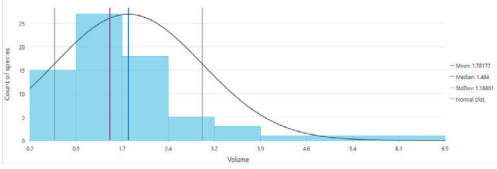

Figure 14. Volume of Lower Forest

In the Upper Forest, the predominant timber volume ranges from 0.09 m³ to 2.46 m³, encompassing most tree species, with a total of 79 trees within this range. Conversely, in the Lower Forest, the dominant volume falls between 1.1 m³ and 1.5 m³, with 19 trees recorded in this interval.

Additional comparisons, displayed on the right side of each graph, include the mean and standard deviation. These statistical indicators provide further insights into the distribution of timber volumes, highlighting differences in variability and central tendencies between the two forest areas.

Figure 15 represents the tree heights in both the upper and lower forests. As shown in the legend, the heights are categorized into five distinct

ranges, each represented by a specific colour: white for trees ranging from 10 to 14 meters, green for those between 15 and 18 meters, light blue for trees between 19 and 21 meters, blue for heights between 22 and 26 meters, and dark blue for towering trees measuring between 26 and 30 meters. This color-coded classification offers a clear and visually informative representation of the variation in tree heights across the two forests (Sestras et al., 2019).

Figure 15. Thematic Map for tree height classification

Using the graphs provided below (Figure 16 and Figure 17), a direct comparison can be made between the Upper Forest and the Lower Forest with respect to tree heights, categorized into five distinct classes.

Further comparisons are provided through the mean values and standard deviations, offering additional insights into the distribution of tree heights in both forests and emphasizing the differences in variability and central tendencies between the Upper Forest and the Lower Forest (Felicisimo et al., 2002). Figure 18 illustrates the tree diameters in both the Upper and Lower Forests. According to the legend: in the Upper Forest, tree diameters range from 0.10 meters to 1.1 meters, with a gradual colour transition from white to dark green and in the Lower Forest, tree diameters range from 0.16 meters to 0.58 meters, following a similar colour progression from white to dark green. This color-coded representation emphasizes the variation in three sizes across both forests, offering a clear and visually informative view of their structural composition (Curovic et al., 2020).

Using the graphs from Figure 19 and Figure 20, a direct comparison can be made between the central tendencies of diameter distributions in the Upper and Lower Forests. In the Upper Forest, the most common diameter range is between 0.1 meters and 0.3 meters, encompassing 69 trees. In contrast, in the Lower Forest, the predominant diameter range is between 0.24 meters and 0.33 meters, with 31 trees within this range. Additional comparisons, including mean values and standard deviations, offer further insights into the distribution of tree diameters in both forests.

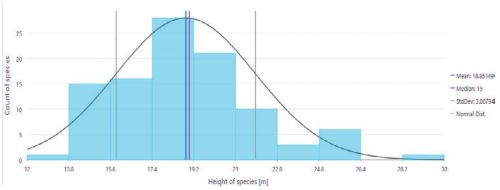

Figure 16. Tree Height in the Upper Forest

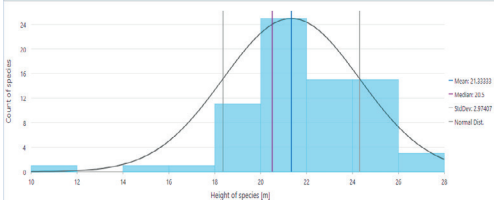

Figure 17. Tree Height in the Lower Forest

Figure 18. Thematic Map for Tree Diameter Classification

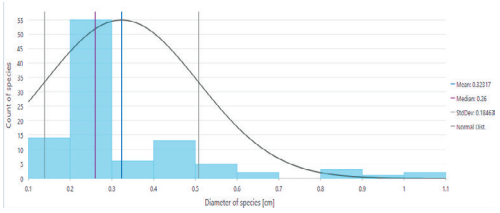

Figure 19. Diameter of the Upper Forest

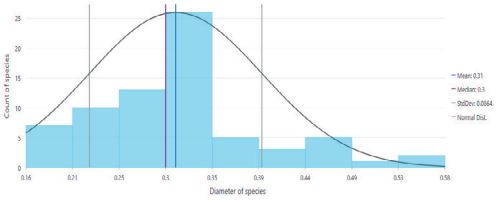

Figure 20. Diameter of the Lower Forest

Figure 21 presents the Digital Elevation Model (DEM), which offers detailed information exclusively about the terrain. This DEM is critical for understanding the area's topography. According to the legend, the elevation difference spans 255 meters, from the lowest to the highest point. This substantial variation in elevation is fundamental for various geospatial analyses and can impact a range of applications, from infrastructure planning to natural resource management.

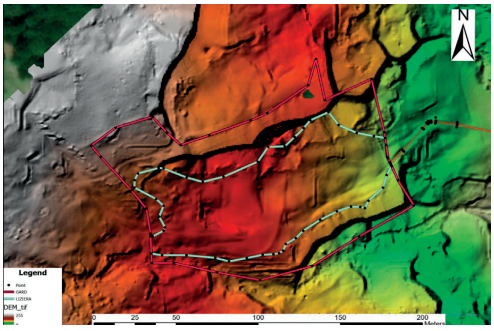

Figure 21. DEM - Digital Elevation Model

Figure 22 presents the Digital Surface Model (DSM), which depicts the elevations of all surface features within the terrain. Unlike the Digital Elevation Model (DEM), the DSM incorporates not only the ground level but also the heights of structures such as buildings, trees, and other forms of vegetation.

The DSM essentially captures all surface elements, providing a comprehensive and detailed representation of the topography and all objects located above the ground.

It offers valuable insights into the canopy structure, including its height and density. These models are particularly useful for monitoring temporal changes, such as deforestation, reforestation, and forest health.

Figure 23 illustrates the aspect, which indicates the orientation of slope exposure. This information is essential for planning future afforestation efforts, as it influences microclimatic conditions, soil moisture distribution, and species selection (Pasqualini et al., 2011).

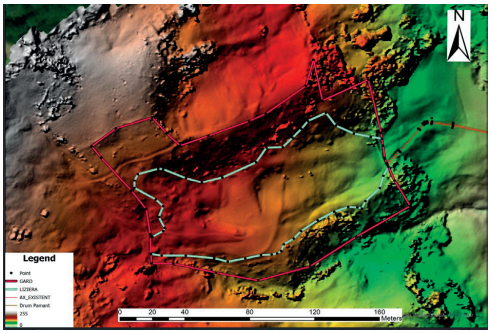

Figure 22. DSM - Digital Surface Model

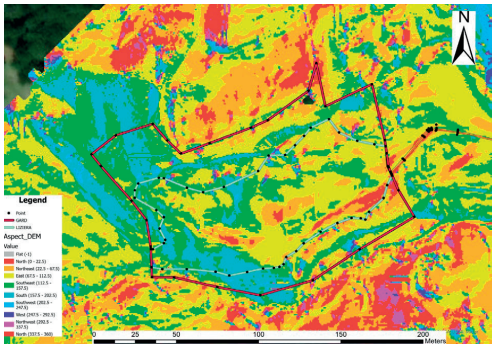

Figure 23. Aspect

Figure 24 presents the Curvature tool, which facilitates the analysis of landforms and geological processes. This tool is instrumental in land use planning, natural resource management, and environmental studies. By utilizing curvature analysis, a detailed assessment of terrain morphology can be conducted, providing essential data for various geological and environmental applications.

Figure 25 presents the HillShade tool, which generates a shaded relief raster from a surface raster by simulating the effects of a light source and shadow formation. This tool assumes a distant light source to create a realistic terrain representation. The resulting raster contains integer values ranging from 0 to 255, indicating the intensity of light and shadow distribution across the terrain, enhancing the visualization of topographic features.

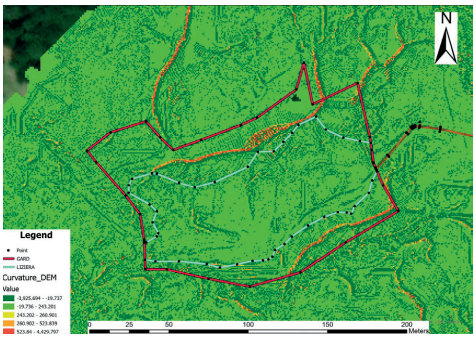

Figure 24. Curvature

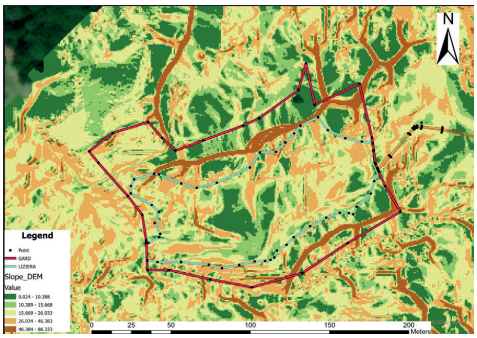

Figure 26. The terrain slope

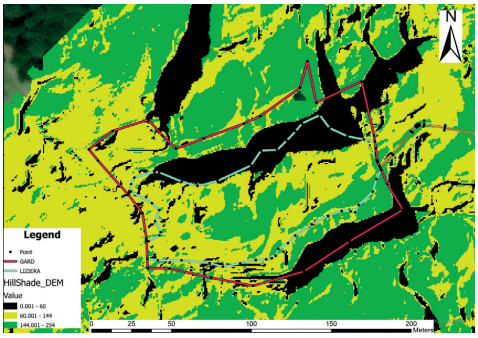

Figure 25. HillShade

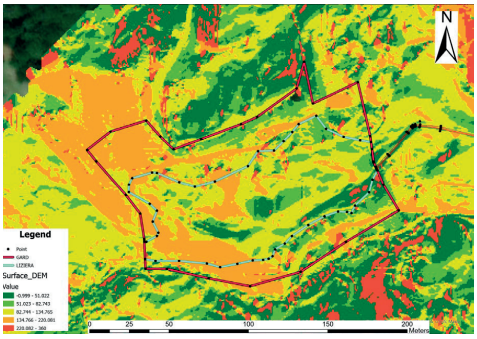

Figure 27. Surface parameters aspect

Figure 26 illustrates the terrain slope. According to the legend, the slope is categorized into five classes based on degrees of inclination. The green range represents slopes between 0 and 11 degrees, while the brown range corresponds to slopes between 47 and 87 degrees.

The Surface Parameters tool in ArcGIS Pro is a key resource for analyzing raster surface characteristics, including aspect, slope, and curvature. These parameters provide crucial information about terrain orientation and inclination across different locations. For example, the aspect defines the direction of the terrain slope and is classified into five categories, expressed in degrees, as indicated in the Surface result legend.

Figure 27 illustrates the natural risk assessment, which supports informed decision-making and strategy development. Areas highlighted in red represent risk zones located outside the studied terrain but requiring stabilization measures, such as planting deep-rooted trees to enhance slope stability.

CONCLUSIONS

The integration of advanced software tools, GPS technology, and traditional forestry methods enabled precise delineation of property and forest boundaries, ensuring accurate measurements and mapping. Modern inventory technologies, including mobile applications, specialized forestry tools, and Point Cloud technology, facilitated an efficient and secure assessment of forest resources.

By utilizing ArcGIS Online and smartphone-based geolocation, a detailed forest inventory was created, documenting essential attributes such as species, diameter, height, and volume. Photogrammetric flights and subsequent data processing yielded high-precision results, contributing to effective land and forest management. Geospatial analyses provided key topographic insights: the Digital Elevation Model (DEM) revealed a 255-meter elevation difference between the lowest and highest points, the Digital Surface Model (DSM) captured terrain objects such as buildings and vegetation, aiding in monitoring deforestation,

reforestation, and forest health, aspect analysis provided slope exposure data, supporting afforestation and land management planning, contour lines illustrated terrain relief, while curvature analysis enhanced the understanding of landforms and geological processes, slope classification divided the terrain into five categories based on incline, aiding in landscape and the Surface Parameters tool in ArcGIS Pro enabled the evaluation of aspect, slope, and curvature, offering essential data for environmental and resource management applications.

These comprehensive assessments support sustainable forestry practices, informed decision-making, and effective land use planning.

ACKNOWLEDGEMENTS

Abstract

This study presents a case analysis of an integrated surveying and mapping initiative conducted at the Dolj Chim industrial complex in Romania, with the primary objective of determining material volumes expected from impending demolition activities. Employing a multi-faceted approach, the research combined data acquisition using a handheld LiDAR system for the interior and data acquired through a UAS equipped with high-resolution imaging sensors for the exterior. These complementary datasets were georeferenced using ground control points collected via Global Positioning System (GPS) receivers and Total Station measurements, ensuring a consistently accurate and spatially coherent representation of the site. This integrated approach streamlines data management and enhances the utility of subsequent analyses. The results emphasize the significance of selecting and integrating appropriate surveying technologies tailored to the complexities of industrial environments. By leveraging the strengths of various methods, high-density interior scanning and external imaging, reinforced by reliable ground-based control, the study achieves an enriched and precise dataset conducive to informed decision-making in demolition planning. Beyond its immediate relevance, this approach demonstrates broader applicability in complex geospatial contexts, illuminating best practices for harmonizing sensor technologies and conventional surveying techniques. Consequently, the research contributes insights into optimizing data quality, operational efficiency, and overall methodological rigor in contemporary geospatial applications.

Key words*: LiDAR, photogrammetry, industrial survey, demolition planning, 3D modelling, Romania.*

INTRODUCTION

This paper explores the crucial role that surveying and mapping plays in various engineering and geospatial applications and the implementation of integrated surveying techniques in the context of the Dolj Chim industrial complex demolition project.

The main objective of the study is to quantify the volumes of various construction materials (e.g. concrete, iron, wood, glass etc.) that will result from the demolition process, by harnessing the synergetic potential LiDAR scanning for interior spaces and UAS based photogrammetry for the roof of the buildings and surrounding area. In the case of industrial demolition, precise 3D modelling is essential to ensure cost-effective waste management while complying with environmental and work safety regulations, as underscored by (Nikmehr et al., 2021).

While traditional surveying methods can be time-consuming and challenging in degraded industrial environments (Zhan et al. 2020), this study aims to demonstrate the efficiency of integrating LiDAR, UAS photogrammetry and ground-based control points to achieve an accurate and comprehensive 3D model for demolition planning.

This project presented challenges that are common in old industrial complexes throughout Romania due to their advanced state of degradation, including water damage, overgrown vegetation and hazardous conditions such as shattered glass and unstable structures (Matsimbe et al., 2022).

The aim of this study is to highlight how modern surveying technologies complement traditional methods, leading to improved data acquisition and processing efficiency in complex industrial areas, offering a template for best practices in the field.

MATERIALS AND METHODS

In modern surveying, SLAM and UAS both enable spatial data acquisition. SLAM's real-time 3D mapping suits complex indoor environments, ensuring mobility. Meanwhile,

UAS excels at broad aerial surveys. The optimal choice depends on specific project needs, environment, and data requirements. A GeoSLAM Zeb Horizon RT LiDAR scanner (Figure 1) was used to scan the interior of the buildings and the ground level of the entire complex. The technical specifications of the GeoSLAM Zeb Horizon, which was used in the data acquisition process, are presented in Table 1.

Figure 1. GeoSLAM Zeb Horizon RT

Table 1. GeoSLAM Zeb Horizon technical specifications

Scanner	
Type	VLP-16
Acquisition	300.000 pts/sec
Channels	16
Range	100 m
Class	Class 1 eye safe laser
Wavelength	903 nm
Angular resolution	2°
Angular resolution	0.1-0.4°
Weight	1.3 kg
Raw data file size	100-200 MB a minute
Rotation	10 Hz
Datalogger	
Battery	PAG L90 SLIM, 90 Wh, 14.8V, 6.1 Ah
Operational time	3.5 hours
Storage	120 GB
Operational temp	0 – 50°
Weight	2.4 kg
System	
Protection Class	IP54
Processing	Post
Accuracy	1-3 cm
Protection Class	IP54

This device captures high density point clouds in near real-time at a rate of 300.000 points per second and has a range of up to 100 meters. It utilizes an inertial measurement unit (IMU) and Simultaneous Localization and Mapping (SLAM) algorithms to achieve a relative accuracy of up to 6 millimeters, depending on the environment which made it the ideal equipment for this project.

For the exterior and for the roofs of the buildings a DJI Mavic 3 Enterprise (Figure 2), equipped with a high-resolution imaging sensor, was deployed, enabling wide-scale coverage at various altitudes and oblique angles resulting in aerial imagery for photogrammetric processing. The technical specifications of the DJI Mavic 3 Enterprise, employed for aerial data collection, are detailed in Table 2.

Stabilization	3-axis (tilt, roll, pan)
Mechanical Range	Tilt: -135° to 100° Roll: -45° to 45° Pan: -27° to 27°
Controllable Range	Tilt: -90° to 35° Pan: Not controllable
Max Control Speed	100°/s
Angular Vibration Range	±0.007°

To ensure proper georeferencing and alignment of data sets, ground control points were placed throughout the area of interest. The distribution of these points was influenced by existing vegetation, accessibility constraints, varying floor elevations and isolated structures.

A total of 50 ground control points were surveyed using a Trimble R10 GNSS receiver and a Trimble Geodimeter 5000 Series Total

Station in places where GPS signal was obstructed and on the facade of the buildings (Figure 3). This approach is in line with similar studies that emphasize the necessity of combining ground-based control methods with aerial and LiDAR data to ensure spatial coherence (Son et al., 2020).

Figure 3. Distribution of ground control points

The ground control points used for georeferencing the spatial data are listed in Table 3.

A subset of these control points was not used in the georeferencing process, instead they served as verification markers to assess the accuracy of the final merged data set. Verification points are used to provide an independent check on alignment errors and is recommended in large scale surveying projects (Salzano et al., 2024). The ground control points utilized for the verification of spatial accuracy are presented in Table 4.

Data processing consisted in converting the raw LiDAR scans into georeferenced point clouds through the manufacturer's proprietary software, which facilitates simultaneous localization and mapping (SLAM) algorithms. Initial denoising operations entailed statistical outlier detection and removal, aimed particularly at mitigating irregularities caused by reflective surfaces, shattered glass and metal debris. These operations aligned with protocols noted in earlier research, where industrial sites frequently produce erroneous reflections in laser-based recordings (Zakaria et al., 2025).

The aerial imagery was processed using Agisoft Metashape 2.0, generating an independent three-dimensional point cloud. The software automatically identified tie points through feature matching followed by a bundle adjustment procedure to optimize camera orientations and intrinsic parameters.

Georeferencing was completed by incorporating the ground control points.

The point cloud was generated using the depth maps computed for each image by stereo-

matching algorithms. The resulting point cloud was then filtered by removing redundant points, outliers and noise. The filtering was done using iterative statistical filtering and confidence-based filtering, as recommended by (Zakaria et al., 2025), to eliminate the noise derived from unstructured debris piles and partial obstructions, therefor consolidating a more homogeneous and trustworthy dataset.

After generating and filtering the LiDAR and photogrammetric point clouds, the datasets were imported into Trimble Business Center for co-registration. Tie points were first manually identified in overlapping areas to ensure rough alignment, followed by refinement using the iterative closest point algorithm, as applied in similar complex survey environments (Abreu et al., 2023).To quantify the quality of the merged data, a series of verification points (Table 4), distinct from the control points used for georeferencing (Table 3), were surveyed on-site using the Total Station and then compared to their corresponding positions in the unified point cloud. Figure 4 illustrates the verification points used to assess the accuracy of the merged dataset.

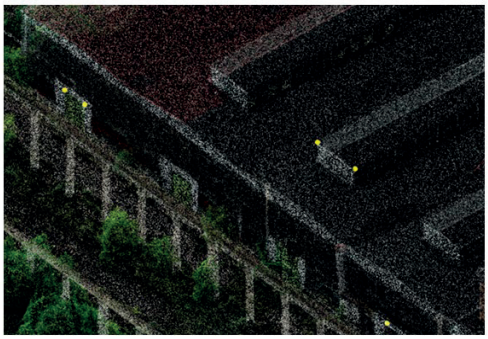

Figure 4. Verification points

The root means square errors and the probable error along the X, Y and Z axes were computed to characterize horizontal and vertical deviations as shown in (Table 5).

Once the point clouds had been successfully fused, they served as the foundation for constructing a three-dimensional model of the industrial complex. In the initial stage of this modeling process, three horizontal cross-sections were extracted from the point cloud at the ground level, as well as the first and second floors (Figure 5). These cross-sections provided the reference data necessary to generate accurate floor plans for each building within the complex. Subsequently, vertical sections were derived along each principal building axis (Figure 6), and the combined use of horizontal and vertical cross-sections enabled precise modeling of all structural elements.

Each modeled component was then classified according to its constituent material (e.g., concrete, metal, wood, or glass).

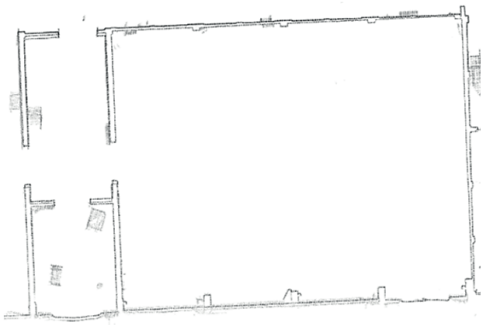

Figure 5. Horizontal section of the point cloud

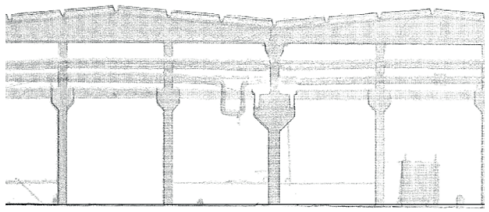

Figure 6. Vertical section of the point cloud

Studies focusing on point cloud–to–CAD workflows in complex industrial environments highlight the recurring challenges posed by irregular geometries, occlusions, and noise (Abreu et al., 2023).

In the Dolj Chim project, structural complexity was addressed through the use of repetitive, prefabricated elements - particularly standardized concrete beams - a strategy aligned with approaches used in projects involving repetitive architectural components (Abreu et al., 2023). The merged point cloud facilitated the extraction and visualization of key structural elements within the industrial complex. As shown in Figure 7, the resulting 3D model accurately represents the spatial and architectural configuration of the site, forming a reliable basis for further spatial analyses, documentation, and integration into planning or monitoring processes.

To assess surface material accumulation, Figure 8 illustrates the debris volume derived from the processed point cloud. This sheet displays the spatial distribution and elevation variation of debris, enabling quantitative evaluation necessary for planning site clearance, estimating transport needs, and assessing environmental impact.

Figure 7. 3D elements of the industrial complex

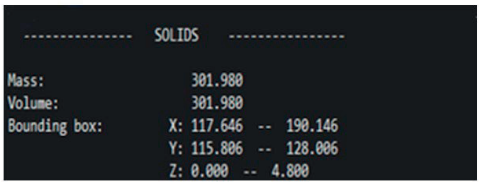

Figure 8. Debris volume sheet

Following the completion of the full 3D model (Figure 10), it was possible to estimate the total volume of debris projected from demolition

activities. Calculations were conducted separately for each material class. The results were compiled into dedicated volume sheets that specify debris quantities by material type, allowing for more accurate planning and resource allocation. The final material-specific volume estimates are presented in Figure 9.

For more complex structural components, such as reinforced concrete, it was necessary to estimate the internal steel content. To this end, standardized material ratios were applied, and the corresponding values used for these calculations are presented in Table 6.

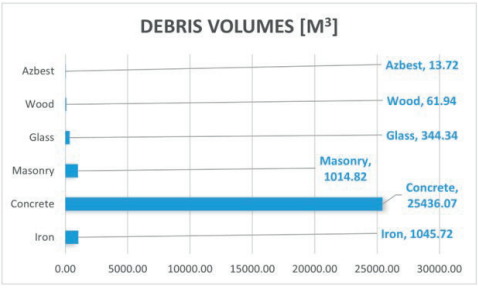

Figure 9. Bar chart representing debris values

Table 6. Amount of iron in complex structures

Element	Iron [kg/m³]
Foundation structure	40
Structural framework	100
Concrete wall structure	80
Floor slab	80
Roof slab	60

The final stage of the workflow involved the preparation of a comprehensive bill of quantities, detailing the demolition costs for each individual structure alongside associated expenses for logistics, environmental remediation, and labor. This cost assessment highlights the critical value of integrating detailed 3D modeling with economic and environmental parameters - an approach that is increasingly acknowledged as best practice in modern industrial demolition planning.

RESULTS AND DISCUSSIONS

The circular economy and the recycling of construction materials are essential strategies for reducing the negative impact on the environment. In this context, accurately determining the value of construction waste resulting from demolition is a critical element for the conservation of natural resources and the development of a more sustainable and economically efficient construction sector (Oliveira, Schreiber & Jahno, 2024).

The final integrated point cloud provided a comprehensive depiction of the Dolj Chim industrial complex, encompassing both interior and exterior elements in a single, unified coordinate system. The RMSE and probable error values underscored the high fidelity of the merged dataset and align with benchmarks reported in comparable industrial scanning endeavours (Gibson & Alderson, 2019; Zhan et al., 2020).

The final dataset achieved high georeferencing accuracy, with a mean square error (MSE) of ±0.048 meters in the X-axis, ±0.039 meters in the Y-axis, and ±0.039 meters in the Z-axis. The probable error values were ±0.032 meters in the X-axis, ±0.026 meters in the Y-axis, and ±0.026 meters in the Z-axis (Table 5). These values indicate a high level of precision, ensuring that the resulting point cloud was reliable for demolition volume estimation.

Notably, the LiDAR system achieved superior results in capturing enclosed spaces devoid of strong ambient illumination, whereas the UAS-derived photogrammetry excelled in mapping extensive exterior surfaces and rooftops. These findings reaffirm established conclusions from parallel studies, which highlight the complementary nature of LiDAR and photogrammetry in scenarios that demand both detailed internal scans and large-scale external mapping (Zakaria et al., 2025; Son et al., 2020).

The differences between the LiDAR and UAS-based point clouds were evident due to the nature of the data collection methods. The UAS-generated point cloud, being a product of photogrammetric processing, exhibited a more uniform structure resembling a "sheet" draped over the buildings. In contrast, the LiDAR-derived dataset was denser and contained more irregularities, capturing finer details of the structures. Although these datasets did not align perfectly due to their inherent differences, the integration of control points allowed for an acceptable level of matching that met project requirements.

The efficiency gains achieved through this integrated approach were significant. The entire data collection phase was completed within

three days, a fraction of the time required for traditional methods, which could have taken weeks. Traditional surveying would have been especially challenging in this case due to the lack of sufficient lighting inside the buildings, making it nearly impossible to obtain detailed measurements without advanced scanning technology. Additionally, the availability of drone imagery and LiDAR data significantly reduced human error, as surveyors had comprehensive datasets to reference instead of relying solely on manually collected points and field notes.

In conjunction with precise 3D reconstruction, attention was directed toward the potential integration of Building Information Modeling (BIM) in demolition planning. Although BIM has historically been employed for new construction, its application in demolition contexts (Salzano et al., 2024) has grown in recent years owing to increased awareness of sustainability and resource management issues (Nikmehr et al., 2021). The detailed as-built data generated in this study can serve as a basis for a retrospective BIM, thus offering significant advantages in managing the dismantling of complex industrial structures. Empirical studies suggest that a robust BIM framework can reduce construction and demolition waste by optimizing the quantity and reusability of extracted materials (Nikmehr et al., 2021). While the Dolj Chim complex predates widespread BIM adoption, the dataset assembled here can streamline sustainable demolition procedures by enabling precise volume calculations, safety assessments, and resource allocation (Sestras et al., 2025).

Furthermore, a comparative analysis of the Dolj Chim survey with similar multi-sensor projects revealed numerous shared benefits and recurring obstacles. One frequently encountered challenge in industrial environments is the presence of heavy clutter or debris, which can generate considerable levels of noise in raw point clouds (Zakaria et al., 2025). The Dolj Chim dataset exemplified this issue but benefited from repeated structural designs and standard prefabricated elements, thereby alleviating some of the modeling difficulties. This finding is consistent with research indicating that templated modeling and semi-automated segmentation can reduce the manual labor required for point cloud processing in repetitive architectural environments (Abreu et al., 2023; Gibson & Alderson, 2019). Nonetheless, further work is required to optimize these processing pipelines, especially when such workflows must contend with expansive, congested, or partially collapsed structures.

One of the key improvements noted from this project was the realization that excessive data collection could be a challenge. In this case, the slow pace of LiDAR scanning resulted in a very large dataset, which increased processing time. To optimize future projects, a higher walking speed was adopted in subsequent surveys, reducing unnecessary data density while maintaining accuracy. Additionally, future projects included a greater number of control points inside buildings where conditions allowed, further improving georeferencing quality.

Overall, this study demonstrated that integrating LiDAR and UAS-based photogrammetry provides a robust and efficient method for industrial demolition planning. The approach is adaptable to various environments, though urban applications may require special permissions for UAS flights.

CONCLUSIONS

The integrated LiDAR and photogrammetric methodology employed in this study proved highly effective for generating an accurate and comprehensive 3D model of the Dolj Chim industrial complex (Figure 10).

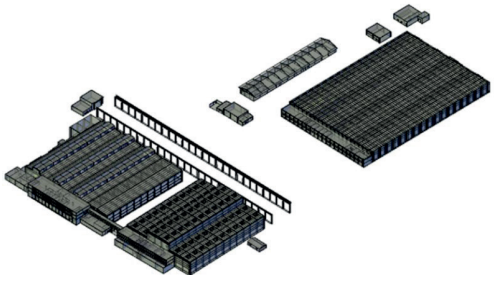

Figure 10. 3D model of Dolj Chim industrial complex

By leveraging the respective strengths of high-density interior scanning and wide-area exterior imaging, this approach yielded precise data for volume estimation, despite the presence of degraded, cluttered, and poorly illuminated

structures. The resultant root means square errors aligned well with benchmarks reported in comparable industrial surveys, thereby confirming that a multi-sensor data fusion framework is vital in contexts demanding a thorough understanding of both internal and external site conditions (Son et al., 2020).

In addition, this study reinforces the growing importance of integrating as-built 3D data into BIM-driven workflows. Although the Dolj Chim facility was not originally modeled in BIM, the accurate digital data obtained here can facilitate subsequent retrospective modeling, an approach that promises to improve demolition planning and waste management (Nikmehr et al. 2021). Future efforts should examine ways to refine data processing routines, particularly with respect to advanced feature recognition and template-based modeling, as these techniques could further accelerate the extraction of 2D and 3D deliverables (Abreu et al. 2023). Enhanced scanning speeds, improved dynamic SLAM capabilities, and expanded use of indoor GCPs stand as promising directions for achieving still greater accuracy and operational efficiency.

The methodological insights gained through this project appear highly transferable to similar industrial or urban settings, with the principal constraint being regulatory limitations on drone operation and on-site safety considerations. Consequently, this study contributes practical and theoretical knowledge that can inform subsequent surveys and research. By bridging multiple data sources and adopting rigorous registration processes, scholars and practitioners alike can develop robust, data-rich models that foster safer, more sustainable, and more cost-effective demolition projects.

ACKNOWLEDGEMENTS

This research work was carried out and financed with the support of GAUSS S.R.L. The authors wish to acknowledge the invaluable assistance of the site management team and all colleagues who contributed to the data collection and processing stages.

Abstract

This study represents an assessment of the spatio-temporal dynamics of anthropic pressure in the Olteț Piedmont (a subdivision of the Getic Piedmont), located in the southern part of Romania. With the help of ArcGIS 10.5 software, we managed to process the statistical data provided by Dolj, Olt, Gorj and Vâlcea County Statistics Offices (for 2004 and 2014) by creating a vector database and calculating the following environmental indicators: population density, human pressure through arable land use (0.68 ha/inh. - 2014), landscape naturality (0.29 ha/ha - 2014), environmental change (12.91 ha/ha - 2014) and landscape artificialization (0.053 ha/ha - 2014). By comparing the results, for the two reference years (2004 and 2014), we managed to identify some areas were the anthropogenic impact on the environment of the Olteț Piedmont is significantly. Thus, the southern part of the piedmont is the most affected especially by the expansion of rural areas around the major urban areas (such as Craiova, Filiaşi, Balş, Piatra-Olt, and Drăgăşani cities); built-up area increased from 17,110 hectares to 17,248 hectares. The central and northern part of the piedmont, widely forested, is very little affected by the impact of human activities.

Key words*: human pressure; environmental change; naturality index; Olteț Piedmont, Romania.*

INTRODUCTION

In Romania, the excessive fragmentation of croplands remains prevalent even in areas with high agricultural potential. This persistence is the result of a combination of factors related to both land governance and farm-level characteristics (Dogaru et al., 2024).
Land cover and land use changes play a critical role in the sustainable development of local communities, as well as in shaping natural systems (Hooke et al., 2012; Marin et al., 2023). The expansion of cropland has been one of the primary drivers behind the widespread transformation of natural landscapes into anthropogenic ones. The intensification of anthropogenic impact, beginning in the late 19th and early 20th centuries, led to a significant imbalance in the natural environment. This was largely due to extensive deforestation aimed at converting land for agricultural purposes - such as crop cultivation, orchards, vineyards, pastures, and hayfields - as well as for the expansion of rural and urban settlements (Bălteanu et al., 2011)
Human activities have significantly influenced the environment and landscape, contributing to increased land vulnerability and ecological imbalances (Mi et al., 2016). Vegetation, as both an indicator and regulator of human impact, plays a crucial role in modulating carbon, water, and energy cycles (Huryna et al., 2014). It also influences climate by sequestering greenhouse gases and affecting the distribution of solar energy (Huryna & Pokorný, 2016). However, vegetation is increasingly sensitive to climate change, largely due to ongoing anthropogenic pressures.
Following the fall of the communist regime in Romania in December 1989, the country experienced profound transformations across all sectors, particularly in agriculture. One of the major consequences of Law no. 18/1991

was the excessive fragmentation of agricultural land and the shift in ownership from the state to private individuals. This led to the emergence of small-scale subsistence farms characterized by inadequate agricultural practices, including poor fertilization, unregulated use of fertilizers and pesticides, and limited mechanization. As a result, the land use system became more vulnerable to extreme environmental disturbances - marked by notable land use/land cover changes - and less resilient to both climatic and anthropogenic pressures (Grigorescu et al., 2012).

MATERIALS AND METHODS

The use of GIS software has proven its usefulness and functionality in various studies, with diverse themes such as: assessing green urban infrastructure (Wu et al., 2025), road infrastructure assessment and traffic dynamics (Freulda et al., 2025), risk assessment in the transportation of dangerous goods (Tomasoni et al., 2025), enhancing spatial interpretability of fluoride in groundwater (Singh et al., 2025), illegal abandoned waste sites (Ragazzo et al, 2025) and also the assessement of human pressure on the environment (Filimon et al., 2024; Fan et al., 2017; Sencovici & Pehoiu, 2016; Ekim et al., 2021; Mammides, 2020).

Study area

The Olteț Piedmont, a subdivision of the Getic Piedmont (Figure 1), with a surface of approximately 3771 km^2, whose altitudes decrease from north to south, from the contact with the Getic Subcarpathians towards the contact with the Oltenia Plain.

It's an intensely populated area (93 administrative-territorial units from four counties - Gorj, Vâlcea, Dolj and Olt, overlap over the piedmont) with an attractive natural and economic potential, that led to a steady population growth and expansion of the settlement network (Bălteanu et al., 2003). Human activities have a major impact on the environment, due to land cover/use changes, which amplify the degradation of the land through geomorphological processes (gullying, rilling, sheet wash, surface erosion and sometimes landslides). Activities like deforestation, excess grazing, plowing along the slope line etc. are an important factor in the development of gullying (Popovici et al., 2010).

Beside land cover and land use changes, among the activities with negative impact on the biodiversity (conservation status of protected habitats and species of plants and animals) are: the construction of mineral aggregate sorting stations, extraction of gravel, sand, clay, kaolin, uncontrolled expansion of accommodation units (hotels, guesthouses), the removal from the forest fund of some terrains intended for construction, expansion of mineral aggregate mining quarries, the expansion of the urban areas.

In this study, we aim to evaluate the spatio-temporal dynamics of human pressure in the Olteț Piedmont - a subdivision of the Getic Piedmont - located in the southern Romania. Using GIS techniques, we processed the statistical data provided by the County Statistics Offices of Dolj Olt, Gorj and Vâlcea for the years 2004 and 2014.

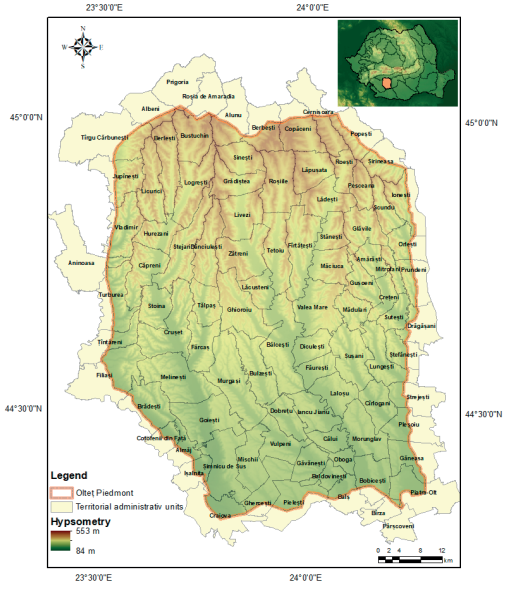

Figure 1. Study area - Olteț Piedmont (Romania)

The evaluation was conducted using a set of environmental indicators, including population density, human pressure through arable land, the landscape naturality index, the environmental change indicator and the landscape artificialization indicator.

With the help of ArcToolbox feature Extract, we managed to identify and draw out all the 93

administrative-territorial units that overlap our study area. In the newly created layer, we added multiple fields and inserted the statistical data collected from the four County Statistics Offices for 2004 and 2014. In addition, in the Attribute Table of this layer we used the Field Calculator function to insert the equation for each environmental indicator and calculate the values for each parameter for every administrative-territorial unit. The results were displayed in cartographic materials, for a better a better view of the areas that are most vulnerable to human activities.

For our study we chose the datas from 2004 and 2014. Prior to 2004, some of the settlements that overlap the study area were part of different administrative territorial units (ATU). In that year, the Law No. 84/2004 led to the administrative reorganization of several communes throughout Romania and the emergence of new administrative territorial units, whose limits have not changed until now. In 2014, The National Cadastre and Real Estate Advertising Agency started.

The national cadastre and land register program in order to intabulate all the terrains from Romania, and because of that, until the ending of this program no newer data available regarding land cover/use at administrative territorial unit level. Therefore, because of these two restrictions we couldn't expand our study and focused only on the 2004-2014 period.

In order to give an overview of the impact of human activities on the environment in the Olteț Piedmont, for each of the two statistical years we calculated human pressure on the environment indicators like:

- *population density* (P_d = *No. inhabitants/ Total area);*
- *indicator of human pressure through arable use of land* (P_a = Arable area/No. inh.);
- *naturality index* (N_i = *Forest area/Total area);*
- *environmental change index* (E_{ch} = Forest+pasture+hayfield area/Built-up area);
- *landscape arficialization index* (Ai = Built-up+industry+communication roads/Total area).

Several Romanian researchers have published studies (Bălteanu et al., 2010; Pătroescu et al., 2010; Ionuș et al., 2011; Zarea et al., 2012; Popovici, 2010; Petrișor & Petrișor, 2021) in which they successfully employed human pressure indicators to assess the impact of anthropogenic activities on the environment across various regions of Romania. These regions include the Getic Piedmont, the Romanian Plain, the Oltenia Plain or the Bâsca Chiojdului River basin.

Whether applied to smaller or larger territorial units, these studies have demonstrated the effectiveness of such indicators in improving our understanding of the ways in which human activities influence the natural environment.

RESULTS AND DISCUSSIONS

Population density

Population density is the first indicator that was determined and represents the number of inhabitants that live in an area of 1 ha (Figure 2).

The total number of inhabitants living in the 93 administrative territorial units is 618113 persons (2014), with the highest number of 308114 inhabitants in Craiova Municipality and the lowest number of 940 inhabitants in Mitrofani commune.

The average population density of the study area is 1.08 inhabitants/hectar, the lowest value is 0.21 inh./ha in Ghioroiu commune and the highest value is 37.85 inh./ha in Craiova Municipality.

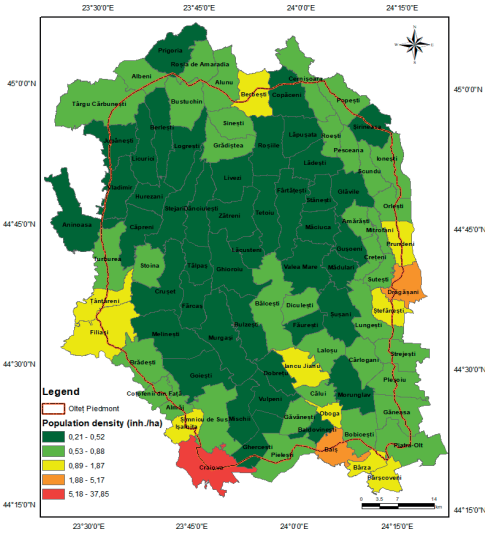

Figure 2. Population density in the Olteț Piedmont (2014)

Higher values are registered in towns like Balș (5.17 inh./ha), Drăgășani (4.43 inh./ha), Filiași (1.87 inh./ha) and Berbești (1.04 inh./ha).

The lowest values of the population density are registered in communes: Ghioroiu (0.21 inh./ha), Bulzești (0.23 inh./ha) and Murgași (0.25 inh./ha).

Human pressure through arable use of the land

This indicator represents the intensity of anthropic activities on the environment through arable use of the land. The main use of the lands in the study area is agricultural use. The total arable surface in the study area in 2004 is 180306 ha and 178447 ha in 2014.

In 2004 the mean value of this indicator was 0.66 ha/inh., with the highest values recorded in the communes of Ghercești (2.52 ha/inh.), Mischii (2.21 ha/inh.), Bulzești (1.72 ha/inh.), Baldovinești (1.68 ha/inh.), Dobrețu (1.68 ha/inh.) and the lowest values in Craiova (0.01 ha/inh.), Drăgășani (0.11 ha/inh.), Balș (0.12 ha/inh.), Berbești (0.22 ha/inh.) towns (Figure 3).

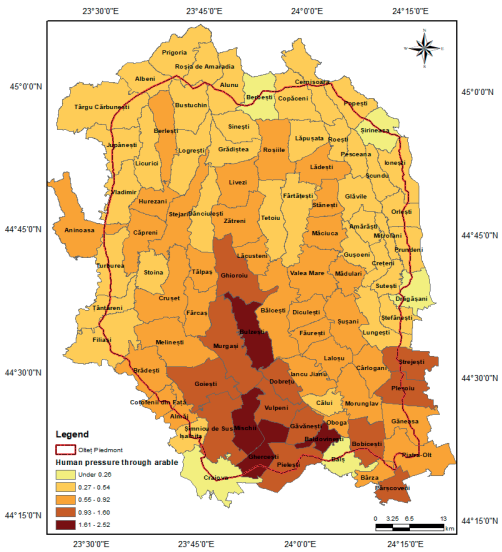

Figure 3. Human pressure through arable use of the land (2004)

The biggest changes of the values for this indicator (from 2004 to 2014) were recored in the administrative territorial units of Orlești (from 0.35 to 0.40), Fârtățești (from 0.46 to 0.50), Lungești (from 0.49 to 0.53), Tetoiu (from 0.52 to 0.56), Vladimir (from 0.51 to 0.57), Glăvile (from 0.53 to 0.60), Dănciulești (from 0.54 to 0.66), Stănești (from 0.55 to 0.66), Stejari (from 0.60 to 0.71), Morunglav (from 0.64 to 0.78), Lăcusteni (from 0.57 to 0.83), Vulpeni (from 1.13 to 1.44), Bulzești (from 1.72 to 1.92).

In 2014 the mean value was 0.68 ha/inh. A decrease of the values of this indicator can be seen in Baldovinești, Oboga, Pârșcoveni and an increase of the values in Găneasa, Vladimir, Dănciulești, Tetoiu and Găvile (Figure 4).

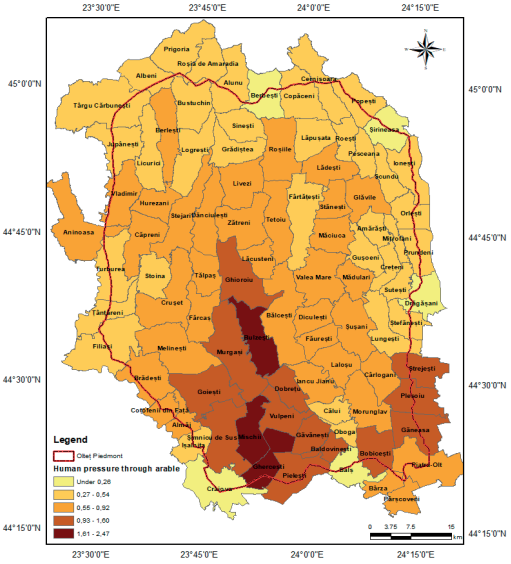

Figure 4. Human pressure through arable use of the land (2014)

Landscape naturality indicator

The landscape naturality indicator represents the ratio between the forest area and the total area (thus determining the degree of afforestation), being calculated at the level of administrative-territorial unit.

The total surface of the forests increased from 147186 ha in 2004 to 147361 ha in 2014. The mean value of this indicator, for both reference years was 0.29 ha/ha.

Because the values didn't change very much, in both years, the highest value was recorded in Jupânești (0.62 ha/ha), Șirineasa (0.61 ha/ha), Morunglav (0.59 ha/ha), Călui (0.58 ha/ha) and the lowest values in Drăgășani (0.01 ha/ha), Mischii (0.02 ha/ha), Ghercești (0.02 ha/ha), Pielești (0.02 ha/ha).

Some changes of the values for this indicator were recorded in Vulpeni (from 0.15 to 0.2), Găneasa (from 0.18 to 0.16), Diculești (from 0.30 to 0.28), Sinești (from 0.43 to 0.38).

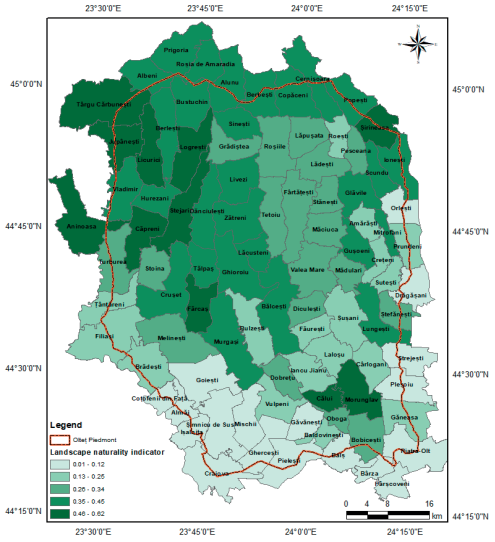

Figure 5. Landscape naturality indicator (2004)

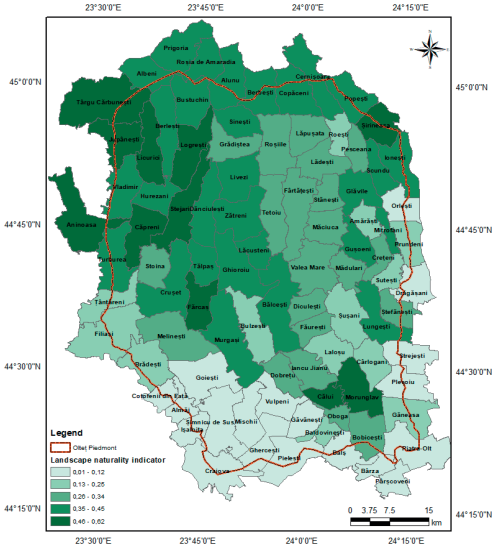

Figure 6. Landscape naturality indicator (2014)

The territorial administrative units with values of the landscape naturality indicator unde 0.10 are considered to have a landscape with very strong affected ecological balance, and those with the values of the indicator between 0.45-0.60 to have a landscape with relatively stable ecological balance (Figure 5, Figure 6).

Environmental change indicator

The environmental change indicator was calculated as the ratio between the natural and the anthropic surfaces.

In 2004 the mean value of this indicator was 12.83 ha/ha with the highest values recored in Ghioroiu (35.49 ha/ha), Copăceni (33.59 ha/ha), Berlești (27.32 ha/ha), Aninoasa (25.15 ha/ha) and the lowest values in Craiova (0.34 ha/ha), Işalnița (0.93 ha/ha), Drăgășani (1.13 ha/ha) and Pleșoiu (1.69 ha/ha) (Figure 7).

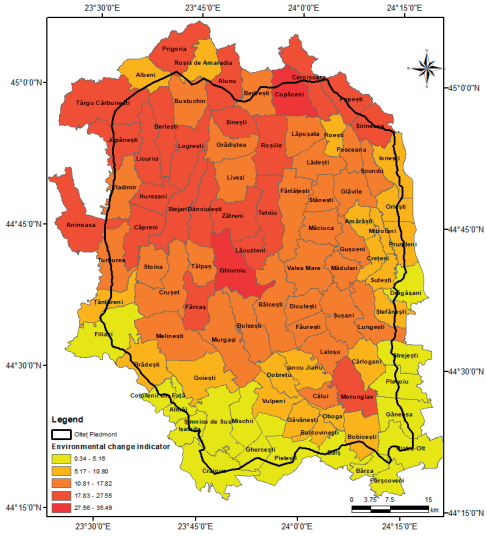

Figure 7. Environmental change indicator (2004)

In 2014 the mean value was 12.91 ha/ha with the highest values in Ghioroiu (36.41 ha/ha), Copăceni (33.59 ha/ha), Berlești (27.55 ha/ha), Aninoasa (25.15 ha/ha) and the lowest values in Craiova (0.34 ha/ha), Işalnița (0.93 ha/ha), Drăgășani (1.13 ha/ha) and Pleșoiu (1.45 ha/ha) (Figure 8).

Important changes of the values of this indicator were recorded in Almăj (from 3.67 to 2.67), Vulpeni (from 6.48 to 4.64), Bobicești (from 7.38 to 5.16), Lăcusteni (from 22.72 to 17.82) and Sinești (from 20.53 to 19.01).

The territorial administrative units with a high value of the environmental change indicator are located mainly in the northern and north-

western part of the Olteț Piedmont and have the least affected landscape.

In the eastern, southern and south-western part of the piedmont, the territorial administrative units have a lower value of this indicator; they are located near big cities like Craiova, Filiași, Balș, Piatra-Olt, Drăgășani and therefore subjected to the influence of the development of these urban areas.

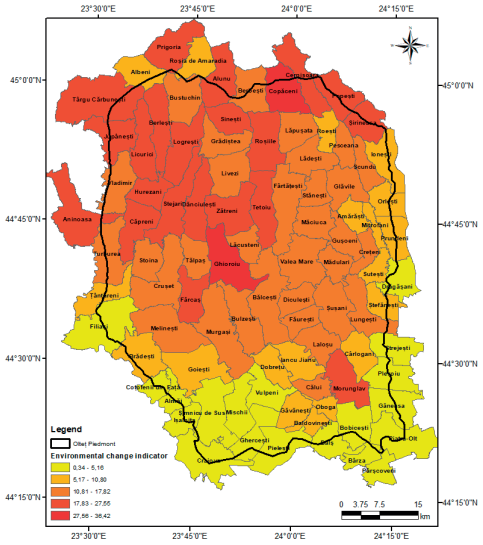

Figure 8. Environmental change indicator (2014)

Landscape artificialization indicator

The landscape artificialization indicator represents the ratio between the built-up areas and the total area of the administrative-territorial unit and is often used to complete the landscape naturality indicator.

The mean value of the landscape artificialization indicator in 2004 was 0.052 ha/ha with the highest values recorded in Craiova (0.47 ha/ha), Işanița (0.17 ha/ha), Drăgășani (0.15 ha/ha), Balș (0.12 ha/ha) and the lowest values in Ghioroiu (0.02 ha/ha), Copăceni (0.02 ha/ha), Pârșcoveni (0.03 ha/ha), Morunglav (0.03 ha/ha).

In 2014 the mean value of the indicator increased to 0.053 ha/ha with the highest values in Craiova (0.48 ha/ha), Işalnița (0.17 ha/ha), Drăgășani (0.15 ha/ha), Balș (0.13 ha/ha) and the lowest values in Ghioroiu (0.02 ha/ha), Copăceni (0.02 ha/ha), Morunglav (0.03 ha/ha), Berlești (0.03 ha/ha).

Small changes in the values of this indicator were recorded in Pârșcoveni (from 0.3 to 0.4), Turburea (from 0.4 to 0.5), Bobicești (from 0.4 to 0.6), Balș (from 0.12 to 0.13).

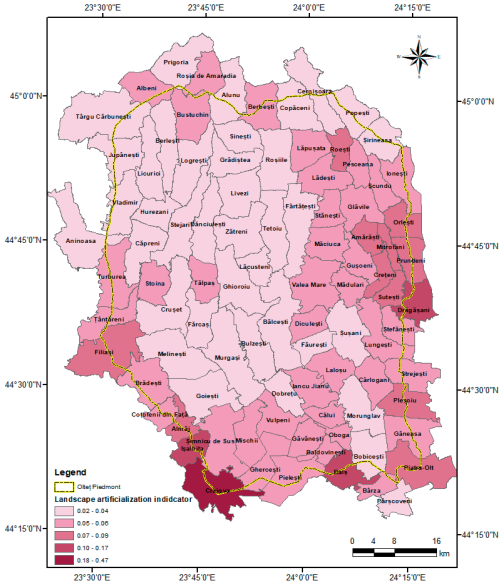

Figure 9. Landscape artificialization indicator (2004

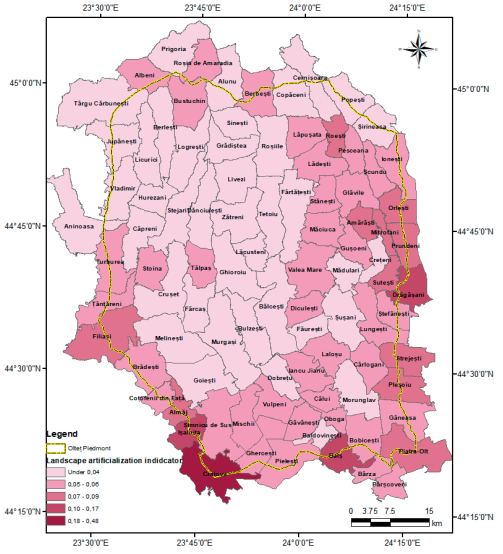

Figure 10. Landscape artificialization indicator (2014)

An analysis of Figures 9 and 10 reveals that the areas with the highest degree of landscape artificialization are located in the eastern, southern, and southwestern parts of the Olteț

Piedmont. This pattern is primarily influenced by the expansion of urban centers such as Craiova, Filiași, Balș, Piatra-Olt, and Drăgășani.

Between 2004 and 2014, the built-up area increased from 17,110 hectares to 17,248 hectares, while the area occupied by road infrastructure expanded from 8,701 hectares in 2004 to 8,904 hectares in 2014. This growth is largely attributable to residents of these cities seeking to escape urban congestion by relocating to nearby rural communes, where they constructed vacation or secondary residences.

CONCLUSIONS

In order to assess the impact of human activities on the environment, as well as to follow the evolution over time of the phenomenon of environmental degradation, there is a need to use a global assessment method of the state of health or environmental pollution at a given moment.

Anthropic activities exert pressure on the environment, which differs from one type of space to another and from one society to another.

Our study highlights the predominance of agicultural activities in the southern part of the Olteț Piedmont and built-up areas around urban areas, like Craiova, Balș, Piatra-Olt and Filiași cities, to be the main anthropic activities that exert a pressure on the enivronment. The constant expansion of these cities and of their periuban areas (many people have built a second home in the communes near the urban communities) define how the landscape is transformed every day.

Because we only managed to assess the changes between 2004 and 2014, we consider that a future study (when newer data will be available, having as a target the year 2024) is needed to determine a trend of the impact of human activities on the environment of the Olteț Piedmont. Also, new research regarding the land use/land cover changes in the study area, for a period of 20 years, is needed in order to have a better understanding of how human activities have transformed and will impact on the environment.

Abstract

The case study was carried out with the help of satellite technologies for the spatial positioning of the various characteristic points of detail in the town of Suiug, Bihor county, and has as its objective the spatial positioning of the points of detail with the GPS system, through the post-processing kinematic method (pseudokinematics) Stop and Go, for the realization of the topographic plans in digital format, and respectively, of the digital models of the land, necessary for the rehabilitation and expansion of the roads in the locality. Trimble R3 receivers were used as base, and Trimble R4 as rover. When recording data from the field, we worked with the Trimble Digital Fieldbook and Trimble Access programs, and the processing with the Trimble Total Control (TTC) program. The coordinates of the base and initialization points of the rover were determined with the Trimble R4 receiver, with information acquired from the Oradea GNSS station, within the ROMPOS system. Mapsys 10.0 and Surfer programs were used to obtain the plan and land model in digital format.

Key words*: characteristic points of detail, Stop and go method, digital terrain model.*

INTRODUCTION

Modern Global Navigation Satellite System (GNSS) technologies provide highly accurate spatial positioning for topographic features, with the selection of a specific method being influenced by both logistical considerations and terrain conditions (Crainic, 2024). GNSS-based satellite positioning systems enable the automation and efficiency of data acquisition across diverse geographic areas, ensuring precise planimetric coordinates vital for applications such as cartography, navigation, transport infrastructure, and emergency response services (Mohanty & Gao, 2024; Kunisada & Premachandra, 2022).

In standard Stop & Go workflows, a static receiver is installed at a known geodetic control point, while a mobile receiver initiates the positioning process, which is influenced by both the equipment's technical capabilities and the field environment. The initialization consists of resolving the ambiguities linked to the carrier phase measurements, which involves determining the integer number of wavelengths of the received signal (Adam et al., 2006).

Technological advances have made it possible to perform this process "on-the-fly" (OTF), allowing real-time initialization while moving, thereby eliminating downtime. Once initialized, the mobile receiver (rover) sequentially occupies each target point, maintaining uninterrupted contact with satellites throughout movement. As a result, the rover must follow clear-signal paths within the work area to avoid satellite signal loss, which would otherwise require reinitialization (Adam et al., 2004; Hofmann-Wellenhof et al., 1997).

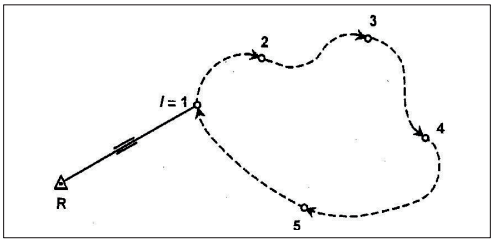

Figure 1. Stop & Go measurement scheme (from Adam et al., 2004)

For short distances between points along the predefined route, the operator typically moves on foot, carrying the mobile receiver mounted on a fixed-length support known as a bipod. This setup allows for quick stationing with high accuracy and operational efficiency. When the

target points are situated farther apart or at significant distances from the base station, the rover can be transported by vehicle, if satellite signal continuity is maintained and the connection to at least five satellites is ensured. This condition also applies to pedestrian movement over open terrain. Although not mandatory for on-the-fly (OTF) initialization, maintaining such signal stability can significantly reduce the required data acquisition time and help avoid signal disturbances (Hofmann-Wellenhof et al., 1997).
At the base station - positioned at a known reference coordinate - the fixed receiver and antenna are mounted on a tripod via a dedicated base featuring an optical centering mechanism. The mobile receiver and its antenna are secured on the bipod, approximately 2 meters in height, equipped with a spherical leveling device to ensure precise vertical and horizontal alignment. Because the antenna height remains constant throughout the process, it only needs to be entered once in the measurement project.
Initial setup involves placing the fixed receiver on the tripod and the bipod-mounted rover at the initial known point, followed by configuring the working parameters in the control unit (U.C.), which interfaces directly with both the receiver and the antenna. If satellite signal is lost, the operator must either return to a previously recorded point (if the system allows reinitialization from that location) or repeat the initialization process entirely (Adam et al., 2004).
As the rover moves from point to point, data collection is optimized by briefly pausing (typically 1-2 minutes) at each new station to ensure accurate data recording, depending on the length of the data collection epochs (Păunescu et al., 2006; Neuner, 2000). Consequently, only those positions where the mobile receiver was properly stationed and data were actively recorded are retained in the final dataset (Adam et al., 2004).
For enhanced efficiency in Post-Processed Kinematic (PPK) surveying, a single fixed receiver may be used to simultaneously support multiple mobile rovers, provided that the appropriate logistics are available.
In single-base PPK configurations, each newly determined point relies on a single position vector. When using two fixed receivers as reference bases, positioning is achieved using two independent vectors for increased redundancy and accuracy (Adam et al., 2004). Optimal conditions for implementing PPK satellite positioning depend on several factors, including:

- the availability of geodetic or GNSS network points within the survey area, with at least two single-frequency GNSS receivers (Zuliani, 2022);
- or one dual-frequency and one single-frequency receiver, along with access to data from a permanent GNSS station.

Under these conditions, several working approaches can be adopted:

- positioning known reference points along the survey route;
- returning to the initialization point to close a measurement loop;
- finalizing at another known point;
- or static positioning at the last station with subsequent post-processing.

Alternatively, when starting from the final surveyed point, software equipped with advanced algorithms can compute the positions of intermediate points where satellite signals were captured (Basso et al., 2021). This flexibility ensures that brief signal interruptions do not invalidate all previous recordings, if the processing model accounts for such gaps.
The method is particularly effective for detailed positioning tasks within a 5-6 km radius from the base station. On smaller areas, it offers a cost-efficient alternative. Recent studies highlight that for short GNSS baselines, PPK performance surpasses that of RTK, although over longer distances, a slight reduction in accuracy is noted. To meet accuracy standards, recording durations should exceed one hour, and the baseline distance must fall within the manufacturer's recommended range (Jemai et al., 2023).
PPK offers several advantages:

- data recording is faster since a continuous base-rover link is not needed, allowing for extended operational distances;
- fewer base stations are required compared to total station surveys;
- it provides high positional accuracy;
- and it can operate with minimal equipment - sometimes even a single dual-frequency receiver - if access to permanent

GNSS stations is available within 30-50 km (Zavate, 2008; Adam et al., 2004).

Despite the requirement of maintaining visibility to at least five satellites between consecutive points (Adam et al., 2004), the horizontal accuracy typically ranges from 1-3 cm, and vertical accuracy between 1-10 cm (Pirti, 2021). The method has proven efficient and reliable in cadastral surveys within both urban and rural contexts (Tang et al., 2017; Sicoe et al., 2023), as well as in environmental assessments and real-time or post-processed GNSS applications (Bodog et al., 2024; Jaskowski et al., 2022).

Moreover, research demonstrates that PPK solutions anchored by high-precision ground control points yield more accurate results than those derived from low-precision observations, particularly in drone-based photogrammetric workflows. Thus, the number, spatial arrangement of control points, and baseline length to the GNSS station are critical factors for achieving optimal results (Tamimi & Toth, 2023).

In the civil engineering sector (Costinaș et al., 2024), the success of infrastructure projects relies heavily on accurate site plans derived from GNSS data, alongside effective logistical planning (Costinaș et al., 2024; Sabău, 2010; Coşarcă, 2003). For the planning and construction of roads in rural or urban settings and for improving forest accessibility, detailed coordinate inventories and cartographic materials - both analog and digital - are indispensable (Călina & Călina, 2022; Călina et al., 2020; Coşarcă, 2003). The geometric layout of transportation routes must follow the terrain configuration and the precise spatial coordinates of topographic elements to accurately reflect the real-world situation (Belc, 1999).

Thus, field surveys must capture the transverse and longitudinal profile elements in the national reference system to support the development of execution projects.

MATERIALS AND METHODS

The case study was carried out in the village of Șuiug, part of Abram Commune, Bihor County, Romania (Figure 2). The main goal of the research was to evaluate the applicability and efficiency of GNSS technology - specifically the Stop & Go method using Post-Processed Kinematic (PPK) positioning - for determining the spatial coordinates of topographic detail necessary in the planning and rehabilitation of rural transport infrastructure.

The Stop & Go technique is particularly suitable when rapid, yet highly accurate point positioning is required, with minimal time spent at each location. This method relies on post-processing of satellite data, hence the term Post-Processed Kinematic (PPK) (Chiţea et al., 2009; Neuner, 2000).

Accurate positioning is ensured by employing at least two GNSS receivers: one serves as the fixed base station, while the other(s), referred to as rovers, operate as mobile units to measure the detail points.

Methodological Approach

The study employed a combination of the following research methods:

- *Bibliographic review:* analysis of specialized literature, standards, and previously completed contracts involving similar GNSS-based topographic work.
- *Field observation*: including route inspection and on-site evaluation of positioning conditions.
- *Experimental work:* application of GNSS positioning methods under real terrain conditions.
- *Comparison and analysis:* assessment of technical performance and outcome reliability.

Figure 2 presents the geographical location of the study area.

GNSS equipment and data collection

The experiment involved the spatial positioning of detailed topographic points using GNSS technology and the Post-Processed Kinematic (PPK) method, conducted along three separate routes, tailored to field conditions. To carry out the measurements, two Trimble R3 GNSS receivers paired with A3 antennas and one Trimble R4 dual-frequency receiver were employed. One Trimble R3 unit, equipped with an A3 antenna, was mounted on a tripod to serve as a base station, while the second R3 receiver, installed on a 2.04-meter bipod, was used as a rover for positioning characteristic detail points along the routes.

Figure 2. Location of the case study: Şuiug village, Abram commune, Bihor County (https://ro.wikipedia.org/wiki/Suiug,_Bihor)

In addition, satellite recordings from the permanent GNSS station in Oradea were accessed via the ROMPOS service to enhance positioning accuracy through the RTK method. The Trimble R4 receiver, also mounted on a 2.00-meter bipod, was used as a rover for data acquisition on Routes 1 and 2.

Field data were collected using Trimble Digital Fieldbook (for the R3 receiver) and Trimble Access (for the R4 receiver), both licensed programs provided with the equipment. A critical step during the fieldwork involved defining specific layers for recording each positioned point and assigning corresponding attribute codes. These codes were applied during stationing with the rover and are essential for the organized import of final coordinates into mapping software. This structured approach ensures efficient graphical representation and accurate generation of digital plans.

Data processing and graphical reporting

The graphic representation of the final coordinates of the characteristic detail points, referenced to the national coordinate systems STEREO-1970 and MN-1975, as well as the generation of the detailed digital plan, was performed using the Mapsys 10.0 software (Marton, 2007). The experiment followed a structured sequence of steps, including field data collection, data transfer, validation and processing, computation of ellipsoidal coordinates, transformation into the national reference system, and the preparation of the final coordinate inventory. These stages, along with the graphical reporting process and detailed plan generation, are summarized in the schematic diagram shown in Figure 3.

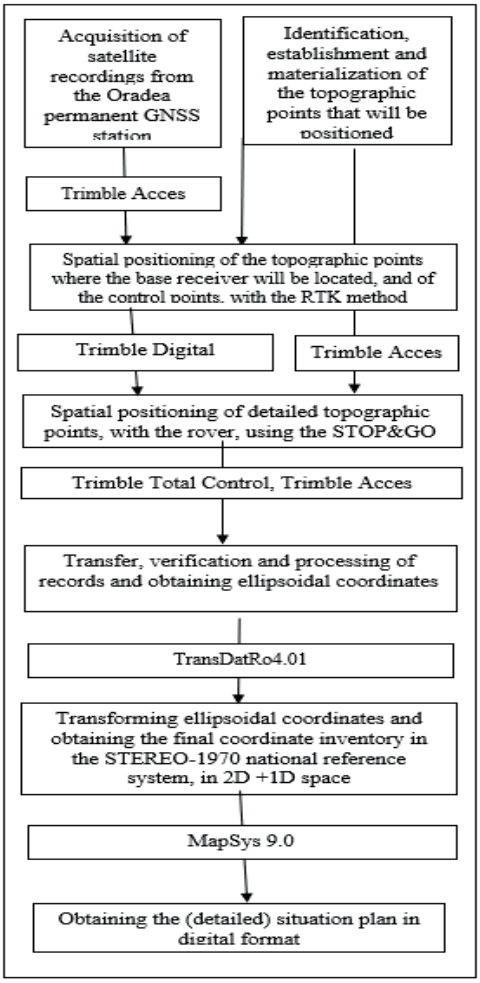

Figure 3. Summary presentation of the stages of carrying out the case study

The case study was further evaluated by comparing the technical implementation and

results with similar projects conducted under both comparable and varying field conditions. Based on this comparative analysis, several insightful conclusions were drawn.

RESULTS AND DISCUSSIONS

The processing of satellite recordings was performed using specialized computational models (Borko & Even-Tzur, 2021; Amiri-Simkooei et al., 2016). The data were processed differently depending on the type of receiver used. Specifically, the Trimble Access software was employed to process data recorded with the Trimble R4 receiver, as well as data obtained from the permanent GNSS station in Oradea using the RTK method, in order to determine the coordinates of the base and control points along the three routes. Additionally, Trimble Access was used to process recordings collected via the PPK method with the same receiver type.

Data recorded with Trimble R3 receivers were processed using Trimble Total Control (TTC) software. The ellipsoidal coordinates obtained from both programs were then converted into the national reference system using the TransDatRo4.01 software (Păunescu et al., 2010).

After completing these work stages, the final coordinates were inventoried by activating the corresponding layers within the mapping software.

The analysis of the plan with the reported details can be done in digital format, or after printing in analog format. In digital format, the details that need to be materialized on the plan will be activating all the layers that contain attributes, depending on the corresponding codes.

The graphical reporting of the measured detail points was conducted using orthophoto imagery for visual verification and planimetry purposes. The spatial distribution and positioning accuracy of the detailed points collected using the PPK method are illustrated in Figures 4, 5, and 6, which correspond to the three surveyed routes. These visual outputs demonstrate the precision and completeness of the data acquisition process across different sectors of the study area, facilitating the generation of the final site plan.

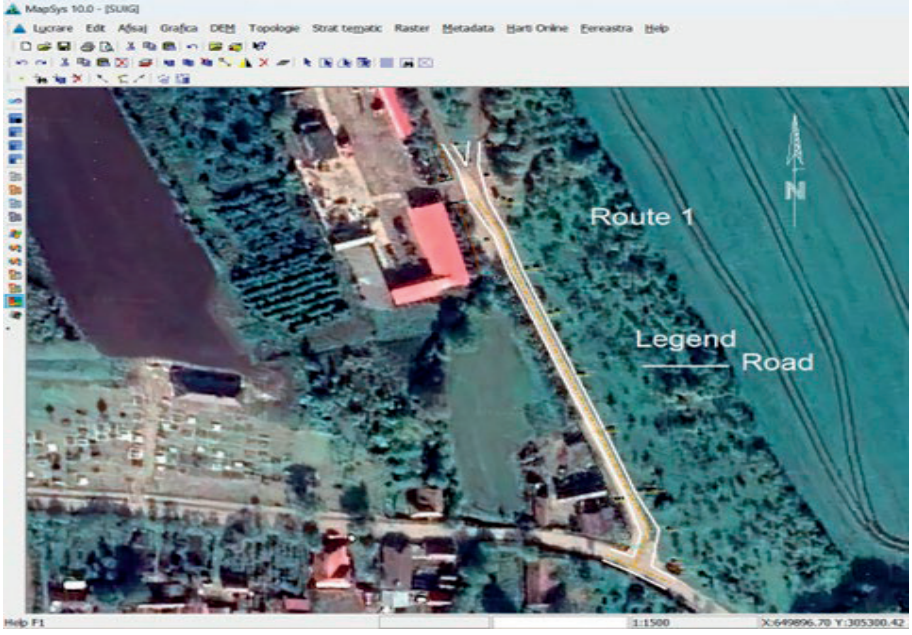

Figure 4. Reporting on the orthophoto plane of the routes on which the positioning of the detailed points carried out, using the PPK method (Route 1)

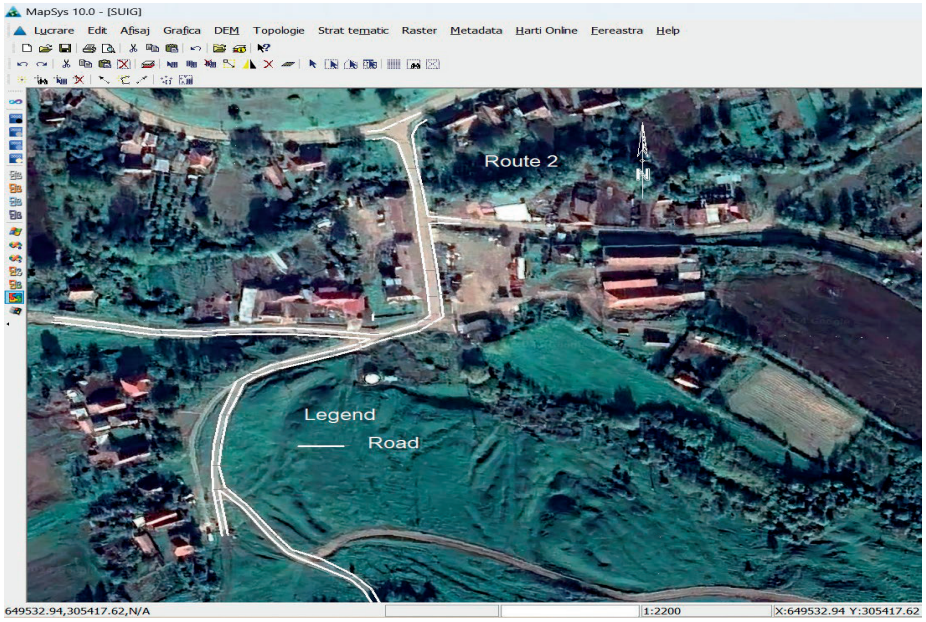

Figure 5. Reporting on the orthophoto plane of the routes on which the positioning of the detailed points were carried out, using the PPK method (Route 2)

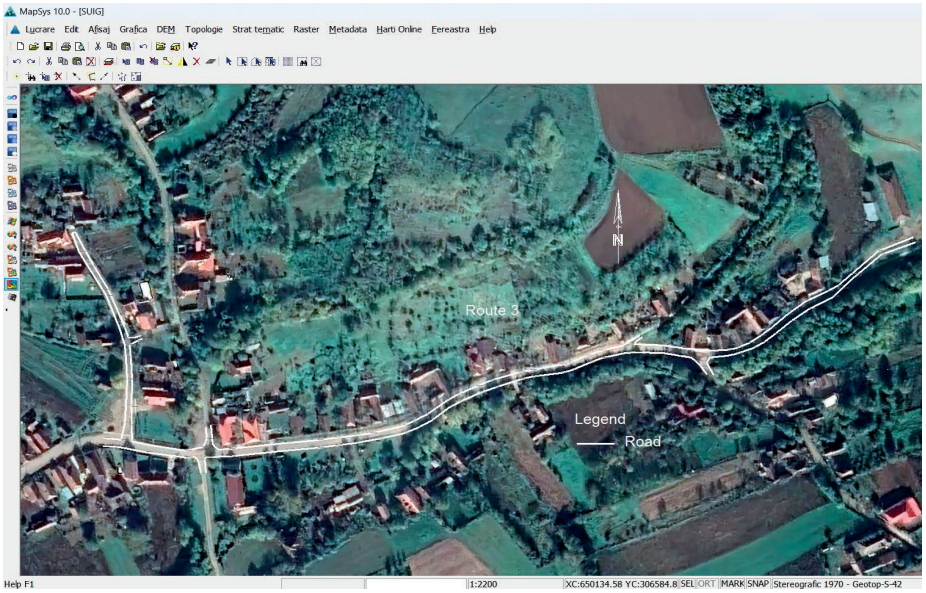

Figure 6. Reporting on the orthophoto plane of the routes on which the positioning of the detailed points were carried out, using the PPK method (Route 3)

The reporting of the final coordinates of the characteristic points was carried out with the found that a number of 1048 detail characteristic points, 292 lines, 680 symbols and 724 text attributes were graphically reported for the creation of the situation plan.

A representative extract from this inventory of coordinates is presented in Table 1. As a result,

1048 detail points were positioned on the three routes traveled.

535	649869.78	305161.42	150.86	10

From the analysis of the data presented in Table 2, it was found that topographic detail points represent the largest share of elements included in the situation plan (38%), followed by text attributes (26%), symbols (25%), and lines (11%). These proportions are visually illustrated in Figure 7, offering a synthetic overview of the spatial features graphically reported using the MapSys 10.0 software.

Extracts from the situation plans, illustrating the reported topographic details, are presented in Figures 8, 9, and 10.

The results of comparative research indicate that the PPK-GPS method is clearly superior to classical topographic positioning methods, which have as their main objective the preparation of contour topographic maps, on very large surfaces. Consequently, it was found that by applying this method the estimated time of the works was reduced by approximately 70% (El Shouny et al., 2017).

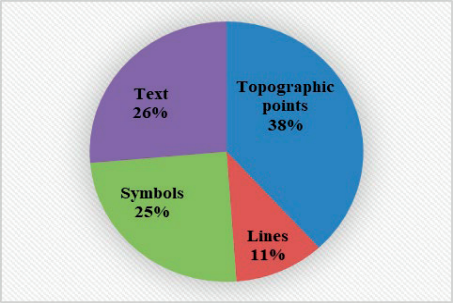

Figure 7. Graphical distribution of the elements included in the detail plan for the three surveyed routes

The application of RTK/PPK GNSS methods, for carrying out drone flights, which aim to map inaccessible forest areas, led to obtaining slight standard deviations in the plane of 0.026 m on the OX axis and 0.035 m on the OY axis, and on the OZ axis of 0.082 m. Consequently, RTK/PPK technology in combination with drones, constitutes a feasible and sufficiently precise solution for mapping areas covered with forest vegetation, and characterized by reduced accessibility (Tomaštík et al., 2019).

CONCLUSIONS

The spatial positioning of the detailed characteristic points necessary for the design and rehabilitation of transport routes in rural areas can be achieved under optimal conditions with GNSS technology, through the Stop and Go method, if at least two GNSS receivers with single and dual frequency are available.

The optimal length of the routes on which positioning is performed with the PPK method, from the base to the end of the route, should not exceed 4-5 km.

Obtaining superior precision for the coordinates of the positioned points and substantially reducing working time is conditioned by the continuous recording of the signal by the base and rover receivers used, along the travel routes.

The use for base and control points of the coordinates of points in the geodetic network or those determined by the RTK method, with the use of recordings from permanent GNSS stations, through the ROMPOS system, ensures the PPK positioning method has extensive applicability.

The use of control points, with known coordinates, along the route and at the completion of the recordings, optimizes the positioning process within the PPK method, contributing to increasing the accuracy of determining the coordinates of new points.

To optimize the positioning process with the Stop and Go method, especially to reduce working time, multiple single-frequency GNSS receivers can be used as a rover, and the base will be located approximately in the middle of the route, depending on the field working conditions.

If two receivers are used as rovers on a single route, it is optimal for them to move from the base point towards the ends of the route, and the base is optimal for it to be located halfway along the route.

For two or more positioning routes with the PPK method, it is optimal to place the base at approximately equal distances from them, and to perform positioning with a rover for each route.

If the routes are located at large distances from each other, the base will be conveniently located in terms of distance and access to satellite recordings, for each separate route.

In the variant where multiple single-frequency GNSS receivers are available, for example four, the necessary base and control points can be positioned later using the traditional static method, and the recordings are post-processed. Also, the coordinates of the base and control points can be determined at the completion of the route positioning, by the RTK method, with a dual-frequency receiver, using the records from the nearest permanent GNSS station. They can also be determined with the total station, by a framed polygonometric survey, or by the free station method, if there are points from the support network in the work area.

ACKNOWLEDGEMENTS

The research was carried out with the support of S.C. TOPOSISTEM and S.C. ECOPROD FOREST SRL, which provided the logistical base and facilitated access to the case study location and participation in the case study. We also thank the Local Council of Abram Commune, Bihor County, for their collaboration.

Abstract

In order to achieve the various objectives related to the sector of terrestrial measurements in areas occupied by forest vegetation, high-performance satellite technologies are currently used. The case study was carried out within the radius of Câmpani, Bihor County, having the objective of analyzing the possibilities of positioning the topographical details, with integrated modern technologies, in areas with forest vegetation. The GNSS receivers Trimble R8, Trimble R10, Trimble R12I, the Trimble S6 total station, as well as real-time data collection and processing software - Trimble Access, were used. The rover-based real-time kinematics (RTK) method was used, with data transmission between receivers via external radio, and framed polygonal journeys. To determine the spatial position of the base points, the data recorded from the permanent GNSS station Beiuș, were used. The data collected were processed in the 2D+1D space, and the results obtained were characterized by superior precision.

Key words*: spatial positioning, GNSS technology, total station, integrated technologies, digital topographical plan.*

INTRODUCTION

The implementation of urban development projects in rural areas, situated across diverse geographic regions, necessitates adequate infrastructure. Consequently, the provision of essential utilities for various sectors requires the establishment of access routes and a minimum level of comfort for the population within the targeted administrative-territorial units. In hilly and mountainous regions, forest vegetation constitutes a significant proportion, comprising approximately 92% of the national forested area (Florescu & Nicolescu, 1996). As a result, the establishment of infrastructure to support the spatial positioning of topographic elements in these forested terrains presents distinct technical and operational challenges, requiring tailored methodologies and equipment adapted to the environmental context (Rus, 2004). Currently, the determination of planimetric and altimetric coordinates for various characteristic topographic points within the national reference system can be efficiently performed using Global Navigation Satellite Systems (GNSS), total stations, drone-based photogrammetric recordings, or integrated combinations of these methods (Păunescu et al., 2006; Neuner, 2000). Therefore, the selection of appropriate spatial positioning technologies and corresponding working methods requires a comprehensive analysis of the site-specific working conditions, the technical requirements established by the project beneficiary, as well as the available logistics and existing infrastructure relevant to terrestrial surveying activities (Crainic, 2024; Chiţea et al., 2009).

When conditions allow for GNSS-based positioning of detail points, the most widely used method is Real-Time Kinematic (RTK) positioning. This technique employs a dual-frequency GNSS setup, consisting of a fixed receiver (base station) and a mobile receiver (rover), which work together to ensure high spatial accuracy (Adam et al., 2004).

The fixed receiver (reference station) is stationed at a point of known coordinates, and is equipped with a transmitter, and the mobile receiver - the rover (Figure 1) is equipped with a receiving device. A real-time radio link is established between the two receivers (Figure 2) (Adam et al., 2004).

The components of the reference station are represented by: GPS antenna (1), controller (3), GPS receiver (4), tripod (4), radio antenna (5) and radio modem (6) (Adam et al., 2004).

The mobile receiver is made up of the following components: GPS antenna (1), antenna support rod (2), GPS receiver (2), controller (3), radio modem (5) and radio antenna (6) (Adam et al., 2004).

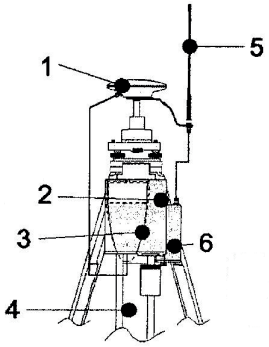

Figure 1. Elements of the reference station (Adam et al., 2004)

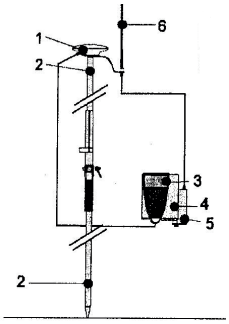

Figure 2. Mobile receiver éléments (Adam et al., 2004)

Once the receivers are mounted and the positioning method and recording parameters are configured, the initialization process - resolving carrier-phase ambiguities - is performed. With modern receivers, this process typically takes only 1-2 minutes (Adam et al., 2004).

The fixed receiver, positioned at a reference point with known coordinates, acts as a radio station that captures satellite signals and relays them, unprocessed and without delay, to the mobile receiver located at a new point. The mobile receiver then interprets this radio signal to determine its position relative to the stationary point. The position is computed by combining the components of the vector between the base station and the rover with the WGS84 coordinates of the reference station, thus obtaining the coordinates of the new point in the WGS84 system (Adam et al., 2004). These coordinates are subsequently converted into the national reference system using established transformation parameters, providing real-time final positioning data (Crainic, 2024; Teunissen & Khodabandeh, 2015).

This workflow is illustrated in Figure 3, which presents the RTK positioning method used in this study.

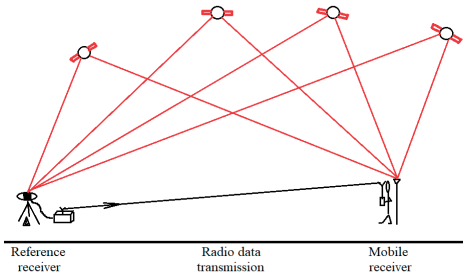

Figure 3. RTK positioning method (processing after Adam J. et al., 2004)

RTK-based spatial positioning can achieve high accuracy, efficiency, and reliability when at least five satellites are available and properly configured. The widespread adoption of this method is largely due to advancements in the rapid transmission of satellite data between receivers - now achieved within fractions of a second (Xingxing et al., 2019; Adam, 2004) - as well as the continuous refinement of computational models that enhance data processing (Odijk et al., 2016).

The accuracy obtained using this GPS measurement method is ± 1-3 cm. This GPS measurement method is recommended for tracing construction elements, positioning details in cadastral works, extension and rehabilitation of communication routes, extension and rehabilitation of water supply and sewage networks, in the agricultural and forestry sectors (Sicoe et al., 2023; Pica et al., 2022), etc. Although in specialized treatises it is not recommended for determining the coordinates of support or thickening network points, currently, due to the existence of an appropriate infrastructure in the terrestrial measurement sector and efficient logistics, geodetic network thickening works can also be carried out, with optimal precision (Adam et al., 2004).

The RTK positioning method appeared in the first half of the 1990s, using single-frequency receivers. In this case, the distance between the fixed and mobile receivers did not exceed a few km, due to the technical possibilities of performing initialization over long distances and transmitting records at an increased distance from the base (Adam et al., 2004; Hofmann-Wellenhof et al., 1997). With the rapid development of satellite positioning technology, and the existence of permanent GNSS stations, at optimal distances in each county, the remote RTK method emerged (Zavate, 2008). In this variant, the distance between the reference receiver, which can be represented by the permanent GNSS station (or a virtual station, as the case may be), and the mobile one, can reach even 30-40 km, in which case dual-frequency receivers will be used (Adam et al., 2004).

Modern programs can perform the initialization again in case of signal loss, even while moving - on-the-fly (OTF) technique, recordings made with the second frequency also play an important role (Adam et al., 2004). Currently, increasing the distance between the reference receiver and the rover is only required by the possibility of transmitting recordings in record time, continuously, using a modern infrastructure, appropriate for these applications and respectively high-performance computational models (Basso et al., 2021; Haojun et al., 2018). Variations in atmospheric conditions can negatively influence the atmospheric error modeling process, resulting in significant atmospheric errors that affect the coordinate determination accuracy, initialization speed, and efficiency of network RTK positioning. Consequently, there is now the possibility of using a fast and reliable network RTK positioning method that uses sequential ambiguity resolution (SAR) of combined multi-frequency observations (Liu et al., 2024).

Also, current research has highlighted the fact that there is currently the possibility of integrating conventional RTK-GNSS methods with a new working technique that capitalizes on recordings from surplus satellites, namely those that were not initially used for positioning, to more efficiently identify incorrect fixation solutions. Consequently, this positioning variant improves positioning accuracy, characterized by high reliability (Fredeluces et al., 2024).

In some situations, working conditions determined by the terrain configuration and respectively the presence of forest vegetation become unsuitable for the use of established positioning methods with GNSS technology. As a result, in these situations, the total station (T.S.) can be used to determine the coordinates of the detail points, using established working methods, such as: polygonometric tracking framed with erasures, polygonometric tracking closed on the starting point, with views to known points and the free station.

Consequently, to streamline the positioning process of detailed topographic points, integrated working methods can be used, related to satellite technology and total station technology, respectively. An opportunity for integrated use of positioning technologies is represented by the presence of permanent GNSS stations, at optimal distances in each county (Rus, 2004). In this context, the existence of an appropriate infrastructure and, respectively, of a high-performance equipment, ensures the obtaining of coordinates with high precision and accuracy (Tang et al., 2017).

MATERIALS AND METHODS

The case study was conducted in Cîmpani Commune, Bihor County (Figure 4).

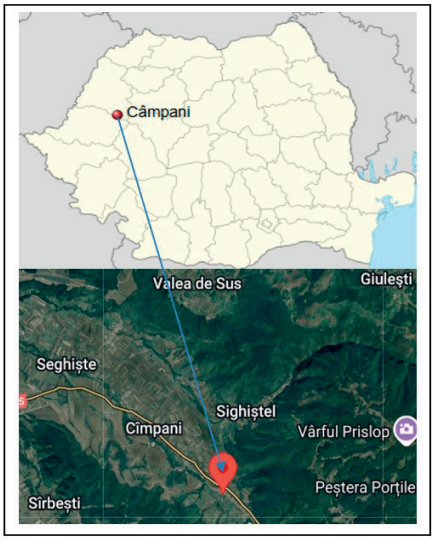

Figure 4. Case study location
(https://ro.wikipedia.org/wiki/C%C3%A2mpani,_Bihor; https://comuna.info/harta-campani-bh/)

The objectives of this case study focus on the research and analysis of spatial positioning methods for topographic detail points required in the design and implementation of water supply and sewage network expansion and rehabilitation projects in the forested areas of Câmpani commune, Bihor County, Romania. Additionally, the study explores the specific aspects of generating detailed plans in both digital and analog formats for the case study site.
The research methodology employed includes bibliographic review, on-site and in-station observations, experimentation, simulation, comparison, and analysis.
The bibliographic documentation covered spatial positioning techniques for topographic details in forested environments, based on specialized literature, technical reports, and related project documentation.
Observations conducted in the field and at control stations aimed to identify and mark detail points, define the positioning technologies, and establish the field routes.
The experiment involved the practical spatial positioning of the detailed points required for infrastructure development.
Simulation was used to generate final products based on experimental data.
All methods, outcomes, and observed particularities were critically analyzed and compared, leading to the formulation of conclusions.
The equipment and software used included:

- GNSS receivers with internal and external radio transmission, accompanied by data logging and processing programs;
- recordings from the Beiuș permanent GNSS station;
- a total station with corresponding software;
- digital cartography software for reporting the coordinates and producing graphical outputs in both digital and print formats.

Although low-cost single- and dual-frequency GNSS receivers (SF-LC and DF-LC) can perform comparably to geodetic-class receivers in open-sky conditions, geodetic receivers are preferred for large-area surveys requiring high precision (Hamza et al., 2025).
Satellite data acquisition was conducted using high-performance GNSS receivers from the Trimble range: R8, R10, and R12I. RTK-GNSS and UAV-based multispectral photogrammetry both offer high-precision mapping. A comparative study showed minimal geometric discrepancies between maps derived from the two methods - only −0.26% in perimeter and −0.23% in area (Dlamini & Ouma, 2025). Therefore, in forested yet accessible areas, RTK-GNSS remains the preferred solution.
Studies have demonstrated that geodetic positioning using network RTK, even with GNSS baselines up to 40 km, does not significantly affect coordinate accuracy (Gökdaş & Özlüdemir, 2020). When nearby permanent stations are inaccessible, a Virtual Reference Station (VRS) may be used, generating correction data from surrounding GNSS stations without extra hardware. This approach provides horizontal accuracy of 1- 2 cm and vertical accuracy of 2-5 cm, even in forested areas (Kurtulgu & Pirti, 2025).
The spatial positioning method applied was the real-time kinematic (RTK) base-rover configuration. In the first stage, ten base points were established for detail point measurements. This process occurred in three phases using data from the Beiuș permanent GNSS station.
In the second stage, topographic detail points were positioned using RTK-GNSS receivers wherever satellite signal reception was optimal. Routes and point attributes were predefined for consistency.

- At base points 1 through 8, the Trimble R8 (4W external radio) functioned as the base, while R10 and R12I units (2W internal radios) served as rovers.
- For base points 9 and 10, the R10 (2W external radio) was used as the base and the R12I as the rover.

In areas with suboptimal GNSS signal due to forest cover, a Trimble S6 total station was used. Surveying was performed via framed polygonal traverses or closed traverses connected to known points. These methods were applied on portions of the routes connected to GNSS base points 1, 2, 7, 8, and 10.
As a result, integrated positioning methods were adopted, tailored to site-specific conditions - an approach previously validated in similar research (Crainic, 2024).
Data collection, processing, and conversion were performed using:

- Trimble Access – for recording and processing GNSS and total station data;

- TransDatRo4.01 – for transforming ellipsoidal coordinates into the national reference system;
- MapSys 11.0 – for graphical reporting of positioned points (Marton, 2007).

The stages of the experimental process are summarized in Figure 5, which was developed following extensive field inspections and consultations with project beneficiaries.

The case study involved a high volume of fieldwork, primarily due to terrain configuration and challenges related to spatial positioning in densely vegetated areas.

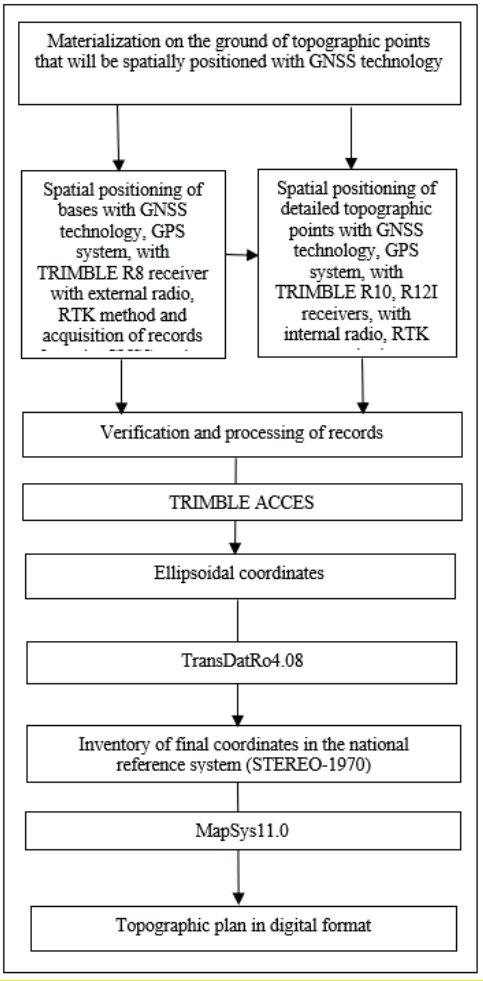

Figure 5. The sequence of steps for carrying out the case study

RESULTS AND DISCUSSIONS

The GNSS-based positioning results were obtained in two stages. First, the coordinates of ten densification base points were determined via the RTK-distance method using data from the Beiuș GNSS station (Table 1). Second, coordinates for the detail points positioned from these bases using RTK and total station measurements were recorded, with a representative sample shown in Table 2.

The identified detail points are essential for implementing the water supply and sewage network expansion and rehabilitation project in the case study area. To ensure efficient data integration, each point was assigned a code corresponding to a specific layer, depending on the type of detail it represents. The relationship between point codes and their respective layers is summarized in Table 3.

To streamline the use of the final coordinates in accordance with the project's technical requirements, the data was organized into a .txt file. This was subsequently imported and graphically rendered using the MapSys 11 software, resulting in a digital topographic plan containing all the positioned detail points. Overlaying the topographic plan onto the orthophoto map of the project area provides a comprehensive visual representation of the spatially positioned features (Figure 6). Representative excerpts from the graphic outputs are shown in Figures 7 and 8. The digital plan enables versatile usage - either in digital or printed analog format (Figure 9).

Printing of the detail plan was carried out after the layout, sheet coverage, and sequencing were established (Figure 10). In addition, a printed version of the coordinates inventory was prepared for delivery to the project beneficiary.

Based on the analysis of the results obtained during the case study, the total surveyed area was S = 399,550 m², with a cumulative measured route length of L = 32,000 m.

CONCLUSIONS

Given the topographic and vegetation characteristics of the analyzed area, appropriate spatial positioning methods were selected to ensure the successful completion of the case study. The use of GNSS receivers with radio communication between base and rover units - within the RTK framework - proved to be a technically efficient solution under challenging field conditions, particularly those imposed by rugged terrain and forested areas.

Data transmission from the base station was performed using a 4W external radio module, while data reception at the rover was handled by a 2W internal radio, both operating with high efficiency. Under optimal conditions, this configuration enables transmission over distances of up to 20-25 km. In contrast, when both transmission and reception are managed by 2W modules, the effective communication range varies from 5-6 km in suboptimal conditions to a maximum of approximately 11 km under ideal conditions.

The selection of base points was made with strict consideration for uninterrupted satellite signal reception throughout each observation session, accounting for the presence of forest canopy or other local obstructions. The integration of recordings from the Beiuș permanent GNSS station - located within a reasonable range of the study area - further optimized the RTK method's application. Additionally, the use of a total station in zones where satellite positioning was impeded proved to be a suitable alternative, enabling continued detail acquisition. This dual approach - merging GNSS-based satellite positioning (for densification points) with total station surveying methods - resulted in a cohesive, integrated spatial positioning strategy. Finally, the use of the MapSys 11 digital cartography program allowed us to produce comprehensive graphical outputs, facilitating multi-format usage of the final deliverables (alphanumeric, digital, and analog). Moreover, derivative products such as databases and GIS components specific to the surveyed site and associated activities were generated under optimal conditions.

ACKNOWLEDGEMENTS

The research and studies were carried out with the collaboration and logistical support of S.C. TOPOSISTEM S.R.L. from Oradea, within the project "Priority works for the expansion and rehabilitation of water supply and sewage networks in the Commune of Câmpani - Bihor County", carried out in 2024.
We also thank the Local Council of the Commune of Câmpani, Bihor County, for their collaboration.

Abstract

Since in the mountain area the area occupied by forest is over 60% of the area of the national forest fund, making forests accessible is an obvious necessity for the sustainable management of various forest resources. The research was carried out within the III Galbena production unit, Sudrigiu Forest District, within the scope of the Bihor Forestry Directorate, with the objectives of applying combined methods of spatial positioning of topographical details, necessary for the design and construction of transport facilities, in the perspective of making 15 inaccessible stands accessible, on an area of 174.48 ha. For the positioning of the topographical details, GNSS technology, GPS system and total station were used, and the working methods used are represented by real-time kinematic positioning (RTK), combined with polygonometric mapping framed with erasures, carried out with the total station. The use of modern combined methods for positioning topographic details in the inaccessible forest fund in the mountain area ensures the obtaining of products in alphanumeric and digital format with superior precision, necessary for the design and construction of transport installations in optimal technical conditions.

Key words: *combined technologies, contour lines, digital terrain model, forest accessibility, GNSS technology, spatial positioning.*

INTRODUCTION

The implementation of forestry strategies established by forest management plans relies on the existence of appropriate infrastructure to ensure effective access to the forest fund. In Romania, current infrastructure allows access to approximately 4.1 million hectares of forest - around 65% of the total 6.3 million hectares - within a maximum collection distance of 2.0 km. The remaining 2.2 million hectares (35%) remain inaccessible (Ciubotaru, 2007).

Internal accessibility works enable the creation of access networks within forest stands to support silvicultural operations, starting from the thicket stage, and the application of specific treatments (Order no. 2,534 of September 28, 2022). Improving accessibility aims to:

- enable operations across the entire stand under safe and efficient working conditions;
- prevent damage to retained trees;
- facilitate timber collection and reduce skidding distances;
- lower operational costs and increase recoverable wood volume.

Developing and maintaining a functional forest road network serves not only silvicultural, technical, and economic purposes but also:

- supports the rational exploitation and utilization of timber and forest products (Săndoiu, 2010; FAO, 2016);
- assists in forest fire prevention and control (Iordache et al., 2016);
- protects hunting species and biodiversity (Iordache et al., 2016);
- connects forest stands to primary transport networks;
- promotes sustainable forest management (Florescu & Nicolescu, 2000);
- enables recreation and tourism (Dumitru, 2014);
- contributes to local economic development.

Prior to establishing access infrastructure, a comprehensive field survey must be conducted to collect data on existing access routes (such as roads, paths, and parcel lines), their condition and dimensions, local hydrography, slope and terrain morphology, the structural and compositional characteristics of the stands (including density, age, and previous

interventions), as well as the optimal directions for timber extraction.
This information helps determine the feasibility and urgency of access works, define road network layouts, estimate costs, and produce a sketch of existing and proposed routes.
Technical, ecological, and economic criteria for designing tractor roads include:

- Avoiding areas with natural regeneration;
- Operating during dry or cold weather to prevent road damage;
- Protecting edge trees using guards;
- Minimizing costs and route lengths;
- Avoiding marshy areas;
- Ensuring a transverse slope of 4–6% and terrain-specific longitudinal slopes;
- Designing a 3-4 m wide platform (OM 1540/2011);
- Incorporating safety features like curbs in dangerous bends;
- Installing temporary wooden bridges over streams;
- Ensuring proper gradient: 25% empty/10% loaded for universal tractors, 40% empty/18% loaded for forestry tractors;
- Mechanized, low-cost construction with daily maintenance using local materials;
- Fixing road alignments by a certified technician or engineer.

According to the updated OM 1540/2011, the maximum width of the tractor road is 4 meters. A standard example of its transverse profile is illustrated in Figure 1 (Ciubotaru, 1996).

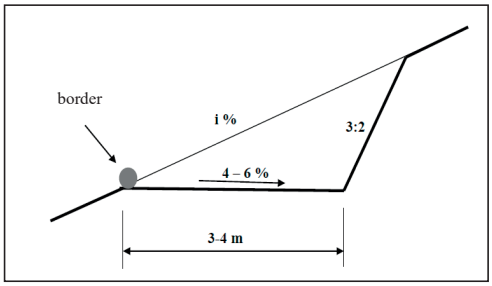

Figure 1. Transverse profile of the tractor road (Ciubotaru, 1996)

This study aims to analyze the spatial positioning methods used for detailed topographic points necessary for designing transport infrastructure in mountainous forest stands with extremely low accessibility. These detail points will be positioned using suitable technologies and surveying methods tailored to the site conditions.

MATERIALS AND METHODS

The research was conducted in inaccessible deciduous and coniferous stands located in a mountainous area, within Production Unit (P.U.) III Galbena, managed by the Sudrigiu Forestry District under the authority of the Bihor Forestry Directorate. The study was carried out in the context of doctoral research.
The targeted stands are located in plots 43B, 44A, 44D, 44C, 45A, 45B, 46A, 46B, 47A, 47B, 47C, 47D, 48A, 48B, 48C, and 49A, covering a total area of 174.48 ha in a highly inaccessible mountainous region (Figures 2 and 3).
The research methodology included bibliographic review, direct observation of trees and access routes, experimentation, simulation, comparative analysis, and image recording on digital media.
The bibliographic documentation phase provided a thorough understanding of the need to improve accessibility in the studied forest areas and its implications for forestry operations. For this purpose, the forest management plan, the associated management map, and the applicable technical regulations were examined.
In addition, documentation regarding available technologies and equipment for high-precision spatial positioning in mountainous deciduous and coniferous stands was also required.

Figure 2. Case study location (https://www.google.com/maps/d/viewer?mid)

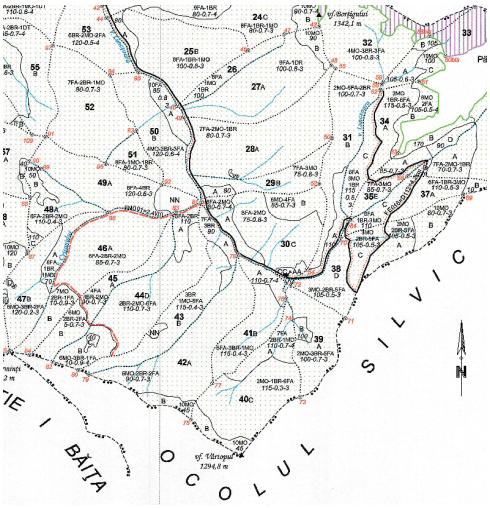

Figure 3. Positioning of the researched and studied stands (according to the Management Map of U.P. III Galbena, 2014)

The positioning of topographic detail points was carried out in the inaccessible stands, including those located in plot 43B, characterized by steep slopes, dense forest vegetation, and limited access infrastructure. Figure 4 illustrates the specific field conditions encountered during the positioning work in this plot.

Figure 4. The inaccessible grove in plot 43B where the positioning of the topographic detail points was carried out (original photograph)

Field observations were conducted by thoroughly surveying the designated stands, during which the proposed routes for forest road construction were identified. Characteristic topographic detail points were also marked and spatially positioned to determine their planimetric coordinates and elevations within the national reference system.

The experiment involved positioning these detail points, determining their coordinates, graphically representing them, and proposing accessibility solutions for the study area. GNSS technology, specifically the NAVSTAR GPS system, as well as total station measurements, were employed for this purpose.

Previous and recent studies have shown that satellite-based positioning in forested areas is significantly influenced by the structural and functional characteristics of the stands. These factors can lead to statistically significant variations in spatial coordinates. Variables such as DOP values affect the precision - though not the accuracy - of the topographic point coordinates (Căteanu & Moroianu, 2024).

One viable method for positioning forest detail points under specific working conditions using GNSS technology is the static method - applied in traditional, rapid, or GPS tracking variants (Ádám et al., 2004). This approach involves placing a GNSS receiver at the point of interest for a variable period, while three additional receivers are stationed at control points with known coordinates. The duration of each stationing depends on technical and environmental conditions, as well as the spatial configuration of the known reference points, either from legacy geodetic networks or the passive GNSS network.

Final coordinates are obtained through post-processing of the satellite data, with results varying depending on the software and computational algorithms used. Despite offering high precision and accuracy, this method is time-intensive and requires well-trained personnel, which limits its current widespread use (Crainic, 2011).

Recent comparative studies using four GNSS receivers - both GIS - and geodetic-grade - revealed notable differences in performance. The GIS-grade receiver yielded an accuracy of 1.38 m and a precision of 1.29 m, whereas the geodetic-grade receiver achieved 0.74 m in

accuracy and 0.91 m in precision. These discrepancies, despite identical data collection conditions, are primarily attributed to the distinct operational principles and processing algorithms of each device type, alongside forest-specific challenges such as cycle slips and the multipath effect (Brach, 2022).

The real-time kinematic (RTK) method is widely used today for positioning various topographic features, due to its high precision, operational efficiency, and accessibility when appropriate logistics and infrastructure are available. In forestry, spatial accuracy is critical for numerous applications, and GNSS-based technologies provide effective solutions for acquiring geolocation data (Căteanu & Moroianu, 2024).

RTK delivers results almost instantaneously - within fractions of a second - after data acquisition and transformation into the national reference system. The method can be applied in two configurations: short-range and long-range (Ádám et al., 2004). The applicability of the long-range variant was significantly expanded following the introduction of the ROMPOS service in August 2008, which enabled high-accuracy transformation parameters across regional and geographical zones. In this configuration, the base station is a permanent GNSS reference point, allowing real-time positioning of detail points using a rover at distances of 30-70 km (Figure 5).

Drones equipped with high-precision GNSS receivers offer another alternative for field measurements, significantly reducing time on site while ensuring high data accuracy. However, recent studies indicate that the RTK method yields superior accuracy, particularly in elevation data for forest road longitudinal profiles. For instance, using drone-based GNSS data resulted in over 22.64% higher calculated embankment volumes compared to RTK-based point positioning, highlighting substantial discrepancies (Lepoglavec, 2023).

The short-range application of the real-time kinematic (RTK) method involves the use of two dual-frequency GNSS receivers: one is stationed at a spatially determined base point, while the other (rover) is used to record data at target points, with short occupation times. To ensure real-time positioning, both receivers must be equipped with radio modules for transmitting and receiving satellite data and differential corrections (Crainic, 2011; Pica, 2022).

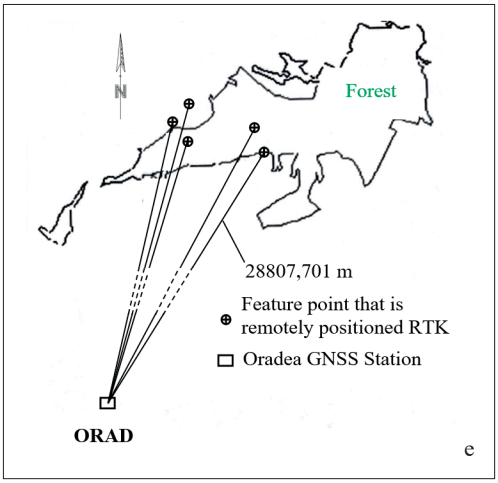

Figure 5. The method of positioning topographic points in the forest fund using the RTK method at long distance (adapted from Crainic, 2011)

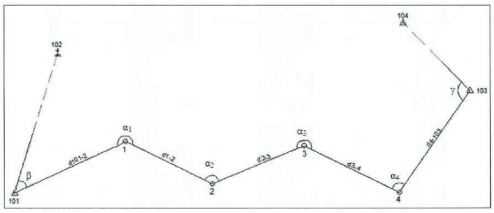
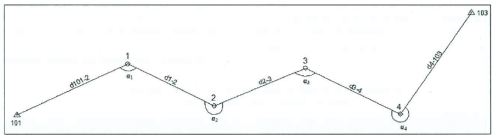
This approach is effective even in forested environments, particularly when the base receiver uses a 4W internal radio and the rover a minimum 2W radio. Under these conditions, the connection between the devices is reliably maintained up to 10-12 km, and data transmission can reach distances of 22-25 km, regardless of terrain complexity.



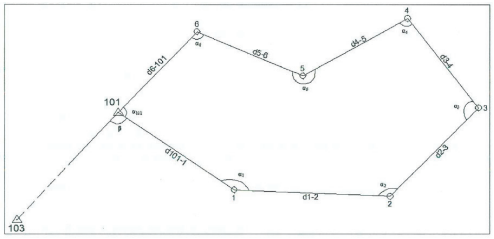
Recent studies demonstrate that individual tree selection for extraction can now be conducted using digitally acquired data from forest inventories. Consequently, tree locations can be identified in real time using RTK-GNSS with dual-frequency receivers and short-range radio communication. When operating within 1 km of the base station, the horizontal positioning error (RMSE) was found to be 0.26 m in *Larix kaempferi* stands and 0.48 m in *Pinus koraiensis* stands, confirming the method's reliability for detailed forest applications (Cho et al., 2024).

With the introduction of additional satellite systems such as BEIDOU, GALILEO, and QZSS - alongside GPS and GLONASS - the broader concept of Multi-GNSS has emerged. This integration increases satellite availability, enhancing performance under challenging conditions like dense canopy cover. Studies in forest environments with 40–90% tree cover



confirm that RTK positioning using Multi-GNSS systems provides superior coordinate accuracy compared to traditional GNSS RTK, even in areas with highly restricted satellite visibility (Andreas, 2019).

For accuracy assessment of GNSS-based coordinates in forested areas, reference values are typically obtained using high-precision total stations via polygonometric traverses, supported by orientation marks. These measurements are processed with specialized software using rigorous adjustment models (Feng et al., 2021).



When satellite positioning is impractical due to forest canopy or rugged terrain, several polygonometric surveying methods may be employed to determine new point coordinates: (i) framed (supported) traverses on spatially defined points with orientation marks (Figure 6.a), (ii) unsupported traverses without orientation marks (Figure 6.b), and (iii) closed traverses with orientation marks (Figure 6.c). These methods are carried out using advanced total stations, with robotic models offering the highest efficiency (Sabău, 2010).

a. Main traverse supported (framed) with orientation visas

b. Main traverse supported without orientation visas

c. Main traverse closed with orientation visas

Figure 6. Principle of creating polygonometric roads (Cranic, 2011)

This method is frequently used in the preparation of forest maps, when carrying out the forest management plan.

Considering the particular conditions of spatial positioning of topographic points on surfaces covered with forest vegetation, efficient combinations of modern geospatial technologies can also be used. Consequently, their positioning principles will be integrated, ensuring obtaining coordinates characterized by superior accuracy and precision.

The positioning of various topographic details in the forestry sector and the preparation of related graphic representations can currently be achieved using combined working technologies such as GNSS systems and total stations. Consequently, alphanumeric and graphic final products of high accuracy and precision are obtained, directly correlated with the logistics used and the working methods used (Călina et al., 2020).

In extreme working conditions, determined by the lack of points in the classical geodetic network or the passive GNSS, the free station method can also be applied at the limit. In this case, a total station and at least two accessible points of known coordinates are required, which have usually been positioned with satellite recordings. As a result, an intersection will be made at the limit, and the point where the total station will be stationed can be determined with high precision through post-processing, if specialized calculation programs are used, with rigorous compensation, for example TERRAMODEL, MATLAB (Crainic, 2011; Nero, 2023). In this situation, a major inconvenience arises regarding logistics and, respectively, working time.

The logistics used to carry out the case study are relatively varied.

Currently, the use of low-cost multi-constellation and multi-frequency receivers for obtaining high-precision coordinates in various stands of deciduous and coniferous trees is facilitated by the use of high-performance software for data recording and processing. For example, the Google Pixel 5 smartphone model and the u-Blox ZED F9P standalone receiver are two variants of low-cost receivers that can be used to position details under the tree canopy. Obtaining accurate results with these receivers was facilitated by using the latest version of the

Demo5 fork of the RTKLIB software. Consequently, the use of low-cost receivers can be effective in the variant of using high-performance software, but also with hardware improvements, especially of the antenna, which is an absolute priority (Tomaštík & Everett, 2023).

Although there is currently a wide range of GNSS receivers and various satellite constellations, the spatial positioning accuracy in trees depends on the class of the receiver, and obviously on the working methods. As a result, geodetic-class GNSS receivers ensure superior accuracy, even in the case of autonomous solutions, compared to modern dual-frequency Smartphones. The obvious differences in accuracy between the various types of satellite receivers are mainly determined by their composition and the software used to record and process satellite information. Consequently, geodetic-class receivers ensure the determination of highly accurate coordinates, in the centimetric-decimetric range, and modern Smartphone-type receivers determine coordinates with GIS accuracy, in the metric-decametric range (Purfürst, 2022).

The logistics used for spatial positioning were provided by S.C. TOPOCONSULT S.R.L. from Oradea, Bihor County, Romania, and were represented by:

- two dual-frequency GNSS receivers, one TRIMBLE R10 with internal 4W radio for the base, and the other TRIMBLE R12I with external 2W radio, as rover;
- TRIMBLE S8 robot total station with all related accessories;
- recordings from the Beiuş GNSS station, using the ROMPOS service;
- TRIMBLE ACCESS program for collecting and processing field data.

The MapSys10.0 program for graphical reporting of positioned points, creating the database and obtaining the related graphic products in digital format was used within the topography laboratory.

The forest management plan (management plan) for Production Unit (P.U.) III Galbena and the forest map at a scale of 1:20000 in digital format, for the area of Production Unit (P.U.) III Galbena, were provided by the Sudrigiu Forest District, Bihor Forestry Directorate.

The experiment related to the case study (research) was carried out in several integrated stages, depending on the working methods used and the working conditions in the field.

In the first stage, the point that was used as a GPS base was established. It was located at an appropriate altitude, in order to receive and record satellite data in optimal conditions.

In the second stage, in order to carry out measurements with the total station, the routes on which the supported polygonometric roads were carried out were established. These were designed through the plots that are to be covered with silvotechnical interventions, and implicitly to be accessible. Consequently, the station points were established and materialized on the ground, where the device will be stationed.

In the next stage, the points that were positioned with GNSS technology, as points for thickening the support network, and which were used to support the polygonometric roads, were established and materialized.

These were located in areas where there were optimal conditions for receiving the satellite signal, without obstructions. These were mostly represented by the open meshes for the installation of natural regeneration, in the stands engaged in the exploitation-regeneration process, and in those caused by felling and wind breakage, as a result of extreme weather phenomena. It was also necessary that they could be observed and targeted from the nearest polygonometric survey station points, in order to comply with the rigorous data processing and compensation algorithm.

All the projected points that were positioned were materialized on the ground by wooden posts with a square section, 5x5 cm, and the mathematical center of their cross-section was marked with a nail, at the intersection of the diagonals.

In the next stage, the base point was positioned with the remote RTK method and the ROMPOS service, the records from the Beiuş GNSS station being also used. Also, the density points were positioned with the RTK method, at a shorter distance, thus using radio modules, in areas where working conditions did not allow the recording of satellite data in optimal conditions.

The last field stage was represented by the completion of the polygonometric journey,

which involved stopping at each station point, performing direct and reciprocal sightings, and sighting the points determined from the stations with visibility.

Currently, hierarchical models are being designed for collecting and sharing forest and natural resource management data, which are based on the accuracy and variety of different spatial positioning and location hierarchy methods in the forestry sector. As a result, data with diverse spatial and temporal complexity are transmitted and processed incrementally at lower levels of organization, then merged, synthesized and transmitted to higher levels of management for sustainable forest and natural resource management (Keefe et al., 2019).

The data processing stage and obtaining the final coordinates in the national reference system was carried out differently, depending on the positioning technologies and methods used.

The sequence of the work stages described above is presented synthetically in Figure 7.

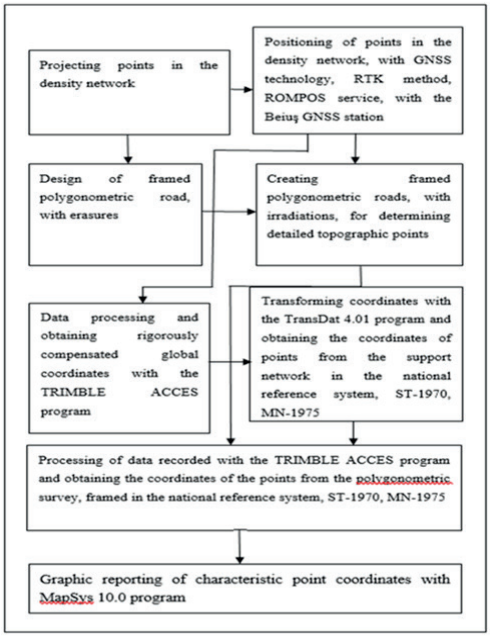


Figure 7. Work steps

After reporting the coordinates of the characteristic points, the obtained travel routes and the optimal accessibility options were simulated, compared and analyzed.

RESULTS AND DISCUSSIONS

The satellite recordings were processed in real time, with the TRIMBLE ACCESS program, obtaining the ellipsoidal coordinates. These were transformed with the TransDatRO4.01 program, using the national transformation parameters recommended for the work area, thus resulting in the final coordinates, in the national reference system (Table 1).

From the analysis of the results of studies conducted in accessible stands of deciduous and coniferous trees, the accuracy of single-frequency GNSS receivers does not depend so much on forest conditions, while the performance of the tested dual-frequency geodetic receiver is very sensitive to satellite visibility. Consequently, in the variant of calculating coordinates with post-processing, especially in combination with data obtained with an IMU inertial system, the improvement of the accuracy of the dual-frequency receiver was significant. As a result, the accuracy of the planimetric coordinates determined with the dual-frequency receiver in real time was 0.7 m, and for the single-frequency receiver, the accuracy ranged between 4.2-9.3 m. The final conclusions resulted from comparing the results obtained with single and dual frequency GNSS receivers, in motion, with those obtained with the total station and a dual frequency GNSS receiver, using the RTK method, for the positions of 224 trees, on the studied route (Kaartinen, 2015).

The data that were recorded during the supported polygonometric surveys were also processed with the TRIMBLE ACCESS program, obtaining directly the final coordinates, in the national reference system (Table 2).

In the case of this case study, the precision of determining the coordinates in the horizontal plane is 3-4 cm and in elevation, 5 cm, an aspect that is also conditioned by the performance of the transformation parameters in the national reference system, for the analyzed location.

All the final coordinates were transferred to a file with the extension txt., configured in five columns, respectively: point number, X (m), Y (m), Z (m) and the code - which represents the layer into which each point will be imported. The points were graphically reported with the

MapSys program 10.0 (Marton, 2007), thus materializing their planimetric position, in the layer corresponding to the code established since the positioning. By joining the station bridges, the routes of the polygonometric roads materialized (Figure 8).

Additionally, sightings to the reference points with known coordinates materialized and used for the precise adjustment of the polygonometric trails. An analysis of the images presented in Figure 8 reveals that the sides of these trails exhibit considerable variability in length. Additionally, sightings to the reference points with known coordinates materialized and used for the precise adjustment of the polygonometric trails.

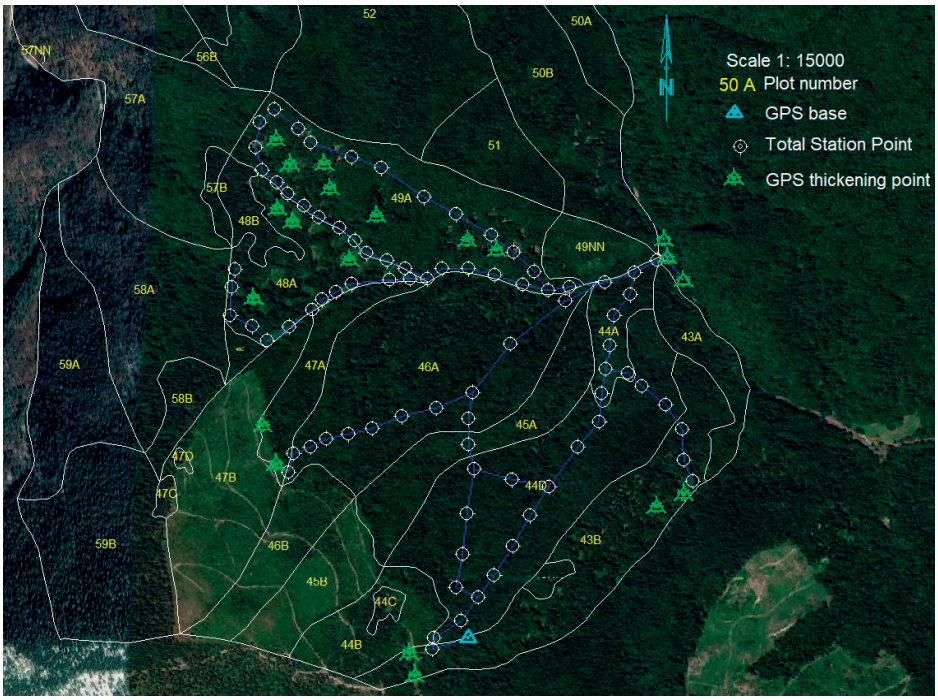

Figure 8. Establishing the GPS base point and total station points
(image capture from MapSys10 program)

An analysis of the images presented in Figure 8 reveals that the sides of these trails exhibit considerable variability in length. This variation is primarily due to limited visibility between station points, caused by the presence of standing trees and natural seedling biogroups within the forest stands. As a result, side lengths range from 34.450 meters to 227.850 meters.

Similarly, the lengths of the sightings to known coordinate points vary depending on their spatial distribution and the presence of visual obstructions such as forest vegetation. The established trails crossed plots undergoing natural regeneration processes, where timber harvesting is currently in progress. In plot 49A, a closed road was constructed and marked with orientation signs to support the efficient planning of transport infrastructure, given the favorable positioning of the area. This newly created road also supports the route along the southern and southwestern boundary of plot 48A.

Closed roads equipped with orientation signs were also constructed in plots 44A, 44D, 45A, and 46A. In contrast, plots 43B and 46 were traversed by supported roads, given their specific positioning and topographical context. The design and implementation of transport infrastructure to improve accessibility in the studied areas will be carried out in stages, in accordance with the current forest management plan and the strategic guidelines established at the forestry district level.

Considering both the provisions of the forest management plan and the dynamics of natural regeneration, priority will be given to the design and construction of transport facilities in plots 43B and 49A (Irimie & Timofte, 2023). Subsequent interventions will focus on improving accessibility in the other plots undergoing natural regeneration - namely 44A, 44D, 45A, 46A, and 48A - based on the condition of the forest stands and the urgency of regeneration and timber harvesting operations.

As a result, roads have also been constructed in stands where maintenance works for natural and mixed regeneration are planned, as well as in those targeted for tending and management cuttings in young and mature stands, depending on their developmental stage.

Regardless of the segment, the spatial coordinates of key topographical detail points will be determined using the total station method, integrated along the full length of each route. The proposed transport infrastructure solutions must ensure full accessibility for all forest stands subject to silvicultural interventions, in compliance with the current forest management plan and applicable technical standards.
Finally, the prioritization of routes and accessibility options for the studied stands will be established through simulations evaluating the realistic potential for timber valorization over the designated management period.

CONCLUSIONS

Making the forest fund accessible is an essential condition for sustainable management
of forests and respectively for the optimal valorization of their wood and non-wood products.
In order to design and build an infrastructure corresponding to the transport facilities in inaccessible mountain areas occupied by deciduous trees mixed with softwoods, and mixtures of softwoods, it is necessary to spatially position the characteristic detail points with high precision.
The use of G.N.S.S. technology, of the G.P.S. system, with TRIMBLE R10 and TRIMBLE R12I dual-frequency receivers, for the positioning of GNSS bases (topographic points of the support network density) in the forest fund, by the remote RTK method, using the records from the Beiuş GNSS station, represents an optimal technical solution.
The positioning of the points necessary for carrying out the supported polygonometric surveys, with the total station, from the GNSS bases, was carried out in optimal conditions using a GNSS receiver with two frequencies with an external 4W radio module for the base, and one with an internal 2W radio module for the rover.
The use of the TRIMBLE S6 robot total station for carrying out the supported polygonometric surveys with radii facilitated the spatial positioning in optimal conditions of the characteristic detail points related to the accessibility variants studied and analyzed.
The variants of transport installations studied and analyzed must ensure the accessibility of all the stands that will be traversed with various silvotechnical interventions, in accordance with the forestry management in force, and respecting the technical norms in force.
The ranking of the routes and accessibility variants of the studied stands will be carried out after simulating the real possibilities of valorization of the wood that will be exploited from them, for the established period of time.

ACKNOWLEDGEMENTS

We would like to thank SC TOPOCONSULT SRL from Oradea for the logistical support and help provided in the process of designing and positioning the GNSS bases and the characteristic detail points, necessary for establishing the accessibility options for the studied stands.
Thanks to the collective of the Sudrigiu Forestry District, Bihor County Forestry Directorate, for their collaboration and support given during the field stage of this research.

Abstract

The use of remote sensing technology can facilitate the acquisition of data pertaining to crop evapotranspiration, which can in turn inform precision irrigation practices. This is achieved through the analysis of satellite image data. The acquisition of accurate information regarding the utilisation of water is of significant importance within the domain of agricultural water management and crop production, particularly at the scale of human impact on the natural water cycle, in the context of global climate change and the increased prevalence of droughts. The objective of this study is to investigate and provide a summary of the potential for using satellite imagery and in situ measurements for meteorological factors, crop vegetation and soil water content, with a special focus on the assessment of evapotranspiration. The studies conducted are of significant value in predicting the potential water requirements of plants, the capabilities of irrigation systems and the efficient utilisation of irrigation water in agriculture through the implementation of adaptive irrigation regimes.

Key words*: evapotranspiration, irrigation, satellite imagery, vegetation indices.*

INTRODUCTION

Evapotranspiration is a critical component of the water system, playing a pivotal role in the hydrologic cycle. Evapotranspiration, in conjunction with precipitation and runoff, exerts a profound influence on the availability and distribution of water on the land surface. This dynamic process plays a critical role in crop growth and water demand, making it a pivotal factor in hydrological processes and environmental dynamics.

The accessibility of accurate estimations of evapotranspiration is of critical importance for a multitude of applications within diverse scientific disciplines. These include, but are not limited to, climatology, meteorology and agricultural science (Guzinski et al., 2020; Douglas et al., 2009).

Evapotranspiration (ET) is crucial for determining irrigation requirements, optimizing water use, and improving crop yield in agriculture. Understanding ET helps farmers and irrigation planners balance water supply and demand, ensuring efficient water resource management (FAO, 1998). It is imperative to meticulously monitor soil conditions throughout the growing season to optimise production efficiency. As the crop matures, there is a concomitant change in transpiration and altered water requirements. For example, as a key indicator of crop growth, ET has been identified by scientists as a key indicator of crop growth. The calculation of the amount of water utilised by crops has been demonstrated to show the enormous potential in growing crops under irrigated conditions (Allen et al., 1998a; 1998b). The development of digital technology has led to an increase in techniques for calculating and modelling evapotranspiration based on advanced remote sensing techniques. These advancements have been developed to manage water resources more efficiently and facilitate a deeper understanding of the relationship between plant development and water demand, including climate feedback (Teuling et al., 2009; Vazifedoust et al., 2009; Hollmann et al., 2013; Wagle et al., 2017; Allam et al., 2021).

The most widely used and accessible methods for determining ET on a large scale are those carried out by means of Earth observation and satellite imagery, as well as spectral indices of vegetation. To optimize their effectiveness, images for evaluation of ET must have a spatial resolution that aligns with terrain characteristics and field size (Anderson et al., 2004; Guzinski et al., 2019)

To achieve this objective, it is imperative to undertake a comparative analysis of field measurements of ET with those obtained from remote sensing methodologies.

The comparison of field measurements of ET with those obtained from remote sensing has two principal purposes: to determine the accuracy of remote sensing of ET and to validate the remote sensing algorithms used for ETo estimation (Anderson et al., 2004; Mcabe et al., 2006; Kustas et al., 2018; Mokhtari et al., 2019). To evaluate ET data obtained from satellite imagery or other remote sensing methods and determine whether their scatter in determination is appropriate for crop irrigation, it is critical that they be confirmed with field measurements of ET. (Anderson et al., 2004; Guzinski et al., 2019). The spatial resolution can range from 10 m per pixel to 300 m, depending on the temporal resolution of the acquisition (Allen et al., 2007). Reliable estimates of actual ETo and crop water requirements are best achieved using satellite observations in the visible/near-infrared and thermal infrared electromagnetic spectrum (Anderson et al., 2012; Hoffmann et al., 2016).

The objective of this study is to investigate and provide a summary of the potential for using satellite imagery and *in situ* measurements for meteorological factors, crop vegetation and soil water content, with a special focus on the assessment of evapotranspiration.

MATERIALS AND METHODS

SYNTHESIS OF EXISTING LITERATURE

Description for evapotranspiration and Data Collection

The framework of the study is to integrate in situ and spatial measurements to determine ET during crop vegetation, such as traditional in field measurements with modern remote sensing data.

Evapotranspiration (ET) is the combined process by which water transfers from the land surface to the atmosphere both by evaporation from soil and plant surfaces and by transpiration through plant stomata. It represents the actual water loss under given field conditions (mm/day or mm).

Reference Evapotranspiration (ET_0)

The rate of evapotranspiration from an idealized reference surface - typically a well-watered, actively growing grass of uniform height - under prevailing climatic conditions. ET_0 provides a standard baseline (mm/day) that is independent of crop type or management; it is used to compare atmospheric demand for water across locations and times.

Crop Evapotranspiration (ETc)

The evapotranspiration rate of a specific crop under standard field conditions. It is calculated by adjusting reference evapotranspiration (ET_0) with a crop coefficient (Kc):

$$ETc=Kc\times ET_0$$

where:

- Kc accounts for crop characteristics (e.g. canopy cover, growth stage), climate and soil evaporation;
- ETc represents the crop's water use requirement (mm/day).

Traditional ETo Estimation Methods

ET can be quantified using two primary methodologies:

Direct Measurement Methods:

Climatic Parameters: continuous recordings of air temperature, relative humidity, solar radiation, wind speed, and precipitation levels are used to calculate baseline ETo estimates.

*Crop Characteristics***:** detailed information on crop type, variety, growth stage, and morphological features (such as plant height and density) is collected. These factors are critical since they influence the rate of transpiration and, consequently, the overall ET.

Soil and Agrotechnical Conditions: variations in soil properties, moisture content, and cultivation practices (including tillage and irrigation methods) are monitored. These conditions modify the microclimate around the crop canopy, impacting both soil evaporation and plant transpiration.

Lysimeters: instruments that directly measure changes in soil moisture, thereby estimating the amount of water lost through ET. Although highly accurate, lysimeters are typically expensive and labour-intensive.

Field Moisture Sensors: devices that monitor the water content in the soil, offering real-time data on moisture variations within the root zone.

The only factors affecting ETo are climatic parameters. Consequently, ETo is a climatic parameter and can be computed from weather data.

The methods for calculating evapotranspiration from meteorological data require various climatological and physical parameters. Some of the data are measured directly in weather stations. Other parameters are related to commonly measured data and can be derived with the help of a direct or empirical relationship. (FAO,1998).

To facilitate the management of water resources, it is imperative to make estimates of evapotranspiration ET. This is particularly crucial in the context of climate change, as ET estimates are necessary to predict potential changes at both global and regional scales (Allen et al., 2005; Teuling et al., 2009).

Evapotranspiration is not easy to measure. Determining evapotranspiration requires specialized equipment and accurate measurements of various physical parameters or soil water balance in lysimeters. The methods are often expensive and demanding in terms of accuracy. Although these methods are not suitable for routine measurements, they remain important for evaluating ET estimates obtained by more indirect methods.

***Indirect Estimation Methods**:*

A variety of empirical and physically based models have been developed to estimate crop or reference-crop evapotranspiration (ET_c and ET_0) from readily available meteorological data, yet each is valid only under climatic and field conditions. The FAO-56 Penman-Monteith equation combines radiation, temperature, humidity and wind speed to yield a robust reference ET (ET_0) applicable across humid, arid and temperate zones when comprehensive data are available (Allen et al., 1998).

By contrast, Shaumyan's temperature-based model (ET = k (T + a)) relies solely on mean monthly air temperature (T) and regionally calibrated coefficients (k and a), making it useful where only thermal records exist but requiring local calibration (Shaumyan, 1960).

Turk's semi-empirical formula, ET = 0.013 (T/(T+15)) (23.885R_s+50), incorporates solar radiation (R_s) and temperature (T), performing well in humid climates but underestimating ET under arid conditions (Turc, 1961).

Finally, the Blaney-Criddle method, ETc = p (0.46T+8), uses temperature and daylight fraction (p) to estimate crop ET in temperate to semi-arid regions, though it omits humidity, wind and detailed radiation terms and thus loses accuracy in tropical or highly variable climates (Blaney & Criddle 1950).

The following conclusions and implications can be deducted from the practical applications of evapotranspiration determination.

- The FAO Penman-Monteith method has been approved as the standard method for the determination and calculation of reference evapotranspiration (ETo).

$$ET_0 = \frac{0.408\Delta(R_n - G) + \gamma\frac{900}{T+273}u_2\,(e_s - e_a)}{\Delta + \gamma(1 + 0.34u_2)}$$

where:

- ETo reference evapotranspiration (mm day^{-1});
- R_n net radiation at the crop surface (MJ m^{-2} day^{-1});
- G soil heat flux density (MJ m^{-2} day^{-1});
- T mean daily air temperature at 2 m height (°C);
- u_2 wind speed at 2 m height (m s^{-1});
- e_s saturation vapour pressure (kPa);
- e_a actual vapour pressure (kPa);
- e_s - e_a saturation vapour pressure deficit (kPa);
- Δ slope vapour pressure curve (kPa/ $°C^{-1}$);
- γ psychrometric constant (kPa/$°C^{-1}$) (Allen R. G. et al., 1998).

The crop surface evapotranspiration and crop-specific coefficient (Kc) are determined, thus relating the crop evapotranspiration to reference (Glen et al., 2010). The estimation of ET and soil moisture content is fundamental to the management of water resources, the provision of drinking water and irrigation, and the intensification of the water deficit crisis (Anderson et al., 2007; Mokhtari et al., 2019). Soil moisture content is directly related to the ET process, as it is contained in the soil surface and plant needs (Norman et al., 1995; FAO, 1998).

Empirical models derive ET estimates from relationships between climatic variables and crop characteristics. Single-factor models and multi-factor approaches (including the Penman-Monteith equation, Shaumyan's, Turk's, and Blaney-Criddle methods) are commonly used.

Remote Sensing Models

These methods utilize satellite data to estimate ET. Two prominent approaches include:

Spectral Vegetation Indices (SVI): these indices are derived from reflectance values in the visible and near-infrared spectra. They provide insight into crop vigour and canopy density, which are directly related to water use.

Energy Balance Models: these incorporate both optical and thermal data to assess the energy exchange at the land surface. Models such as Surface Energy Balance Algorithm for Land (**SEBAL**), Mapping Evapotranspiration with Internalized Calibration (**METRIC**), and the Surface Energy Balance System (**SEBS**) use thermal imagery to derive sensible and latent heat fluxes, thereby estimating ET.

Applications and case studies

Sensor Resolution Impact:

McCabe investigated the use of multiple satellite sensors to estimate evapotranspiration (ET) across different spatial scales. The focus is on understanding how satellite sensor resolution affects the accuracy of ET measurements, particularly in agricultural regions. The importance of ET in hydrological and agricultural systems is emphasized as it controls water availability, and there's a strong interest in improving its estimation for water resource management (McCabe et al., 2006).

The utility of satellite imagery is limited by temporal resolution. For practical purposes (i.e. irrigation scheduling/water allocation), the bi-monthly temporal observations offered by high-resolution platforms are insufficient. For estimating the average daily evapotranspiration of a watershed, MODIS provides an extremely valuable data source for assessing the current condition of the land and vegetation - useful for weather forecasting, flood forecasting, and other areas of water resource management.

The authors present different energy balance models that differ in their ability to characterize surface flux at specific model scales, the results presented can serve to predict evaporation flux at different scales regardless of the model used.

Data Fusion Techniques:

Researchers have examined the potential of Sentinel-2 and Sentinel-3 satellites to estimate high-resolution evapotranspiration (ETo), a process vital for agricultural and water resource management. Sentinel satellites have various spatial and spectral resolutions. They lack high-resolution thermal sensors, crucial for precise ET monitoring. The research uses machine learning algorithms to enhance Sentinel-3's low-resolution thermal data with Sentinel-2's high-resolution optical data. The enhanced data is then integrated into a land-surface energy balance model, facilitating more precise ET estimations (Guzinski et al., 2019).

Cloud Cover Mitigation:

Chintala focuses on modeling high-resolution actual evapotranspiration (ETa) using data from the Sentinel satellites, specifically addressing challenges like cloud cover during the monsoon season. The study uses the Sen-ET plugin, combining Sentinel-1, Sentinel-2, and Sentinel-3 data, to improve ETa flux estimations (Chintala et al., 2022)

Crop-Specific Models:

Rozenstein (2018) conducted a study to validate evapotranspiration for cotton water consumption using Sentinel-2 imagery and ground measurements. The research examined the relationships between the crop coefficient and various vegetation indices. The obtained results aim to support the development of irrigation models for cotton crops.

Singh and others researches explored a novel approach to estimate daily evapotranspiration (ET) using a fusion of Landsat 8 and Sentinel-2 data. ET is a critical component for hydrology, agriculture, and climate models, but field measurements are costly and impractical over large areas. While Landsat provides medium-resolution thermal data (30 m, 16-day revisit), Sentinel-2 offers higher spatial resolution (10–20 m, 5-day revisit) but lacks thermal bands. This study bridges these gaps by combining data from both satellites to enhance spatio-temporal resolution for ET estimation. (Singh et al., 2020)

Irrigation Detection:

Chakhar et al. (2024) investigated time series from Sentinel-1 and Sentinel-2, along with biophysical coefficients, to improve irrigation in orchards. The authors utilized meteorological data, specifically rainfall data from SAR (Synthetic Aperture Radar). To obtain time series of derived indices from the Sentinel-1 and Sentinel-2 satellite missions, Python scripts were used during development to retrieve processed NDVI.

Both remote sensing datasets have a spatial resolution of 10 m and are configured to have a temporal resolution of 7 days. In terms of temporal resolutions, the goal was to acquire

weekly information from both remote sensing sources and to use this information in an integrated manner. It should be noted that the normal coverage (temporal resolution) of Sentinel-2 in the study area is typically 3-4 days, while for Sentinel-1 it is 6 days.
(https://servicio.mapa.gob.es/websiar/ accessed on March 27, 2023), provided by the Spanish Ministry of Agriculture, Fisheries, Food, and Environment.

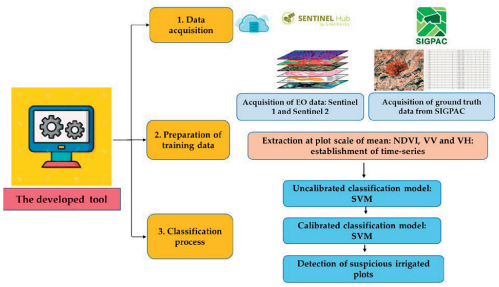

Figure 1 General workflow (Chakhar et al., 2024)

In conclusion, the authors found that integrating in situ measurements with multispectral sensors and radar imagery yields the highest accuracy and efficiency. The proposed method estimates crop water consumption through image classification and time series analysis. As a key outcome of the study, they optimized the Support Vector Machine (SVM) model for detecting irrigated plots, enhancing its performance and reliability. (Chakhar et al., 2024)

RESULTS AND DISCUSSIONS

Comparative insights between traditional and remote sensing approaches

Field measurements of evapotranspiration (ET) are accompanied by methods that are difficult to conduct with the requisite degree of accuracy in situ. Most methodologies rely on the estimation of ET from meteorological data. In contrast, Earth observation has been a powerful and advanced tool for estimating ET over large areas. Satellite imagery is utilized to analyze ET in spatial and time series that cannot be achieved by in situ measurements. The utilization of satellite imagery to estimate ET can be systematized into two primary approaches: spectral vegetation indices (SVI) and energy balance methods.

Evaluation of spatial and temporal resolution needs

Satellite imagery provides the ability to analyze ET in spatial and time series that cannot be achieved by in situ measurements. Research of the spectral vegetation indices time series, such as the normalized difference vegetation index (NDVI) and the soil adjusted vegetation index (SAVI), are evaluated to estimate crop coefficients for cotton and sugarbeet. (González-Dugo et al., 2008) This helps to estimate crop evapotranspiration in irrigated areas by multiplying reference evapotranspiration values by appropriate crop coefficients.

Cost-effectiveness and feasibility of field vs. satellite methods

Accurately measuring evapotranspiration (ET) in the field is often both challenging and expensive. In contrast, remote sensing has become a more practical and cost-effective alternative for estimating ET across large areas. This approach relies on satellite sensors that operate in the electromagnetic spectrum, particularly optical multispectral and thermal bands. One well-established model, the Surface Energy Balance Algorithm for Land (SEBAL), utilizes data from sources such as Landsat 7 and has been extensively calibrated and validated to assess spatial variations in crop yield, ET, and water productivity (Bastiaanssen et al., 1998).
The Surface Energy Balance System (SEBS), introduced by Su (2002), is a remote sensing-based model designed to estimate surface energy balance components. It offers a more detailed representation of the atmospheric boundary layer and surface roughness. SEBS is recognized for its reliability across various climatic conditions and has been successfully applied in a wide range of environments. An advancement of the SEBAL model, known as METRIC, was developed by Allen et al. (2007). This model enhances accuracy through additional calibration steps that incorporate ground-based reference evapotranspiration (ET) data.

Accuracy and limitations of current satellite-based ET Models

The two primary approaches for estimating ET using satellite imagery - spectral vegetation

indices (SVI) and energy balance methods - have been extensively validated using lysimeters. Studies and analyses derived from the energy balance method exhibit a greater degree of similarity to the actual changes in crop condition. However, there are limitations to current satellite-based ET models, including the need for accurate calibration and validation to ensure the reliability of the estimates.

Knowledge gaps and future directions

Satellite base models for estimating crop evapotranspiration have their advantages and continue to develop and improve, despite some limitations.

Advantages:

- High spatial and temporal resolution: energy balance methods can provide detailed ET estimates over large areas and at frequent intervals, which is not feasible with traditional field methods.
- Validation and calibration: these methods have been extensively validated using ground-based measurements like lysimeters, ensuring their reliability.

Limitations:

- Data Requirements: accurate estimation requires high-quality input data, including surface temperature, radiation, and meteorological data.
- Complexity: the models can be complex to implement and require expertise in remote sensing and energy balance principles
- Need for standardization in remote sensing algorithms across climate zones
- Gaps in high-resolution thermal data for ET estimation
- Challenges in integrating multi-source satellite data

To improve the effectiveness of the models and their applicability in practice, it is necessary to make synchronous observations of the ground according to the specific soil, vegetation and climatic conditions. This is necessary due to the lack of sufficient data to validate the models themselves, which still work with wide range values and large scale area.

CONCLUSIONS

The variability in evapotranspiration is governed by a complex interplay of climatic conditions, crop development, and soil management practices. Satellite imagery emerges as a powerful tool for assessing these dynamics over vast areas with diverse landscape features. The integration of high-resolution optical, radar and thermal data, especially when enhanced through data fusion techniques, significantly improves the precision of ET estimates. These advancements support the development of adaptive irrigation regimes and contribute to the sustainable management of water resources in agriculture. The development of sustainable models for precise irrigation management is dependent upon the validation of current spatial observations of vegetation cover according to the specific soil and climatic conditions of a given crop. Future research should continue to refine these remote sensing methodologies to further reduce uncertainties and enhance their applicability across different environmental conditions.

Abstract

It is known that meteorological parameters, among others, are highly determinant for the growth of the agricultural crops. On the other hand, vegetation indices computed on remote sensing data are widely-used for crop monitoring. In this paper we focus on temperature, one of the determinant meteorological parameters, and the Normalized Difference Vegetation Index (NDVI), the most used vegetation index. We use temperature and NDVI time series, the latter one computed based on Copernicus data. Based on the hypothesis that effect accumulations of temperature in time determine the plant age and growth and, implicitly, its vegetation status, we study the influence of temperature on NDVI and attempt to model it. We present a use case for the monitoring of two potato crops during the 2023 and 2024 seasons in Braşov area, Romania and formulate the conclusions.

Key words*: temperature, NDVI, time series, Copernicus data, potato crop.*

INTRODUCTION

It is currently estimated that the world population will increase from 7.5 to 9.7 billion by 2050 (Gu et al., 2021), resulting in a high demand of agricultural products and a high pressure on natural resources. Despite the fact that agriculture is still the major activity in many countries, we face a global decrease in both production and employment in agriculture. The solutions to boost productivity are agricultural investments and technological innovations (Godfray et al., 2010).

In the context of Agriculture 5.0 (Ivanovici et al., 2024), Earth Observation (EO) data is widely used for the monitoring of agricultural crops. Nowadays remote sensing technologies provide support for precise agricultural operations at the scale of farmers' fields, as well as to the management and strategic planning of agricultural production both at regional and national levels (Guo et al., 2017). EU Copernicus programme provides free EO data which can be used for various applications in smart agriculture (EU, 2014).

We focused our research in an area situated in Brasov County, in the central part of Romania. The area is part of the region used to be called *Potato Country* in Romania, being renowned for its large areas cultivated with potatoes. However, in the last decade, due to climate change, the area cultivated with potatoes has dropped to approx. 25%. The potato (*Solanum tuberosum* L.) thrives in moderate temperatures, typically between 14°C and 22°C, and is sensitive to environmental changes during storage (Teper-Bamnolker, 2010). The suitable relative soil moisture content for potato growth and development is 55% to 85%, and the suitable temperature is 15°C to 25°C. The growth and development of potato plants under drought and high-temperature stress conditions are inhibited, and plant morphology is altered, which affects the process of potato stolon formation, tuberization and expansion, ultimately leading to a significant reduction in potato tuber yields and a remarkable degradation of the market grade of tubers, the specific gravity of tubers, and the processing quality of tubers (Fang et al., 2024). According to (Sánchez-Correa, 2024), optimal potato development occurs at temperatures between 15°C and 20°C, with yields ranging from 12 to 60 tons of tubers per hectare. However, observations show a decline in yield when the ambient temperature exceeds 24°C. This is due

to a combination of independent morphological, physiological and developmental issues. According to (Timlin, 2006), the optimum temperature for canopy photosynthesis is 24°C (but this decreases with the plant age) and the total biomass was highest at 20°C. However, the ideal temperature for potato crop may vary with plant growth stages (Singh, 2019).

In this paper we use temperature and NDVI time series for the analysis of their relationship for two potato crops in Brasov area, Romania, in 2023 and 2024. We build our model based on the hypothesis that the accumulations in time of temperature effects determines the plant age and growth and has impact on vegetation status, as observed through vegetation indices such as NDVI. The temperature impacts the entire potato plant (Lazarević et al., 2022). Based on the proposed model, we study the influence of temperature to the vegetation status indicated by NDVI computed on Copernicus data. We present the materials and methods, then we show experimental results, as well as a discussion, and conclude the paper.

MATERIALS AND METHODS

For the current study, we used Sentinel-2 data, more specifically, the satellite images were freely downloaded from the Copernicus browser (https://browser.dataspace.copernicus.eu/). In particular, we were interested in monitoring the evolution of potato crops belonging to the National Institute of Research and Development for Potato and Sugar Beet (NIRDPSB), Braşov, Romania (see Figure 1).

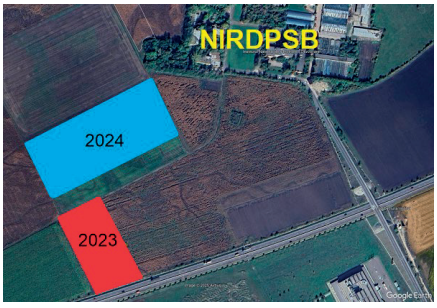

Figure 1. NIRDPSB and the two potato crops of interest, Braşov area, Romania (source: Google Earth)

With more than 60 years of experience, NIRDPSB plays an important role in the preservation of the potato heritage at the national level (Chiru et al, 2017). Through its activities, NIRDPSB promotes both fundamental and applicative research in the domain of potato and sugar beet cultivation. In Figure 1 we show a satellite view with the under-study potato crops for 2023 and 2024 highlighted with red and blue, respectively, with respect to the location of NIRDPSB, for easy identification. For the two potato crops of interest, the time period of interest was from 1st May to 31st of August (122 days), both for 2023 and 2024.

In Figure 2 one can see the evolution of average daily temperature for 2023 and 2024, with a minimum of approximately 10ºC (both in 2023 and 2024) and a maximum of 28ºC in 2023 and 30ºC in 2024. The temperature readings were provided by the NMA Braşov-Ghimbav Station, located at approx. 3 km from the potato crops.

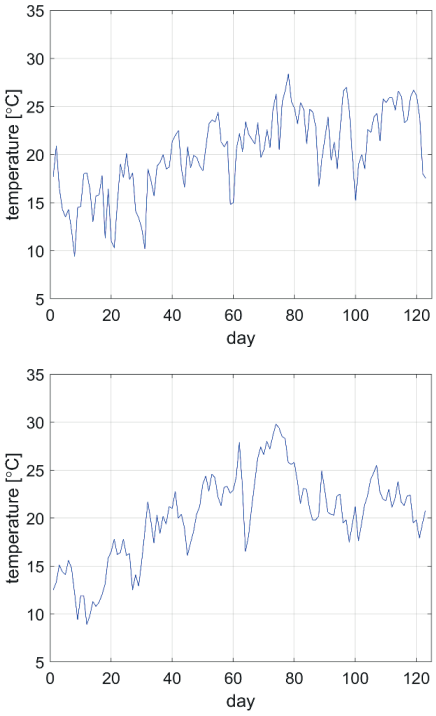

Figure 2. The average daily temperature for 2023 (top) and 2024 (bottom) for the potato crops of interest

From the Copernicus data we downloaded the NDVI product for the two corresponding potato crops, for 2023 and 2024, respectively. The two

original NDVI time series are depicted with black in Figure 3. One can notice that for some dates the NDVI values are erroneous, i.e. they exhibit very low values. These erroneous values were filtered out by using a morphological filter in order to produce a smoother variation of the NDVI – depicted with green. The filtering was applied both for the 2023 and 2024 time series.

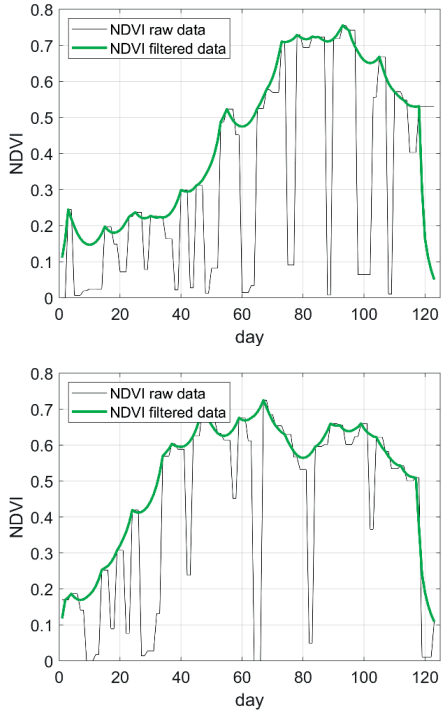

Figure 3. The NDVI time series for 2023 (top) and 2024 (bottom) for the potato crops of interest

In order to build our model, we considered the following observations. Potato develops best at approximately 20°C (Rykaczewska, 2015). An increase with 5°C above this optimum temperature causes a reduction in the photosynthetic rate with 25%, which ultimately affects biomass accumulation and, later, the sink activity (Obiero et al., 2019). Transitory or constant high temperatures cause an array of morpho-anatomical, physiological and biochemical changes in plants, which affect plant growth and development and may lead to a drastic reduction in economic yield (Wahid et al. 2007; Lal et al., 2022). These inhibitory effects occurred at all developmental stages (Van Harsselaar et al., 2021), including growth inhibition at the seedling stage (Daim and Zhangzz, 2018), decreased number of stolons and hindered tuber expansion, which resulted in lower yields, abnormal tuber morphology and fewer salable tubers (Liu et al., 2025).

Based on these observations, we propose the following approach to perform the analysis of temperature influence on NDVI (see the block diagrams in Figure 4). The first block maps the daily temperature to the degree of influence of temperature to the overall vegetation status and, implicitly, NDVI, assuming a purely Gaussian model (in blue), similar to the ones seen in the literature. Alternatively, we propose the usage a piecewise linear model (in red), better matching the observations made above. The second block cumulates the degrees of influence over a specified period of time, significant for the process of plant growth. The resulting cumulated degree of influence is then correlated with the NDVI time series, resulting in the Pearson correlation coefficient ρ.

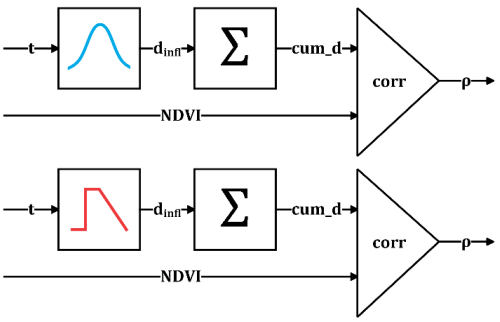

Figure 4. The block diagram of the proposed approach – based on the Gaussian (top) and piecewise linear (bottom) model for the temperature degree of influence

There exist several attempts to model the influence of the temperature for the development of the roots of plants. We make the assumption that such a model can be designed for the degree of influence of temperature to the overall vegetation status of the plants. Consequently, we assume a direct relationship between the degree of influence of temperature and the measured NDVI (as it is measured by means of remote sensing). For the degree of influence of temperature to NDVI, we considered a generic, symmetric Gaussian model, as the one depicted in Figure 5. This

choice was inspired by the existing models for other crops (Walne, 2022). We assume a symmetrical mapping of the range of temperatures from 0ºC to 40ºC to the [0,1] interval. The maximum degree of influence corresponds to a temperature of 20ºC. This particular choice was merely to have a starting base for experiments, the shape can be later on determined by experiments or by inverting the model. In red, we propose a piecewise linear model that better suits the observations made in the literature.

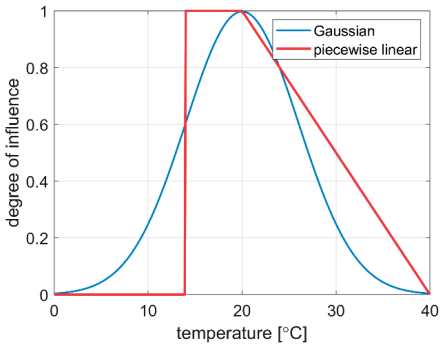

Figure 5. The chosen Gaussian model for mapping the temperature to the degree of influence

After mapping the daily temperature to the degree of influence, we further cumulate the degrees of influence over a time period significant to the plant development process. Basically, we compute a moving sum over N samples, as described in eq. (1):

$$cum_d_{infl}(i) = \sum_{k=0}^{N-1} d_{infl}(i-k) \qquad (1)$$

The summation corresponds to the accumulation effects (e.g. of biomass) in the plant, as a direct consequence of the temperature to the plant's growth processes.

RESULTS AND DISCUSSIONS

In Figure 6 we present the daily degree of influence of temperature d_{infl} computed for 2023, with thin blue line, which shows values from 0.2 to 1 (for the Gaussian model) and from 0 to 1 (for the piecewise linear model). The thick blue line corresponds to the averaged degree of influence over a period of 13 days, which roughly corresponds to two weeks. The noticeable difference is for the beginning of the season, when lower temperatures are impacting in different ways the plant's growth. In Figure 7 we show the same comparison for the year 2024.

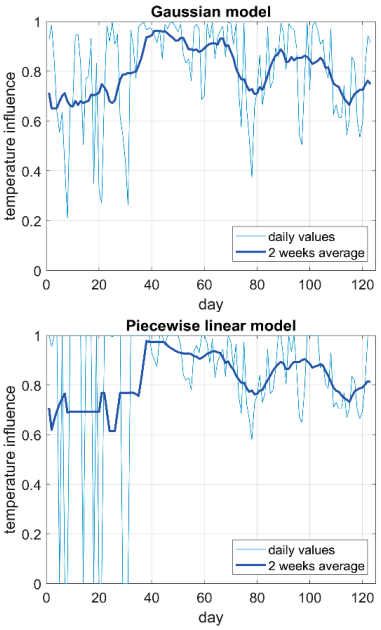

Figure 6. The degree of influence of temperature d_{infl} and for 2023. Gaussian (top) vs. linear (bottom)

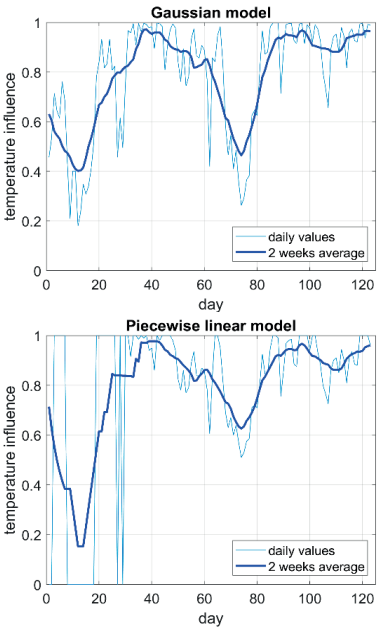

Figure 7. The degree of influence of temperature d_{infl} and for 2024. Gaussian (top) vs. linear (bottom)

In Figure 8 we show, for a qualitative comparison, the normalized filtered NDVI time series (in blue) and the normalized cumulated degree of influence of temperature *cum_d*$_{infl}$ (in green), when the Gaussian model is applied, the latter one being computed over three summation intervals corresponding to 1, 2 and 3 weeks. One can notice a good resemblance between the NDVI time series and the cumulated degree of influence. However, differences may be due to the fact that influence of other parameters (such as solar radiation, precipitations, or soil-related parameters, as well as the occurrence of diseases that may affect the plants) was disregarded in this study.

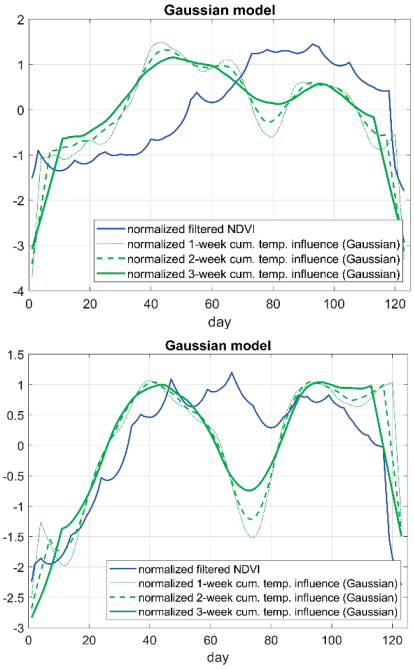

Figure 8. The normalized filtered NDVI time series (in blue) and the normalized cumulated degree of influence of temperature *cum_d*$_{infl}$ (in green), Gaussian case, for 3 summation intervals, for 2023 (top) and 2024 (bottom)

One may notice that the choice of the size of the summation interval has some considerable impact on the shape of the curve. The analysis results for both 2023 and 2024 are shown. The resemblance of the curves is higher for 2024.
The same comparison is presented in Figure 9 for the case when the linear model is used, for both 2023 and 2024. Again, the choice of the size of the summation interval has a relatively small impact on the shape of the curve and the similarity of the curves is, again, higher for 2024.

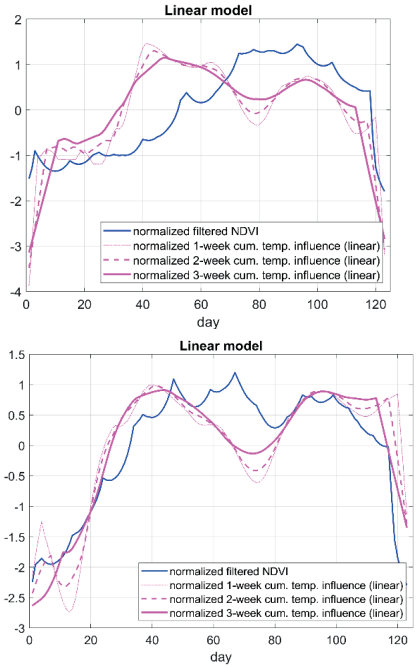

Figure 9. The normalized filtered NDVI time series (in blue) and the normalized cumulated degree of influence of temperature *cum_d*$_{infl}$ (in green), linear case, for 3 summation intervals, for 2023 (top) and 2024 (bottom)

Furthermore, we performed a comparison between the two models for the degree of influence of temperature (Gaussian versus piecewise linear). From a quantitative perspective, in Table 1 we show the values of the Pearson correlation coefficient ρ as a function of the choice of the length of the summation interval (N = 5, 7, 13 and 21 days) for the analysis performed for the 2023 crop, for the two cases – the Gaussian and the linear model. One can notice that the correlation coefficient increases with the increase of the summation interval, however the length of the interval should be chosen or determined to be pertinent to the plants' growth processes. The values, however, indicate a relatively weak correlation for the Gaussian model and slightly larger for the linear model. In Table 2 we show the same comparison for the analysis performed

on the 2024 potato crop. We see higher values of the correlation coefficient for the analysis of the 2024 potato crop, indicating a stronger correlation between NDVI and the temperature influence. Both for 2023 and 2024, the proposed piecewise linear model led to higher correlation. Figure 10 compares normalized NDVI (blue) with normalized cumulative temperature influence over three weeks, showing both the Gaussian (green) and linear (magenta) cases for 2023 and 2024.

Table 1. The Pearson correlation coefficient ρ as a function of the number of samples N (the length of the summation interval) for the crop in 2023

Cumulative sum over N =	5 days	7 days	13 days	21 days
Pearson correlation coeff. (Gaussian model)	0.3669	0.3907	0.4384	0.4573
Pearson correlation coeff. (Piecewise Linear model)	0.4770	0.4994	0.5416	0.5529

Table 2. The Pearson correlation coefficient ρ as a function of the number of samples N (the length of the summation interval) for the crop in 2024

Cumulative sum over N =	5 days	7 days	13 days	21 days
Pearson correlation coeff. (Gaussian model)	0.5613	0.5977	0.6934	0.7701
Pearson correlation coeff. (Piecewise Linear model)	0.7022	0.7357	0.8204	0.8745

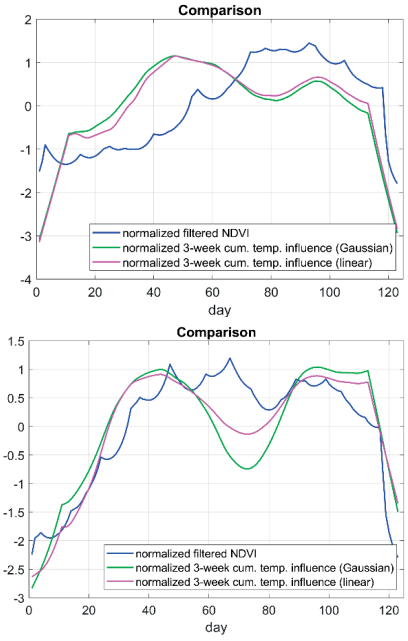

Figure 10. Normalized NDVI (in blue) and cumulated temperature influence over 3 weeks, for the Gaussian case (in green) and the linear case (in magenta), for 2023 (top) and 2024 (bottom)

One may notice that the difference between the Gaussian and the proposed piecewise linear models is better emphasized for the analysis performed on the 2024 data.

CONCLUSIONS

In this study we propose a model for the influence of temperature to the measured NDVI, as temperature is one determinant parameter for the plant growth processes. The proposed model is based on the hypothesis that the temperature has a certain degree of influence to the plant growth and that degree has, eventually, a cumulative effect on NDVI. We model the degree of influence of the temperature both as a Gaussian and a piecewise linear model. The proposed piecewise linear model better matches the observations made in the literature about the influence of temperature on the potato plant growth and vegetation status.

We show experimental results for a potato crop in Brasov area, Romania, in 2023 and 2024. The cumulated degree of influence curve showed good resemblance to the NDVI curve and the computed Pearson correlation coefficient between the two showed that there is significant correlation between the two times series. Differences, however, may be due to the fact that we did not consider in our study the influence of other parameters which have also an important role in the development of plants. The proposed piecewise linear model showed better performance compared with the Gaussian. As future work, we consider including in our study other parameters such as soil moisture, solar radiation, precipitations etc. In addition, given the correlation between NDVI and the proposed cumulative degree of influence, we consider assessing the causality between temperature and NDVI time series.

Abstract

While the technology in Earth observation and Surveying fields advances, it's possible to learn more information in less time. This research aimed to design a web application that provides useful information about the public monuments from Cluj-Napoca near the user's location. Users can fix their position on the map, define the range of interest, and identify the monuments on the web map. Also, they can find the best route to the touristic objectives, pictures of the monuments, and their history. To achieve these, we first retrieved the coordinates of the statues and monuments using the Mobile Topographer application. We included these coordinates and information about the studied objectives' history and type in a geodatabase. Secondly, we used ArcGIS Pro to obtain information based on the collected data, and a map was created. We created customized scalable icons for each studied monument type. Once data was analysed, it was uploaded into ArcGIS Online as a hosted feature layer based on which a web application was built. This application will be publicly accessible, without conditional on software licenses or the device used.

Key words*: ArcGIS, monuments, Satellite Geodesy, web application.*

INTRODUCTION

Romania has more than 50 historic towns (Bucurescu, 2018). Cluj-Napoca is one of the most notable Romanian historic towns due to its rich cultural heritage and architectural significance (Popescu et al., 2018). Its foundation can be traced back to the Napoca village from the Roman province, Dacia, which was elevated to the rank of municipality 1,900 years ago by the Roman emperor Hadrian (Pascu et al., 1974; Ropa & Ropa, 2017). In time, Cluj-Napoca was adapted to different ages and needs, and due to its distinctive structural and functional features, it became a very refined monumental cultural landscape with a strong identity and a space rich in cultural significance (Maroşi et al., 2019). The Ministry of Culture 2015 records listed 1,791 historical monuments in Cluj county (Romania's Ministry of Culture). Part of the cultural heritage, the statues and monuments, generically called in this paper 'monuments', are symbols of cultural identity, power, and remembrance, helping us understand who we are (UNESCO). Understanding the meaning of a place may improve the public perception of the authenticity of urban heritage (Garcia-Esparza & Altaba Tena, 2020).

Europe's economic growth is interconnected with culture and tourism (Dulau & Coros, 2005). Cultural tourism in urban areas represents the most dynamic aspect (Bucurescu, 2015). While in 2015 the tourist inflow to Romania was negligible compared to this country's significant number of UNESCO-listed heritage sites (Lupu C. et al., 2015), an increase in the number of visitors was reported in 2023 compared to 2019 (WTTC, 2024). In 2016, the tourism density recorded for Cluj-Napoca was almost two times higher than at the country level (Popescu et al., 2018). Prior research found that the presence of educational material enhances the experience of visiting a historic site and that the more easily accessible a location is, the more enjoyable it is to see a historical monument or statue (Cameron & Gatewood, 2000). One challenge associated

with this issue is that, while some locations are strongly linked to a specific historical event or period, others may lack such associations or be tied to multiple, overlapping narratives (Ries & Schwan, 2023). Furthermore, to foster public awareness and ensure the preservation of cultural heritage, it is essential to systematically document and visually present relevant information (Horbinski & Smaczynski, 2023). This highlights the growing need to assist potential visitors of Cluj-Napoca in connecting a monument's visual representation with its detailed description and precise geographic location through an interactive map. Recently, the expansion of information technology, especially mobile applications, and web platforms has enhanced tourist experiences by facilitating access to data needed by tourists to know the locations, distance to, and description of the monuments (Markhasi Rupilu et al., 2018). Digital documentation has transformed visitor interaction with heritage sites, enhancing education and surpassing user expectations (Comes et al., 2020). However, even if there exist some web applications for monuments in Romania, including Cluj-Napoca (e.g., Attractive Romania, Cluj Tourism App, Explore Romania - Official App, Monuments Romania, Cluj Now), the problem is that the list of monuments is very brief, hard to find, or no longer contains up-to-date information. Consequently, people who want to find information about the historical, cultural, and religious monuments in Cluj-Napoca will encounter great difficulties.

Monuments mirror Cluj-Napoca's historical evolution, offering visitors an emotional and enjoyable connection to the past (Ries & Schwan, 2023). Yet, without awareness of their historical significance, the psychological impact on visitors remains minimal (Ries & Schwan, 2023). To address the above-mentioned issues, needs, and problems, we aimed to design an interactive map with updated, detailed information about the monuments in public places of the Cluj-Napoca municipality, a map shareable as a web application and usable as a guide or information resource for all potential users. This agrees with the aim of cultural heritage organizations joining efforts to preserve and share information about our common heritage (Vilceanu et al., 2022).

The importance of our work in environmental engineering is emphasized by: the sustainable integration of cultural heritage in the urban landscape, using interactive mapping as a tool for informed spatial planning; awareness of the built environment like monuments, and improving tourism in Cluj-Napoca.

Some of the unique features that our web application offers to users are:

- precision and accuracy in mapping, by including the rectangular coordinates in our app, hence providing high-precision geographic information to users who need exact geospatial data, whether for academic, governmental, or navigational purposes;
- localized and in-depth focus on Cluj-Napoca, offering more detailed and accurate information about its public monuments;
- customizable user experience. The interactive map with dynamic search and navigation, enables the users i) to visualize monuments within a selectable area, which adds a dynamic, real-time mapping; ii) to choose their starting location, and the application automatically generates a route to the monument they selected; iii) to search a monument by its name;
- historical and contextual information about monuments, providing users with a richer educational experience that might help them learn about the cultural significance of each monument;
- friendly, with no special accounts required, making it more accessible and convenient for the users.

These features generate certain benefits of our web application, for example:

- serves tourists who want to navigate the city and learn about its historical context;
- facilitates public cultural awareness, giving users the possibility to understand the significance of the monuments in their urban environment and contributing to a sense of pride and deeper connection to local heritage;
- offers potential for future expansion, as the structure we created could turn into a scalable model for other places;
- it is free and open to the public, so tourists, locals, and anyone interested can access it without worrying about hidden costs, subscriptions, premium features, or login requirements.

The unique features and benefits emphasize the novel contributions of our web application compared to the existing solutions in the field.

MATERIALS AND METHODS

The list of monuments per county, issued in 2015 encompasses 33 historical monuments in the Cluj-Napoca municipality (Romania's Ministry of Culture). However, our study is based on the most comprehensive source relevant to this topic, which describes over 150 monuments (Ciorca, 2020). A study from 2015 indicated that 75% of existing monuments in Cluj-Napoca are concentrated in its historic centre, particularly in the Fortress of Cluj (Orban & Puiu, 2015). Monument selection followed the criteria in Figure 1, and the methodology involved six steps, as shown in Figure 2.

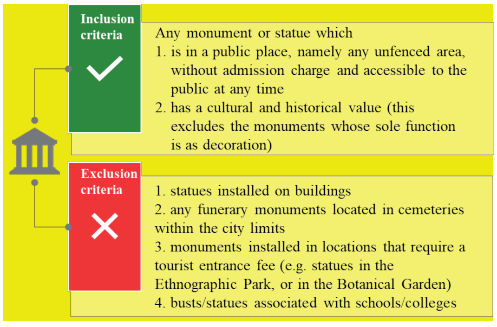

Figure 1. Monuments' selection criteria

Figure 2. Flow of the study steps
(Icons used in this diagram were freely downloadable from Freepik.com)

1. Collecting data on the monuments. These data fall into two categories: data on the location and data on the significance of the monuments. We obtained the data on the position of monuments using the procedures detailed in the next sub-section. The information on the monuments' significance was gathered from the main source document (Ciorca, 2020) and was entered into the database. The information conceptualization consisted of identifying information that could be represented as a map. Data on the monuments' chronology were also collected. For many of them, the information on the monument installation was incomplete, and often, only the year of origin was identified.

2. Determining the position of monuments. Given that monuments are located in urban environments, in areas with constant vehicular or pedestrian traffic, the conditions for determining rectangular coordinates by the resection method are not favorable, as often the sights from the station to the monument may be blocked by buildings, cars, or pedestrians. Thus, we decided to use satellite geodetics, specifically GPS determination of point coordinates using the Mobile Topographer application, running version 9.3.2., from a Samsung smartphone, model Galaxy A54 5G. In this application, we selected the Projection System Stereo 70 from the settings. Coordinate determination was performed by connecting to GPS constellations, Glonass, Beidou and Galileo, with access to an average of 25 satellites for each measurement. We stationed as close as possible to each monument for approximately 5 minutes to increase the accuracy of the measurements. The position determination procedure was repeated for each monument, on different days, due to weather and time factors. The coordinates were recorded in a database and organized in a Microsoft Excel file to facilitate the project's next steps.

3. Designing the icons. The icons we created represent in a very suggestive, visual way the type of monuments to which they correspond in the interactive maps and web application. We chose to generate these icons in the Inkscape software version 1.3.2. because the outcome is vector images, which maintain their resolution at different zooming levels. In the case of the icon for the monuments, the Carolina Obelisk was taken as a model. For the group of statues

icon, the Transylvanian School group of statues was taken as a model. The icons were drawn in such a way as to be recognizable and distinct from any distance. The created icons have a minimalist style so that their meaning is immediately apparent to any user without the need for written information.

4. Creating the monuments map in ArcGIS Pro. The geographic information system (GIS) was implemented using ArcGIS Pro version 3.3.0., projection system Pulkovo 1942 Adj 1958 Stereo 70. The Excel file with the monument's coordinates was added in the ArcGIS Pro, and using the XY table to point function, the points representing the monuments were materialized on the map. We then performed a visual classification by unique values and used the created icons to show each monument's location on the map and its type, symbolized by these icons. Due to the project's complexity, we used ArcGIS Pro to build the map layers that will constitute the hosted feature layer in the web map.

5. Creating the web map. We created a web map, using ArcGIS Online and based on the designed GIS. First, we exported the map layers from the project created in ArcGIS Pro. These map layers contain coordinate data for monuments. Exporting these layers as shape files greatly shortened the work that had to be done in the ArcGIS Online platform. Shapefiles exported from ArcGIS Pro were imported into ArcGIS Online as hosted feature layers. This web map and the project in ArcGIS Pro are intended for geodesy and cartography specialists.

6. Creating and publishing the web application. The web map created in ArcGIS Online platform was used to develop the web application, based on pre-established templates that can be accessed by selecting the 'create web app' option when inspecting a map. We illustrated the nearby function, generated a route to a monument, and searched a monument by its name. This last step of the process will use all the previous operations, with the final goal of creating a map that will serve as a guide for the monuments found in public places in Cluj-Napoca. The web application is for any user, regardless of the level of expertise or software available, and will run on any device without requiring an ArcGIS account or license.

RESULTS AND DISCUSSIONS

Based on the inclusion and exclusion criteria, 76 monuments were included in our study. Of these, 53 monuments (70%) were considered of great interest to future users of the interactive map and the web application, therefore, these were called 'main monuments', while the other 23 monuments were called 'secondary monuments'.

After performing the survey, the determined rectangular coordinates were organized in tabular form to facilitate input into ArcGIS Pro, along with other details like the location, the classification by type of monument, the date when it was installed, and the monument's author.

Table 1 summarizes the main monuments included in the study, with the related available details.

Table 1. Main monuments database

ID	Monument	X coordinate	Y coordinate	Location	Type	Installation date	Authors
1	Lupa Capitolina	586524.993	392629.182	on Eroilor Blvd, vis-a-vis of Greek Catholic Cathedral	M	29.11.2008	Ettore Ferrari

M = monument; RS = religious statue; SG = statuary group; B = bust; S = statue; NA = information not available.

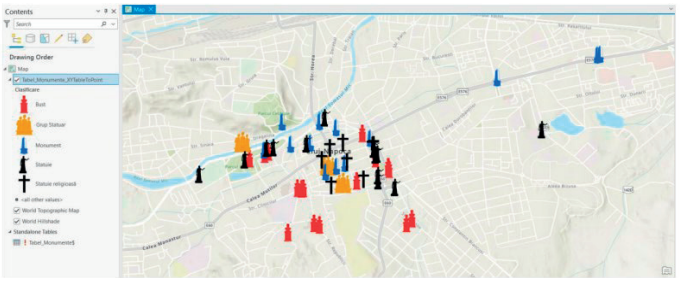

Figure 3. The map with the monuments' classification by type, symbolized by the icons we designed

After including the monuments' coordinates, we classified the monuments based on their types and added their visual symbols. The unique values representation mode from the Symbology section was used to create the point layer. Unique values were designated based on the Classification field in the Attribute Table, which had five values: bust, statue, statuary group, monument, and religious statue.

Figure 3 illustrates the map created in ArcGIS Pro and monuments classified by type, and visually represented by the icons we created in Inkscape. Monuments' classification by type was done according to the criteria specified in Table 2, which also shows the corresponding icon we created for each monument type. Once created, the icons were introduced into the project folder, where they could be accessed from the properties page of the Symbology tab.

Table 2. Monuments' classification criteria and the icons created for each monument type

Type	Classification criteria	Icon
Bust	any monumental installation depicting only the shoulders and head of the personality represented	
Statue	any monumental installation that reproduces in whole or in part, the body of the person represented	
Statuary group	any monumental installation representing several distinct personalities	
Monument	any monumental installation not representing any personality	
Religious statue	any monumental installation representing an ecclesiastical personality or Saints	

The purpose of these icons is to visually and concisely communicate the monument's type while enhancing the map's appearance.
After visual classification by unique values, the created layer was saved as a layer file in the Share ribbon.
Following the classification by unique values, we made a chart with the number and proportion of each monument type (Figure 4).

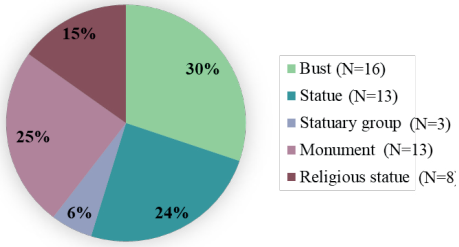

Figure 4. The proportions of various types of monuments out of the overall number of main monuments (N = 53)

The age of the monuments or the installation date, for some of the monuments in our study, is unknown. Since the analyses we performed required such information, we assigned a date, in the following way:

- for monuments with missing information about the day, but with data about the month and year of installation, we indicated the last day of the installation month;
- for monuments with data only on the year of installation, the day and month used in subsequent analyses is the 31st of December;
- for the monuments with no precise information on the installation or building date, we considered them to have been installed within the last three decades because of the available data suggesting this period. Consequently, they were not considered for the following analyses.

Two criteria were taken into account for this determination, i.e., the date of monument installation on its original site and the actual age of the monument, meaning from the day it was built until the present.
Based on the criteria considered, we concluded that the Carolina Obelisk (Figure 5), installed in Museum's Square in 1898, is the oldest monument in Cluj-Napoca. This monument honours the stay of the royal couple Emperor Francis I and Caroline Augusta in Cluj, in 1817. It was built south of the city's Central Square in 1831.
The monument classified as the newest one based on the same criteria, is the Statue of the Virgin Mary (Figure 6), in front of the Piarists' Church. This monument was considered the newest because the present statue is new, created in response to the excessive deterioration of the old statue, which is no longer displayed in public places, but is preserved in museum conditions, together with the original angels. The old statue, erected in 1774 as a sign of gratitude for the protection given to Cluj during the last great plague epidemic between 1738 and 1742, was also named the "Plague Column". The new statue, a faithful copy of the old statue, was installed in 2023, in front of the Piarists' Church, in the place formerly occupied by the old statue.

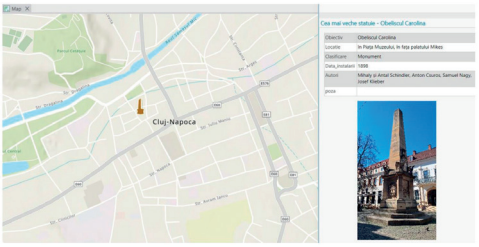

Figure 5. The oldest monument in Cluj-Napoca

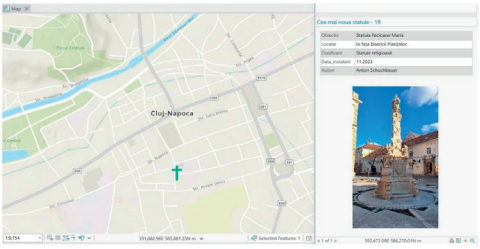

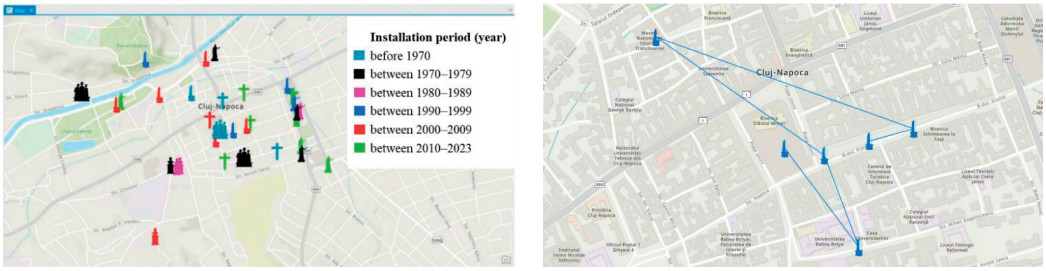

Figure 6. The newest monument in Cluj-Napoca

Another interesting analysis was on the number of monuments installed in the last decades and, of course, visualizing them on the interactive map. Monuments were grouped into ten-year periods according to the date of installation, with two exceptions: i) monuments installed before 1970 were grouped in the same category, because the quantity of these monuments is small and the periods between their installation are too long to justify creating separate categories; ii) monuments after 2010, which also includes statues installed until now. In Figure

7A we have overlaid the layers containing monuments from each defined period. The monuments in each layer have been colored according to the period in which they were installed.

Another analysis performed on the location of the monuments consisted in representing on the map the previous locations for the monuments if it was relocated over time. In Cluj-Napoca, infrastructure changes or construction and renovation of various buildings or parks occur frequently. These works may require moving monuments to facilitate the access of workers and machinery. Depending on the nature and form of the works, the site previously occupied by the monument may become unavailable and as such, it will be allocated a new site. In the case of very old monuments, the reason for their relocation may be war protection. Of the statues and monuments included in this paper, four have been relocated from their original installation site. These are the Statue of the Virgin Mary, Lupa Capitolina, the Carolina Obelisk and the statue of Saint George. Although previous analysis has revealed statues that have been relocated from their original installation site, the exact coordinates of previous monuments' locations are lacking. The only existing information verbally describes the previous locations, but this is not sufficient to represent the previous locations correctly on the map. As a compromise, the monuments' previous locations were marked manually, by placing nodes, which approximate the locations described verbally. The route of the monument's relocations was also marked on the map (Figure 7B).

A B

Figure 7. A. Analysis based on the time in which monuments were installed; B. Illustration of viewing on the interactive map the route of previous locations for the Lupa Capitolina monument

The web map development is an important step towards the project's aim, i.e., to create the web application.

With the shapefiles imported from ArcGIS Pro a map was created, containing two layers named 'Main Monuments' and 'Secondary Monuments'. The 'Main Monuments' layer (Figure 8) contains the monuments considered of major interest to future users.

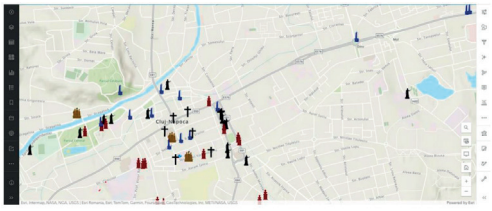

Figure 8. The layer with the main monuments

Monuments in the map layer called 'Secondary Monuments' are monuments that have a lower cultural and historical value. The criterion for classifying monuments as secondary was that their location was within the premises of higher education institutions. The secondary monuments' classification was done by creating a new field in the Attribute Table of the map layer. This field combined the values from the classification and membership fields to facilitate the use of unique value styles to represent them. Based on the unique values, the monuments were symbolized using the icons previously created and colored according to the institution they belong to. For example, in Figure 9, green is for the University of Agricultural Sciences and Veterinary Medicine, red for the University of Medicine and Pharmacy, and blue for Babes-Bolyai University. The web map is then ready to be transformed into a web application. In this

form, the map can be distributed and accessed by anyone wishing to enrich their knowledge of the monuments of Cluj-Napoca.

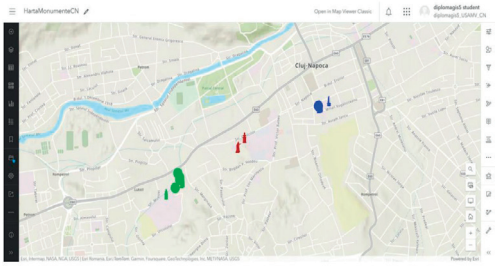

Figure 9. The layer with secondary monuments

Using the models made available through the Instant Apps function of the ArcGIS Online platform, a nearby application was created (Figure 10). This application allows the user to select his/her position on the map by tapping the screen or with a click, and the application will highlight all targets within a selectable radius. The nearby model was chosen because it fits with one of the project's aims, namely to help users discover statues they did not know about. After selecting the application type, we used the express configuration mode.

We set the minimum (100 m) and maximum (2 km) values of the selection area, designated the search sources (Main Monuments and Secondary Monuments layers in the web map), and left the theme-related settings as in the original configuration. We then added the legend and share button because, after configuration, the web application can be published and shared.

The first function of the application, conferred by the template used, is to highlight the monuments located in the selected area (Figure 10). We selected the maximum radius of the coverage area to cover several statues regardless of the point selected by the user.

Another useful feature of the created application is the ability to suggest a navigation route to a monument of interest (Figure 11).

To generate a route, the user chooses a starting position on the map surface. Then, the destination monument is chosen from the list and the route will be generated automatically. At this point, one can choose the traveling method and see an estimate of the time needed to cover the route (Figure 11).

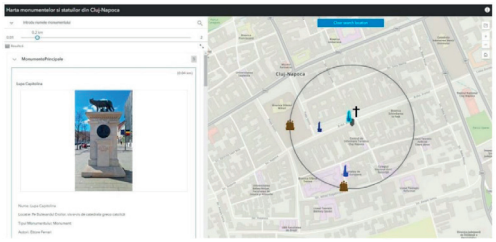

Figure 10. Illustration of the 'nearby' function in the web application

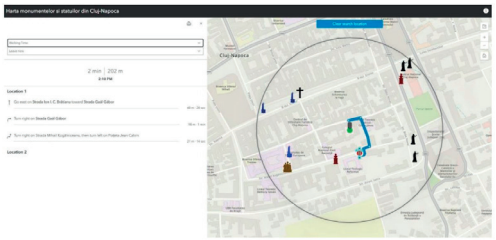

Figure 11. Example of a navigation route generated in the web application

There is also the possibility to search for a specific monument by its name. To do this, one should use the search box, which will present autocompleting suggestions for the name of the monument (Figure 12).

Figure 12. Illustration of the function that searches by monument's name

Selecting a monument on the map will display a list of the monuments in the selection area, where one can see the pop-up windows on the web map. These windows contain the monument's photo, location, type of monument, and information about its significance. The pop-up information has been selected according to its relevance to potential users (Figure 12).

For each monument in the defined proximity area, one can determine the route according to the traveling mode, by using the options included in the pop-up (Figure 13).

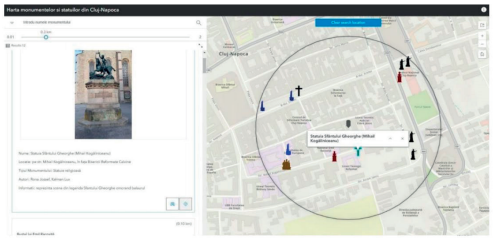

Figure 13. Example of a pop-up list, with information on the monuments

This application can be shared as a link, namely https://usamv-cn.maps.arcgis.com/apps/instant/nearby/index.html?appid=2db1f35fda164895bc87a534b321f9ab&center=23.6815;46.7911&level=13&hiddenLayers=1903b181a0a-layer-4

CONCLUSIONS

The monuments of Cluj-Napoca are numerous and indicate an abundant history, but most are unknown. We classified (as completely as possible) the monuments found in public spaces in Cluj-Napoca, more precisely, their location, type, history, and significance. Using our web application, it is possible to visualize the monuments within a selected area (with a selectable radius of the coverage area, ranging between 100 m and 2 km). In addition, users could also search for a monument by its name, and it is also possible to select the destination monument from the list, choose a starting position on the map surface, and the route will be generated automatically.

Gathering and integrating this data into a web application facilitated the dissemination of information about the monuments. The methods used in our study were effective. Determining the coordinates of the monuments by GPS with the Mobile Topographer application considerably shortened the measurement time. The ArcGIS software ecosystem also proved to be a powerful tool in processing the data needed to create the web application that may be a guide to the Cluj-Napoca statues and monuments.

The personalized route generation is a standout feature of our web app, particularly useful for visitors or those exploring the city.

Our interactive map (and the related web app) is similar to other web applications in that it provides non-experts without extensive training in GIS applications (Kydonakis et al., 2012). It represents a basic toolset to add value to the cultural heritage record and supplies topographic and cartographic information to show the monument's precise location and address (Kydonakis et al., 2012) being the most localized, user-centric, and comprehensive tool for exploring the historical monuments of Cluj-Napoca. Moreover, the costs implied to develop it are incomparably lower than for advanced measurement techniques and processing of the measurement data (e.g., laser scanning technology and low-altitude photogrammetry) (Horbinski & Smaczynski, 2023). Compared to the more general or broader apps available, our web app focuses on the city, interactive map features, ease of access, and detailed historical information. It is particularly valuable for anyone looking to navigate Cluj-Napoca's rich history, whether visiting or exploring their hometown in more depth, to enjoy the diversified offer of historical and cultural patrimony (Popescu et al., 2018).

In summary, we provide a tool that may educate and make the city more accessible and engaging for a wider audience, from history enthusiasts to casual explorers. By leveraging advanced mapping technology with comprehensive cultural insights, our study's results advance tourists' interaction with Romania's monuments, enriching the travel experience and contributing to the appreciation of Romania's vast heritage.

Abstract

Land use changes monitoring and predicting, as well as assessing their impact on carbon storage dynamics, play a pivotal role in addressing environmental challenges and ensuring effective land use management. This study aims to identify land use changes and their impact on carbon storage in the Marowijne district of Suriname from 2017 to 2024 and predict changes for 2034. Sentinel-2 images were used to analyze land change patterns and predict future trends. A hybrid approach combining Markov chain analysis, cellular automata, multilayer perceptron, support vector machines, and logistic regression was used to forecast future land use dynamics, while InVEST and YASSO models were utilized for carbon storage and sequestration predictions. The support vector machine-Markov chain hybrid model achieved an impressive accuracy of over 97%, outperforming other hybrid models. This model is recommended for generating land use change prediction maps, providing a crucial baseline for sustainable land use management. During the subsequent decade (2024-2034), the net loss of high-carbon areas is expected to intensify, affecting 15-20% of the district's territory. The identified spatiotemporal distribution of carbon storage provides valuable insights that will play a key role in achieving the objectives of Suriname's national green development strategy.

Key words: *land cover change dynamics, hybrid prediction models, carbon storage dynamics.*

INTRODUCTION

With significant impact on ecosystems and human lives, land use change is one of the major forces behind environmental and socioeconomic transformations. Analysing spatiotemporal patterns of land use and land cover (LULC) changes provides essential insights for sustainable land management and environmental conservation (van Ommeren-Myslyva et al., 2024; Devi & Shimrah, 2023; Girma et al., 2022). Understanding and managing land assets, natural resources, and environmental dynamics requires creating reliable LULC change predictive models (Song et al., 2020; Kafy et al., 2021). By providing valuable data on land potential and degradation risks, these models offer relevant and useful information on land suitability for various types of use or exploitation (Lambin & Meyfroidt, 2019; Aloqaili et al., 2021). Additionally, LULC modelling contributes to climate change mitigation by improving our understanding of carbon sequestration potential across different land cover types (Deng et al., 2020; Luo et al., 2021). Predicting land use change requires advanced methodologies that analyze historical data and observed trends to project future land cover patterns (van Ommeren-Myslyva et al., 2024). Several modelling approaches are commonly used, including statistical methods (Yeh & Liaw, 2021), Cellular Automata (CA) models (Muhammad et al., 2021), Markov Chain (MC) models (Mohamed & Worku, 2020), hybrid models (Asif et al., 2023), and multi-agent-based models (Robinson et al., 2021). Among these, hybrid models, which combine multiple predictive techniques to

leverage their respective strengths, have shown greater accuracy in forecasting future LULC changes. Suriname's forest ecosystems play a crucial role in global carbon dynamics, acting both as a major carbon reservoir and a significant net carbon sink. Between 2001 and 2023, these forests sequestered approximately 28.3 $MtCO_2e$ per year while emitting an average of 8.38 $MtCO_2e$ annually, resulting in a net carbon sink of -19.9 $MtCO_2e$ per year (Global Forest Watch, 2024). Land use and land cover are fundamental to carbon regulation, as changes in LULC deeply affect the capacity of ecosystems to store and sequester carbon (Sarathchandra et al., 2021). Suriname's ranking among the top three countries for High Forest Cover and Low Deforestation (HFLD) underscores its pivotal role in mitigating climate change. However, the ability of its forest ecosystems to store and sequester carbon is at risk due to changes in forest cover, whether from land conversion, land consumption, deforestation, or other land use and land cover alterations. To understand how these changes affect carbon storage, it is essential to evaluate carbon dynamics and predict the potential impacts on carbon budgets. This information is essential for creating land management plans that safeguard Suriname's forests and strengthen their ability to combat climate change. Marowijne – a district in Suriname – is facing increasing pressure on its land due to factors like urban growth, infrastructure development, and natural challenges such as a changing coastline and the impacts of climate change. To ensure the region's long-term sustainability and protect its natural environment, it's crucial to better understand these ongoing changes. Despite the clear occurrence of land use changes in Marowijne, there is a significant gap in studies that focus on detecting current trends, predicting future land use and land cover dynamics, and assessing the impact of land use changes on carbon storage and sequestration.

This study aims to achieve four interconnected objectives: (1) to collect and process geospatial data on land use and land cover; (2) to evaluate the accuracy and reliability of hybrid predictive models combining Markov chains with cellular automata (CA), multilayer perceptron (MLP), support vector machines (SVM), and logistic regression (LR) in predicting future land use changes within the Marowijne district of Suriname; (3) to develop a robust hybrid simulation model for forecasting LULC changes over the next 10 years; and (4) to project the spatial distribution of carbon storage and sequestration.

MATERIALS AND METHODS

Study area

The area of interest is Marowijne, a district of Suriname covering a total area of 4803 km^2, situated in the north-eastern part of the country. Geographically, Marowijne is located to the north between 4.0° and 5.95° N and to the west between 54.0° and 54.80° W mostly within the Young and Old Coastal Plains (only the southern and south-eastern parts are situated within the Savanna Belt and Interior Uplands), ranging from 35 below to 572 m above MSL. The district is divided into six administrative units (resorts), namely Galibi, Moengo, Moengo Tapoe, Wanhatti, Albina and Patamacca.

Figure 1 depicts the research area's location. The climate of the study area is tropical-equatorial (Af) according to the Köppen-Geiger climate classification. The soil cover is represented by Umbric Gleysols, Albic Plinthosols and Albic Arenosols according to the international soil classification system (WRB, 2014).

Datasets used. This study used three satellite image sets to analyze LULC change dynamics and build a predictive model (Table 1).

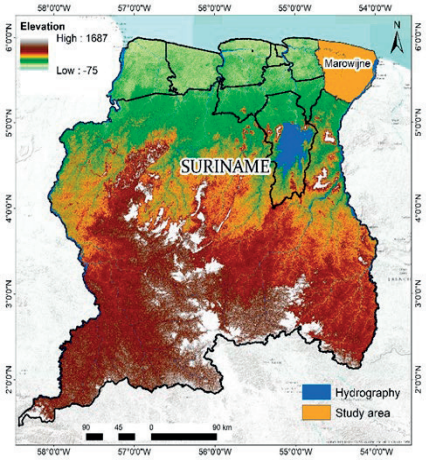

Figure1. Location of the study area

Table 1. Characteristics of data collected

Data	Source	Acquisition year	Scale/ Resolution
Multispectral satellite imagery	Esri Land Cover: https://livingatlas.arcgis.com/ladcover/	2017 2020	10 m
	Google Earth Engine Data Catalogue: https://developers.google.com/earth-engine/datasets/catalog/	2024	
Digital Elevation Model (DEM)	30-Meter SRTM Tile Downloader: https://dwtkns.com/srtm30m/	2018	1-arcsecond (3601x 3601 pixels)
Shape-file with locations of gold mining activity	National Environmental Authority: https://nimos.org/en/about-us/	2018	–
Shapefile with locations of deforestation areas	National Land Monitoring System of Suriname GONINI https://www.gonini.org/	2023	–

Slope, distance from water bodies (rivers and creeks), distance from roads, distance from gold mining and deforestation areas, distance from key settlements (growth poles), and population density datasets were developed individually in 2024 with a spatial resolution of 10 m. These datasets were processed in QGIS 3.34 and ArcGIS 10.8. The Euclidean distance function was employed to generate distance maps from roads, rivers, gold mining areas, and growth poles using vector data of the features (Kafy et al., 2021; Gharaibeh et al., 2020). The DEM was processed in ArcGIS Spatial Analyst tools to create elevation and slope maps.

Image classification. Sentinel imageries for the year 2024 were classified using the Random Forest (RF) classifier and Google Earth Engine (GEE) capabilities.

Random Forest is a non-parametric, multivariate technique known for its ability to handle high-dimensional data and multicollinearity effectively. It is also robust against overfitting and tolerant of suboptimal training data quality (Hemmerling et al., 2021).To evaluate classification accuracy, a random sample comprising 30% of the reference data for 2024 was used. The error matrix, generated in Google Earth Engine (GEE), included key metrics such as overall accuracy and the kappa coefficient (Congalton & Green, 1999; Lu & Weng, 2007). These metrics are widely recognized for measuring the agreement between the classification results and the validation dataset (Mhanna et al., 2023).

The bands 4–3–2 combination (true colour combination), bands 8–4–3 combination (false colour combination) and bands 12–11–4 combination were utilised to perform Sentinel-2 image classification.

A total of 5000 LULC reference data points representing various land use categories, including water, forest-covered and flooded areas, agricultural land, bare ground, built-up areas, and rangelands, were collected within the Marowijne district (Table 2).

Table 2. Major land use land cover types used and their descriptions

LULC class	Class description
Water bodies	Areas covered by rivers, streams, canals and reservoirs
Forest covered area	Landcover with primary trees, palm, and bamboo with a minimum crown tree cover of 30% with the potential to reach a canopy height of a minimum of 5 m and a minimum area of 1.0 hectares
Flooded area	Areas of any type of vegetation with obvious intermixing of water throughout a majority of the year; seasonally flooded area that is a mix of grass/shrub/trees/bare ground
Agricultural land	Includes areas used for perennial and annual crop production, irrigated areas, commercial farms
Bare ground	Includes land areas of exposed soil, bare soil and open areas consisting of sand, rocks and loam
Built-up area	Includes commercial areas, urban, residential, and rural settlements, industrial areas
Rangeland	Open areas covered in homogenous grasses with little to no taller vegetation; wild grasses with no obvious human plotting (i.e., not a plotted field)

Adopted from Karra et al., 2021. Retrieved from https://www.arcgis.com/

This data was derived from field surveys, expert knowledge, and high-resolution imagery from Google Earth Pro (https://earth.google.com/web). The dataset was then randomly split into two groups: 70% for training and 30% for validation (Aryal et al., 2023; Amindin et al., 2024). The training data were used to perform supervised classification, while the validation data were used to evaluate the accuracy of the resulting map (Sawant et al. 2023).

The classification performance was assessed by calculating key metrics, including overall accuracy, user accuracy, producer accuracy, and the kappa coefficient, based on the confusion matrix. The overall accuracy and kappa coefficient for the classified LULC map of 2024 were 90% and 84%. This indicates a reliable and accurate classification of image for analysing land use/land cover change. Figure 2 shows the statistical distribution of LULC classes for 2017, 2020, and 2024 within the area of interest.

Driving variables. Driving variables, also known as driving factors or drivers, represent various biophysical, socioeconomic, and infrastructural elements that influence land use patterns and the processes of land transformation over time.

Recognizing the need to incorporate the potential influence of independent variables in simulating LULC changes (Gharaibeh et al., 2020), this study considered eight key driving variables (Figures 3 to 6).

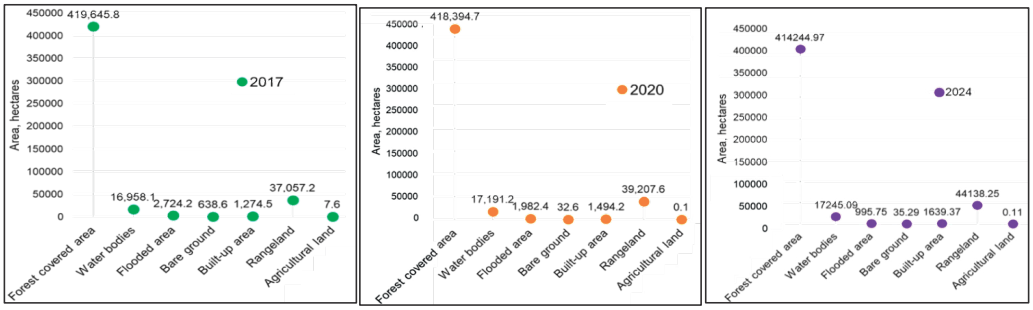

Figure 2. Area of LULC classes in Marowijne district for the years 2017, 2020, and 2024

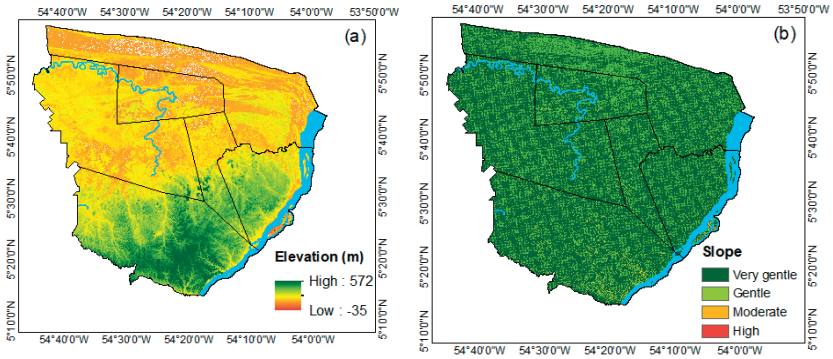

Figure 3. Biophysical driving variables: elevation (a) and slope (b)

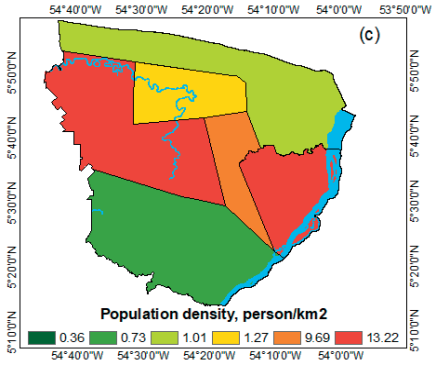

Figure 4. Socioeconomic driving variables: population density (c)

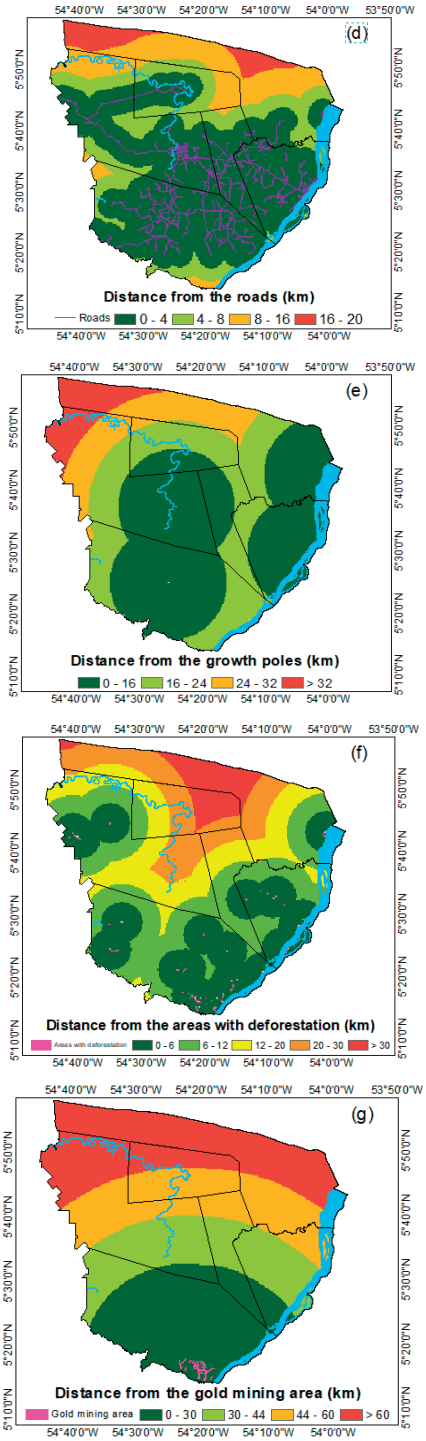

Figure 5. Proximity driving variables: distance from roads (d), growth poles (e), areas with deforestation (f) and gold mining area (g)

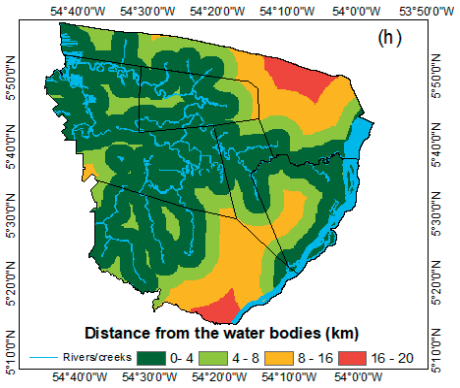

Figure 6. Proximity to water bodies (h)

InVEST model. The InVEST carbon pools model was used to calculate carbon storage and sequestrate potential of landscapes. The carbon storage module of the InVEST model assesses carbon storage using land use types as the units of measurement for the land surface. It can effectively evaluate the quantity and value of ecosystem services. The total carbon storage in the study area was estimated by multiplying the total area of different land types by their corresponding average carbon densities.

The InVEST model was utilized to analyze carbon storage and predict its spatial distribution based on simulated LULC in the area by 2034. The equations are as follows:

$$Ci = Ci_{above} + Ci_{below} + Ci_{soil} + Ci_{dead} \quad (1)$$

$$C_{total} = \sum_{i=1}^{n} Ci \times Si \quad (2)$$

where:

- i is the i-th land use type;
- Ci is the total carbon density of land use type i (Mg·hm^{-2});
- Ci_{above}, Ci_{below}, Ci_{soil} and Ci_{dead} are the aboveground, underground, soil, and dead organic average carbon density of land use type i (Mg·hm^{-2}), respectively;
- C_{total} is the total carbon storage (Mg); Si is the area of land use type i (hm^2);
- n is the number of land use types, with a value of 7 in this study (Maanan et al., 2019; Natural Capital Project, 2023; Li et al., 2023).

The carbon density values of the four carbon pools corresponding to different land use types are shown in Table 3.

YASSO Model. Due to the lack of local data about soil organic matter content the YASSO model (Yasso20) was utilized to assess the soil carbon pool within the study area. This model is a dynamic soil carbon model used to simulate carbon dynamics both in litter and soil organic matter.

Table 3. Biophysical data used in the InVEST carbon storage and sequestration model (unit: Mg/hm^2)

LULC class name	Above ground carbon pool	Below ground carbon pool	Soil carbon pool	Dead wood carbon pool	Data sources
Forest cover	155.34	35.91	27.5*	4.54	Eggleston et al., 2006; SBB; CELOS; CATIE; NZCS, 2017
Flooded area	44.41	10.66	26.55	2.9	
Rangeland	72.63	8.96	26.55	1.94	
Water bodies	0	0	0	0	CELOS; CATIE; NZCS, 2017; Zhang et al., 2019
Bare ground	0	0	0	0	
Built-up area	4.11	0.98	13.5	1.94	
Agricultural land	4.11	0.98	13.5	1.94	Dida et al., 2021; Natural Capital Project, 2023

* – value was estimated with YASSO model.

It predicts the decomposition of organic materials (like plant litter) and the resulting carbon storage and release over time. The model uses climate data (temperature and precipitation) and litter input data to estimate carbon fluxes and long-term soil carbon storage (Viskari et al., 2022).

LULC change detection and simulation. The Land Change Modeler (LCM) within the TerrSet software was applied to analyze and project future LULC changes in the study area. This data-driven, step-by-step approach included change detection, modelling transition potentials, and forecasting changes based on historical data from 2017 to 2020. A Markov probability matrix was employed to estimate the likelihood of transitions between LULC classes over time. Transition potential maps, representing the probability of land use transitions, were generated using a multi-layer perceptron neural network (MLP), support vector machine (SVM), cellular automata (CA), and logistic regression (LR).

Validation of model outputs. The validation process was conducted using the Validate module in the TerrSet software. This module calculated kappa statistics to assess the agreement between the hard prediction and reference map. The computed metrics included kappa for no information (K_{no}), kappa for grid cell-level location ($K_{location}$), kappa for stratum-level location ($K_{locationStrata}$), and kappa standard ($K_{standard}$) (Girma et al., 2022; Mishra et al., 2018). Generally, a strong and acceptable kappa value is considered to be around 80% or higher (Girma et al., 2022; Gharaibeh et al., 2020). For forecasting, the LULC maps from 2017 and 2020 were used as input variables to predict the 2034 LULC distribution. The LULC maps from 2024 and 2034 were utilized as input variables for the InVEST model to predict the 2034 carbon storage and sequestration. Figure 7 illustrates the modelling and validation processes employed in this study.

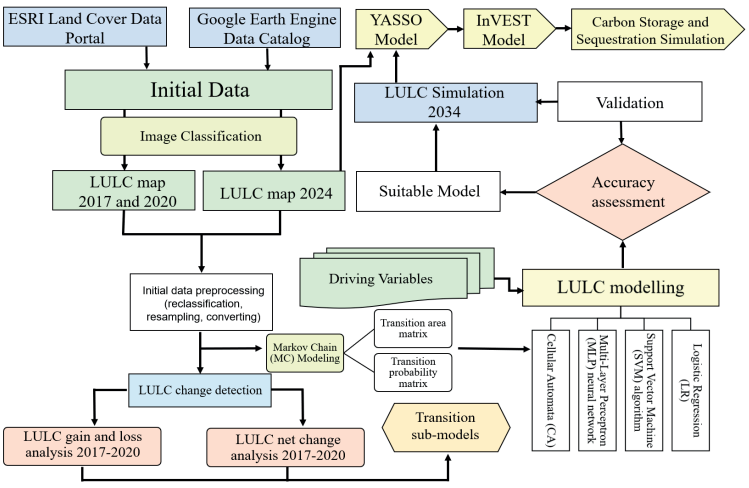

Figure 7. Research design flowchart

RESULTS AND DISCUSSIONS

To accurately predict future LULC trends over the next 10 years, it is pivotal to identify and comprehend past trends in land use and land cover changes (Girma et al., 2022; Regasa et al., 2021). The study area underwent notable landscape transformations and shifts in land use between 2017 and 2020, as shown in Figures 8 and 9.

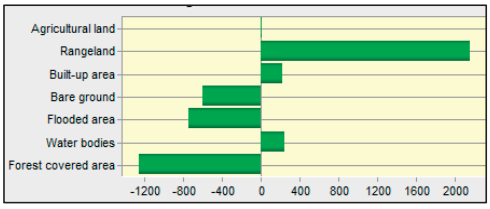

Figure 8. Net changes in LULC within the limits of Marowijne district between 2017 and 2020, hectares

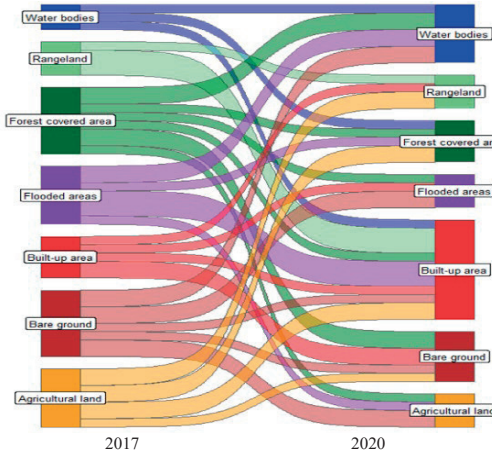

Figure 9. Sankey diagram of LULC classes mutual conversion from 2017 to 2020

A significant conversion of forest-covered areas into rangeland indicates ongoing forest loss, which may negatively impact biodiversity and carbon storage. Considering that over 86% of the district's territory is forested, logging and land clearing for commercial or subsistence farming have been the primary drivers of deforestation from 2017 to 2020.

A decrease in flooded areas suggests the drying or degradation of wetlands, which adversely affects water resources and ecosystem services. These changes are driven by altered hydrological cycles due to climate change, poor water management, and deforestation. The notable net increase in rangeland is primarily attributed to the reduction in forest cover and bare ground. Although built-up areas constitute only 0.3% of the total land in the Marowijne district, they have expanded significantly during the observed period, signaling the intensification of urbanization, particularly within established urban growth poles. The net change in water bodies is mainly influenced by shifts in forest cover and bare ground. The outcomes of the LULC change analysis serve as the foundation for constructing transition sub-models (Table 4). Based on these results, considering the most significant gains and losses for each land use class, seven sub-transition models were identified, the best of which was incorporated into the final predictive model.

This study employed biophysical, socioeconomic, and proximity-related driving variables to predict LULC changes. Before incorporating these drivers into the predictive model, their explanatory power was evaluated. Cramer's V was used to assess the strength of association, while p-values were applied to determine statistical significance (Table 5).

Table 4. Transition sub-models and their descriptors

Transition sub-model	Land cover transition	Description
Forest covered areas losses (FLO)	Forest-covered areas to rangeland, water bodies and built-up area	FLO sub-model describes the process of deforestation where forest areas are replaced by other land-use types such as rangeland, water bodies, or urban development
Forest covered areas gains (FGA)	Bare ground and flooded areas to forest covered areas	Represents reforestation or afforestation where non-forested areas like bare ground or flooded areas are transformed into forest-covered areas
Water bodies transformation (WAT)	Forest-covered areas, flooded areas, bare ground, built-up area and rangeland to water bodies	This refers to the conversion of land types such as forests, flooded areas, bare ground, rangeland, and urban areas into water bodies, often due to flooding or human interventions like dam creation

Transition sub-model	**Land cover transition**	**Description**
Flooded areas transformation (FAT)	Flooded areas to forest covered areas, rangeland and water bodies	Involves the draining or reclamation of flooded areas for conversion into forest, rangeland, possibly for agriculture or urban development
Bare ground transformation (BAT)	Bare ground to forest covered areas, flooded areas, water bodies, built-up areas and rangeland	Bare land transitions into various types, including forest cover, urban areas, or agricultural rangelands, driven by natural ecological succession or deliberate land-use planning
Urban expansion (UEX)	Forest-covered areas, flooded areas, bare ground and rangeland to built-up areas	Describes urban expansion, where natural landscapes like forests and rangelands are converted into residential, industrial, or commercial areas to meet the demands of a growing population within the key settlements
Rangeland transformation (RAT)	Rangeland to forest covered areas, flooded areas and bare ground	Involves the transformation of rangelands into forests or bare land, often resulting from land reclamation initiatives, degradation processes, or targeted reforestation efforts.

Table 5. Cramer's V and p-value for each of the explanatory variables

Driver variables	Cramer's V	p-value
Distance from deforestation	0.2363	<0.0001
Slope	0.2847	<0.0001
Elevation	0.3888	<0.0001
Distance from water bodies	0.3705	<0.0001
Distance from roads	0.3779	<0.0001
Distance from growth poles	0.4012	<0.0001
Distance from gold mining area	0.4026	<0.0001
Population density	0.4600	<0.0001

According to Eastman (2016), Cramer's V values above 0.15 are considered "useful," and values over 0.4 are seen as "good." In this study, population density stands out with the highest Cramer's V of 0.4600, making it the most important factor in explaining changes in land use. The distance from gold mining areas (0.4026) and from growth poles (0.4012) also show strong connections, suggesting that mining and urbanization play major roles in shaping land-use patterns. The proximity to roads (0.3779) and water bodies (0.3705) are somewhat important, reflecting how accessibility and water resources influence land changes. Elevation (0.3888) and slope (0.2847) show a moderate to strong link, emphasizing the role of terrain features in determining land use. While distance from areas of deforestation (0.2363) has the weakest association, it is still statistically significant. All variables are found to be significant predictors of land-use change (p-value <0.0001), with population density, proximity to gold mining, and growth poles having the strongest associations. On the other hand, elevation and slope appear to have the least impact. This analysis underscores the significant role of human-driven factors in land-use changes within the Marowijne district.

To find the most suitable transition sub-model, accuracy rates were calculated for each hybrid model and its respective sub-models. The performance of the LR-MC hybrid model was assessed using the ROC method (Myslyva et al., 2023). A summary of the accuracy assessment for various transition sub-models is provided in Table 6.

Table 6: Hybrid modelling approaches and their accuracy

Transition sub-model	Modelling approach accuracy rate (%)		
	MLP-MC	SVM-MC	LR-MC
FLO	78.95	85.33	72.50
FGA	81.34	91.49	75.20
WAT	64.63	71.50	59.80
FAT	63.97	78.36	57.45
BAT	69.77	73.64	65.30
UEX	92.66	97.14	87.50
RAT	79.45	88.66	73.80

The suitability assessment for various transition sub-models was not conducted for the CA-MC predictive model, as it relied on a transition areas file generated through Markov Chain analysis, which accounted for all-to-all transitions. However, due to the limited availability of historical data on LULC dynamics (covering the period from 2017 to 2020), this model was still selected to predict LULC changes. A model accuracy of 80% or higher is generally considered acceptable to validate training results (Gharaibeh et al., 2020; Silva et al., 2020). As a result, only the LR-MC hybrid model with the UEX transition sub-model, the MLP-MC hybrid models with the FGA and UEX transition sub-models, and the SVM-MC hybrid models with the FLO, RAT, FGA, and UEX transition sub-models met the suitability criteria for LULC

change prediction. However, the overall agreement between the actual LULC map and the CA-MC model-simulated map did not reach the satisfactory range. While previous studies report higher accuracy rates for MLP (Girma et al., 2022; Leta et al., 2021; Gharaibeh et al., 2020; Gibson et al., 2018), this study demonstrated that SVM is a more effective machine learning approach, offering a robust and flexible solution for LULC change prediction. SVM excels at handling complex, non-linear relationships between land cover and its driving factors, resulting in high accuracy. The superior performance of SVM can also be attributed to its ability to work effectively with smaller datasets (Myslyva et al., 2024), such as the limited four-year dataset used in this study. This higher accuracy is reflected in the SVM-MC model, as shown by the parameters in Table 7.

Table 7. Model parameters and accuracy

Parameter	Value
Modelling approach	SVM learning algorithm
Sub-model	Urban expansion (UEX)
Kernel type	Radial Basis Function
Epsilon (ε)	0.0100
Class number	8
Total cross-validation number	272
Total sample number	2272
Overall cross-validation accuracy	0.9714
Overall out-of-sample accuracy	0.9751
Overall skill measure	0.9503

To validate the model, the Kappa statistic (k- index) for quantity and location was computed by comparing the hard simulation with the reference map of 2024 (Table 8).

Table 8. The k-index values of the simulated LULC map of 2024

Index	Value
K_{no}	0.9824
$K_{location}$	0.9848
$K_{locationStrata}$	0.9848
$K_{standard}$	0.9723

The statistics reveal that all kappa index values surpass the satisfactory range (≥ 80%). The overall disagreement between the reference and predictive maps is generally low, primarily attributed to allocation errors (0.0083) rather than quantity errors (0.0071). Despite the presence of allocation errors, the overall agreement between the actual and simulated maps is high, reaching 98.47%.

The developed model was then used to predict future land use changes during next 10 years under the business-as-usual scenario. Figure 10 illustrates the LULC predictive map for the year 2034 and Figures 11 and 12 depicts the transformations in LULC classes between 2024 and 2034.

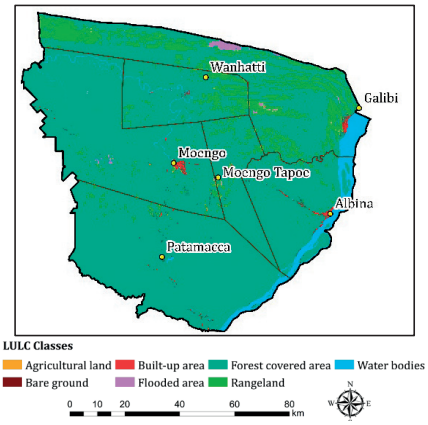

Figure 10. Projected LULC map for the territory of the Marowijne district for 2034

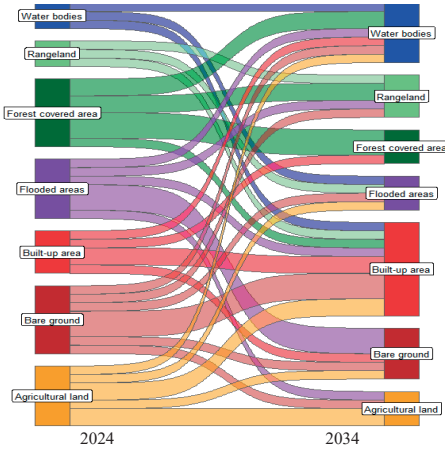

Figure 11. Sankey diagram of LULC classes mutual conversion from 2024 to 2034

The prediction of LULC changes over the next decade offers key insights into how carbon storage and sequestration might be impacted within the area of interest. Between 2024 and 2034, forest-covered areas, essential for storing carbon, are expected to increase slightly by 3,332.39 ha, which could contribute modestly to carbon sequestration. On the other hand, the

significant decrease in rangeland (about 5300 ha) could reduce its ability to act as a carbon sink, especially if these areas are converted to built-up spaces.

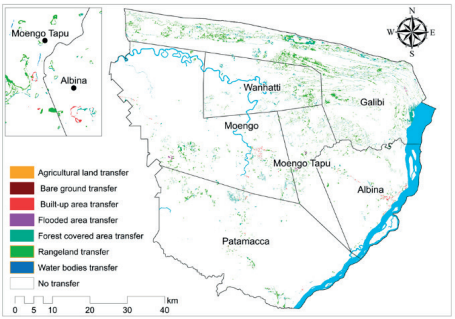

Figure 12. Areas where land use types will change from 2024 to 2034

Urbanization, with built-up areas expanding by about of 1000 ha, will likely lower the carbon sequestration potential as vegetation gives way to impervious surfaces. The rise in flooded areas (also about 1000 ha) could also affect carbon dynamics, as wetlands can either store carbon or release methane, depending on the type of flooding and vegetation. The small reduction in bare ground (-4.64 ha) and minimal changes in agricultural land and water bodies are unlikely to significantly impact carbon storage. Overall, these shifts highlight the complex relationships between land use changes and carbon balance.

The modelling results revealed the spatial and temporal dynamics of carbon storage and sequestration in the Marowijne district from 2017 to 2034 (Figures 13 and 14).

In 2017, areas with high carbon storage (1.8–2.23 MgC/pixel) made up around 40–50% of the district, while those with moderate storage (1.35-1.79 MgC/pixel) covered about 30–40%. Low-storage areas were relatively rare. By 2024, the high-carbon storage areas had decreased to roughly 30-35%, and the moderate storage areas expanded to 40-50%. At the same time, low-carbon storage areas (0.46-0.89 MgC/pixel) will began to spread, covering around 15-20% of the district. Looking ahead to 2034, the high-carbon storage areas are expected to shrink further to 20-25%, while both low and moderate storage areas will likely cover about 25-30% and 50-55%, respectively.

Between 2017 and 2024, reductions in carbon storage affected about 20-25% of the district, primarily in coastal zones and areas around Albina and Moengo. Increases in carbon storage were limited to less than 5%, reflecting localized improvements likely due to afforestation. During the subsequent decade (2024–2034), reductions in carbon storage are expected to intensify and spread to broader areas, particularly in central and coastal zones, affecting 15-20% of the district and focusing on already degraded areas. Only a few areas (under 3%) are projected to exhibit increases, further highlighting a net decline in carbon sequestration potential within the limits of the study area.

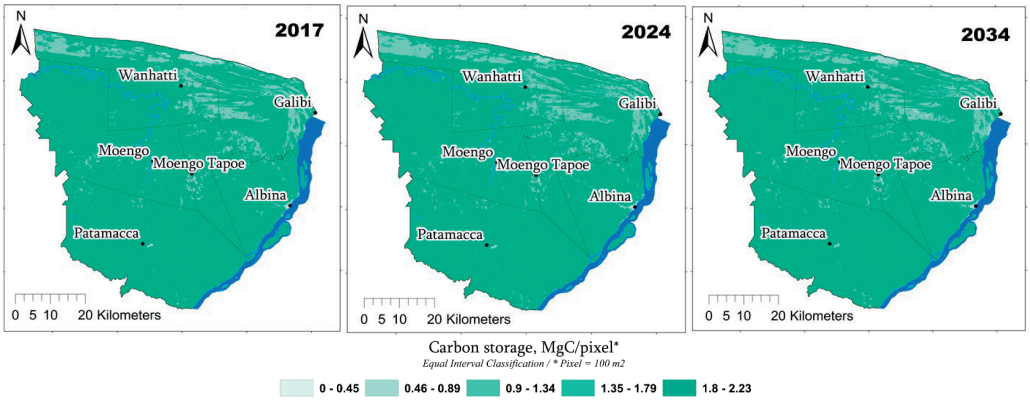

Figure 13. Dynamic of carbon storage and sequestration in Marowijne district

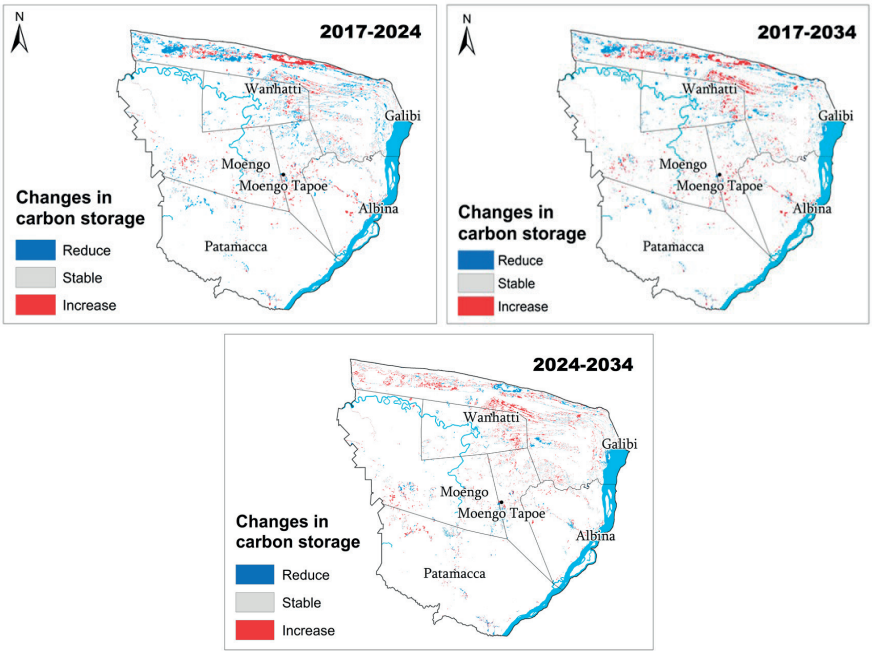

Figure 14. Change areas of carbon storage and sequestration in Marowijne district

Coastal and settlement areas, such as Albina and Moengo, are expected to experience the most significant losses in carbon storage, with reductions impacting 30–35% of the district by 2034. The net loss of high-carbon areas (~15–25%) between 2017 and 2034 reflects intensifying anthropogenic pressures and underscores the urgent need for effective land-use management strategies.

CONCLUSIONS

The transformation of land use and land cover (LULC) in the Marowijne district of Suriname from 2024 to 2034 was simulated using four hybrid predictive models: Markov chain analysis with cellular automata (CA-MC), multilayer perceptron (MLP-MC), support vector machines (SVM-MC), and logistic regression (LR-MC). This research utilized a combination of dependent (driver) and independent spatial datasets, analyzed through both statistical and graphical methods. Eight biophysical, socioeconomic, and proximity variables were identified as the primary drivers of LULC change. Based on the land use change analysis and the most significant gains and losses for each land use class, seven sub-transition models were developed. Among these, the urban-expansion model was selected as the most appropriate for inclusion in the final predictive model.

Accuracy assessments revealed that the SVM-based model, which incorporated the UEX transition sub-model for transitions such as the conversion of forest-covered areas, flooded areas, bare ground, and rangeland to built-up areas, achieved an overall accuracy of 97.14%. While previous studies indicated higher accuracy for MLP models, the SVM model proved superior in this study due to its robustness with small datasets and its ability to effectively handle high-dimensional data. The reliability of the SVM model was further confirmed by a Kappa statistic of 98.47% for predictions in 2024.

Using the business-as-usual scenario, future LULC changes for 2034 were forecasted. The model predicts a slight increase in forest-covered areas, a significant reduction in rangelands, expansion of built-up areas, and an increase in flooded areas. These trends underscore the intricate interplay between human activities and environmental factors,

highlighting the urgent need for sustainable land management practices.

The expected decline in carbon storage suggests a decrease in carbon sequestration, which could have negative effects on both climate regulation and the overall stability of ecosystems. To counteract this loss, it's crucial to implement strategies like reforestation and more stringent land-use policies.

Given the unique characteristics of different resorts in Marowijne, future research should aim to create more specific predictive models that take into account the particular driving factors of each separate resort. This would improve the accuracy of LULC predictions and support more focused, effective land management practices.

Abstract

Land fragmentation is a phenomenon that affected Western Europe in the past and, starting from 1989, the countries of Eastern Europe. One of the ways in which the effect of land fragmentation can be diminished is the process of land consolidation. Through land consolidation, owner can get better shaped parcels that can help increase agricultural productivity. Using the existent literature in the field of land consolidation, this exploratory study proposes a series of factors for land evaluation for the land consolidation process. These factors are applied in Saschiz administrative unit in Romania using different type of data to calculate the score for each factor. The result shows how this framework functions in real conditions.

Key words*: systematic land registration, cadastre, operations, processes, cadastre.*

INTRODUCTION

Climate change and the growth of world population are challenges that have pushed decision makers around the globe to look for policies for a more efficient use of land and its soil. This must be done in a sustainable way to improve the use of its resources and systems (Mihailescu & Cîmpeanu, 2019; Coman et al., 2016). Subsistence agriculture cannot anymore feed the growing population of the world. There is a need for extending the arable land areas, sustainable land use and increase of farm yield (Nsabimana et al., 2023; Moteva, 2016).
Attaining food security by increasing agricultural productivity can make possible the achievement of the 17 Sustainable Development Goals and its 169 associated targets as defined by the United Nations. One of the ways in which land professionals can contribute to goals like: gender equality, increasing agriculture productivity or sustainable use of freshwater is by using the process of land consolidation that can reduce land fragmentation and increase agricultural output (Veršinskas et al., 2020; Hartvigsen, 2015).
Land fragmentation is a problem that increases production costs in agriculture, inefficiency and land abandonment (Di Falco et al., 2010; Latruffe & Piet, 2014). Eastern Europe has had the problem of land fragmentation after the anti-communist revolutions from 1989 when property started to return from state ownership to private ownership (Șuba et al., 2019; Sabates-Wheeler, 2002; Van Dijk, 2003). However, not in all these countries land reforms conducted in the 90s had the same effects. Baltic countries, Slovakia or the Czech Republic have a much less fragmented ownership than Romania or Bulgaria (Van Dijk, 2005; Van Holst et al., 2018), due to different ways in which the land was given back to the owners.
Romania is the country that has been affected the most by land fragmentation. According to (Eurostat, 2022) one third of the farms in existence in the EU are in Romania, more than twice than in Poland that is the next country in the classification. The problem does not only consist in the number of farms in existence, but also in the size of the farms. Over 90% of them have sizes that are less than 5 hectares

(Eurostat, 2022). This fragmentation is mainly caused by the land reforms conducted in the 90s. Through successive inheritances the land was split between the heirs, in accordance with the existent rural traditions (Rusu et al., 2002).

To counteract the effects of land fragmentation, most countries have implemented land consolidation projects (Hartvigsen, 2014). In this landscape, Romania is an exception. There have been few attempts to implement land consolidation projects in the country. None of these projects ended with a redistribution of parcels. The problems that have been signalled by different authors refer to lack of specialized institutions, legislation and the fact that land registration in Romania hasn't been finalized (Blenesi-Dima, 2010; Ciobanu, 2021; Dima et al., 2007; Păunescu et al., 2024).

This paper aims to provide a framework for evaluating land in the process of land consolidation for projects that may be developed in Romania in the future. The factors for evaluation of land in the land consolidation process will be taken from the existent literature regarding the subject and adapted to the specificities of the country. The land evaluation factors will be tested by applying them in a study area containing 766 parcels, in the Saschiz administrative unit from county Mures, Romania.

In the first section of this research, the literature concerning land fragmentation, land consolidation and land evaluation for land consolidation processes is analysed. In the second section, the methodology of the study is described in detail. In the third section, the factors for evaluation are determined from the existent literature and are applied in the study area. The fourth section of the study contains the conclusion of the research.

1. Land fragmentation

Land fragmentation is a sign of an underdeveloped agricultural system (Teshome et al., 2016). The effect of land fragmentation is less income for farmers and waste resources in agricultural production (Mert et al., 2023; Rashidpour & Azar, 2016). For (Ntihinyurwa et al., 2019) land fragmentation can be considered when: "more than 10 users are in 10 hectares, the average parcel is less than 1 ha, more than 50% of the owners have more than 2 parcels with irregular forms located in more than two different places more than 500 meters from home with more than two uses, land is fragmentated because of inheritance laws, land sharing or land redistribution". On the other hand, several authors have underlined some advantages that land fragmentation can provide in some instances. Having different parcels in different areas with different land use can constitute a form of protection against environmental changes and increase food security (Chigbu & Kalashyan, 2015; Van Hung et al., 2007). Regular shape parcels may not be appropriate where there are natural limits. Moreover, (Delgado, 1998; Bezus & Samofal, 2019) affirm that in some cases family farms can be more productive than large scale agricultural exploitations. However, contradicting these affirmations (Agarwal, 2010) and (Ruben & Lerman, 2005) show that group farms can mobilize more resources in a more efficient way, while (Sabates-Wheeler, 2005) talk about the increase agricultural output that group farms have.

2. Land consolidation

Land consolidation has been a tool implemented in many countries in Europe and Africa for a more efficient land management and sustainable development of rural areas (Demetriou, 2016). The result of the reallocation of land is parcels with better dimensions and shapes (Sklenicka, 2006).

Land consolidation represents an efficient instrument for agricultural development helping farmers to have less, bigger, better shaped parcels and proposes measures to adjust terrain parcel configuration (Akdemir et al., 2024). Land consolidation is designed to counteract the effect of land fragmentation, but its purpose goes further, involving complex social and economic reforms (FAO, 2007). Land consolidation is applied in the case of disparate parcels and represents a repositioning of the spatial location of the private ownership in order to form new land ownership that contain one or as less parcels possible with the same or higher value than the initial ones (FAO, 2007). In this process no owner should lose (Oldenburg, 1990). In a European context, land consolidation consists in "rearrangement and/or putting together of different, distributed

plots; removal of terraces and defiles; construction of rural roads; restructuring of local streams; and soil improvement" (Bronstert et al., 1995). However, in many countries, land consolidation has remained oriented to agriculture. This can be seen mostly in countries in Eastern Europe and East Asia where land consolidation is more concerned with the agricultural aspects of the process than with land improvements (Gorgan & Bavorova, 2022).

For (Louwsma et al., 2022) there are four types of land consolidation:

- Voluntary land exchange. It is the simplest type of land consolidation and implies voluntary exchanges of parcels between owners. The size and shape of parcels hardly change.
- Voluntary land consolidation. It is also based on the voluntary participation of the people but has a more systematic approach and it is coordinated by the authority. Improvements may be done on a small scale.
- Majority based land consolidation. It is based on the consent of the majority of the landowners and is done in a systematic way. Medium to large scale improvements is possible.
- Mandatory land consolidation. Land consolidation is decided by a public authority. Besides the redistribution of parcels there are a lot of improvements that are implemented.

In short, the process of land consolidation consists of the following steps (FAO, 2003; FAO, 2007):

- Initiation of the land consolidation project.
- Design of the project or the feasibility study in which the cost-benefit analysis is conducted, and the area is chosen.
- Inventory of the existing situation in which the legal rights for every parcel must be determined and an evaluation of land is conducted.
- Elaboration of the land consolidation plan in which the preferences of the owners are considered, and the parcels are relocated and reallocated in accordance with the evaluation conditions.
- Implementation of the land consolidation plan.
- Concluding phase in which the cadastral map is actualized with the new formed parcels, the owners are compensated for eventual loses and the new legal situation is established.

For the process of land consolidation to be applied with success, the cadastral situation of all land in the area must be clear. Information in the land administration system is diverse and can contain data concerning: the ownership, the location of parcels, the legal status of the parcels, land use and other data (Constantin et al., 2015). Without it, it is very difficult to apply the land consolidation process.

3. Evaluation of parcels in the land consolidation process

The process of land consolidation needs to have a type of land evaluation. There are two types of land evaluation that can be applied (Demetriou, 2016):

- Evaluation that reflects land productivity and soil quality that can be expressed in a form of a score for every parcel.
- Land market evaluation that is done to find out the monetary value of every parcel according to the traditional evaluation standardized methods.

In land consolidation, market-based valuation is often less relevant, as farmers tend to prioritize agricultural productivity over potential sale value. Consequently, Van Dijk (2003) considers agricultural output and soil quality as the key evaluation factors. However, Demetriou (2014) notes that these criteria are applicable mainly in extra-urban areas where construction is prohibited. Several factors are considered when assessing agricultural productivity for land consolidation, each assigned a specific weight. The weighted scores are summed to determine the overall value of each parcel. For Wyatt (1996) factors can be of four types: physical, legal, locational and economic. Branković et al. (2015) indicate that land evaluation in Serbian land consolidation projects considers soil fertility, climate conditions, and economic factors, while Tezcan et al. (2018) propose a broader approach with at least 14 evaluation factors (Table 1).

Table 1. Factors of land evaluation proposed by several authors

Demetriou, 2018	Tezcan et al., 2020	Ertunç & Uyan, 2022	Asiama et al., 2018	Ertunç et al., 2021	Wyatt, 1996
Factors of evaluation	Factors of evaluation	Factors of evaluation	Factors of evaluation	Factors of evaluation	Factors of evaluation
Size of the parcel	Parcel area	Area of parcel	Land tenure	Size of parcels	Size of the parcel
Shape of the parcel	Parcel share situation	Shape of the parcel	Proximity to town square	Soil fertility	Shape of the parcel
Slope of the parcel	Parcels adjacent to agricultural areas	Share statue of parcel	Road access	Slope	Slope
Elevation	Existing land use	Soil fertility of the parcel	Soil quality	Market value of the parcel	Elevation
Aspect	Fixed facility	Distance of the parcel from the village centre	Parcel shape	Distance to village centre	Land tenure
Stream	Zoning situation of agricultural area	Distance of the parcel to the road	Proximity to main road	Distance to water source	Soil type
Soil type	Distance to the district centre	Distance of the parcel to the water source	Slope	Distance to main road	Soil quality
Access (through different kind of roads)	Distance to a highway	Economic value of the parcel	Land use	Accessibility to main road	Distance to main road
Distance from the main road to the motorway	Availability of agricultural drainage system	-	Soil type	Parcels near the river edge	Distance to town square
Land use	Distance to natural resources	-	Elevation	-	Access to national/regional road
Irrigation	Availability of electrical power	-	-	-	Access feeder roads
Sea view	Proximity to forest	-	-	-	Access to other roads
Distance from residential zone	Presence of historical resources	-	-	-	Land use
	Status of state support	-	-	-	-

Each evaluation factor is assigned a score, and the sum of these scores determines the parcel's overall value in the land consolidation process. These scores are typically weighted based on the relative importance of each factor, with weights ranging from 0 to 1 or 0 to 10. While some researchers, like Zhou et al. (2017), emphasize soil quality, others prioritize factors such as area or shape. Alternatively, Asiama et al. (2018) suggest that equal weights can be used or adjusted based on landowners' preferences.

MATERIALS AND METHODS

1. Paradigm of research

Researchers generally operate within two main paradigms. The **positivist paradigm** views reality as objective and measurable through scientific methods (Park et al., 2020; Kaboub, 2008), aiming for objectivity and broad generalization (Firestone, 1987). In contrast, the **constructivist paradigm** sees reality as socially constructed, shaped by individuals' experiences, interpretations, and contextual influences (Adom et al., 2016; Alharahsheh & Pius, 2020).

This study, focused on land evaluation in the land consolidation process in the Saschiz administrative unit, adopts a predominantly constructivist approach. While it incorporates statistical methods aligned with positivism, the overall perspective reflects constructivist principles. These paradigms are not mutually exclusive but rather represent ends of a methodological spectrum, allowing researchers to draw from both as needed to explore complex realities (Morgan & Smircich, 1980).

2. Methodology and methods

Given the limited coverage of this research area in Romanian literature, legislation, and practice, the study adopts an exploratory approach, drawing on both positivist and constructivist paradigms. The methodology is predominantly qualitative and is structured as a case study focusing on a real-world context (Yin, 2009; Anderson, 1993). The study analyzes 766 parcels located in the Saschiz administrative unit, Mureș County, Romania. As such, the findings are context-specific and not intended for generalization.

The first method employed was content analysis, which involved a critical review of literature on land evaluation in consolidation processes, recognizing that texts are shaped by their social and contextual background. Content analysis, defined as "a method of analysing written, verbal or visual communication messages" (Cole, 1988), allows for categorizing terms or phrases with shared meanings (Cavanagh, 1997). From this analysis, a framework of evaluation factors relevant to the study area was developed.

In addition, statistical methods were used to assess each land evaluation factor - parcel shape, size, location, road accessibility, slope, flood risk, legal restrictions, irrigation, and soil quality - with results expressed in percentages and scores. Two software tools supported the analysis: "Reparcelare", developed specifically for land consolidation projects, and Global Mapper 18.1, a GIS application. These tools were used to calculate scores for each factor, as detailed in Table 2.

Table 2. The data use for calculating each factor

Factor	Application used	Data used	Explanation
Shape of the parcel	Reparcelare	Secondary data: data existent in the cadastral database	The application "Reparcelare" calculated automatically the score of each parcel based on the number of sides and the preset intervals
Surface of the parcel	Reparcelare	Secondary data: data existent in the cadastral database	The application "Reparcelare" calculated automatically the score of each parcel based on the preset surface intervals
Location of the parcel	Reparcelare	Secondary data: cadastral geodatabase with the location of each parcel	The application "Reparcelare" calculated automatically the distance to every parcel and calculated the score according to preset intervals
Accessibility to roads	Reparcelare	Secondary data: the location of the roads and the parcels from the cadastral geodatabase	"Reparcelare" calculated automatically the surface of road that the parcel has access to
Slope	Global Mapper Reparcelare	Primary data: Digital Terrain Model from aerial pictures. Secondary data: position of the parcel from the cadastral geodatabase	From the DTM, slopes were calculated automatically in Global Mapper for every parcel. The values of slope were introduced in application "Reparcelare" and intervals were preseted. The application calculated the score for every parcel
Legal restrictions	Reparcelare	Secondary data: textual data from the cadastral database	The application "Reparcelare" calculates automatically the score based on the type of restrictions
Irrigation	-	There is no data concerning irrigation in the area	-
Flood risk	Global Mapper Reparcealare	Primary data: DTM from aerial pictures Secondary data: historic data concerning the level of water overflow position of the parcel from the cadastral geodatabase	Based on the DTM an overflow of water was simulated to see the parcels that are affected by flood. Depending on this risk, intervals were preset in the application "Reparcelare" and the score was automatically calculated
Soil quality	Global Mapper Reparcelare	Secondary data: Pedologic map of the area georeferenced in Glaobal Mapper The values representing soil quality were introduced in "Reparcelare" application that calculates the score for each parcel	

3. Limitations

The premise of the study was that this was a voluntary land consolidation process in which all the owners agree with the project proposed and no litigations regarding the use of land exists. In practice, situations of conflict may arise. These situations were not considered for this study.

There are limitations concerning the use of research paradigms. Constructivist's methods and methodologies have a high degree of reliability, but they cannot be generalized. The lack of generalization has led authors like (Liu & Matthews, 2005) to affirm that "where no absolute truth, any truth exists is good as the other". However, the constructivism paradigm compensates with a high degree of reliability because of the small samples used. The findings are restricted only to that case and cannot be generalized.

There is no legislation in Romania concerning land consolidation. In this study, no legal obstacles were considered in the process of land evaluation for the land consolidation process. In the eventuality of such evaluation in practice, the legislation, if existent, must be considered.

RESULTS AND DISCUSSIONS

1. Evaluation factors

Taking into consideration Table 1, it can be observed that there are several features that are common for most authors in designing any process of land evaluation for the land consolidation process. Distance and access to roads are the most common conditions that appear, the transport of agricultural goods being an important factor for farmers. Size or area of the parcel is another important feature appearing in four different instances as well as land use, soil quality, slope, access to water sources or the existence of irrigation systems and the legal situation of the parcel. Another aspect that appears three times in Table 1 is the shape of the parcel. One of the purposes of the land consolidation process is to have better shaped parcels.

Considering the literature studied, the factors considered for land evaluation for the land consolidation process for this study were: shape of the parcel, surface of the parcel, location of the parcel, accessibility to the parcel, slope, irrigation and soil quality. However, the evaluation procedure must consider specificities to the area in which are applied. Romania has been confronted with floods on large surfaces that brought considerable damage to the agricultural sector and loss of life. There are parcels that are in the flood risk areas and that can decrease their value for the land consolidation process. That is why; the flood risk factor is introduced in the list for land evaluation for land consolidation purposes.

Although land tenure is commonly cited by many authors, it was not considered in this study. The research is based on the assumption that land consolidation in the area was voluntary, with all landowners consenting to participate - even in cases of shared ownership. Instead, legal restrictions, like areas that cannot benefit from improvements of are under legal constrains from exchanging or selling the land were considered. Therefore, the factor legal restrictions were introduced for this study.

The weight assigned for each factor can be express in percentages or from values from 0 to 1. There can be different weights, or all factors can have the same weight. For this study the same weight was assigned for each factor (Table 3).

Table 3. Weights assigned for each factor

Factor	Weight %
Shape of the parcel	11.11
Surface of the parcel	11.11
Location of the parcel	11.11
Accessibility to roads	11.11
Slope of the land	11.11
Flood risk	11.11
Legal restrictions	11.11
Irrigation	11.11
Soil quality	11.11

2. Application of land evaluation factors in the study area

The administrative unit of Saschiz, where the case study takes place, is situated in Mures County in Romania. The area chosen for the case study comprises 766 parcels.

Shape. The ideal parcel has four sides. These are the parcels that received the highest score. For every extra side, the score of the parcel was

reduced. In Table 4 it can be observed that under 1% of the parcels have an ideal shape and got the highest score, while most of the parcels have between 5 and 7 sides.

Table 4. Score for the factor shape

Number of sides	Score	Number of parcels	Percentage
4	10	2	0.26
5	9	374	48.82
6	8	149	19.46
7	7	83	10.84
8	6	52	6.79
9	5	30	3.92
10	4	28	3.65
11	3	14	1.83
12	2	15	1.96
13	1	11	1.44
>13	0	8	1.04

Surface. Saschiz administrative unit is situated in a hilly area. The ideal surface for a parcel in this area is between 20 and 50 hectares (Paunescu et al., 2024). However, the average surface that a parcel has in Saschiz is 4063 square meters. Considering this specificity of the area of study, 10 intervals of 5000 square meters was considered. For every 5000 square meters the parcels were awarded 1 score point extra compared to the previous interval. From Table 5 can be observed that large sized parcels are under 1% in the studied area, while small size parcels are the vast majority. This is not a surprise, as land consolidation is applied exactly to counteract land fragmentation and obtain larger, better shaped parcels.

Table 5. Score for the factor surface

Interval (hectares)	Score	Number of parcels	Percentage
>5.18	10	1	0.13
4.67-5.17	9	1	0.13
4.16-4.66	8	0	0
3.65-4.15	7	0	0
3.14-3.64	6	0	0
2.63-3.13	5	0	0
2.12-2.62	4	3	0.39
1.61-2.11	3	14	1.83
1.01-1.6	2	58	7.57
0.5-1	1	162	21.15
0.5 <	0	527	68.80

Location. As it can be seen in Table 6, the distance from the parcel to the village or district centre is well documented. However, more important for agricultural products is the distance to the processing or storage facilities. A point was placed, that represents the point of collection for agricultural products, outside of the study zone (Figure 1). In "Reparcelare" software, the shortest distance was calculated from the point of collection to the closest point of the parcel. The distance is calculated by application by simulating the shortest route on existent roads. The longest calculated distance is 5100.01 meters, while the shortest distance is 1297.23 meters. The shortest distance was deducted from the longest distance and the difference was split into ten intervals as in Table 6. It can be observed that the score of the parcels for this factor is dispersed in a more homogenous manner, in comparison with other factors.

Figure 1. The study area as seen in "Reparcelare" application

Table 6. Score for the factor location

Interval (meters)	Score	Number of parcels	Percentage
380.278<	10	1	0.13
380.278-760.556	9	33	4.31
760.556-1140.834	8	48	6.27
1140.834-1521.112	7	76	9.92
1521.112-1901.31	6	138	18.02
1901.31-2281.668	5	112	14.62
2281.668-2661.946	4	92	12.01
2661.946-3042.224	3	137	17.89
3042.224-3422.502	2	112	14.62
3422.502-3802.78	1	17	2.22
>3802.78	0	0	0

Accessibility. This factor is linked with the access that a parcel has to a road. The highest scores were attributed to the parcels that have the longest distance that overlaps the limit of

the parcel with a road. If the parcel is bordered by more than one road, then the sum of the distances that overlap the parcel was calculated (Table 7).

Table 7. Score for the factor accessibility

Score	Number of parcels	Percentage
10	0	0
9	3	0.39
8	0	0
7	1	0.13
6	4	0.52
5	25	3.26
4	21	2.74
3	19	2.48
2	39	5.09
1	615	80.29
0	39	5.09

Slope. Slope was determined using a digital terrain model obtained from aerial images. To calculate the score, in "Reparcelare" software were introduced the average maximum slope, that is 32.40%, and the average minimum slope which is 1.41%. The difference between the two values was divided into ten intervals. The highest score was awarded to the parcels with the minimum slope. It can be observed from Table 8 that most parcels are in the hilly area with slopes from 0.01 to 6.5 percent.

Table 8. Score for the factor slope

Interval	Score	Number of parcels	Percentage
0	10	0	0
0.01-3.24	9	183	23.89
3.25-6.49	8	231	30.16
6.5-9.74	7	196	25.59
9.75-12.99	6	71	9.27
13-16.24	5	25	3.26
16.25-19.49	4	40	5.22
19.5-22.74	3	18	2.35
22.75-25.99	2	1	0.13
26-29.24	1	1	0.13
29.25-32.40	0	0	0

Flood risk. To assess the risk of flooding for parcels a risk map for the river Scroafa that runs through Saschiz was used. This was done by taking the historic data concerning the level of the water overflow. A simulation was performed in the GIS software Global Mapper in order to see the parcels that can be affected by the overflow (Figure 2).

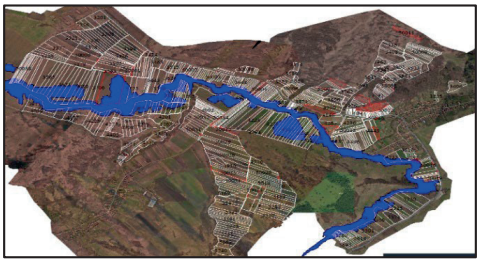

Figure 2. Overflow of the water in the study area as seen in Global Mapper application

The parcels that were least affected received the highest score. Taking into consideration 10 intervals from 0% flood affected parcel and 100% the scores were calculated as in Table 9. It can be observed that most of the parcels are in the safe area.

Table 9. Score for the factor flood risk

Interval (%)	Score	Number of parcels	Percentage (%)
0	10	571	74.54
1-9	9	52	6.79
10-19	8	50	6.53
20-29	7	27	3.52
30-39	6	20	2.61
40.-49	5	22	2.87
50-59	4	5	0.65
60-69	3	5	0.65
70-79	2	10	1.31
80-89	1	3	0.39
90-100	0	1	0.13

Legal restrictions. The legal restrictions considered were the legal impossibility to improve tha land, exchange or sell it. There were no legal restrictions in the study area of such, so all the parcels received the highest score.

Irrigation. There were no irrigation improvements in the area of study. That is why all the parcels received no points for this factor.

Soil quality. The soil quality is assessed using a system of points that takes into consideration a coefficient based on 17 indicators (Musat, 2014). These coefficients are written on pedologic maps. For this study the map for the study area was used. The map was georeferenced in the Global Mapper GIS application and a layer containing the geometry of the parcels was placed above (Figure 3).

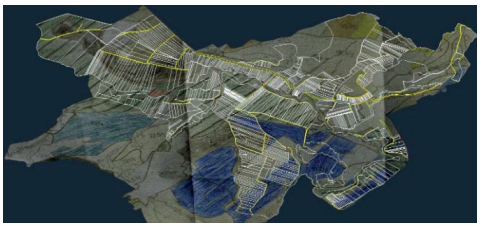

Figure 3. Parcels in the study area overlap on the pedologic map as seen in Global Mapper application

The highest soil quality score is 71.9, while the lowest soil quality score is 14.1. The difference was divided in 10 equal intervals and the score for soil quality was awarded as in Table 10.

Table 10. Score for the factor soil quality

Interval	Score	Number of parcels	Percentage
>72.68	10	50	6.53
66.18-72.68	9	27	3.52
59.67-66.17	8	2	0.26
53.16-59.66	7	2	0.26
46.65-53.15	6	20	2.61
40.14-46.64	5	13	1.70
33.63-40.13	4	16	2.09
27.12-33.62	3	151	19.71
20.61-27.11	2	148	19.32
14.1-20.6	1	335	43.73
<14.1	0	2	0.26

Based on all these factors, by applying the weights, the application "Reparcelare" calculates the score of every parcel that can be seen in the right corner of Figure 4.

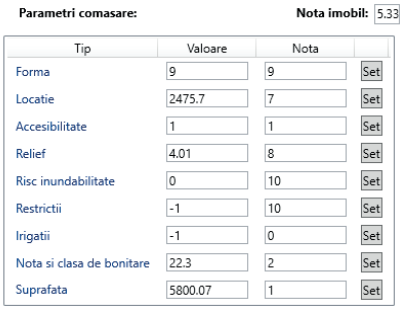

Figure 4. Example of score for one parcel as seen in "Reparcelare" application

Parcels are ranked from highest to lowest based on their total scores. Each owner's cumulative score, calculated by summing the values of all their parcels, determines their position in the reallocation and relocation phase of the land consolidation process (Figure 5).

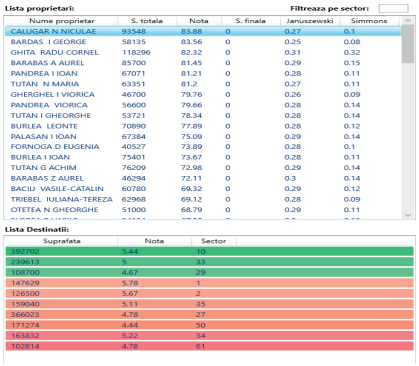

Figure 5. Classification of owners based on the added score of their parcels as seen in "Reparcelare" application

CONCLUSIONS

This research studies the existent literature concerning land evaluation for land consolidation processes. Based on conditions for evaluation determined by other researchers, this study proposes a series of factor for land evaluation that can be applied for a land consolidation project in Romania. These factors are adapted to the specificities of Romania and tested, with real data, in Saschiz administrative unit in Romania.

The factors that are used for land evaluation are: shape of the parcel, surface of the parcel, location of the parcel, accessibility to the roads, slope, legal restrictions, irrigations, flood risk, soil quality. The score is weighted with the same percentage and a score for each parcel is obtained. The results show that these factors can be applied to the study area, and, with the use of software applications and real data, the parcels can be evaluated for land consolidation purposes.

This study complements the studies conducted by (Demetriou, 2018; Tezcan et al., 2020; Ertunç & Uyan, 2022; Asiama et al., 2018; Ertunç, et al., 2021; Wyatt, 1996) and introduces two new factors that are specific to the study area: legal restrictions and flood risk.

The findings in this research can help Romanian researchers and policy makers to:

- Have a framework for land evaluation for land consolidation purposes;

- Design legislation for land consolidation;
- Complement these factors with other, more specific to the country in which land consolidation is applied.

These factors for land evaluation have taken into consideration the area studied and specificities of it and of the country. However, land consolidation is a multidisciplinary process in which are involved: land surveyors, agronomists, infrastructure engineers, landscapers or legal professional. All these professions can contribute to develop more appropriate factors that can be use in practice.

Future research can concentrate on applying these factors in more study cases and reevaluate these factors. Legislation design for land consolidation purposes is needed. Future research can also cover the topic of designing and testing of land consolidation application software that not just evaluate land but also help in the process of reallocating and relocating land parcels for land consolidation.

Abstract

The successful cultivation of vines must be aware of the phenological phases during the growing season. However, conventional phenological measurements on the ground are limited due to their spatial coverage. The use of Sentinel-2 imagery has led to an increased interest in its application to viticulture, with the data providing access to global spatial coverage and the potential for high temporal resolution. The present study was conducted during the period 2021-2022 in the experimental vineyard of the Agricultural University of Plovdiv, with the aim of studying the phenological phases of the wine grape varieties Merlot, Mavrud and Chardonnay. The results will enhance the interpretation of the spatiotemporal dynamics between meteorological data, vegetation indices (Normalized Difference Vegetation Index Normalized Difference Vegetation Index - NDVI), and phenological stages in vine cultivation. This study highlights the effectiveness of remote sensing for monitoring vineyard phenology, both retrospectively and in real time, as a valuable tool for maintaining high-quality standards in precision viticulture.

Key words*: Grape varieties, meteorological data, NDVI, phenological stages.*

INTRODUCTION

Climate is a key factor in enabling plants to complete their vegetative and productive cycles, directly influencing the timing and duration of the main phenological stages (Dalla Marta et al., 2010). The influence of air temperature on grapevine development and the timing of growth phases has been well-documented in numerous studies (Chuine et al., 2013; De Cortázar-Atauri et al., 2009; Parker et al., 2011; 2013; 2020). Network analyses of meteorological stations have been used to characterize temperature variability on regional scales (Bois, 2007; Cuccia, 2013; Madelin & Beltrando, 2005). In the context of global climate change, growers must adapt to the spatial variability of temperature and its temporal evolution. There is broad scientific consensus that the climate is changing (IPCC, 2013). The recent rise in temperatures has already impacted grapevine development, particularly by accelerating the timing of phenological phases (Bock et al., 2011; Duchêne et al., 2012; Tomasi et al., 2011; van Leeuwen et al., 2019). According to Cunha et al. (2010), conducting phenological observations in vineyards is essential for improving the ecological adaptability of grape varieties, as well as for effective crop management and modeling. Traditionally, these observations are made on the ground, offering localized insights but limited spatial coverage and temporal frequency. In contrast, time-series satellite imagery provides a fast and objective view of grapevine dynamics, enhancing vineyard management. Integrating ground-based phenology observations with the temporal profiles of the Normalized Difference Vegetation Index (NDVI), as captured by the SPOT VEGETATION sensor, is particularly useful for regional, inter-annual vineyard monitoring. Earth observation data and NDVI are vital tools for assessing vineyard vegetation health (Pastonchi et al., 2020), while also enabling efficient and accurate data collection in remote areas (Krishna, 2017). The use of vegetation indices (VIs) is a practical approach for applying remote sensing in viticulture, relying on spectral information to assess vine development and yield (Hall et al., 2002; Arnaudova & Stalev, 2024). Remote sensing technologies - such as UAVs, airborne sensors, and satellite imagery - are among the most employed methods for vineyard monitoring (Hall et al., 2002; Matese & Di Gennaro,

2015). UAVs equipped with multispectral sensors, along with radar measurements, provide high-resolution imagery that enables the extraction of various types of information about vineyards (Pichon et al., 2019). However, the high cost of this equipment can limit the spatial coverage needed for generating reliable results (Candiago et al., 2015).

Satellites are more time-efficient and cost-effective for monitoring large areas, but they are less adaptable to growers' needs due to limitations in revisit frequency and spatial resolution (Sozzi et al., 2019). In recent years, the availability of free satellite data - such as that provided by the Copernicus program through the European Space Agency (ESA)'s Sentinel-2 mission - has sparked increased interest in its application to viticulture. Studies have demonstrated that Sentinel-2 imagery can support regional vineyard management by extracting agricultural information and quantifying drought impacts (Devaux et al., 2019; Cogato et al., 2019). The use of geographic information systems (GIS) enhances image acquisition and processing for vegetation indices such as the Normalized Difference Vegetation Index (NDVI) and the Green Normalized Difference Vegetation Index (GNDVI). A geoprocessing approach further integrates environmental parameters - such as rainfall, temperature and soil moisture - as key variables (Jesus et al., 2020).

The objective of this study was to explore the relationship between vegetation indices derived from Earth observation and climatic data, and the phenology of wine grape varieties measured in situ.

MATERIALS AND METHODS

Study area

The experiment was conducted on the experimental training field of the Agricultural University, located in the town of Kuklen, Plovdiv District, in Central-Southern Bulgaria (Figure 1).

In situ measurements

The study was conducted in the experimental vineyard of the Agricultural University of Plovdiv, situated near the town of Kuklen, on the border with the village of Brestnik, in Rodopi Municipality. The vineyard is in full fruit-bearing condition. Vines are planted with a spacing of 3.0 meters between rows and 1.0 meter between vines within a row, resulting in a planting density of approximately 333 vines per hectare.

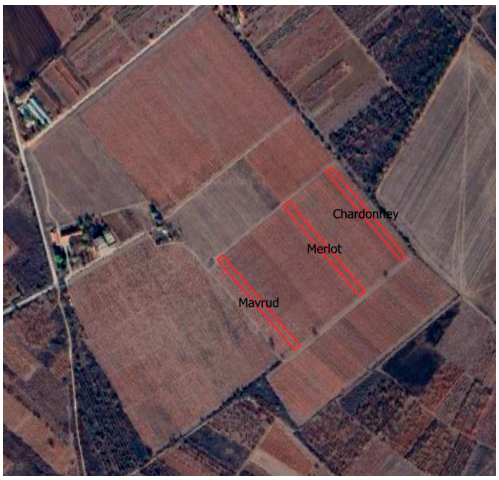

Figure 1. Location of study area
(Google Earth 17.11.2024)
L 42° 3'29.71"N B 24°47'0.18"E

The vineyard rows are oriented northwest–southeast (NW-SE) and are situated on a gentle eastward slope of 3.2% (1.8°), at an average elevation of 194 meters above sea level. Vines are cultivated using a tall-stem training system with a double-sided cordon formation supported by an appropriate trellis structure. The vineyard is managed under non-irrigated (dry-farmed) conditions.

The experimental scheme includes the following variants:

- V_1 - Mavrud variety;
- V_2 - Merlot variety;
- V_3 - Chardonnay variety.

Each variant consists of 60 vines, arranged in four replications of 15 vines each.

A series of in situ observations were made to The phenological development of the main growth stages of vine development during the vegetation period was monitored, including: bud burst, first leaf appearance, mass flowering, "pea"-size berries, veraison, and technological maturity. Observations were conducted on normally developed, fully fruiting vines. For the *Mavrud*, *Merlot*, and

Chardonnay varieties, the phenological stages were recorded as the calendar days when most of the vines (50%) had reached each respective stage. The identification and classification of the phenological phases followed the methodology described by Braykov et al. (2005).

Climatic data for the study period (April to October) in 2021 and 2022 including mean daily air temperature (°C) and daily precipitation (mm) were obtained from the meteorological station located within the university vineyard. According to Del Rio et al. (2024), the following heat indices were calculated from the temperature data:

The Winkler Index (WI) is a viticultural metric used to assess cumulative heat exposure during the grapevine growing season. It is calculated by summing the average daily temperatures that exceed 10°C. Also known as the Winkler Scale or Winkler Regions, this index was developed by Winkler et al. (1974) to classify wine-growing regions based on growing degree-days (GDD). It divides geographical areas into five climatic regions (Regions I to V), with each category corresponding to a range of accumulated heat units (Table 1), thereby guiding the selection of grape varieties suitable for each region.

$$\mathrm{WI} = \sum_{April\ 1}^{Oct31}(T_{mean} - 10^0C)$$

where:

- T_{mean} is the average daily temperature in °C from 1st April to 31 October;
- 10°C is the baseline temperature below which grapevine does not grow.

Table 1. Winkler Index classification (Winkler et al., 1974)

Region	GDD Range (°C)	Climate Type
Region I	< 1,390	Cool
Region II	1,391-1,670	Intermediate
Region III	1,671-1,940	Warm
Region IV	1,941-2,220	Hot
Region V	> 2,220	Very Hot

The Huglin Index (HI) is a bioclimatic heat index developed by Huglin for vineyards. It is a metric used to predict the potential maximum temperature of a given location over a given period (Huglin, 1978). The index is calculated by taking the meaning of the maximum and average daily temperatures recorded from early April to late September (Table 2). The calculated total is slightly adjusted based on the latitude of the area, using the K factor.

$$HI = K\left(\sum_{April\ 1}^{Sept30}\frac{T_{mean}+T_{max}}{2} - 10^0C\right)$$

where:

- T_{mean} is daily mean temperature (°C);
- T_{max} is daily maximum temperature (°C);
- 10°C is the baseline temperature below which grapevines do not grow;
- K is a latitude correction factor (ranges from 1.02 to 1.06).

Table 2. Huglin Index Classification (Huglin, 1978)

HI Range	Climate Classification
≤ 1500	Very Cool
1,500-1,800	Cool
1,800-2,100	Temperate
2,100-2,400	Warm
2,400-2,700	Hot

Growing Season Temperature (GST) - The growing season temperature index is an indicator employed in viticulture to assess the suitability of a particular region for wine production. The GST index is calculated as the mean daily temperature between 1 April and 31 October in the Northern Hemisphere. A positive correlation has been observed between the GST index and the maturity potential of grape varieties (Table 3). Different varieties of wine grapes grow within different GST thresholds (Jones, 2007).

$$\mathrm{GST} = \sum_{April\ 1}^{Oct\ 31}\frac{T_{mean}}{n}$$

where:

- T_{mean} is daily mean temperature (°C);
- n is days from April 1 to October 31.

Table 3. GST Index classification (Jones, 2007)

GST (°C)	Climate Type
< 13°C	Very Cool
13-15°C	Cool
15-17°C	Intermediate
17-19°C	Warm
19-21°C	Hot
> 21°C	Very Hot

Satellite imagery

The Sentinel-2 multispectral images for the NDVI were obtained from the official open-access site of the Copernicus Land Monitoring Service (Copernicus Europe's Eyes on Earth, n.d.). Within this online database, cloud-free images were selected according to their proximity to the dates of the phenological stages.

NDVI was obtained from the Copernicus Land Monitoring Service as a daily update of the NDVI, provided at pan-European level and in near real time. The data were available at 10 m x 10 m spatial resolution from Sentinel-2 HR multispectral satellite imagery (according to Data Viewer - Copernicus Land Monitoring Service).

NDVI defines values from - 1.0 to 1.0, where negative values are mainly formed from clouds, water and snow, and values close to zero are primarily formed from rocks and bare soil.

Very small values (0.1 or less) of the NDVI function correspond to empty areas of rocks, sand or snow.

Moderate values (from 0.2 to 0.3) represent shrubs and meadows, while large values (from 0.6 to 0.8) indicate temperate and tropical forests (Eos Date Analytics, n.d.)

The formula for the NDVI is as follows:

$$\text{NDVI} = \frac{NIR - RED}{NIR + RED}$$

where:

- NIR is near-infrared light;
- RED is red light.

For Sentinel-2:

$$\text{NDVI} = \frac{B_8 - B_4}{B_8 + B_4}$$

where:

- B8 = 842 nm;
- B4 = 665 nm.

The images and sample raster values from NDVI imagery were processed by QGIS 3.34.14.

Time series imageries were downloaded for the main stages of the vine plant in the experimental field and in situ data collection for 2021-2022. The growth stages are calculated in the Days Of the Year (DOY). The correlations between the studied variables were obtained by regression analysis in Excel Microsoft 365 and were valid within the time range studied.

RESULTS AND DISCUSSIONS

The grape varieties included in the study demonstrated varying ripening periods within the Plovdiv region.

Mavrud, a red wine variety, is distinguished by its protracted ripening period, which can extend from late summer to the onset of winter. In 2021, bud burst commenced on 16 April/DOY 116, and technological maturity was achieved on 6 October/DOY 279. The duration of the period from the initial phase to technological maturity is 174 days. In the second experimental year of the study (2022), the onset of budbreak occurred earlier than in the first year, on 9 April/DOY 111. The attainment of technological maturity was observed on 1 October/DOY 274. As presented in Table 4, the duration of the period from the budding growth phase to technological maturity is 176 days.

Merlot is a late-ripening French red wine variety. In 2021, bud burst is initiated on 12 April/ DOY 102, and technological maturity is observed on 13 September/ DOY 256. The duration of the period from the initial growth stage to technological maturity is 155 days. In consequence of the increased temperatures recorded in April 2022, the phenological stage of bud burst occurred earlier than in the first year, on 6 April/ DOY 96, and harvesting took place on 10 September/DOY 256. The duration of the period from bud burst to technological maturity is 158 days.

Chardonnay is a medium ripening French white wine variety. The onset of bud burst is observed on 10 April 2021 (DOY 100), while technological maturity is recorded on 30 August 2021 (DOY 242). The duration of the period from bud burst to technological maturity is 145 days. In 2022, bud burst occurred on 5 April/DOY 95, and technological maturity was attained on 28 August/DOY 240. The vegetation period was therefore 146 days.

The ripening process of the grapes was influenced by the average daily air temperature and the amount of precipitation. During the two experimental years, resulting in changes in the phenological stages during the growing season. At a temperature of 25ºC, the flowering of the

vines was observed to occur at a shorter time. The temperature in July plays a major role in the ripening of the grapes and should be between 28-32ºC for high quality table wines. The highest recorded precipitation (103.8 mm) was in June 2022 (Figure 2 and Figure 3).

Table 4. Phenological stages of Mavrud, Merlot and Chardonnay grape varieties for 2021 and 2022

Phenological Stage	Year	Mavrud	Merlot	Chardonnay
		Date/DOY	Date/DOY	Date/DOY
Bud Burst	2021	16.04.21/116	12.04.21/102	10.04.21/100
	2022	09.04.22/111	06.04.22/96	05.04.22/95
First Leaf Appearance	2021	30.04.21/120	22.04.21/112	19.04.21/109
	2022	24.04.22/114	16.04.22/106	10.04.22/100
Mass Flowering	2021	09.06.21/160	31.05.21/151	27.05.21/147
	2022	03.06.22/153	29.05.22/149	25.06.22/145
"Pea" Size	2021	10.07.21/191	05.07.21/186	30.06.21/181
	2022	06.07.22/187	01.07.22/182	27.06.22/178
Veraison	2021	20.08.21/232	04.08.21/216	29.07.21/210
	2022	16.08.22/228	02.08.22/214	25.07.22/206
Technological Maturity	2021	06.10.21/279	13.09.21/256	30.08.21/242
	2022	01.10.22/274	10.09.22/253	28.08.22/240
Bud Burst - Technological Maturity (Days)	2021	174	155	145
	2022	176	158	146

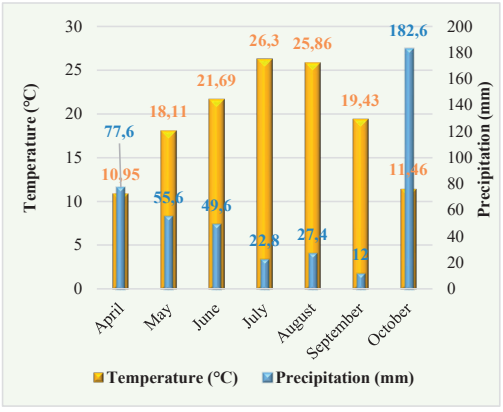

Figure 2. Monthly climate characteristics - mean temperatures and sum of precipitation for 2021

The meteorological data obtained from the station in the vineyard is of great importance for the vines. It enables the monitoring of temperature and precipitation, which influences the growth and development of the vines and plays a decisive role in the quality and yield of the grapes.

An assessment of the microthermal conditions during the grape harvesting period was conducted by determining the Winkler Index, the Huglin Index, and the Growing Season Temperature (GST) Index for the years 2021 and 2022 (Table 5).

The thermal indices allow for the comparison of vineyards with wine-growing areas all over the territory. These indices suggest that the optimal grape varieties are those capable of adapting to both lower and higher temperatures, exhibiting a suitable ripening period, and yielding wines with balanced acidities and flavours.

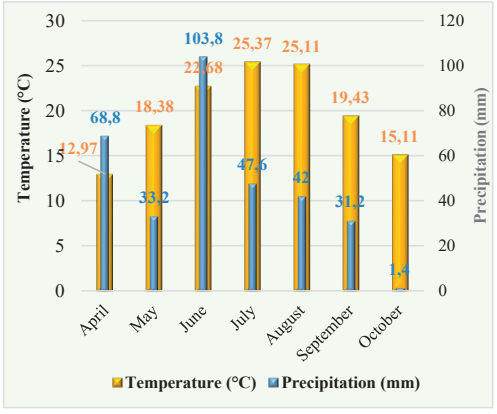

Figure 3 Monthly climate characteristics - mean temperatures and sum of precipitation for 2022

Table 5. Assessment microthermal conditions

	Index	2021Year/ Category	2022 Year/ Category
Meteo station Brestnik village	Winkler (WI)	1990°C Region IV	2132°C Region IV
	Huglin (HI)	2619°C Warm	2689°C Warm
	Growing Season Temperature (GST)	19.4°C Hot	19.8°C Hot

Satellite observations

The dynamics of the NDVI values were traced by the average index values in the plots, obtained from the zonal statistics in QGIS in 2021 and 2022. The index values are for the stages from the first leaf appearance to the technological maturity for the three varieties. Each of the varieties under observation cover an area of 2,500 square meters (Figure 4, Figure 5). The obtained results for the varieties are corresponding to the occurrence of the respective stages in each of the varieties. On the Figure 4 and Figure 5 are presented NDVI images for the growth stages of Mavrud variety in 2021 and 2022.

It is observed that the NDVI values start to increase with the beginning of flowering in May, and reach their maximum at the "pea" size in June. From August, due to the onset of drought and maturity, the leaves turn yellow and the index values decrease. The two years under consideration, 2021 and 2022, differ significantly in terms of climate, particularly with regard to rainfall, which has a direct impact on plant development.

In 2021, July and August rainfall were significantly lower, with values of 22.8 mm and 27.4 mm respectively. This results in a deficiency of moisture in the leaves, consequently leading to reduced NDVI values.

In 2022, the rainfall was almost double that of the previous year, at 47.6 and 42 mm, which is indicative of favourable conditions for the development of the vine crop. Consequently, NDVI values are elevated.

This provides a rationale for the observed delay in the onset of the phenophases, which in 2021 occurred 4-5 days later than in 2022.The phenological development of the varieties was established on the basis of climatic data and in situ observations (Figures 6 and 8).

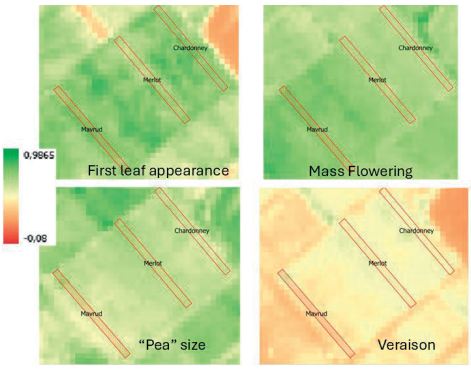

Figure 4. NDVI images for the phenological stages of Mavrud in 2021

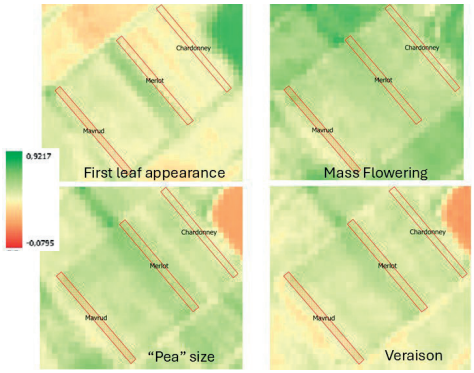

Figure 5. NDVI images for the phenological stages of Mavrud in 2022

There were no significant differences in the index values, but due to the different timing of the phenological phases and the development of the varieties, differences were observed. The analysis indicates a high degree of correlation.

The highest degree of multiple correlation is observed for the red varieties Merlot and Mavrud with R^2=0.99 for 2021 and R^2=0.97 for 2022 and R^2 = 0.90 and R^2=0.94, respectively.

In the case of Chardonnay, the coefficient of possible correlation is lower degree than the others, but also with a very good result. R^2=0.8 for 2021 and R^2=0.73 for 2021.

Figures 7 and 9 illustrate the NDVI from Sentinel-2 images for the verasion growth stage for the three varieties. The phases between the Chardonnay and Mavrud varieties exhibit a 20-day discrepancy, with the Chardonnay variety entering its phase at a more accelerated rate. A clear distinction in the years and index values is evident between the earlier veraison phase in

Chardonnay and the later veraison growth stage in Mavrud.

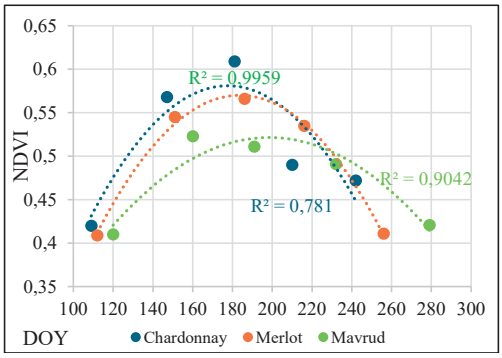

Figure 6. Dynamics of NDVI values for main growth stages for 2021

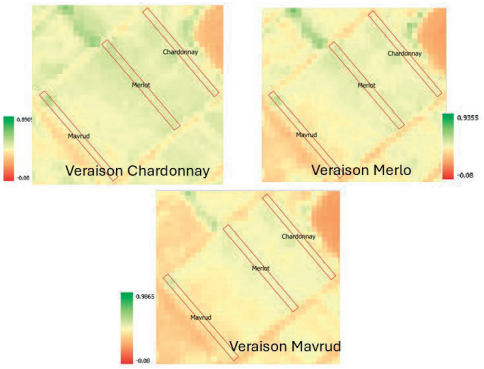

Figure 7. NDVI images for the growth stage Veraison in 2021

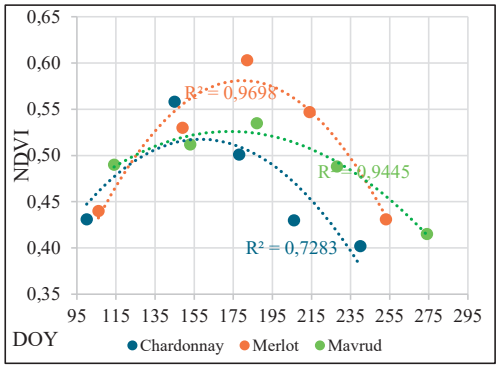

Figure 8. Dynamics of NDVI values for main growth stages for 2022

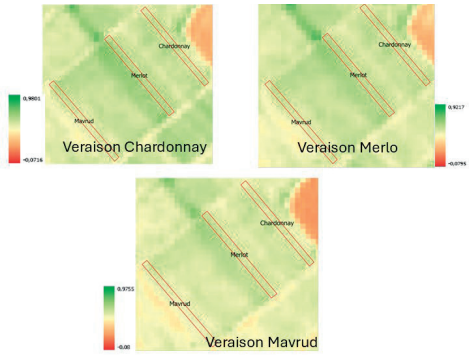

Figure 9. NDVI images for the growth stage Veraison in 2022

CONCLUSIONS

The present study employed regression equations and multiple correlation to evaluate the relationship between NDVI and the phenological phases of cultivars with varying maturation dates and growing season durations. The coefficients' values for R^2 in both years exhibited analogous results. The analysis revealed the highest result for the Merlot and Mavrud varieties. The multiple correlation coefficient for the Merlo variety was found to be $R^2 = 0.99$ and 0.97 for the year 2021 and 2022, respectively.

The NDVI time series has been utilised to monitor vineyard phenological phases, exhibiting a high degree of data validity. The survey is subject to several significant limitations. Firstly, there is a high probability of cloud cover and precipitation during the months of May and June. This may result in a lack of NDVI values during the growth stages of "flowering" and "pea size".

The evaluation of the investigated varieties was conducted by means of thermal indices in the experimental field in which they were cultivated.

The integration of meteorological data, vegetation indices and heat indices has demonstrated its potential in determining the phenological dynamics of diverse grape varieties. The integration process under discussion has been demonstrated to facilitate the identification of the most suitable grape variety for specific regional contexts. This, in turn, has been shown to contribute to the optimisation of viticultural practices.

Abstract

The evaluation of river course variations, such as bank erosion, sediment deposition, and the influence of nearby human-made structures, is facilitated by the use of remote sensing data and topographic analysis. These changes result from natural events, such as floods, as well as human activities, including the removal of fertile soil, sand extraction, and deforestation. This study highlights the impacts of these changes on river corridor ecosystems, as well as on the infrastructure and properties located along the watercourse. Continuous changes to the Earth`s surface are driven by both natural and artificial factors, which contribute to the erosion, transport, and accumulation of sediments. Among geomorphological agents, flowing water exhibits a particularly high erosive capacity. A primary objective of this study is to identify these changes, with a secondary focus on providing an overview of the current state of river corridors and bank erosion. To achieve this, the research utilizes remote sensing (RS) techniques and geographic information systems (GIS), along topographic data, to effectively monitor and analyze these transformations.

Key words*: remote sensing, change detection, river, GIS.*

INTRODUCTION

The Earth's surface is constantly changing due to a variety of anthropological, morphological, and atmospheric factors. The ground's surface degradation processes, such as weathering and erosion, are responsible for changes in landform (Aher et al., 2012).

Flooding and erosion naturally alter land use and land cover, leading to land loss, which significantly impacts livelihoods (Hazarika et al., 2015). Flood risk is expected to rise due to climate change, increasing flood frequency and magnitude, along with growing populations and assets in vulnerable areas. This intensifies riverbank erosion and river shifts, threatening nearby communities, causing land loss, displacement, and instability (Kundzewicz et al., 2014; Bodoque et al., 2023).

When the forces holding soil particles together are exceeded by the power of wind and water on the soil surface, it results in the natural process of soil erosion (Spalevic et al., 2020). Soil erosion is an environmental problem affecting the entire globe. Changes in land use across all river basins influence sediment dynamics, soil vulnerability to erosion, and hydrological responses (Sestras et al., 2023).

Rainfall activates the erosion process, impacting soil erosion through both the intensity and volume of precipitation, which subsequently affects the physical and chemical properties of the soil. Furthermore, topography significantly influences surface runoff, with steeper slopes and longer distances enhancing the erosion potential of precipitation, thereby increasing the risk of soil erosion (Costea et al., 2022).

To ensure the effectiveness of management and mitigation strategies, it is important to understand and examine the hydrological events (Bammou et al., 2024).

In Romania, water erosion affects approximately 3.5 million hectares of land, with certain regions in the Subcarpathian Curvature area (Vrancea and Buzău counties) experiencing erosion rates of 30-45 tons per hectare per year. This is in clear contrast to the soil's regenerative capacity, which is only about 3-6 tons per hectare per year (Mircea et al., 2010).

The shape and size of a river are primarily influenced by factors such as the steepness of the slope, water volume, water velocity, and nature of the river (Aher et al., 2012).

River channel changes, including bank erosion, down cutting, and bank accretion, are inherent processes in alluvial rivers. Bank erosion occurs when water erodes the riverbanks, while down cutting involves water activity on riverbed deepening due to erosion. Bank accretion refers to the accumulation of sediments on the banks, leading to the creation of new landforms. These processes are driven by factors such as water flow, sediment transport and deposition, and climate changes (Langat et al., 2019; Dabojani et al., 2014; Yao et al., 2013).

The bank shift of river path is a natural process in fluvial systems, caused by both human activities and climatic factors (Langat et al., 2019).

MATERIALS AND METHODS

Study Area

The primary aim of this study is to identify changes in the river corridor. The area of interest is located near Corbu Vechi village, in Brăila County, as shown in Figure 1, where the Siret River has been monitored from 2016 to 2025 using satellite images from Sentinel 2 RS (Remote Sensing) data. These changes are validated through topographical data collected in February 2025 with a LiDAR (Light Detection and Ranging) sensor mounted on an UAS (Unmanned Aerial System). This approach provides valuable insights into the evolution of river ecosystems over the specified period, offering a detailed assessment of the river's dynamics.

The Siret River, originating in the Northern Carpathians in Ukraine, flows through Romania for a distance of 559 km before merging with the Danube. Its upper course begins in Ukraine, while the middle course passes through the Suceava Plateau and the border between the Moldavian Sub-Carpathians and the Bârlad Plateau. The river's drainage network includes 1,013 water courses, covering 15,157 km, which represents 19.2% of Romania's total river network. With a drainage basin of 44,871 km², the Siret has the largest basin in Romania, covering 18.1% of the country's total area. From its source to its mouth, the river experiences an elevation difference of 1,236 meters (Romanescu et al., 2013).

Figure 1. Siret River near Corbu Vechi village

The area of interest lies in the lower Siret Valley, with elevations between 3 and 60 meters. During the 70's, extensive engineering projects were undertaken to manage frequent flooding and bank erosion, particularly in the floodplain. These efforts included regularizing the river's course and reinforcing its banks (Olariu et al., 2015).

However, over time, the efficiency of these interventions has diminished due to natural processes such as sediment buildup and erosion, along with changes in land use. As a result, the Siret River continues to present challenges, requiring new rehabilitation, development, and reinforcement works, as well as the adaptation of flood control measures to account for climate change and growing human influence.

MATERIALS AND METHODS

Remote sensing is a technique that allows data collection without physical contact with the target, using sensors to capture or analyze different forms of energy, including

electromagnetic radiation and acoustic signals, as they are emitted, reflected, or dispersed by the object being studied (Yang et al., 2022; Aher et al., 2012; Campbell et al., 2011).

Change detection is the process of finding and evaluating changes in multispectral images that present spatial or spectral variations. It is commonly described as the analysis of two co-registered images of the same geographic region taken at different time periods to detect and evaluate changes over time (Cheng et al., 2024; Goswami et al., 2022).

The area of interest is analyzed using Sentinel-2 satellite data, which provides multispectral imagery with a resolution suitable for identifying changes in the river corridor. For watercourse extraction, the NDWI (Normalized Difference Water Index) is computed, a remote sensing index specialized in detecting and analyzing water bodies. It is calculated based on reflectance in specific wavelengths of the electromagnetic spectrum, specifically the green and NIR (Near-Infrared) bands, according to Gao (1996), or the NIR and SWIR (Short Wave Infrared) bands, according to K. McFeeters (1996), allowing accurate classification of water areas and their differentiation from other surface types, such as vegetation or dry soil.

By integrating satellite-based remote sensing data, the analysis of the Normalized Difference Water Index (NDWI) provides valuable insights into water trends, which can significantly inform decision-making processes. This method helps identify changes in water bodies over time, enabling more effective management strategies (Ghalehteimouri et al., 2024).

The calculation of NDWI and the extraction of information from the obtained results were carried out using GIS (Geographic Information Systems) software, which allowed the analysis and interpretation of spatial data.

GIS and RS are indispensable tools for monitoring and detecting changes in the physical environment, including river dynamics and bank erosion. By utilizing advanced remote sensing technologies and satellite data, these tools enable the tracking of Earth's surface changes, significantly enhancing environmental assessments. Their combined application has revolutionized the way we detect, analyze, and assess environmental transformations, making them essential for sustainable management and decision-making (Ghalehteimouri et al., 2024; Sestras et al., 2023; Bilasco et al., 2021; Aher et al., 2012; Dabojani et al., 2014). Subsequently, remote sensing results from Sentinel-2 were validated in situ through precise topographic information collected with LiDAR technology.

While remote sensing products are commonly used to assess planform changes (2D), they often neglect vertical changes (3D). However, evaluating both planform and vertical changes is essential for understanding morphological transformations. By incorporating spatio- temporal aerial imagery along with topographic data, remote sensing becomes a valuable tool for assessing changes in rivers morphology, providing a more comprehensive picture of the river system's dynamics (Andualem et al., 2024).

LiDAR sensors represent the next generation of efficient and precise land surveys. Aerial and satellite mapping, such as photogrammetry and airborne LiDAR, have greatly improved land surface elevation sampling. Traditionally, topographic data was gathered through ground surveys using total stations, GPS (Global Positioning System), or other GNSS (Global Navigation Satellite System) tools. However, this method can be time-consuming, particularly in complex topographic areas (Sestras et al., 2025; Ouédraogo et al., 2014).

Data processing and spatial analysis were performed using Romania's national projection system Stereographic 1970. The utilized workflow is presented in Figure 2 and includes several essential applications for data downloading, processing, and analysis.

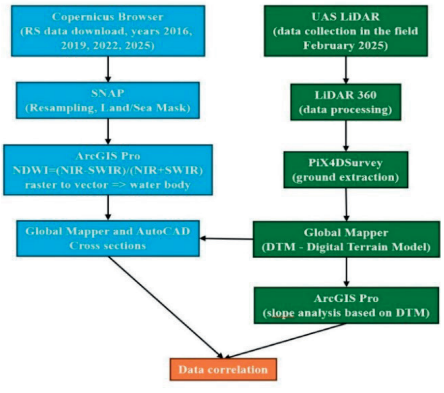

Figure 2. The workflow for satellite imagery and LiDAR data

For downloading satellite RS data, the open-source platform Copernicus Browser was used. Later, for processing the remote sensing data, the applications SNAP and ArcGIS Pro were utilized. After calculating the remote sensing indices, the analysis of the resulting vector data was performed using the applications GlobalMapper and AutoCAD for generating cross-sections. The second part involved collecting 3D data using a system composed of the DJI Matrice M200 PPK drone, equipped with the Topodrone LiDAR 200+ Hesai sensor. Flight processing and the generation of point cloud data were carried out using Topodrone PostProcessing and LiDAR 360. Subsequently, the data was filtered to obtain the necessary ground data for creating the DTM (Digital Terrain Model) using GlobalMapper. Finally, the DTM was used for spatial analysis in ArcGIS Pro.

RESULTS AND DISCUSSIONS

The Siret sector from Movileni to its confluence with the Danube, where the area of interest is situated, faces exceedances of flood protection works, as it is entirely embanked. Rising water levels are sometimes aggravated by a backflow effect from the Danube, which can contribute to an additional rise in water levels in certain sections of the Siret River. In this context, confluence areas, such as those where the Siret meets major tributaries, are exposed to flooding from both the Siret and its tributaries. At the same time, in this sector, the Siret is also affected by phenomena such as bank erosion, as can be observed in Figure 3.

Figure 3. Bank erosion Siret River near Corbu Vechi village - February 2025

To analyze the changes that occurred, Sentinel 2 images for the dates of 4 December 2016, 4 December 2019, 28 December 2022, and 13 february 2025, were downloaded. These images were processed by applying the resampling command in the SNAP software to bring the spatial resolution of all spectral bands to 10 meters. The images were then cropped to focus on the study area, and the NDWI was calculated using ArcGIS Pro. This generated raster images of the index, with values ranging from -1 to 0 indicating areas with bare soil or covered with vegetation without water, while values between 0 and 1 identified water-covered regions.

In Figure 4 and Figure 5, the NDWI index for the years 2016 and 2025 is shown, covering the same area over a span of 9 years. By comparing the two images, changes in the distribution of water and vegetation can be observed.

By comparing the two images, the phenomenon of bank erosion and the process of sediment deposition or accumulation along the river course can be observed, indicating a dynamic evolution of the river during the analyzed period.

The next step involved extracting the water body from each image using the NDWI index calculated for each year. These water bodies were then overlaid to allow the comparison and analysis of changes in the distribution of water over the studied period.

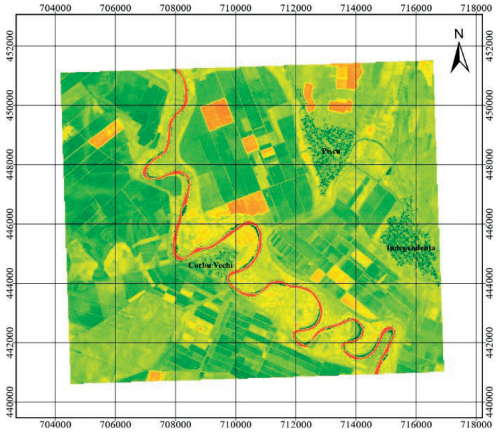

Figure 4. The Normalized Difference Water Index for the year 2016 (red - water bodies, orange and yellow - vegetation and surfaces with moisture content, light and dark green - bare soils and built-up areas)

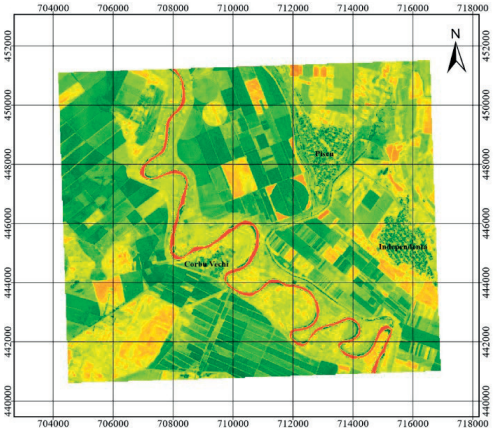

Figure 5. The Normalized Difference Water Index for the year 2025 (red - water bodies, orange and yellow - vegetation and surfaces with moisture content, light and dark green - bare soils and built-up areas)

A closer look reveals the dynamics of the changes that have occurred along the river course, an aspect highlighted in Figure 6. These changes occurring in the water bodies are caused by bank erosion and sediment deposition, which have led to shifts in the river's path.

Figure 6. Spatio-temporal changes in water bodies between 2016-2025 based on NDWI Index

In Figure 7, the evolution of the Siret River between 2016 and 2025 is illustrated using different colors to represent the river's path each year. The river exhibits significant lateral migration over this period, with visible zones of bank erosion and sediment deposition occurring along various segments of its meandering course. These geomorphological processes are primarily governed by the highly sinuous morphology of the Siret River in this sector, where the channel forms pronounced meanders. The observed pattern of bank erosion on the outer curves and sediment deposition on the inner curves is consistent with classical fluvial dynamics described in meandering river systems. In such systems, higher flow velocities on the outer bends lead to increased erosive forces, while lower velocities on the inner bends favor sediment accumulation. This natural mechanism of lateral channel migration contributes to the continuous reshaping of the river corridor over time.

Figure 7. Water bodies dynamics between 2016-2025 based on NDWI Index (orange - 2016, green - 2019, red - 2022 and blue - 2025)

The raster data of water bodies were converted into vector data in polygon format, enabling more accurate analysis and representation. Using Global Mapper and AutoCAD software, 12 cross-sectional profiles were generated along the 27.5 km length of the river course under investigation, as shown in Figure 8.

These cross-sections facilitated the extraction of river width at each specific location. The resulting data, which highlight the variations in the river's morphology along the analyzed stretch, are presented in Table 1.

Based on Table 1 it can be concluded that the studied area exhibits changes in certain profiles. For example, cross-section 2 maintains a relatively consistent width throughout the studied period, with only minor variations. This data can be correlated with Figure 9, where the changes observed in the river's course are influenced by the linear flow of the Siret River and the presence of forest belts along the banks.

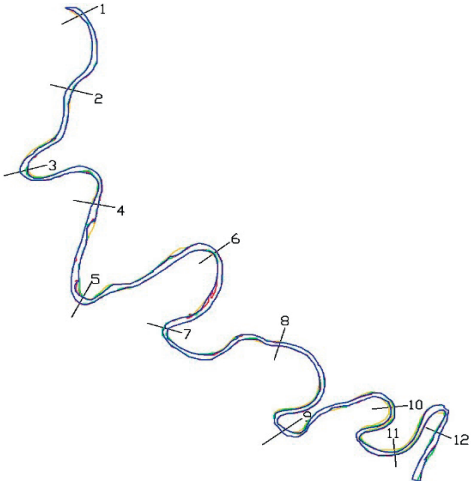

Figure 8. Cross-section of water bodies created in AutoCAD

Table 1. Variation in Siret River width from 2016 to 2025 in the studied area obtained from water bodies cross-sections

Cross section	2016 width (m)	2019 width (m)	2022 width (m)	2025 width (m)
1	112.75	77.17	88.62	89.19
2	107.51	103.23	108.11	105.68
3	151.06	112.44	136.66	144.19
4	116.26	116.32	106.89	106.34
5	150.25	154.56	146.8	138.84
6	95.59	48.88	76.27	78.3
7	91.74	85.75	77.36	69.67
8	86.22	74.86	79.41	74.93
9	92.02	84.87	94.05	88.58
10	71.00	63.95	74.04	73.6
11	98.11	58.27	54.26	56.9
12	107.69	103.24	101.5	92.04

Figure 9. Cross-section 2

The linear flow of the river, characterized by its relatively straight course in this section, contributes to some degree of erosion and sediment deposition. However, its effects are less pronounced compared to areas with more pronounced meanders. The forest belts, on the other hand, provide some stabilization to the riverbanks by acting as a natural barrier against water-induced erosion. While these forest belts can reduce bank erosion to a certain extent, their impact remains limited.

In contrast, cross-section 6 shows major changes, and when correlating the data with Figure 10, it can be concluded that cross section 6 is located on a river meander, where the phenomena of transportation and deposition of alluvial materials occur.

Figure 10. Cross-section 6

Aerial LiDAR data collected was conducted in the areas corresponding to cross-sections 5 and 7. Based on the LiDAR data, the ground was filtered, serving as the basis for vectorizing the necessary elements to create the topographic plan for these areas, as can be seen below in Figure 11.

Topographic observations were requested in these zones due to the execution of bank protection works; however, both upstream and downstream of these riverbank stabilization interventions, the phenomenon of erosion continues to persist. To better understand the effectiveness and impact of the stabilization works, aerial LiDAR data collection was conducted in the areas corresponding to cross-sections 5 and 7. These data were collected by the company BDS Topografie, which

subsequently developed detailed 2D and 3D digital topographic plans. The plans were based on high-resolution LiDAR information gathered on-site, complemented by bathymetric surveys conducted in the same areas.

Figure 11. Topographic plan

The purpose of these data acquisitions was to assess how water interacts with and affects the implemented bank protection measures in these specific zones along the Siret River. The LiDAR-derived point clouds enabled the generation of a high-precision DTM for both areas. This DTM served as foundational tool for analyzing topographic variation and hydrodynamic behavior within the river corridor. In addition, the LiDAR data provided confirmation and refinement of the information obtained through remote sensing analyses, ensuring a multi-source validation of geomorphological changes. All geospatial outputs, including the DTM and topographic plans, were delivered to the project beneficiary to support further assessment and monitoring of the stability and effectiveness of the bank protection works.

Based on the data collected through LiDAR technology and bathymetric surveys, DTM was generated, as shown in Figure 12.

For cross-section 5, which shows a water body width of 138.84 meters according to NWDI, the LiDAR data indicates a width of 152.80 meters. In the case of cross-section 7, where NDWI indicates a width of 69.67 meters, the LiDAR data shows a width of 83.69 meters. The values are close, the data collection periods also being similar, with only a one-week difference between the LiDAR and remote sensing data. However, it should be noted that the remote sensing data have a spatial resolution of 10 meters, which may influence the accuracy of the output.

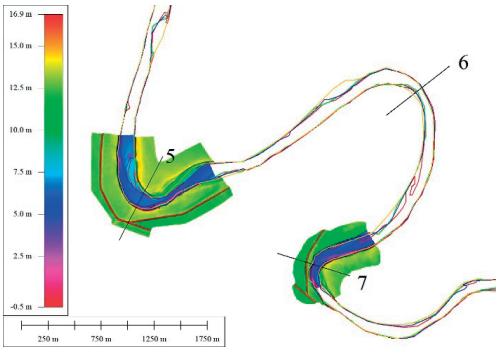

Figure 12. DTM based on LiDAR data

The Digital Terrain Model was imported into ArcGIS Pro for detailed analysis of the slope characteristics within the study area. Through this analysis, regions with higher risk were identified and marked in red as can be observed in Figure 13.

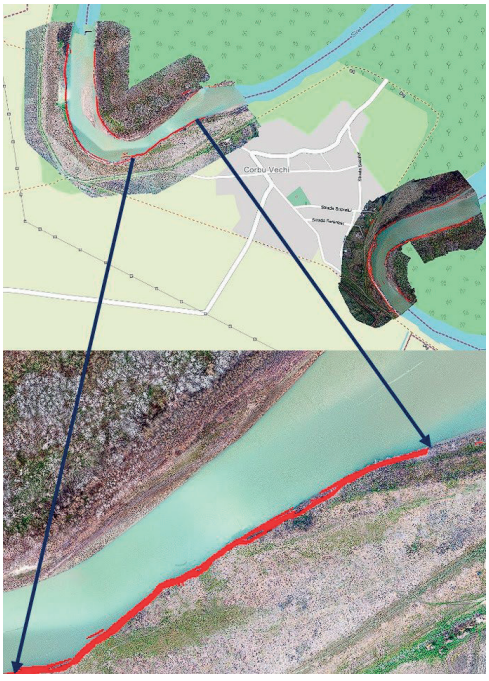

Figure 13. Slopes with an inclination between 30 and 70 degrees - with color red

These areas, where the slope of the riverbank ranges from 30 to 70 degrees, extend over

approximately 2,115 meters on the DTM near the cross-section 5 area and around 1,350 meters in the vicinity of cross-section 7, as determined through slope length calculations performed in ArcGIS Pro. These zones were flagged as particularly vulnerable, specifically, for slopes between 30 and 50 degrees, it is typically recommended to implement bank stabilization measures. These include the installation of protective mesh, as well as the planting of trees, shrubs, and other vegetation to help secure the soil and prevent further erosion. For areas where the slope exceeds 50 degrees, the erosion risk is significantly higher, and more solid engineering solutions are required. In these situations, it is necessary to construct retaining walls, gabion baskets, stone revetments, or even apply concrete to the embankment to stabilize the slope effectively. These engineering measures provide structural support to prevent soil movement and mitigate the long-term risk of erosion, ensuring the durability of the riverbank in the face of continuous environmental pressures.

The slope analysis aligns with the study's main objective outlined in the title and abstract, detecting changes within the Siret River corridor using satellite imagery and LiDAR data. By identifying steep riverbanks ranging from 30 to 70 degrees near cross-sections 5 and 7 based on the DTM, the study highlights areas with elevated erosion risk. These results also support the secondary objective stated in the abstract: providing an overview of the current condition of the river corridor and assessing riverbank stability. Steep slopes significantly influence erosion processes and increase the likelihood of landslides. The use of the Digital Terrain Model enables a detailed spatial assessment of these vulnerabilities, while satellite imagery facilitates the evaluation of changes over time in a spatio-temporal context. These analyses enhance the study's value in detecting changes and evaluating current geomorphological conditions, while also identifying high-risk areas to guide effective mitigation strategies.

CONCLUSIONS

River channels undergo morphological changes due to both human activity and natural processes. Remote sensing and remote sensing indices, particularly the NDWI index applied in this study, provide valuable tools for monitoring and understanding the dynamics of river flows. By using satellite image archives spanning several years or even decades if past satellite missions are considered, these techniques offer a quick and cost-effective means of monitoring changes in water bodies over extended periods.

In the case of the Siret River, the NDWI index was used to track variations in the river's width, which were essential for identifying events like erosion and sediment deposition. With a spatial resolution of 10 meters, the satellite data proved sufficient for this type of study. These satellite data were subsequently verified with topographic information collected using LiDAR technology.

The integration of GIS in processing and analyzing satellite data, combined with LiDAR data, represents an effective approach to extracting and integrating information on the changes occurring in the river course over time. These tools are essential for evaluating risks and identifying vulnerable sections of the riverbanks. For example, in the areas corresponding to cross-sections 5 and 7, detailed topographic observations were carried out. The LiDAR data, collected just one week prior to the satellite data, confirmed and enhanced the initial observations made through remote sensing, providing a comprehensive understanding of the river's dynamics and morphology in these areas. Sustainable management of water resources and safeguarding infrastructure from natural hazards depends on understanding the dynamics of river courses, especially hydrological events such as erosion and sediment deposition. In the case of the Siret River, the combined study of LiDAR data and RS has revealed how the riverbanks have evolved over time.

ACKNOWLEDGEMENTS

This research was carried out with the support of the Ministry of Education and was financed through the CNFIS-FDI-2024-F-0195 project, funded by the National Council for Financing Higher Education (CNFIS).

Abstract

In recent years, Romania has experienced an increasing frequency and intensity of severe storms, driven by climate change and resulting in amplified weather-related risks such as heavy rainfall, windstorms, and flash flooding. To enhance regional preparedness and support risk mitigation, this study proposes a GIS-based multi-criteria decision-making framework using the Analytic Hierarchy Process to identify optimal locations for severe storm refuges in Cluj County, Romania. Seven spatial factors were selected, consisting of elevation, slope, land use/land cover, population density, and proximity to roads, rivers, and healthcare facilities. Each factor was reclassified and weighted based on expert input and AHP pairwise comparisons, followed by a weighted overlay analysis in ArcGIS. The final suitability map categorizes the county into five classes: not suitable, less suitable, moderately suitable, suitable, and highly suitable. Results indicate that 68.67% of the total area (4569.5 km²) is moderately suitable, while only 0.07% (4.3 km²) is classified as highly suitable for refuge development. The most favourable areas are found near Cluj-Napoca, due to optimal elevation, gentle slopes, built-up and vegetated land cover, and high accessibility to infrastructure and services. This spatial approach offers a replicable model for enhancing disaster resilience in storm-affected regions of Eastern Europe.

Key words*: GIS, disaster preparedness, climate change, geospatial data, hierarchy classification.*

INTRODUCTION

In recent decades, high-intensity weather events - including cyclones, windstorms, and severe convective storms - have intensified globally (Hussainzad & Gou, 2024). While tropical cyclones are well-monitored, temperate regions now face more frequent non-cyclonic storms, such as derechos and tornadic supercells. These short-lived, localized events can produce flash floods, infrastructure damage, and fatalities, rivalling the impact of larger systems (Bammou et al., 2024). Between 1970 and 2019, such disasters caused nearly 1.9 million deaths and $1.965 trillion in losses worldwide, with risks amplified by urban sprawl, aging infrastructure, and limited preparedness. To mitigate these threats, monitoring systems and spatial risk assessment are essential (Sbihi et al., 2024). Tools like real-time mapping and geospatial modelling help identify hazard-prone zones and inform emergency planning. The integration of Geographic Information Systems (GIS) with multi-criteria decision analysis (MCDA), particularly the Analytic Hierarchy Process (AHP), has proven effective for vulnerability mapping and storm shelter planning (Mamun et al., 2024), strengthening both response strategies and long-term resilience.

In Romania, convective storms are becoming more frequent and intense, especially in regions like Cluj County. These events bring damaging winds, hail, floods, and tornado-like conditions, with thunderstorm activity reaching 270 to 390 hours annually. Wind gusts exceeding 30 m/s often disrupt infrastructure, and over 760,000 lightning flashes occur each year (Calotescu et al., 2024). Climate change has intensified these

hazards through increased moisture, rising temperatures, and shifting airflows (Oprea, 2009), while thunderstorms have surpassed synoptic winds as the main driver of Romania's extreme wind climate (Cristian et al., 2024).

In this context, GIS has become essential for hazard mapping and shelter site selection (Bilașco et al., 2021). By integrating layers such as terrain, land use, hydrology, infrastructure, and demographics, GIS enables spatial analysis for planning and evacuation (Parajuli et al., 2023). Weighted overlays and remote sensing help classify land into suitability zones, improving infrastructure and emergency coordination (Khalaj et al., 2021).

AHP further supports this by ranking decision criteria through expert-driven pairwise comparisons (Das et al., 2024). It accommodates both physical and socio-economic factors (Swain et al., 2020), and its outputs, like weights and consistency ratios, increase transparency and replicability. Widely applied in shelter and hazard mapping (Hasan et al., 2024), AHP becomes more effective when embedded in GIS.

This study presents a GIS-AHP-based methodology to assess storm refuge suitability in Cluj County, Romania, an increasingly vulnerable region. It integrates environmental and infrastructural variables such as elevation, slope, land cover, proximity to rivers, roads, hospitals, and population density. By combining reclassification, weighted overlay, and spatial validation, it produces a suitability map to aid local planning. The approach enhances climate resilience in Central and Eastern Europe and serves as a replicable model for disaster preparedness in other hazard-prone regions.

MATERIALS AND METHODS

Study Area

Cluj County, situated in the heart of Transylvania, Romania, serves as the focal area for this study (Figure 1). Covering an area of 6,674 square kilometers, it ranks as the 12th largest county in the country, accounting for approximately 2.8% of Romania's total land area. Geographically, Cluj County is positioned between latitudes 46°24' and 47°28' N, and longitudes 23°39' and 24°13' E, encompassing a diverse landscape that includes the Apuseni Mountains, the Someș Plateau, and the Transylvanian Plain.

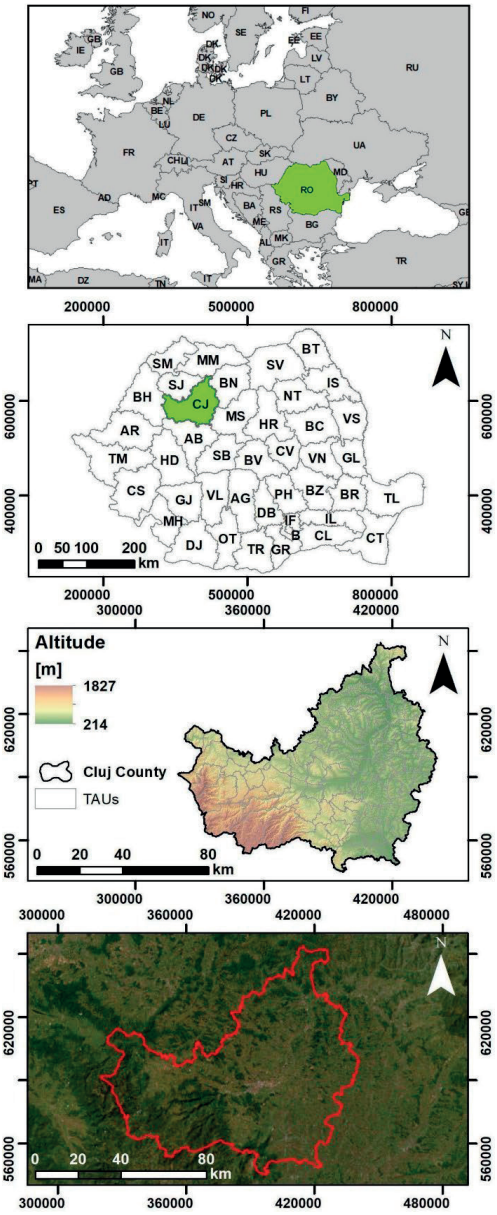

Figure 1. Location and geographic context of Cluj County, Romania. The panels show its position in Europe and within Romania, along with elevation variation and satellite imagery

Cluj-Napoca, the administrative centre of Cluj County and Romania's second-most populous city, is a major cultural and economic hub. The county features a mix of mountainous terrain and plains, creating diverse climate patterns that influence both weather conditions and

infrastructure planning. This varied landscape necessitates tailored hazard mapping and shelter strategies, as local topography directly affects environmental risk and emergency preparedness.

Cluj County was selected due to its increasing exposure to severe convective storms and its strategic role in national disaster planning. Between 2013 and 2022, the county experienced 12 storm-related damage events, including a notable storm on September 17, 2017, with gusts reaching 28.4 m/s. Though historically not a tornado hotspot, Cluj has recorded events like the June 12, 1961, tornado, and rising mesocyclone activity suggests increasing vulnerability (Antonescu & Bell, 2015). Its position along the Carpathian foothills, combined with orographic and climatic factors, leads to frequent summer thunderstorms and high lightning activity (Stan-Sion & Antonescu, 2006). These conditions, especially in the Cluj-Napoca peri-urban zone, highlight the urgency for systematic refuge planning supported by geospatial analysis.

Methodological Approach

This study's methodological framework aims to identify optimal storm refuge locations in Cluj County, Romania, by integrating geospatial data with multicriteria decision-making. The approach includes spatial data collection, preprocessing, AHP-based evaluation, and GIS-weighted overlay analysis. The overall workflow is illustrated in Figure 2. The first step defined the study area within Cluj County, Romania, selected for its rising exposure to severe convective storms and recent documented damage. Geospatial datasets representing seven key variables, elevation, slope, land use/land cover (LULC), population density, and proximity to rivers, roads, and healthcare facilities, were collected from open-access and national sources to ensure spatial consistency for hazard mapping (Nap et al., 2022).

In the preprocessing phase, all data were harmonized in spatial resolution, coordinate system (Stereographic 1970), and study extent. Raster layers were resampled and reclassified into five ordinal suitability classes (1 to 5), enabling comparability and standardized overlay analysis.

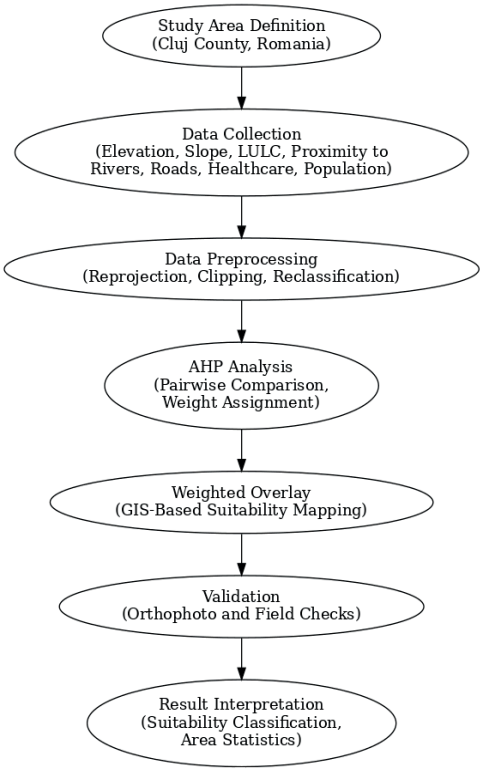

Figure 2. Methodological workflow used for severe storm refuge suitability assessment in Cluj County, Romania, integrating geospatial analysis, AHP-based factor weighting, GIS overlay, and validation steps

To assign importance to each criterion, the Analytic Hierarchy Process (AHP) was applied. Expert-based pairwise comparisons generated weights via the principal eigenvector method, and a consistency ratio (CR < 0.1) validated matrix coherence. This ensured a structured, transparent weighting process.

The core analysis used ArcGIS's weighted overlay tool. Each raster was multiplied by its corresponding AHP weight, and the weighted layers were then summed to generate a final suitability index, which was classified into five categories ranging from 'Not Suitable' to 'Highly Suitable'. Each raster was multiplied by its AHP weight, and the layers summed to produce a final suitability index, classified into five categories: not suitable to highly suitable. The resulting map identified optimal zones for storm shelters or natural refuges.

Model outputs were validated through visual comparisons with 2022 orthophoto imagery and

expert review of known safe zones. "Highly suitable" areas were field-verified for feasibility. Spatial statistics and area metrics summarized storm preparedness potential across Cluj County.

Data Sources and Processing

The methodological strength of this study lies in the integration of geospatial datasets capturing Cluj County's physical, infrastructural, and demographic attributes. These serve as the foundation for the GIS-based multi-criteria analysis aimed at identifying optimal storm refuge sites (Bammou et al., 2024). Seven key thematic layers were selected, elevation, slope, land use/land cover (LULC), population density, and proximity to rivers, roads, and healthcare facilities, due to their relevance in assessing terrain accessibility, environmental risk, and infrastructure connectivity. As in comparable studies, these diverse datasets were converted into standardized raster layers with a uniform spatial resolution and reclassified on a common scale from 1 (not suitable) to 5 (highly suitable). This standardization ensured consistency and enabled integration through weighted overlay analysis. The careful selection and processing of these layers reflect local geographic realities while aligning with international disaster resilience frameworks, thereby enhancing the model's reliability, transferability, and practical relevance.

The geospatial database for this study was meticulously assembled to enable a robust multi-criteria evaluation of storm refuge suitability in Cluj County. Diverse spatial datasets were acquired based on their relevance to storm exposure, accessibility, and demographic vulnerability. Processing was conducted primarily using ArcGIS 10.8, which supported data reprojection, rasterization, reclassification, and spatial analysis (Sestras et al., 2019).

A core input was the 25 m/pixel resolution digital elevation model (DEM) from the Shuttle Radar Topography Mission (SRTM), from which both elevation and slope layers were derived - critical for assessing runoff, flood risk, and structural vulnerability (Sestras et al., 2023).

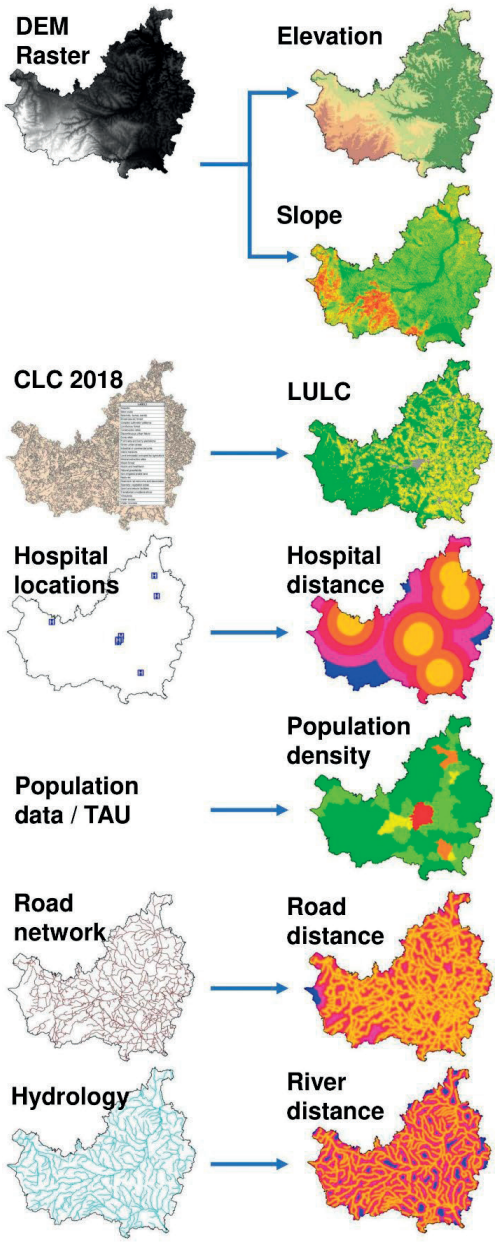

Figure 3. Input geospatial datasets used for storm refuge suitability assessment in Cluj County, including elevation, slope, land use/land cover (CLC 2018), distance to hospitals, population density, road network proximity, and distance to rivers

Land use and land cover were sourced from the Corine Land Cover 2018 (CLC 2018) dataset, developed under the Copernicus program. This standardized European classification system, mapped at 1:100,000, provided surface typologies such as urban, agricultural, and forested areas, each influencing storm impact and shelter feasibility (Popescu et al., 2024). Demographic layers, including population density and hospital proximity, were generated from Romanian government portals, producing rasters of population distribution and healthcare accessibility.

Hydrographic and transportation data were obtained as open-access shapefiles from national and EU platforms, then converted into continuous distance rasters representing proximity to rivers and roads, vital for minimizing flood exposure and ensuring emergency mobility. All raster layers were standardized in resolution, reclassified into five suitability classes, and structured for weighted overlay analysis. This spatial database forms the analytical core of the study, enabling a scientifically sound model for identifying suitable storm refuge zones amid increasing climate-related hazards.

RESULTS AND DISCUSSIONS

Spatial Distribution of Suitability Factors and Final Refuge Suitability Map

Elevation is a key factor in storm refuge planning, influencing both hazard exposure and accessibility. The Elevation Map of Cluj County (Figure 4), derived from 25-meter resolution SRTM data using ArcGIS 10.8, illustrates the county's varied terrain. Elevation was classified into five ranges, from 214 meters (lowest) to 1827 meters (highest), reflecting the topographic gradient from lowland basins and rolling hills in the east and northeast to rugged mountain zones in the south and southwest, notably the Apuseni Mountains.

Lower elevation zones (214-439 m), shown in dark green, are concentrated in the Someșul Mic valley and adjacent plains. These areas typically offer better infrastructure, higher population density, and easier evacuation, making them more suitable for storm refuges. In contrast, zones above 916 meters, marked in brown and orange, are less accessible and prone to hazards such as landslides or snow, making them unsuitable for rapid response or shelter deployment.

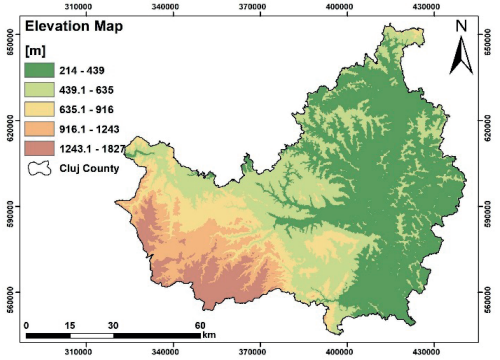

Figure 4. Elevation map of Cluj County derived from SRTM data, reclassified into five elevation ranges to support refuge suitability analysis based on terrain accessibility and storm-related exposure

In cyclone-prone areas, shelters are often built on elevated ground to avoid flooding. While Cluj County doesn't face storm surges, flash floods and heavy rainfall, intensified by climate change, pose serious risks. Thus, elevation must strike a balance: avoiding low-lying flood zones while remaining accessible. The 439-635 meter range was deemed optimal, minimizing flood risk without compromising access for emergency services.

Elevation also influences drainage, infrastructure stability, and emergency logistics. Moderately elevated areas with gentle slopes offer safer, more stable ground. The elevation layer was therefore reclassified to reflect these criteria, increasing the model's relevance for shelter site selection.

By aligning international shelter planning practices (Hasan et al., 2024) with local terrain, the elevation variable strengthens the model's utility for climate-resilient planning in Cluj.

Slope is another critical factor, affecting land use, construction feasibility, and resilience to storms. Derived from the 25-meter SRTM DEM, the slope map (Figure 5) classifies terrain into five categories, from gentle (0-9%) to very steep (49.1-87%). Low-gradient areas in the north and east are ideal for shelter siting due to ease of construction and accessibility, especially for vulnerable groups.

Steeper slopes, concentrated in the southern Apuseni foothills, are unsuitable because of erosion risks, poor access, and construction difficulty (Sestras et al., 2023). Slope also affects runoff, erosion, and infiltration (Costea et al., 2022). Research suggests ideal shelter sites lie on 2-5% slopes, not exceeding 7%, to support safe evacuation and emergency response. Steep areas exceed this threshold, reducing safety and logistics efficiency.

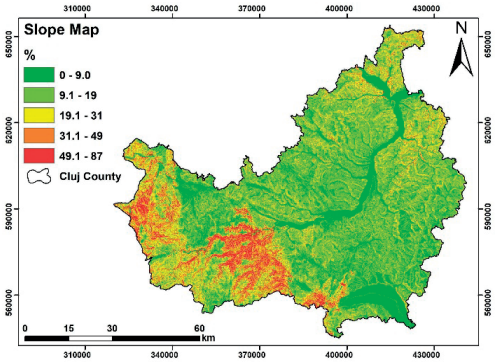

Figure 5. Slope classification map of Cluj County, derived from SRTM data, used to assess terrain suitability for storm refuges based on five slope categories ranging from flat to very steep

In this study, slope is used as a restrictive criterion, assigning higher suitability scores to flatter areas in the AHP model. This approach excludes high-risk or inaccessible terrain, aligning with international best practices, such as those from the IFRC, for emergency shelter siting. Including slope as a core biophysical factor enhances the model's ability to identify stable, accessible refuge zones and supports storm preparedness in diverse topographies.

Land Use and Land Cover (LULC) is another critical spatial variable influencing refuge suitability by affecting environmental stability, functionality, and site accessibility. The LULC map of Cluj County (Figure 6), developed from the Corine Land Cover 2018 dataset using ArcGIS 10.8, reflects five primary land types: agricultural land, vegetation (mainly forests), built-up areas, barren land, and water bodies (Bilașco et al., 2016).

Vegetation-dominated zones, especially in the west and south, overlap with hilly and mountainous terrain. While forests serve as natural buffers during storms and offer protection in rural or peripheral settings, they are generally rated as moderately suitable due to access limitations, rough terrain, and environmental restrictions (Curovic et al., 2020).

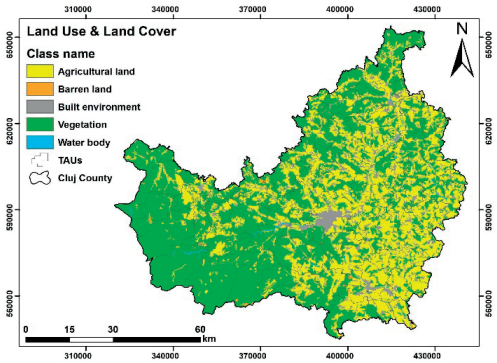

Figure 6. Land Use and Land Cover (LULC) map of Cluj County classified into five categories, supporting the assessment of land suitability for severe storm refuge placement

Agricultural lands, mainly in central and eastern Cluj County, lie on accessible, gently sloped terrain (Chiorean et al., 2024). Though primarily used for farming, they can accommodate storm refuges, especially on less cultivated or public plots. While generally rated as less suitable, with proper land-use planning they can support multipurpose shelter roles.

Built-up areas in cities like Cluj-Napoca, Turda, and Dej include schools and public buildings that are ideal for conversion into storm refuges. Their infrastructure and proximity to dense populations enhance suitability. However, urban congestion and limited space may restrict new shelter construction, reinforcing the need to integrate storm safety into existing urban design.

Barren land, though scarce, is typically open and underused, making it highly suitable for shelter development due to minimal environmental constraints. Conversely, water bodies and floodplains are unsuitable, being prone to flooding, unstable soils, and high exposure during extreme weather.

Including LULC in the multicriteria analysis offers a land-based understanding of site suitability, considering functional roles, adaptability, and environmental priorities (Chiorean et al., 2024). This helps balance refuge placement with ecological and

development needs, supporting a more resilient storm preparedness strategy in Romania.

Population density is another crucial factor, indicating human exposure and emergency logistics needs. The Population Density Map (Figure 8), based on TAU-level data, categorizes values from 702 to 286,598 residents into five classes, from dark green (low) to red (high). This enables targeted refuge planning in high-risk, densely populated zones, where vulnerability and response demands are highest. The Population Density Map (Figure 7), derived from TAU-level data, classifies population values ranging from 702 to 286,598 residents into five categories, from dark green (low density) to red (high density). This classification supports targeted refuge planning in high-risk, densely populated areas where vulnerability and emergency response needs are highest.

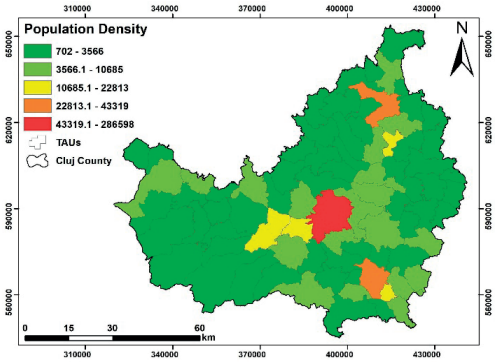

Figure 7. Population density distribution across Cluj County, categorized into five classes, highlighting high-density zones essential for prioritizing storm refuge locations

Cluj-Napoca, marked in red, is the demographic core of Cluj County, with significantly higher population density than surrounding areas. As the administrative and economic hub, it needs a well-distributed shelter network to ensure equitable access. Planning must consider limited space, urban mobility, and integration with existing public buildings, ideally within 1.5 km, following global guidelines for rapid access and minimal evacuation delays.

The orange and yellow zones, representing populations between 10,000 and 43,000 residents, encompass cities such as Turda, Dej, and surrounding peri-urban areas. While these zones are less densely populated, they often lack adequate emergency infrastructure, making them reliant on mobile or temporary shelters. Including these areas in the suitability model ensures that resources are distributed based on both density and spatial coverage.

Rural areas, shown in green, span most of the county but have sparse populations. Despite lower exposure, their isolation, weak healthcare access, and poor transport increase vulnerability. Smaller, strategically placed shelters are essential for timely response.

Population density was weighted in the AHP model to align site prioritization with real-world needs. Dense zones were prioritized for efficiency, while rural communities were considered proportionally to enhance regional resilience. This inclusive, people-centred approach supports equitable storm preparedness.

Access to healthcare is also crucial during and after storms. The Distance from Hospitals Map (Figure 8), created using Euclidean analysis in ArcGIS, divides proximity into five classes from 0 to over 44,000 meters. The most accessible zones, within 9,040 meters, appear in blue to orange and cluster around urban centres like Cluj-Napoca, Turda, Dej, and Huedin. These well-connected areas are ideal for shelters, ensuring rapid medical response during emergencies and improving survival outcomes.

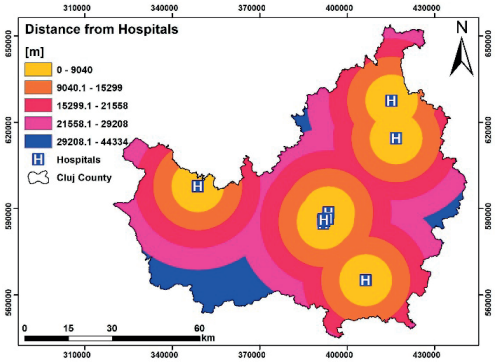

Figure 8. Euclidean distance from hospitals across Cluj County, classified into five distance zones, used to assess healthcare accessibility in emergency refuge site selection

Peripheral and southern rural areas, shown in dark pink and violet, fall into the least accessible zones, often over 29 km from the nearest hospital. These sparsely populated regions face major emergency challenges due to limited

infrastructure. Shelters here risk delayed medical response unless supplemented with mobile clinics or stocked supplies. Thus, hospital proximity is a key constraint in determining site suitability.

Including hospital access in the MCDA framework ensures the model supports human-centred planning, not just physical analysis. Globally, co-locating shelters near medical services is best practice, as immediate access to trauma care, maternal support, and mental health services is vital during disasters. This is echoed in the Sendai Framework, which promotes healthcare resilience and coverage.

In Cluj County, where harsh winters and rural health disparities complicate access, hospital distance is crucial. Including it in the AHP model supports socially responsible storm shelter planning, using realistic travel thresholds to ensure emergency accessibility. Proximity to roads is another essential factor for refuge suitability. The Distance from Roads Map (Figure 9), produced via Euclidean analysis in ArcGIS 10.8, classifies areas within 545 meters of roads as highly suitable, while those beyond 5 km are least suitable. This variable has strong operational relevance. In Cluj's mountainous terrain, evacuation success hinges on road access. Studies show people often delay evacuation, so short, reliable access routes are crucial. Shelters near road networks reduce delays and serve vulnerable populations more effectively. In rugged areas, road proximity often determines whether a refuge is functionally viable.

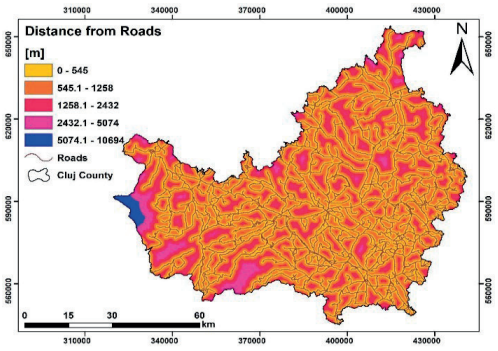

Figure 9. Road distance map of Cluj County showing Euclidean proximity to primary and secondary roads, essential for evaluating emergency accessibility and evacuation efficiency in storm refuge site planning

Most highly accessible zones in Cluj County, shown in yellow and orange, overlap with densely populated, economically active areas, making them ideal for storm refuge placement. In contrast, blue and purple areas in remote and forested regions have limited road access, increasing the risk of evacuation delays, isolation, and restricted emergency response during storms.

Including road proximity in the GIS-based multicriteria model ensures that shelters are not only structurally feasible but also functionally accessible. Prioritizing transport connectivity strengthens an inclusive, resilient shelter network serving both urban and rural communities facing climate-driven storm risks.

Proximity to rivers is equally important in assessing storm refuge suitability, as areas near watercourses are vulnerable to flooding, erosion, and overbank flow during heavy rainfall. Figure 10 shows Euclidean distance from Cluj County's river networks, grouped into five suitability classes, from 0-404 meters (least suitable) to 2073-4480 meters (most suitable). These were derived using hydrological vector data and ArcGIS 10.8 spatial analysis, clearly outlining flood-sensitive zones.

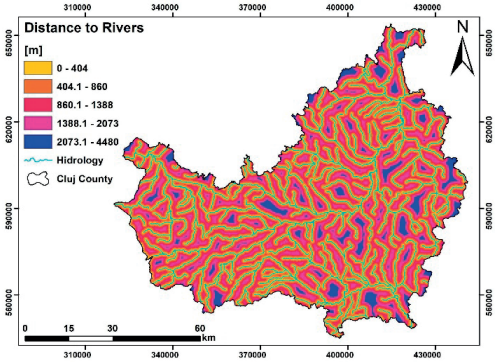

Figure 10. River distance map of Cluj County derived through Euclidean analysis, used to assess flood exposure and prioritize storm refuge sites located at safer distances from hydrological networks

Shelters near rivers face increased risks during storms due to overflow, runoff, and saturated soils. Evacuation delays or structural failures in these areas can threaten safety. Greater distances from rivers often align with higher elevation and slope, reducing flood exposure and improving shelter performance (Yang et al., 2022). This

highlights the need to balance accessibility with environmental resilience.

Standard practice considers locations over 2 km from rivers as highly suitable, minimizing flood risk and supporting evacuation. In Cluj County, these zones, marked in blue, lie on interfluves and plateaus, offering secure and practical options. Areas within 860 meters of rivers (yellow to red) are less suitable and should be avoided.

Incorporating Distance to Rivers into the multicriteria analysis improves the overall resilience of the shelter network. It ensures sites are outside flood zones, helping to safeguard infrastructure, maintain emergency access, and enhance public safety.

The final Severe Storm Refuge Suitability Map for Cluj County (Figure 11) represents the output of a GIS-based multicriteria analysis (MCA) using the Analytic Hierarchy Process (AHP). It combines seven key spatial factors, elevation, slope, land use/land cover, population density, and proximity to rivers, roads, and hospitals, each contributing to the safe and accessible placement of storm refuges.

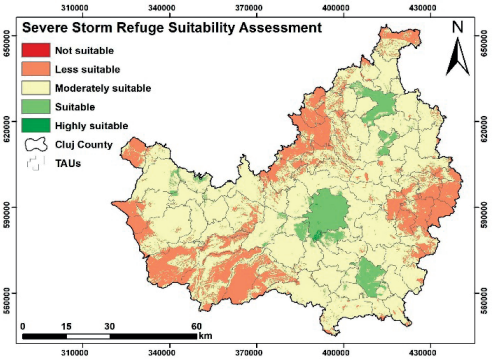

Figure 11. Final storm refuge suitability map for Cluj County, illustrating five suitability classes derived from weighted overlay analysis, integrating elevation, slope, land use, population density, and proximity to infrastructure and rivers

The process began with reclassifying each spatial factor into five standardized suitability classes, followed by a pairwise comparison matrix based on Saaty's (1987) AHP method, informed by expert input and field knowledge. The normalized weights prioritized healthcare proximity (25%) and population density (22%) due to their role in protecting vulnerable, high-density zones. These were followed by proximity to roads (18%) and elevation (16%) for access and hazard mitigation. Slope (7%), LULC (6%), and river distance (6%) had lesser weights due to localized variation.

A weighted overlay in ArcGIS 10.8 then generated a composite map categorizing Cluj County into five refuge suitability levels: Highly Suitable, Suitable, Moderately Suitable, Less Suitable, and Not Suitable. This serves as a clear decision-making tool for emergency planners and local authorities.

The results show that moderately suitable areas dominate the county's central region, with stable terrain and moderate access. Highly suitable zones are located around Cluj-Napoca and peri-urban areas, while mountainous and remote regions, particularly in the southwest and northeast, are largely unsuitable due to steep slopes and limited infrastructure.

Overall, the map offers a reliable, integrated planning tool, combining topographic, infrastructural, and demographic data to support informed storm preparedness and climate resilience strategies.

Interpretation of Suitable Refuge Zones: Spatial Insights and Planning Implications

The final composite figure presents the GIS-based multi-criteria analysis results, showing storm refuge suitability across Cluj County. Generated through an AHP-guided weighted overlay, the map categorizes the area into five classes: not suitable, less suitable, moderately suitable, suitable, and highly suitable. Supporting charts indicate that 68.67% of the region is moderately suitable, while only 0.07% (4.308 km²) qualifies as highly suitable, reflecting the stringent conditions for optimal shelter placement.

A notable highly suitable area is the Făget neighbourhood in southern Cluj-Napoca, characterized by moderate elevation, low slopes (<5%), and a mix of built-up and vegetated land, enhancing accessibility and natural buffering. Its proximity to roads and hospitals and distance from rivers further improve suitability, as assessed through Euclidean distance metrics.

A detailed zoom-in, overlaid with orthophoto imagery, validates the GIS outputs and supports local-scale planning. This visualization serves as

a tool for municipal authorities to prioritize interventions and guide resource distribution.

The study aligns with global emergency planning standards, where factors like elevation, slope, and infrastructure access are central to GIS-AHP approaches. Its successful adaptation to Romania's varied terrain demonstrates the method's versatility. By combining spatial analysis with policy-relevant insights, the study offers a transferable model for disaster preparedness in Eastern Europe and similar regions.

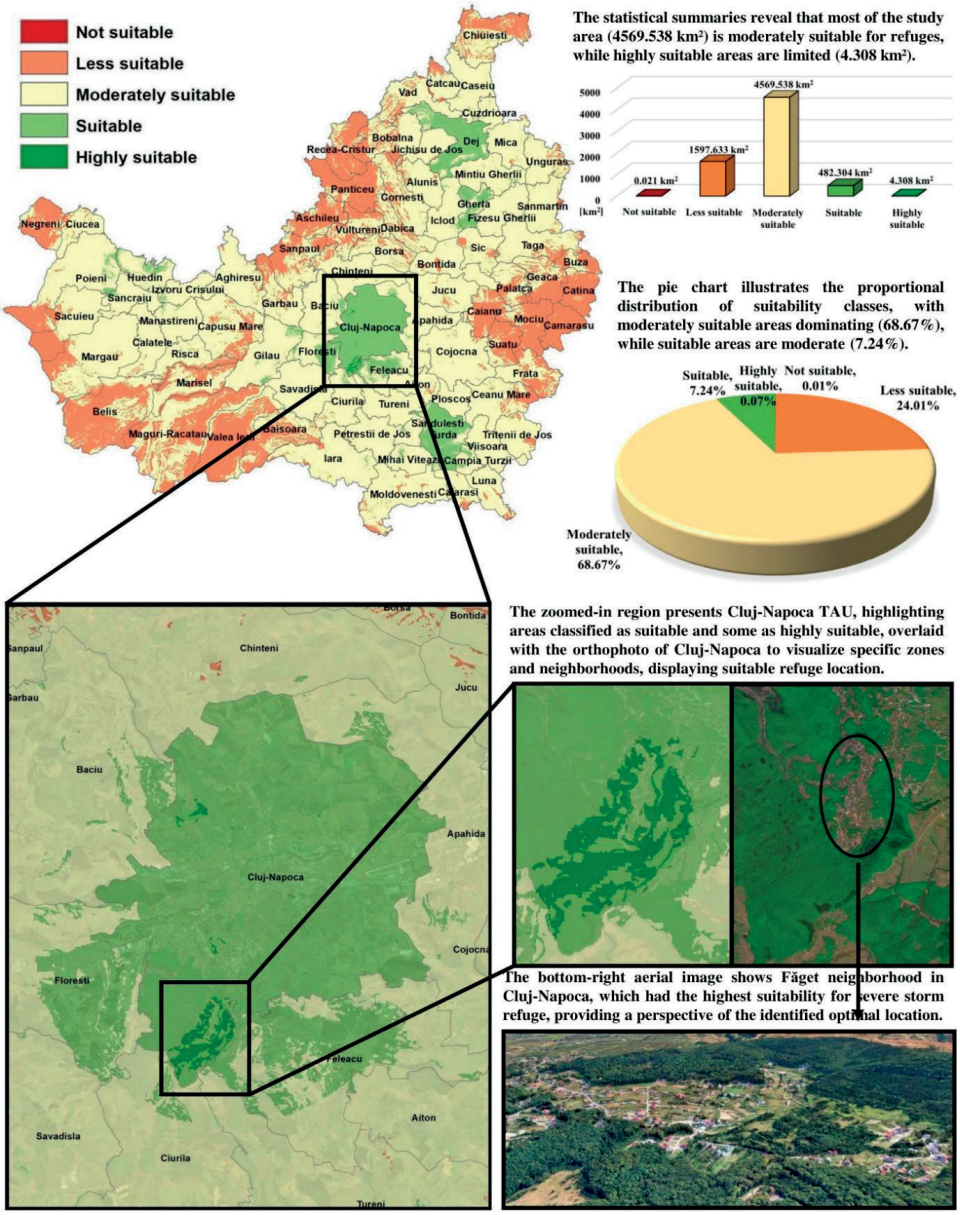

Figure 12. Spatial and statistical synthesis of the final storm refuge suitability analysis in Cluj County, highlighting highly suitable zones around Cluj-Napoca. Includes area statistics, proportional class distribution, orthophoto overlays, and aerial imagery of Făget neighbourhood, identified as the optimal refuge location

CONCLUSIONS

This study employed a GIS-based multicriteria approach to identify optimal storm refuge locations in Cluj County, Romania, an area increasingly exposed to extreme weather due to climate change. Using the Analytic Hierarchy Process, seven critical factors were weighted: elevation, slope, population density, land use/land cover, and proximity to rivers, roads, and healthcare facilities.

The final suitability map, validated through orthophoto overlays and field verification, showed that most of the county (68.67%) is moderately suitable, while only 0.07% is highly suitable. The Făget neighbourhood in Cluj-Napoca stood out as an ideal refuge site due to its balanced elevation, low slopes, strong infrastructure access, and diverse land cover.

These results demonstrate the value of GIS-AHP models for disaster risk reduction and spatial planning. The methodology offers a replicable, objective framework for shelter site selection, providing a model for climate resilience strategies not only in Romania but across other vulnerable regions in Eastern Europe.

Abstract

This study analyses the physiological response and visual quality of several grass varieties grown on four experimental lots, using multispectral imaging for monitoring. The control lot did not receive irrigation, while the other three experimental lots were subjected to distinct irrigation regimes: rotors (lot 1), sprays (lot 2), and underground drip irrigation (lot 3). Multispectral data allowed the assessment of vegetative parameters, to analyse the differences in vegetative state and water stress levels between the lots and grass varieties. The results showed significant variations between the experimental lots, depending on both the type of irrigation and the grass variety, highlighting the efficiency of different irrigation systems in both water conservation and maintaining an optimal vegetative state. The study offers valuable insights for optimizing irrigation practices and selecting grass varieties suited to both specific site conditions and the implementation of sustainable maintenance strategies.

Key words*: monitoring, multispectral imagery, remote sensing.*

INTRODUCTION

Parks represent an important resource in the sustainable and lasting development of cities and municipalities. The grass within these areas serves numerous roles, besides its aesthetic function, it also contributes to maintaining adequate air quality (Chiesura, 2004). Maintaining green spaces with lawns presents a challenge in terms of irrigation while also ensuring efficient water management (Schebella et al., 2014). The management of water resources, particularly in the context of climate change and the rapid expansion of large cities at the expense of diminishing water supplies, remains a constant concern for specialists (Kenna & Horst, 1993). The use of multispectral imaging to assess the efficiency of irrigation systems and optimize turfgrass mixtures to reduce water consumption is an important focus in the current context of climate change and urban development (Krum et al., 2010). Building on previous studies (Kerry et al., 2024), our research differs by implementing a field experiment differently as other studies (Orta et al., 2023) with four test lots, each subjected to three different irrigation treatments, along with a control lot that received no irrigation. The irrigation treatments delivered the same amount of water to the grass in each respective lot. Additionally, all test lots contained 12 different turfgrass mixtures, allowing us to evaluate their behaviour using multispectral imaging. The study was conducted during autumn, just before the dormancy period, to highlight the resilience of turfgrass based on the accumulated vegetative growth over the season. Furthermore, the research aimed to emphasize the importance of fertilizer application in maintaining turfgrass performance and adaptability.

MATERIALS AND METHODS

This study investigates the influence of different irrigation types on various vegetation indices across multiple lawn mix types. The vegetation indices analysed include the Green Normalized Difference Vegetation Index (GNDVI; Gitelson et al., 1996), Leaf Chlorophyll Index (LCI; Sousa-Souto et al., 2018), Modified Chlorophyll Absorption Ratio Index (MCARI; Daughtry et al., 2000), Normalized Difference Red Edge Index (NDRE; Gitelson et al., 1996), Normalized Difference Vegetation Index (NDVI; Tucker, 1979), and Structure Insensitive Pigment Index (SIPI_2; Peñuelas et al., 1995). The study aims to determine the most effective irrigation method for maintaining optimal plant health and nutrient absorption.

A series of field trials were conducted on multiple lawn mix types under different irrigation treatments. The experimental design of the field and office works are presented (Sestras et al., 2019) in Figure 1.

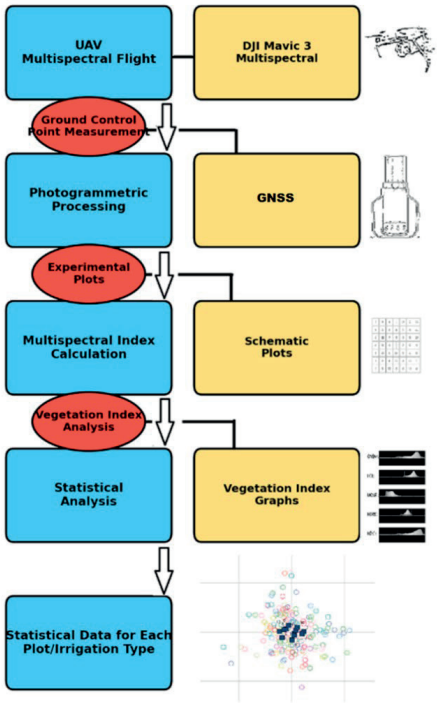

Figure 1. Experimental design

Measurements were taken using remote sensing techniques, and statistical analysis was performed to identify trends among irrigation types and lawn mix performance. For this study, a DJI Mavic 3 Multispectral (3M) drone was utilized, equipped with two advanced cameras that enable high-precision scanning and analysis of various crops. The photogrammetric processing was conducted in Agisoft Photoscan and the Ground Control Points (GCPs) served just as verification points, as the drone was equipped with RTK Module. All the indices were computed in Agisoft metashape, using raster calculator, then exported as raster images. This type of equipment is widely used in agriculture and forestry applications, providing valuable insights into vegetation health and land management. The analyses were preformed using ArGis (Popescu et al., 2024; Bilaşco et al., 2016; Sestras et al., 2018), and IBM SPSS Statistics (SPSS).

The main characteristics of the equipment are presented in Table 1. Because we were able to fly at low altitudes, we obtained a spatial resolution under 1 cm/pixel.

Table 1. Multispectral drone specifications

Component	Specification
Multispectral Camera - Spectral Bands	Green (560 ± 16 nm), Red (650 ± 16 nm), Red Edge (730 ± 16 nm), Near-Infrared (860 ± 26 nm)

These spectral bands offer valuable insights for assessing plant health, identifying stress factors, and enhancing precision agriculture practices. By integrating both RGB and multispectral imaging capabilities, the DJI Mavic 3M drone proves to be a versatile instrument for remote sensing in agriculture, forestry, and environmental monitoring.

In this study, experimental plots featuring twelve distinct lawn types were analyzed, arranged as shown in Figure 2.

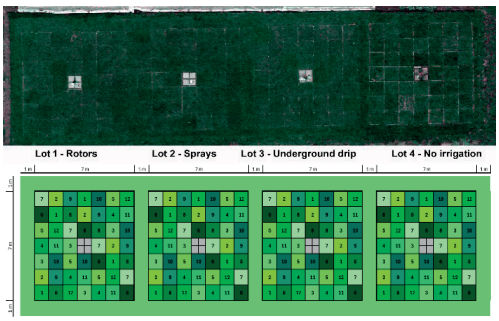

Figure 2. Experimental lots

The twelve lawn mix types are described in the Table 2, with all the mixt numbering correlated with the lots and all the components and the percentage of each lawn used (Hitter et al., 2021). As shown in the experimental design, we conducted a multispectral image acquisition and then applied diverse spectral vegetation indices are presented in Table 3.
The desired quantity of water used for irrigation is presented in Table 4.

Table 2. Lawn Mixes and composition

No.	Mix Name	Composition
1	**BRB Bar Power RPR**	*Lolium perenne* 40%, *L. perenne* 20%, *Festuca rubra commutata* 20%, *F. rubra rubra* 10%, *Poa pratensis* 10%
2	**BRB Rapid**	*Lolium perenne* 30%, *L. perenne* 25%, *L. perenne* 20%, *Festuca rubra* 15%, *Poa pratensis* 10%

11	**ICL Landscaper Pro Rapid**	*Lolium perenne* 75%, *Festuca rubra rubra* 15%, *Poa pratensis* 10%
12	**ICL ProSelect Regenerator Plus**	*Lolium perenne* 75%, *Poa pratensis* 25%

Table 3. Spectral Vegetation Indices used

Index	Description	Calculation Formula	Author
NDVI (Normalized Difference Vegetation Index)	Assesses vegetation health and vigour.	(NIR - Red) / (NIR + Red)	Tucker, 1979
GNDVI (Green Normalized Difference Vegetation Index)	Evaluates chlorophyll levels and plant health.	(NIR - Green) / (NIR + Green)	Gitelson, 1996
NDRE (Normalized Difference Red Edge Index)	Measures nitrogen uptake and chlorophyll concentration.	(NIR - RedEdge) / (NIR + RedEdge)	Haboudane, 2004
LCI (Leaf Chlorophyll Index)	Estimates chlorophyll concentration in leaves.	(NIR - RedEdge) / (NIR + RedEdge)	Souto, 2018
MCARI (Modified Chlorophyll Absorption in Reflective Index)	Determines chlorophyll absorption and plant stress levels.	1.2 * (2.5 * (NIR - Red) - 1.3 * (NIR - Green)) / (normalized to reflectance in red, green, and NIR bands)	Daughtry, 2000
SIPI_2 (Structure Insensitive Pigment Index)	Analyses pigment ratios and stress resistance in plants.	(NIR - Blue) / (NIR + Red)	Peñuelas et al., 1995

Table 4. Desired Irrigation quantity

Irrigation Type	Precipitation Rate (mm/h)	Run Time (minutes)	Desired depth of water application (mm/sqm
Spray Irrigation (2)	40	6	4.5
Rotor Irrigation (1)	24	12	4.5
Drip Irrigation (3)	18.37	15	4.5
No Irrigation (0)	0	0	0

RESULTS AND DISCUSSIONS

The photogrammetric survey was made on 7th As shown in the Figure 4 it could be clearly seen that the moisture is decreasing gradually, as there was no irrigation used on this period, having in mind that the lawn was prepared for winter. Also correlating this graph with the weather graph presented in Figure 3 it can be clearly seen that the temperatures were below 0 degrees, so that no irrigation could have been applied.
November 2024, in order to see how the post vegetative stage affects the grass health, and in what percentage the fertilization and the accumulated nutrients help the plants to maintain a healthy aspect. The weather evolution before the photogrammetric survey it is presented Figure 3.

The soil moisture was also recorded on the ground level, at approximately 5cm underground, the main results for soil moisture are presented in Figure 4, as a medium value of three sensors each placed on lot 1, 2 and 3.

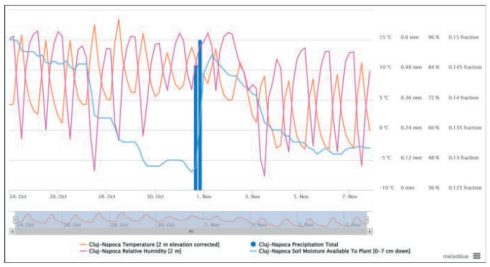

Figure 3. Weather and precipitations before and around the survey (Source Meteoblue)

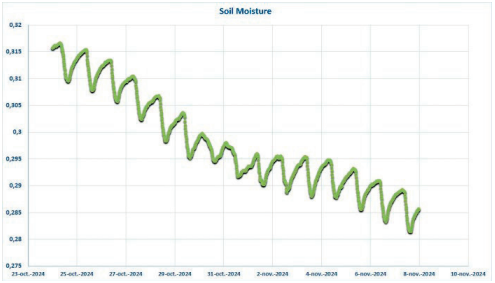

Figure 4. Soil Moisture graph for the period before the survey

The NDVIis a widely used metric for assessing vegetation health and density based on spectral reflectance. It measures the difference between the absorption of red light by chlorophyll and the reflection of near-infrared (NIR) light by plant structures (Herbei& Badaluta-Minda, 2024).
In Figure 5 it can be seen the results obtained for the NDVI index applied on our experimental lots.

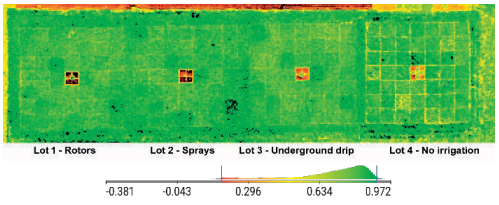

Figure 5. NDVI Index applied on the experimental lot

Range: NDVI values typically vary between -1 and +1, providing insights into vegetation cover and health (Constantinescu et al., 2018).
High NDVI Values (close to +1): represent dense, healthy green vegetation with high chlorophyll content. These areas appear bright green on NDVI maps.
Moderate NDVI Values (around 0): indicate sparse vegetation or grassland areas with lower chlorophyll levels. These zones are often shown in yellow or light green.
Low NDVI Values (close to -1): correspond to barren land, exposed soil, or rock surfaces, where vegetation is absent. Such areas appear in brown or reddish tones.
The Green Normalized Difference Vegetation Index (GNDVI) is a widely used vegetation index that measures the amount of healthy green vegetation within an area. By comparing the reflectance values of specific spectral bands, GNDVI provides a quantitative assessment of vegetation health and vigour. The results for our experimental lots are presented in Figure 6.

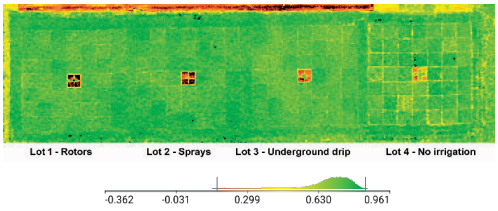

Figure 6. GNDVI Index applied on the experimental lot

GNDVI values range from -1 to +1, with higher values indicating denser and healthier vegetation cover.
High GNDVI values (closer to +1) suggest areas with high chlorophyll content and strong photosynthetic activity, typically associated with lush, healthy vegetation.
Moderate GNDVI values indicate areas with some vegetation, such as grasslands or sparse crops, where plant health varies.
Low GNDVI values (close to 0) are characteristic of bare soil, urban areas, or areas with low vegetation density.
Negative values suggest the presence of water bodies, barren land, or non-vegetated surfaces.
For our studied area, the distribution of GNDVI values shows a peak in the positive range, indicating a predominance of vegetation with healthy chlorophyll levels.
The colour gradient in the legend transitions from grey (-1) to orange (low values), yellow (moderate values), and green (high values),

which visually represents the varying density of vegetation.
The histogram peak in the green region suggests that most of the analysed area consists of healthy and dense vegetation, while smaller portions fall in the yellow and orange ranges, indicating areas with moderate or lower vegetation health.
The Normalized Difference Red Edge Index (NDRE) is a vegetation index closely related to NDVI but incorporates Red Edge light instead of the traditional Red band. The Red Edge wavelength penetrates deeper into the leaf structure, allowing for a more accurate assessment of chlorophyll content and plant stress.
The results for our experimental lots are presented in Figure 7.

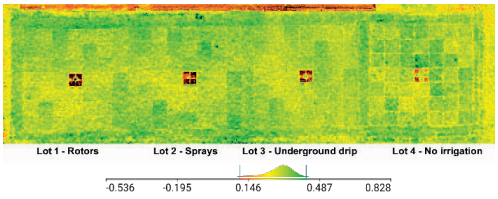

Figure 7. NDRE Index applied on the experimental lot

The representation of NDRE, as shown Figure 7, follows a gradient:
Negative values or values close to zero (grey to dark orange) represent barren land, non-vegetated surfaces, or unhealthy vegetation.
Moderate values (yellow to light green) indicate areas with some vegetation, but with possible stress or lower chlorophyll content.
High values (bright green) are associated with dense, healthy vegetation, indicating strong chlorophyll activity and robust plant health.
The NDRE histogram suggests that most of the measured values are concentrated in the positive range (yellow to green), indicating overall good vegetation health in the analysed area.
A gradual transition from orange to yellow and then to green demonstrates variations in plant vigour, with some areas experiencing stress while others remain healthy.
The use of Red Edge light makes NDRE particularly valuable for detecting subtle variations in vegetation health before visible symptoms appear, making it a powerful tool for precision agriculture and crop monitoring.
The Leaf Chlorophyll Index (LCI) is a vegetation index designed to measure chlorophyll content in leaves, offering valuable insights into plant health and photosynthetic efficiency. LCI utilizes the Near Infrared (NIR) and Red Edge spectral bands, as NIR is sensitive to the internal structure and moisture content of the leaf, while Red Edge strongly correlates with chlorophyll concentration. The results for our experimental lots are presented in Figure 8.

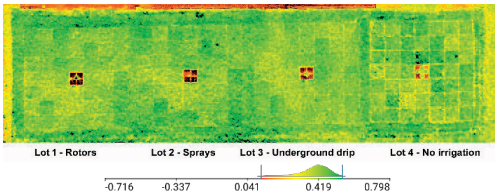

Figure 8. LCI Index applied on the experimental lot

The representation of LCI, as shown in Figure 6 colour scale, follows a gradient:
Low values (grey to dark orange): indicate areas with low chlorophyll content, which could be associated with barren land, non-vegetated surfaces, or vegetation experiencing severe stress.
Moderate values (yellow to light green): represent regions with some vegetation, but with possible deficiencies in chlorophyll due to environmental stress or suboptimal nutrient availability.
High values (bright green): correspond to healthy, thriving vegetation with high chlorophyll concentration, indicating strong photosynthetic activity and robust plant growth.
The LCI histogram suggests that most of the measured values are concentrated in the positive range (yellow to green), indicating overall good vegetation health in the analysed area.
A gradual transition from orange to yellow and then to green illustrates variations in plant vigour, with certain areas experiencing mild to moderate stress while others exhibit optimal growth.
The combination of NIR and Red Edge bands enhances LCI's ability to detect subtle chlorophyll variations, making it particularly useful for monitoring nutrient status, irrigation effectiveness, and early stress detection.
The Modified Chlorophyll Absorption Ratio Index (MCARI) is a vegetation index designed to measure the intensity of chlorophyll absorption in plants. It is highly sensitive to

variations in chlorophyll concentration and the Leaf Area Index (LAI), making it a valuable tool for assessing plant health and stress levels. Unlike some other indices, MCARI is less influenced by lighting conditions, soil background reflectance, and non-photosynthetic materials. The results for our experimental lots are presented in Figure 9.

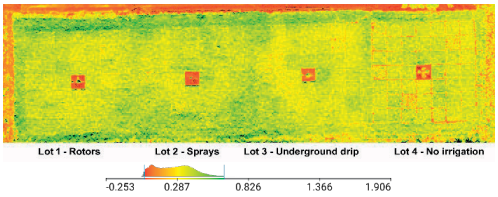

Figure 9. MCARI Index applied on the experimental lot

The MCARI colour scale presented on Figure 9 provides a visual representation of its values:
Low values (dark to light green) indicate a higher chlorophyll content, meaning healthier and more vigorous vegetation.
Moderate values (yellow to orange) represent areas with moderate chlorophyll levels, possibly indicating some plant stress or early signs of nutrient deficiency.
High values (dark orange to red) correspond to regions with low chlorophyll content, which may be associated with plant stress, chlorosis, or reduced photosynthetic activity.
The MCARI histogram shows that most of the analysed area has values in the moderate-to-high range, suggesting a mix of healthy and slightly stressed vegetation.
A strong presence of orange and red areas highlights zones with lower chlorophyll content, possibly indicating stress or poor nutrient absorption.
Since MCARI is primarily used for detecting chlorophyll variations, it is often interpreted in combination with NDVI or LAI to gain a more comprehensive understanding of vegetation health.
The Structure Insensitive Pigment Index (SIPI_2) is a vegetation index that helps assess plant stress and pigment composition, particularly the ratio of carotenoids to chlorophyll. It is widely used to evaluate plant health, stress resilience, and photosynthetic efficiency. Unlike indices that are highly influenced by leaf structure, SIPI_2 minimizes these structural effects, providing a more stable assessment of pigment balance. The results for our experimental lots are presented in Figure 10.

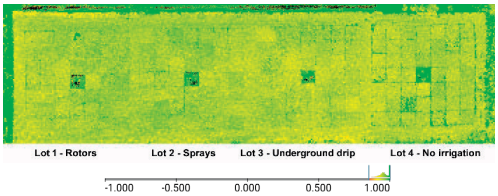

Figure 10. SIPI 2 Index applied on the experimental lot

The SIPI_2 colour scale presented in Figure 10 provides a visual representation of its values:
Low values (dark green to light green) indicate a higher chlorophyll-to-carotenoid ratio, representing healthy, unstressed vegetation with optimal photosynthetic capacity.
Moderate values (yellow to orange) suggest a more balanced ratio, possibly indicating early signs of stress or pigment imbalance.
High values (red to dark orange) correspond to regions with a lower chlorophyll-to-carotenoid ratio, often associated with plant stress, senescence, or nutrient deficiencies. The SIPI_2 histogram shows that most of the analysed area falls within the high-value range (orange to red), suggesting that a significant portion of the vegetation is experiencing some level of stress or chlorophyll degradation.
The limited presence of green areas indicates that only a small portion of the analysed vegetation is in an optimal health state.
A concentration of high SIPI_2 values may be a sign of drought stress, nutrient limitations, or advanced stages of plant aging, which can impact overall biomass production and vigour.
Later, some analyses were conducted on each lot, and we extracted the statistical values for each applied index. The lawn mixes were vectorised, and each one got its own zonal statistic value as a table (Coroian I. et al., 2020).
As could be seen in Figure 11, some statistical analyses were conducted later on. In figure 11 the Clustered boxplot on each Lawn mixt type for the GNDVI index could be seen.

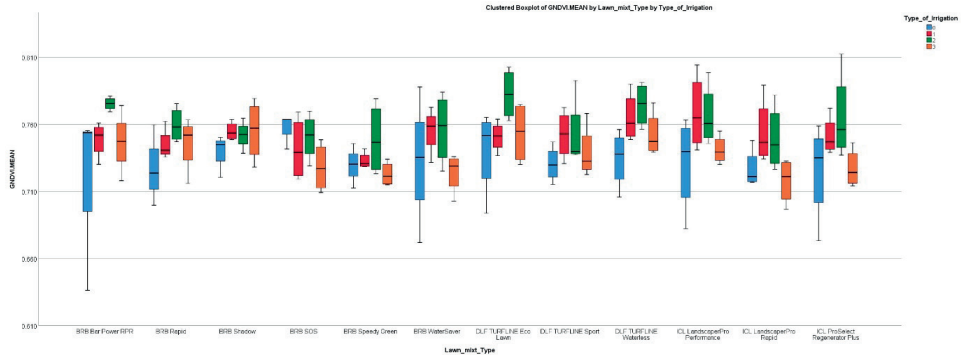

Figure 11. GNDVI index boxplot for each lawn mixt type

This boxplot illustrates the distribution of GNDVI Mean values for various Lawn Mix Types under different irrigation methods. Type 0 (blue) represents No Irrigation, Type 1 (red) represents Rotor Irrigation, Type 2 (green) represents Spray Irrigation, and Type 3 (orange) represents Underground Drip. Since GNDVI (Green Normalized Difference Vegetation Index) reflects plant health, higher values indicate better vegetation quality and water efficiency.

For BRB Bar Power RPR, No Irrigation shows high variability and the lowest median GNDVI, while Spray Irrigation achieves the highest values. BRB Rapid exhibits inconsistent chlorophyll levels under No Irrigation, with Spray performing best. BRB Shadow has a compact distribution across irrigation types, with Rotors and Underground Drip slightly outperforming Spray. BRB SOS performs worst with Underground Drip, while Spray and Rotors yield better results. BRB Speedy Green shows a stable GNDVI distribution, with Spray and Rotors having slightly higher medians. BRB WaterSaver is among the top-performing mixes, with Spray producing the highest chlorophyll content.

DLF TURFLINE Eco Lawn performs better with Rotor and Underground Drip compared to No Irrigation. DLF TURFLINE Sport maintains consistently high GNDVI values, with Spray providing the best results. DLF TURFLINE Waterless shows a large variation across irrigation types, but Spray leads in performance. ICL LandscapePro Performance has a narrow GNDVI spread, with Rotors and Spray performing slightly better than No Irrigation. ICL LandscapePro Rapid achieves high GNDVI values across all irrigation types, with Spray as the top performer. ICL Professional Regeneration Plus exhibits moderate variability, where Spray and Underground Drip perform better than Rotors.

Overall, Spray Irrigation consistently yields the highest GNDVI values, followed by Underground Drip and Rotor, while No Irrigation results in the lowest and most variable GNDVI, indicating water stress.

In Figure 12 the Clustered boxplot on each Lawn mixt type for the LCI index could be seen.

This boxplot illustrates the distribution of LCI Mean (Leaf Chlorophyll Index) values for different Lawn Mix Types under various irrigation methods, including No Irrigation, Rotor Irrigation, Spray Irrigation, and Underground Drip. Since LCI measures chlorophyll content, higher values indicate healthier and more photosynthetically active plants.

For BRB Bar Power RPR, No Irrigation shows high variability and a lower median, indicating inconsistent chlorophyll content and potential water stress. Spray Irrigation and Underground Drip provide more stable distributions and better performance, while Rotor Irrigation performs moderately, with a slightly lower median than Spray and Drip. BRB Rapid has a broad spread and a lower median under No Irrigation, reflecting inconsistent chlorophyll content. Spray Irrigation achieves the highest median, suggesting optimal plant health, while Rotor and Underground Drip show moderate and similar performance. BRB Shadow exhibits similar performance across irrigation types with a moderate spread, with Spray and Underground Drip slightly outperforming No Irrigation.

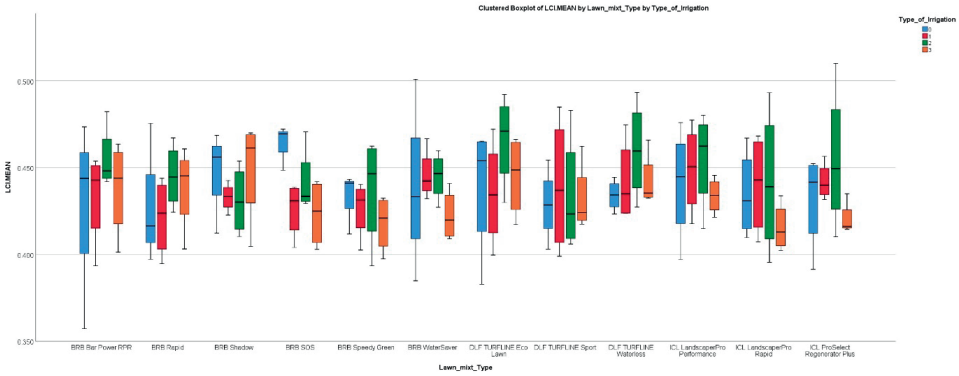

Figure 12. LCI index boxplot for each lawn mixt type

BRB SOS has the lowest median under Underground Drip, suggesting less effectiveness, while No Irrigation, Rotor, and Spray show higher and more stable LCI values. BRB Speedy Green has a compact LCI distribution, indicating consistent performance, with Spray and Rotor Irrigation slightly improving chlorophyll levels. BRB WaterSaver is one of the highest-performing mixes, with Spray Irrigation achieving the highest median, indicating optimal chlorophyll levels, while No Irrigation shows the widest variability and inconsistent performance. DLF TURFLINE Eco Lawn performs slightly better with Rotor and Underground Drip than with No Irrigation, which results in lower LCI values and suggests water stress.

DLF TURFLINE Sport maintains consistently high LCI values across irrigation types, with Spray performing best and No Irrigation showing greater variability and fluctuating chlorophyll levels. DLF TURFLINE Waterless exhibits large variation across irrigation types, with Spray producing the highest median and No Irrigation displaying a widespread, indicating inconsistent plant health. ICL LandscapePro Performance has a narrow LCI spread, reflecting consistent vegetation health, with Rotors and Spray performing slightly better than No Irrigation. ICL LandscapePro Rapid achieves high LCI values across all irrigation types, with Spray producing the highest median and Underground Drip offering stable performance with minimal variation. IL Professional Regeneration Plus shows moderate LCI variability across irrigation types, with Rotor slightly underperforming compared to Spray and Underground Drip.

Overall, Spray Irrigation is the best-performing method, consistently achieving higher LCI values and indicating better chlorophyll levels and plant health. Underground Drip provides stable performance and is often comparable to Rotor Irrigation, though slightly less effective than Spray. Rotor Irrigation shows moderate performance, performing better than No Irrigation but lower than Spray and Drip in most cases. No Irrigation results in moderately variable LCI values, with median levels that are not consistently the lowest across indices - suggesting that while water stress may occur, it does not always lead to the poorest or most inconsistent plant health outcomes

In Figure 13 the Clustered boxplot on each Lawn mixt type for the MCARI index could be seen.

This boxplot illustrates the distribution of MCARI Mean (Modified Chlorophyll Absorption Ratio Index) values for different Lawn Mix Types under various irrigation methods, including No Irrigation, Rotor Irrigation, Spray Irrigation, and Underground Drip. MCARI is an index used to estimate chlorophyll content and stress levels in vegetation, where higher values indicate better chlorophyll retention and lower stress, while lower values may suggest chlorosis, senescence, or water stress.

For BRB Bar Power RPR, No Irrigation shows high variability and the lowest median, suggesting inconsistent chlorophyll content and potential water stress. Spray and Rotor Irrigation have higher median values, indicating better performance, while Underground Drip shows moderate results with a slightly lower median.

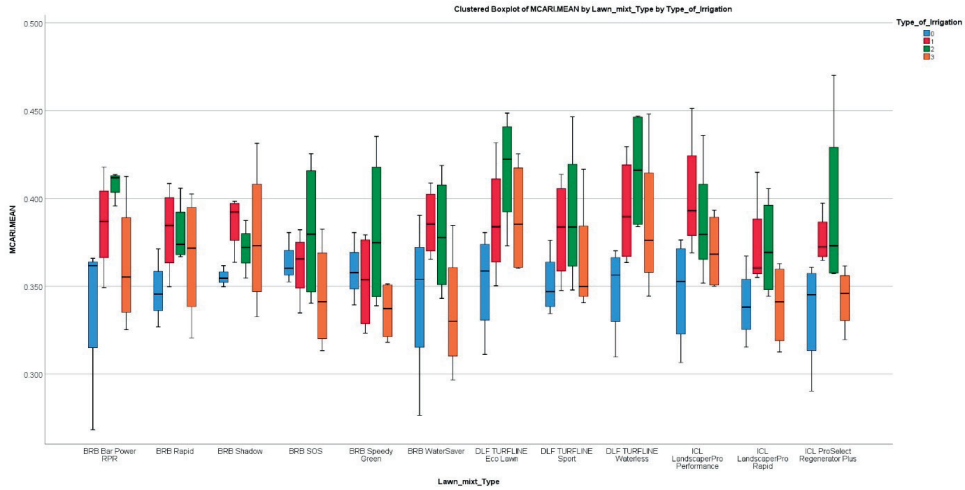

Figure 13. MCARI index boxplot for each lawn mixt type

BRB Rapid has a low median and high variability under No Irrigation, reflecting unstable chlorophyll levels. Spray Irrigation achieves the highest median, suggesting optimal chlorophyll content, while Rotor and Underground Drip demonstrate moderate performance. BRB Shadow exhibits less variability across irrigation types, indicating consistent chlorophyll content, with Spray and Rotor performing slightly better than No Irrigation.

BRB SOS has the lowest median under Underground Drip, suggesting reduced effectiveness, whereas No Irrigation, Rotor, and Spray exhibit higher and more stable MCARI values. BRB Speedy Green maintains a compact MCARI distribution, reflecting consistent chlorophyll levels, with Spray and Rotor achieving higher median values that suggest better chlorophyll retention. BRB WaterSaver is among the highest-performing mixes, with Spray reaching the highest median and indicating optimal chlorophyll content, while No Irrigation presents wide variability and inconsistent plant health. DLF TURFLINE Eco Lawn performs slightly better with Rotor and Underground Drip than with No Irrigation, which results in lower MCARI values and suggests water stress.

DLF TURFLINE Sport consistently maintains high MCARI values across all irrigation types, with Spray performing best, while No Irrigation introduces more variability and fluctuating chlorophyll levels. DLF TURFLINE Waterless exhibits large variations across irrigation types, with Spray achieving the highest median and No Irrigation displaying a widespread, indicating inconsistent plant health. ICL LandscapePro Performance has a narrow MCARI spread, reflecting consistent vegetation health, with Rotors and Spray slightly outperforming No Irrigation. ICL LandscapePro Rapid attains high MCARI values across all irrigation types, with Spray achieving the highest median and Underground Drip providing stable performance with minimal variation. IL Professional Regeneration Plus shows moderate MCARI variability across irrigation types, with Rotor slightly underperforming compared to Spray and Underground Drip.

Overall, Spray Irrigation is the best-performing method, consistently producing higher MCARI values and indicating better chlorophyll retention and lower stress. Underground Drip provides stable performance, often comparable to Rotor Irrigation but slightly less effective than Spray. Rotor Irrigation shows moderate performance, performing better than No Irrigation but lower than Spray and Drip in most cases. No Irrigation produces the lowest and most variable MCARI values, highlighting water stress and inconsistent plant health.

In Figure 14 the Clustered boxplot on each Lawn mixt type for the NDRE index could be seen.

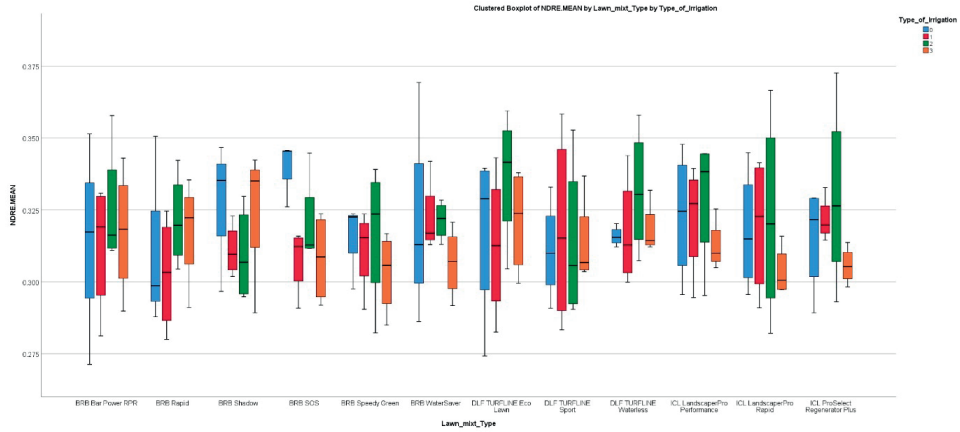

Figure 14. NDRE index boxplot for each lawn mixt type

This boxplot illustrates the distribution of NDRE Mean (Normalized Difference Red Edge Index) values for different Lawn Mix Types under four irrigation types: No Irrigation, Rotor Irrigation, Spray Irrigation, and Underground Drip NDRE is a vegetation index that measures chlorophyll content and nitrogen status in plants. Higher values indicate better plant health, increased nitrogen uptake, and stronger chlorophyll levels, while lower values suggest potential nutrient deficiency or stress.

For BRB Bar Power RPR, No Irrigation presents a moderate spread and a slightly lower median, indicating chlorophyll stress due to water deficiency. Spray Irrigation and Underground Drip show higher medians, suggesting improved nitrogen uptake, while Rotor Irrigation exhibits moderate performance with some variability. BRB Rapid displays a higher spread and lower median under No Irrigation, reflecting unstable chlorophyll levels. Spray Irrigation has the highest median, indicating optimal chlorophyll content, whereas Rotor and Underground Drip demonstrate moderate performance. BRB Shadow maintains similar NDRE values across irrigation types, showing consistent nitrogen uptake, with Spray and Rotor slightly outperforming No Irrigation.

BRB SOS has the lowest median under Underground Drip, suggesting reduced nitrogen uptake efficiency, while Spray, Rotor, and No Irrigation produce higher and more stable NDRE values. BRB Speedy Green shows a compact NDRE distribution, reflecting consistent nitrogen content, with Spray and Rotor achieving higher median values that suggest better nitrogen retention. BRB WaterSaver is among the highest-performing mixes, with Spray reaching the highest median and indicating optimal nitrogen absorption, while No Irrigation presents the widest variability, suggesting inconsistent plant health. DLF TURFLINE Eco Lawn performs slightly better with Rotor and Underground Drip compared to No Irrigation, which results in lower NDRE values and suggests water and nutrient stress.

DLF TURFLINE Sport consistently maintains high NDRE values across all irrigation types, with Spray performing best, while No Irrigation introduces more variability and fluctuating chlorophyll levels. DLF TURFLINE Waterless exhibits large variation across irrigation types, with Spray achieving the highest median and No Irrigation displaying a wide spread, indicating inconsistent plant health. ICL LandscapePro Performance has a narrow NDRE spread, reflecting consistent vegetation health, with Rotors and Spray slightly outperforming No Irrigation. ICL LandscapePro Rapid attains high NDRE values across all irrigation types, with Spray achieving the highest median and Underground Drip providing stable performance with minimal variation. IL Professional Regeneration Plus shows moderate NDRE variability across irrigation types, with Rotor slightly underperforming compared to Spray and Underground Drip.

Overall, Spray Irrigation consistently produces the highest NDRE values, indicating the best nitrogen uptake and plant health. Underground

Drip offers stable performance, often comparable to Rotor Irrigation but slightly less effective than Spray. Rotor Irrigation shows moderate performance, ranking above No Irrigation but below Spray and Underground Drip in most cases. No Irrigation generally shows moderate to high variability in NDRE values, but not consistently the lowest values - indicating that while water and nutrient stress may impact plant health, its effects vary depending on the turfgrass type and conditions.

In Figure 15 the Clustered boxplot on each Lawn mixt type for the NDVI index could be seen.

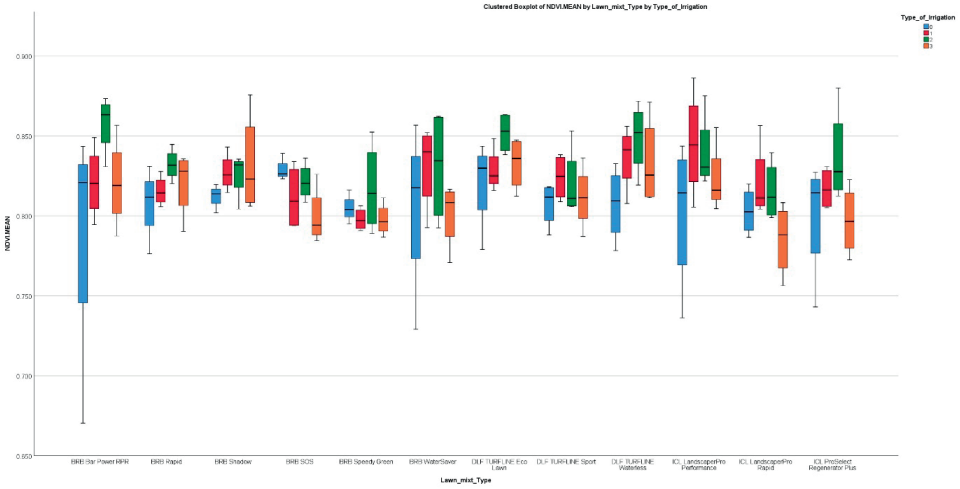

Figure 15. NDVI index boxplot for each lawn mixt type

This boxplot illustrates the distribution of NDVI Mean (Normalized Difference Vegetation Index) values for different Lawn Mix Types under four irrigation methods: No Irrigation, Rotor Irrigation, Spray Irrigation, and Underground Drip. NDVI is a widely used vegetation index that measures plant health, biomass, and chlorophyll levels. Higher NDVI values indicate healthier vegetation with greater chlorophyll content and better water retention, while lower values suggest plant stress due to drought, poor nutrition, or water deficiencies.

For BRB Bar Power RPR, No Irrigation exhibits high variability and the lowest median, indicating inconsistent vegetation health and water stress. Spray and Underground Drip show higher median values, suggesting improved water retention and better plant health, while Rotor Irrigation demonstrates moderate performance with less variability. BRB Rapid has a lower median and high variability under No Irrigation, reflecting fluctuating plant health. Spray Irrigation achieves the highest median, indicating strong chlorophyll levels and water availability, whereas Rotor and Underground Drip display moderate NDVI values. BRB Shadow presents a compact distribution across irrigation types, signifying consistent NDVI performance, with Spray and Rotor achieving slightly higher values than No Irrigation.

BRB SOS has the lowest median under Underground Drip, suggesting less effectiveness in improving NDVI, while Spray, Rotor, and No Irrigation yield higher and more stable values. BRB Speedy Green maintains a compact NDVI distribution, reflecting consistent vegetation health, with Spray and Rotor achieving higher median values, suggesting better chlorophyll retention. BRB WaterSaver is one of the highest-performing mixes, with Spray reaching the highest median and indicating excellent vegetation health, while No Irrigation shows the widest variability, suggesting inconsistent performance. DLF TURFLINE Eco Lawn performs slightly better with Rotor and Underground Drip than with No Irrigation, which results in lower NDVI values and suggests water stress.

DLF TURFLINE Sport consistently maintains high NDVI values across all irrigation types,

with Spray achieving the best performance and the highest median, while No Irrigation introduces more variability and fluctuating chlorophyll levels. DLF TURFLINE Waterless exhibits large variation across irrigation types, with Spray showing the highest median, suggesting better water efficiency and plant health, whereas No Irrigation presents a wide spread, indicating inconsistent performance. ICL LandscapePro Performance has a narrow NDVI spread, reflecting consistent plant health, with Rotors and Spray performing slightly better than No Irrigation. ICL LandscapePro Rapid attains higher NDVI values across all irrigation types, with Spray producing the highest median and Underground Drip providing stable performance with minimal variation. IL Professional Regeneration Plus demonstrates moderate NDVI variability across irrigation types, with Rotor slightly underperforming compared to Spray and Underground Drip.

Overall, Spray Irrigation proves to be the most effective method, consistently producing higher NDVI values and indicating better chlorophyll levels and overall plant health. Underground Drip provides stable performance, often comparable to Rotor Irrigation but slightly less effective than Spray. Rotor Irrigation performs moderately well, ranking above No Irrigation but below Spray and Underground Drip in most cases. No Irrigation results in the lowest and most variable NDVI values, highlighting the effects of water stress on plant health. In Figure 16 the Clustered boxplot on each Lawn mixt type for the SIPI_2 index could be seen.

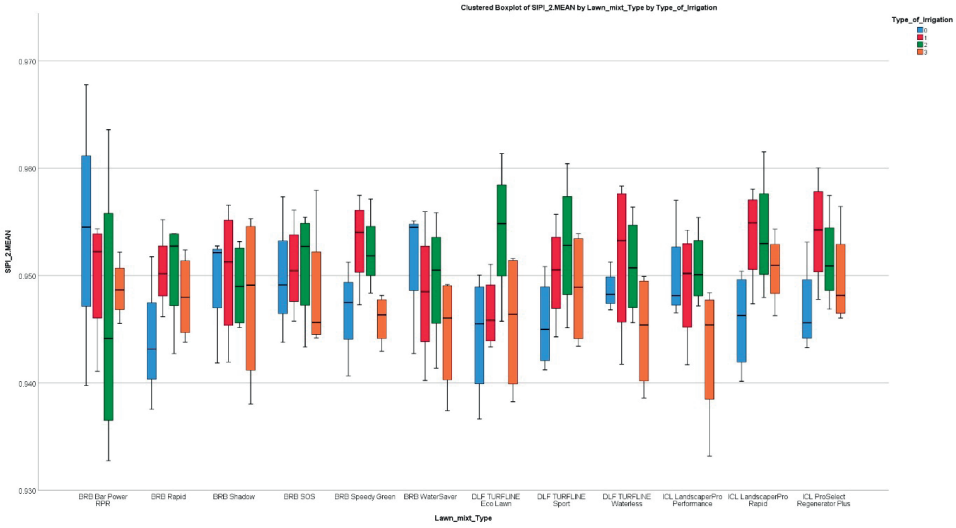

Figure 16. SIPI_2 index boxplot for each lawn mixt type

This boxplot illustrates the distribution of SIPI_2 Mean values across Lawn Mix Types under four irrigation methods: No Irrigation, Rotor, Spray, and Underground Drip. SIPI measures pigment content, where higher values indicate better stress resistance.

Spray consistently achieves the highest SIPI values, reflecting better pigment stability and plant health. Underground Drip provides stable performance, while Rotor performs moderately well. No Irrigation results in the lowest and most variable SIPI values, indicating increased stress and pigment imbalances. Among Lawn Mixes, BRB WaterSaver and DLF TURFLINE Sport show strong pigment retention, while BRB SOS and DLF TURFLINE Waterless exhibit more variability. Efficient irrigation strategies enhance plant resilience and pigment balance.

In order to determine if the multispectral imagery is, or not efficient for lawn monitoring, a canonical discriminant function was applied to the whole data set (Figure 17).

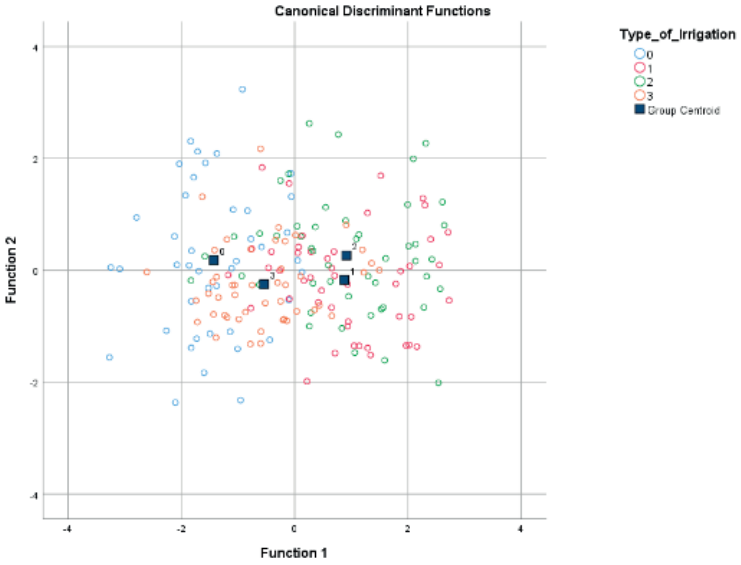

Figure 17. Statistical analysis for the 4 irrigation types – Canonical discriminant function

The Canonical Discriminant Function plot illustrates the distribution of four irrigation types, showing significant overlap, with No Irrigation displaying the greatest separation along Function 1, while Rotor, Spray, and Underground Drip share similar characteristics. However, Underground Drip is closer to No Irrigation due to the lack of applied irrigation and recorded rainfall, which delayed the absorption of granulated fertilizer, further influencing plant response and differentiation.

CONCLUSIONS

The study demonstrates the effectiveness of turf monitoring technology using the multispectral photogrammetric method, highlighting its ability to accurately classify irrigation types and assess their advantages and disadvantages across different lawn mix types.

This study demonstrates that Spray Irrigation (Green) consistently outperforms other irrigation methods across all spectral vegetation indices, making it the most effective for maintaining plant health and optimizing chlorophyll content.

Underground Drip (Orange) provides stable performance, while Rotor Irrigation (Red) is moderately effective. No Irrigation (Blue) results in the lowest values across all indices, indicating significant plant stress and water deficiency.

Best Performing Lawn Mixes: BRB WaterSaver and DLF TURFLINE Sport exhibited the highest resilience and adaptability across multiple irrigation types.

The response to lawn fertilization, in the case of the lot with underground irrigation, had a particularity, most likely due to the fact that, on the one hand, the fertilizer was of the granulated type, with controlled release, and the fact that it did not rain in the period following the fertilizer application prevented the complex of nutrients from reaching the roots.

GIS-BASED SUITABILITY ANALYSIS FOR SKI RESORT DEVELOPMENT IN THE BRAN–RÂȘNOV AREA, BRAȘOV COUNTY, ROMANIA

Cornel Cristian TEREȘNEU

Transilvania University of Brașov, 25 Eroilor Street, Brașov, Romania

Corresponding author email: cteresneu@unitbv.ro

Abstract

This study assesses the suitability of an area located between the localities of Bran and Râșnov in Brașov County, Romania, for the development of a ski resort. A combination of cartographic resources - including orthophoto maps and topographic-cadastral plans - was initially employed, followed by detailed field measurements using GNSS technology. Climatic variables critical to ski infrastructure planning were evaluated using data from four meteorological stations, with a focus on air temperature, frost days, solid precipitation, and snow cover duration and depth. Geospatial analysis was conducted using GIS tools to examine key orographic parameters such as altitude, slope, aspect, shading, land curvature, and drainage patterns. By integrating climatic and terrain data, the study identifies the area as favorable for ski resort development based on both environmental suitability and technical feasibility.

Key words*: ski resort, GIS, GNSS, terrain suitability, climatic assessment, spatial planning.*

INTRODUCTION

This study explores the potential for developing a ski resort in the northern and northwestern sector of the Bucegi Mountains, specifically in the area situated between the localities of Bran and Râșnov (Figure 1). The region is characterized by favorable topographic and climatic conditions and holds untapped potential for winter tourism infrastructure.

Despite Romania's mountainous geography, existing ski areas remain insufficiently developed. According to recent statistical evaluations, many resorts suffer from poor service quality and high operational costs, leading to a decline in domestic tourism in favor of more established destinations such as Austria. Additionally, numerous ski slopes in Romania have been developed at suboptimal altitudes or on poorly oriented terrain, resulting in limited seasonal usability and low investment returns (Comănescu et al., 2009). These issues are exacerbated by recent climate trends, including reduced winter precipitation and rising temperatures, particularly at lower elevations.

Considering these challenges, the identification of more suitable locations for ski infrastructure - both from a climatic and geomorphological perspective - is essential. This paper aims to evaluate such a location using integrated geospatial and climatic analyses.

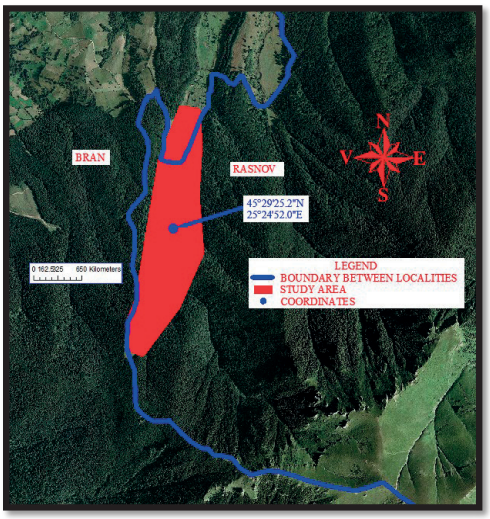

Figure 1. Study area

Both Bran and Râșnov have significant tourism potential, attracting a growing number of visitors during the winter season, including weekend travelers. Although there is an existing sports complex in the area that includes ski slopes, its usability is limited by two major factors: its low elevation and predominantly southern exposure. As a result, snow is either absent for much of the winter or melts rapidly after snowfall. Furthermore, recent years have seen a diversification of winter tourism

activities beyond traditional skiing, increasing the demand for well-situated and versatile winter sports infrastructure.

The proposed ski resort would be located in a forested area, which is beneficial as forest cover positively influences snow retention and microclimatic stability (Nap et al., 2022). However, since the location lies within a protected area, all development plans must adhere to relevant environmental regulations and conservation principles (Olariu, 2019).

It is known that there are a number of constraints regarding the manner of removing an area from the forest fund, but this aspect was also thought beforehand and a suitable area was prepared (at the parity required by the Forest Code) to be introduced into the forest fund. The situation was studied on appropriate plans and maps (Teodor & Dobre, 2015), after which concrete measurements were made in the field. Steps were taken to obtain the appropriate permits.

Another important aspect to be taken into account in such investments is the possibility of snow avalanches (Jamieson & Johnson, 1998; Voiculescu & Popescu, 2011; Voiculescu & Ardelean, 2012).

The site is also favorable from a geomorphological perspective, with advantageous terrain curvature that minimizes excessive slope deformation during tight ski turns (Yoneyama et al., 2010).

To guide the development of the proposed ski area, several fundamental planning principles were applied (Cernaianu & Sobry, 2021):

Environmental integration: planning must ensure the preservation of natural resources - both ecological and visual - by aligning slope design with climate conditions, land use constraints, and natural hazard risks (Mihai et al., 2008, Wegler & Kuenzer, 2024). Understanding local environmental characteristics enhances the return on investment and promotes sustainable development (Ielenicz et al., 2010).

- *Customer-oriented planning:* this includes considerations of accessibility, market size and proximity, resort accessibility, and demographic and socioeconomic characteristics of the target clientele. Easy access is crucial for attracting tourists and investors alike (Lesenciuc et al., 2013). Estimating the proportions of day tourists versus overnight guests is essential for aligning slope capacity with lodging infrastructure. Lifestyle trends, age, income, and education level also influence demand (Gingulescu, 2010).

- *Operational and economic efficiency:* this involves optimizing slope capacity, estimating infrastructure and capital costs, human resource needs, revenue streams, and pricing strategies. These parameters are critical for assessing project feasibility and profitability (Ilieș, 2007).

- *Urban planning and legal compliance:* finally, all development must align with existing general urban plans (PUGs) and be supported by detailed zonal urban plans (PUZs) for both Bran and Râșnov (Ionescu, 2004).

MATERIALS AND METHODS

This study employed a combination of cartographic materials, remote sensing tools, GNSS-based field measurements, and geospatial analysis software to evaluate the suitability of the study area for ski resort development.

Materials

The following datasets and equipment were utilized:

- Orthophoto maps (2020 edition, scale 1:5,000; 2023 edition, scale 1:1,000);
- Topo-cadastral plans L-35-87-B-d-3-IV and L-35-87-D-b-1-II (scale 1:5,000);
- Forest management maps (scale 1:20,000);
- G7 South GNSS receiver with H6 data collectors, providing a horizontal accuracy of 25mm + 1 ppm RMS and a vertical accuracy of 15 mm + 1 ppm RMS;
- Dell Latitude 5411 laptop with Intel® Core™ i7-10850H CPU @ 2.70 GHz and 16 GB RAM;
- ArcMap GIS software;
- AutoCAD Civil 3D software;
- A topographic survey comprising over 4,500 georeferenced points.

Methods

The research methodology integrated the following techniques:

- *Direct geodetic measurements:* coordinates of key points within the study area were determined using GNSS equipment for high-precision spatial positioning.

- *GIS-based spatial analysis:* cadastral plans were georeferenced and vectorized. Custom analyses were conducted using VBA programming within the GIS environment to assess terrain parameters (e.g., slope, aspect, shading, curvature, drainage).

This multi-source approach enabled both the validation of field measurements and the derivation of relevant terrain and climatic indicators to support the site suitability assessment.

RESULTS AND DISCUSSIONS

Initial terrain analysis was conducted using topographic-cadastral plans L-35-87-B-d-3-IV and L-35-87-D-b-1-II, at a scale of 1:5,000. A preliminary evaluation of the study area revealed the following characteristics:

- An elevation difference of approximately 450 meters (the minimum altitude is 955m and the maximum is 1410m);
- Terrain gradients suitable for ski slopes across all skill levels, ranging from slopes of less than 20% (for beginners) to over 45% (for advanced skiers);
- A maximum slope length exceeding 3.2 kilometers.

Following the terrain assessment, climatic conditions relevant to snow retention and winter sports were analyzed. The study considered several key meteorological variables: average air temperature, number of frost days, monthly and seasonal solid precipitation, frequency of snow events, and snow cover duration and depth.

Climatic data were sourced from four meteorological stations in the region: Predeal (altitude 1096 m), Vf. Omu (altitude 2505 m), Sinaia 1500 (altitude 1510 m), Fundata (altitude 1376 m). Notably, two of these stations (Sinaia 1500 and Fundata) are located at altitudes similar to the target development site, providing a relevant climatic reference. The data spans the period 2014–2023, focusing on the core winter months: December through April. All data were collected from the National Meteorological Administration's network stations.

Table 1 presents the multiannual average air temperatures recorded during this period across the four stations.

Table 1. Multiannual average air temperature (°C) for the period 2014-2023

Station	December (XII)	January (I)	February (II)	March (III)	April (IV)
Predeal	-3.2	-4.3	-4.1	-0.2	4.8
Vf. Omu	-8.7	-10.5	-10.7	-8.2	-4.0
Sinaia-1500	-3.3	-4.8	-5.0	-1.5	3.3
Fundata	-3.2	-4.5	-4.5	-0.6	4.5

In terms of the number of frost days - defined as days with minimum temperatures below 0 °C - the observed data from the four meteorological stations over the 2014–2023 period is presented in Table 2.

Table 2. Average number of frost days per month (2014-2023)

Station	December (XII)	January (I)	February (II)	March (III)	April (IV)
Predeal	28.5	29.3	27.2	26.3	13.4
Vf. Omu	31.0	30.9	28.3	31.0	29.7
Sinaia-1500	26.6	29.3	26.8	25.7	13.6
Fundata	25.8	28.0	25.4	24.3	10.3

The next climatic factor considered in the analysis was precipitation, with a focus on parameters relevant to snow availability and sustainability in winter sports environments. The evaluation included the following aspects:

a. *Average monthly solid precipitation:* these values, presented in Table 3, reflect the total amount of monthly precipitation in solid form (e.g., snow, sleet). It is noted that the lowest values typically occur in February. However, this may be due to strong wind activity during that period, which can result in snow being redistributed or blown away, rather than reflecting actual precipitation scarcity.

b. *Average number of days with solid precipitation:* Table 4 summarizes the monthly averages of days featuring solid-phase precipitation, including snowfall, snow showers, sleet, soft drizzle, and fine snow.

c. *Snow cover characteristics:* observations are based on standardized 08:00 a.m. daily measurements recorded by meteorological stations across Romania. Two key parameters were analyzed:

- i. Average monthly snow depth, shown in Table 5;
- ii. Average annual duration of snow cover, presented in Table 6.

Table 3. Average monthly amounts of solid precipitation (mm), 2014-2023

Station	December (XII)	January (I)	February (II)	March (III)	April (IV)
Predeal	48.9	56.7	45.4	65.9	76.2
Vf. Omu	57.8	60.4	54.0	63.7	64.5
Sinaia-1500	73.0	62.7	62.2	58.2	73.5
Fundata	53.6	48.1	43.3	61.8	71.8

Table 4. Average monthly number of days with solid precipitation, 2014-2023

Station	December (XII)	January (I)	February (II)	March (III)	April (IV)
Predeal	11.4	12.3	12.9	12.1	3.6
Vf. Omu	13.0	12.9	13.5	16.6	16.2
Sinaia-1500	9.5	10.9	12.2	10.3	5.5
Fundata	11.0	12.7	13.9	12.7	5.5

Table 5. Average monthly snow depth (cm), 2014-2023

Station	December (XII)	January (I)	February (II)	March (III)	April (IV)
Predeal	18.8	30.7	44.1	33.0	4.6
Vf. Omu	43.1	63.9	83.8	101.0	104.0
Sinaia-1500	21.4	35.6	54.6	54.7	11.3
Fundata	12.3	22.5	32.8	28.6	2.5

Table 6. Average annual duration of snow cover (days), 2014-2023

Station	Average Duration (days)
Predeal	170
Vf. Omu	266
Sinaia-1500	178
Fundata	192

Following the climatic analysis, a detailed field survey was conducted to assess the orographic characteristics of the study area. The topographic-cadastral plans (L-35-87-B-d-3-IV and L-35-87-D-b-1-II) were georeferenced and overlaid on forest management maps obtained from the Bucegi - Piatra Craiului Private Forestry Office (Tereșneu, 2022). This process revealed that the proposed development area spans six forest management subcompartments. Subsequently, an extensive field campaign was carried out, during which over 4,500 spatial data points were collected using a South G7 GNSS receiver and H6 controller. The coordinates of the boundaries for both the forest subcompartments and the proposed ski slope routes - classified by difficulty level - were precisely recorded. Due to the significant elevation differences and dense forest cover, the terrain presented logistical challenges during data acquisition. As a result, some of the initially mapped slope routes were adjusted based on field conditions.

To construct a detailed 3D topographic model of the area, the GNSS data were integrated with contour lines (with an equidistance of 5m) automatically vectorized using ArcScan (Tereșneu, 2013). In areas where GNSS measurements were not feasible, elevation data were extracted from the cadastral maps. To improve vertical accuracy, a custom algorithm was implemented to adjust the contour line altitudes. This correction accounted for historical modeling errors: 3D terrain models in forested areas were originally generated during 1960s-1970s photogrammetric surveys that captured canopy heights, necessitating corrections based on average stand height.

Studies by Tereșneu and Vasilescu (2019) have shown that stand height in mountainous terrain varies considerably - from taller growth at the base of slopes to shorter vegetation near ridgelines. These insights were incorporated into the correction model using data from forest management plans. Adjustments were applied through VBA-coded routines, ensuring that the contour lines accurately reflected ground elevation rather than canopy height.

Further analysis was conducted to evaluate the key orographic parameters relevant to ski slope planning. Each criterion was derived from a digital elevation model and associated spatial datasets, with results visualized in Figures 2 to 10.

- *Altitudinal analysis* (Figure 2). Due to recent climatic changes, ski slopes are recommended at higher elevations where snow cover persists for more than four months annually. In the study area, elevation ranges from a minimum of 955m m to a maximum of approximately 1400 m (1410 m), which is favorable for maintaining consistent snowpack during the winter season (5m resolution model).
- *Slope* (Figure 3 and 4). Slope gradient is a critical factor in ski slope classification. The terrain was analyzed and raster layers reclassified to generate a Boolean map of slope suitability. Areas with acceptable gradients were assigned a value of 1 (favorable), and steeper or flatter regions a value of 0. This analysis revealed that the area can accommodate slopes for all difficulty levels - from very easy to expert - based on the distribution of gradient classes.
- *Aspect (Exposure)* (Figure 5 and 6). Solar exposure significantly influences snow

quality and duration. Northern and northwestern exposures are preferred for preserving snow, especially at altitudes below 1500 m. The terrain was classified into seven 45° segments (sexagesimal) representing cardinal and intercardinal orientations. Southern-facing slopes (112.5°-247.5°) were excluded by assigning a value of 0, while others were assigned a value of 1. This exposure-based suitability analysis indicated that the majority of the area benefits from favorable orientations for slope development (Vorovencii, 2024).

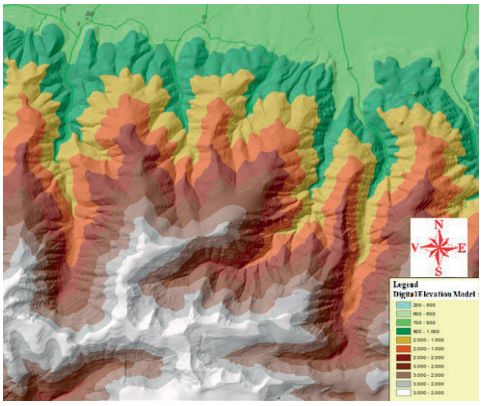

Figure 2. Digital Elevation Model (DEM)

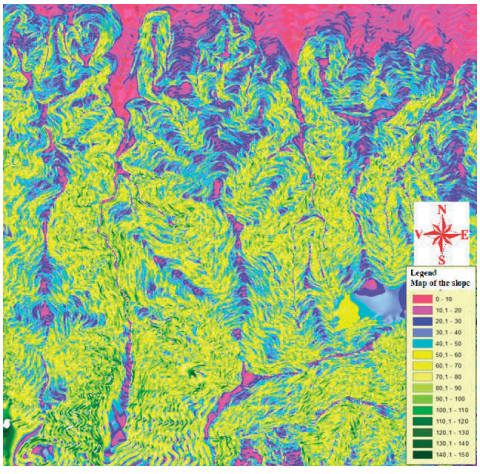

Figure 3. Slope Map of the Study Area

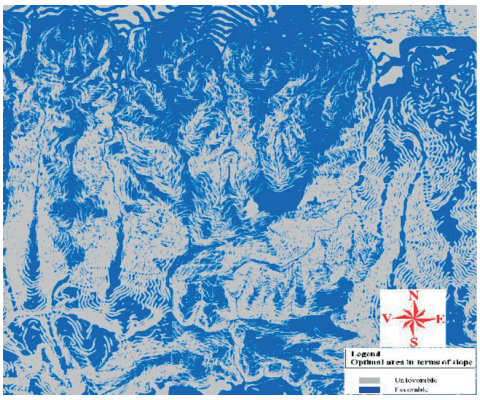

Figure 4. Slope-Based Suitability Map for ski area development

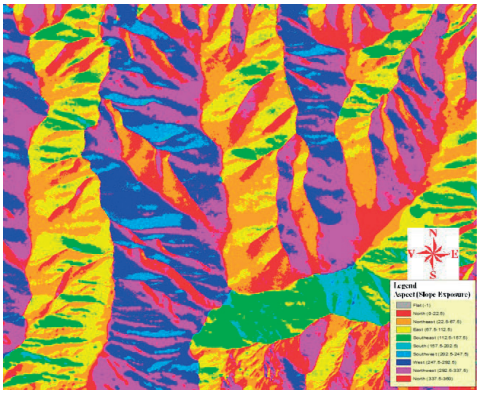

Figure 5. Aspect (Slope Exposure) Map of the Study Area

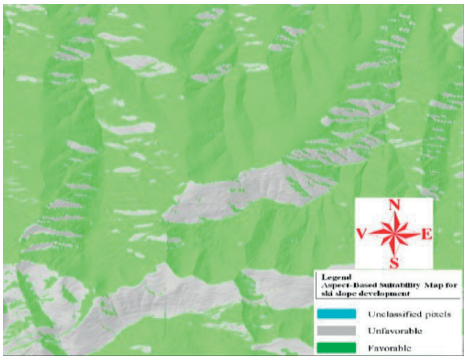

Figure 6. Aspect-Based Suitability Map for ski slope development

- *Shading* (Figures 7 and 8). Shading was analyzed using the Hillshade tool in ArcGIS, which simulates the illumination of the terrain based on specified azimuth and altitude of a hypothetical light source. This technique is not only useful for visual interpretation but also helps identify interpolation artifacts in the DEM. Shading maps were produced for two time points - 10:00 and 15:00 - on February 12 to assess variation in light exposure during typical winter conditions.
- *Land curvature* (Figure 9). Curvature is a morphometric variable that reflects surface convexity or concavity, influencing water runoff behavior and erosion susceptibility. The Curvature tool in ArcGIS was used to compute this parameter as the second derivative of the surface. In the resulting map, red indicates concave surfaces (potential accumulation zones), and yellow indicates convex areas (dispersal zones), which is useful for preliminary landscape stability assessments.
- *Flow Direction* (Figure 10). Hydrological flow paths were calculated using the Flow Direction tool from the Hydrology toolbox in ArcGIS. This analysis determines the direction of water runoff for each raster cell, based on the steepest descent among eight neighboring cells. While flow direction is not a primary determinant in ski slope planning, it is critical for identifying erosion-prone areas and designing sustainable drainage systems. The raster output supports broader environmental risk assessments during both construction and operation phases (Irimuș, 2006; Vorovencii, 2016).

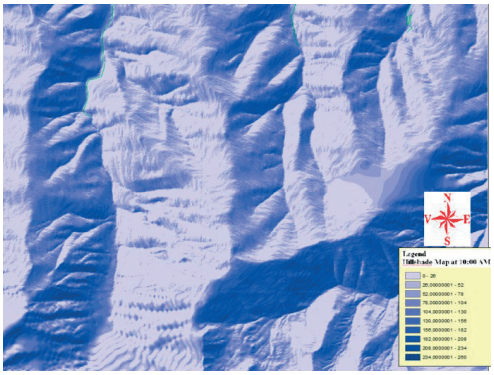

Figure 7. Hillshade Map at 10:00 AM on February 12

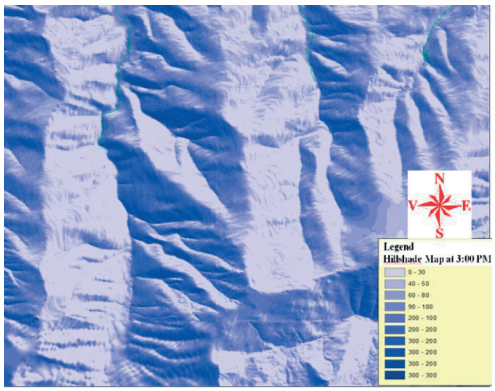

Figure 8. Hillshade Map at 3:00 PM on February 12

The result of the flow direction analysis is a raster in which each pixel's attribute value indicates the direction of surface runoff, calculated relative to its eight neighboring cells by identifying the path of steepest descent (i.e., the "shortest fall"). While flow direction does not directly influence the spatial placement of ski slopes, it is essential for assessing the potential for erosion. Such analyses are particularly relevant in mountainous environments, where natural erosion processes or slope destabilization can be intensified by infrastructure development and intensive slope usage. Understanding drainage patterns is therefore critical for mitigating geomorphological risks throughout both the construction and operational phases of a ski resort (Wang et al., 2024; Irimuș, 2006; Dietenberger et al., 2025; Vorovencii, 2016).

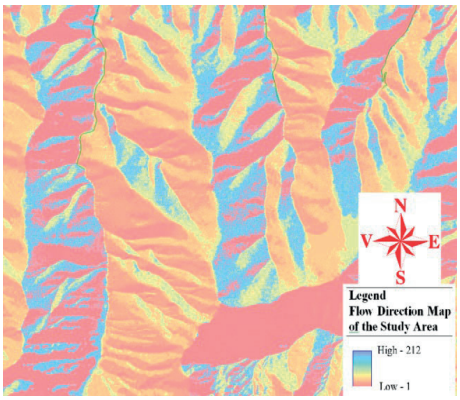

Figure 10. Flow Direction Map of the Study Area

CONCLUSIONS

Based on the integrated analysis of climatic conditions and orographic characteristics, the study area - located between Bran and Râșnov - is deemed suitable for the development of a ski resort. The conclusions are summarized below:

Climatic Factors

- Although recorded air temperatures have increased compared to previous decades (e.g., the 1970s and 1980s), they remain within acceptable ranges for maintaining snow cover, particularly when considered alongside other favorable climatic variables.
- The number of frost days supports the persistence of snow cover into April, extending the operational window of a ski slope.
- Average monthly snow cover, while not exceptionally high, is sufficient to ensure consistent slope usability during the winter season. Artificial snowmaking would be required only occasionally.
- Despite a downward trend, the frequency of days with solid precipitation remains adequate for natural snow accumulation.
- Snow cover characteristics - both in terms of thickness and annual duration - are favorable, confirming the natural viability of the site for winter sports.

Orographic Conditions

- Although the site's elevation (950-1400 m) falls below the ideal threshold of 1500 m, its overall suitability is reinforced through complementary terrain factors.
- The slope configuration accommodates all skier proficiency levels, from beginner to advanced.
- Aspect analysis indicates predominantly northern and northwestern exposures, which help offset limitations related to altitude by enhancing snow retention.
- Shading analysis places the area in a favorable category, particularly at higher elevations, reinforcing snow preservation potential.
- Terrain curvature suggests minimal need for significant grading or earthworks, which is beneficial for sustainable development.
- Flow direction analysis indicates stable drainage patterns and a low risk of landslides, confirming the geomorphological stability of the site.

In summary, the combined climatic and topographical assessment confirms that the studied area is highly suitable for ski resort development. Moreover, its location within an already well-developed tourist region with existing accommodation infrastructure further enhances its potential to attract a substantial number of winter sports visitors.

Abstract

This article investigates the evolving landscape of machine learning and its application in waste management from 2014 to 2024, utilizing data from Scopus and employing the VOSviewer software for bibliometric analysis. The research identified 217 articles related to machine learning in waste management. Our analysis aimed to assess metrics such as yearly publication trends, citation rates, top publishing countries, and the most influential authors in the field. Additionally, we examined the evolution of research on machine learning in waste management, focusing on highly cited articles, leading journals, authors' keywords, co-citation patterns, and co-authorship networks among countries and organizations. This comprehensive review provides a deeper understanding of the growth and collaborative nature of the field. The results indicate a notable rise in machine learning publications in waste management, increasing from 1 in 2016 to 62 in 2024, for a total of 217 publications. China, India, and South Korea led the research output, contributing 19.35%, 15.67%, and 10.60%, respectively. Leading journals such as the Journal of Cleaner Production, Waste Management, and Sustainability Switzerland emerged as critical contributors. A sharp increase in publications was observed post-2020, especially in the Journal of Cleaner Production. One of the most notable findings was the high citation rate of research on machine learning techniques in waste management, underscoring their practical relevance and mathematical significance in optimizing waste handling and reduction. Frequently occurring keywords included "machine learning", "waste management", and "deep learning". The VOSviewer visualizations indicated strong international collaboration networks, highlighting a robust global research framework. Our study emphasizes the growing influence of machine learning in waste management, marked by increasing research activity and international cooperation, and showcases the transformative potential of machine learning driven models in improving global waste management practices.

Key words*: Bibliometric Analysis, Machine Learning, Scopus, VOSviewer Software, Waste Management.*

INTRODUCTION

The rapid pace of urbanization and industrialization in recent years has intensified challenges in waste management (WM), with an increase in waste generation necessitating innovative approaches to ensure sustainable waste handling practices that effectively mitigate environmental impacts. Traditional WM practices generally follow linear processes that include collection, transportation, and disposal, resulting in inefficiencies, higher costs, and low recycling rates. These conventional methods often rely on manual sorting and fixed collection schedules, which limit their ability to effectively manage the complexities of contemporary waste generation. In contrast, Machine learning (ML) has emerged as a transformative tool in response to these pressing challenges, capable of enhancing various facets of waste management. ML techniques have gained substantial attention due to their potential to optimize waste management processes, including waste sorting, predictive modeling, and recycling efficiency. ML has notably enhanced the accuracy of waste generation forecasts across various waste types, such as construction waste (Cha et al., 2021), municipal solid waste (Ayeleru et al., 2021), hospital waste (Golbaz et al., 2019), food industry waste (Garre et al., 2020), and more. By leveraging advanced algorithms, researchers are developing models that facilitate more effective WM. The application of data-driven planning through machine learning not only enhances the efficiency and sustainability of waste management practices but also contributes to the development of smarter, more resilient urban environments (Ahmad et al., 2020).

Moreover, integrating ML with the Internet of Things (IoT) has opened new avenues for efficient WM. Recent explorations into IoT-enabled solutions emphasize the potential of real-time data collection and analysis to promote cleaner, more sustainable urban environments (Rutqvist et al., 2019; Cheah et al., 2022; Patil & Gidde, 2023).

This study performs a bibliometric analysis that focuses on exploring and analyzing the development of ML technologies in WM. This investigation can lead to sophisticated ML models designed to address the complexities associated with WM, such as predicting waste production, sorting automation, and improving collection route efficiency. The bibliometric analysis of ML applications in this field yields important insights into its evolution, identifies major research contributions, and highlights gaps for future investigations. Additionally, it offers an in-depth view of these technologies and the dynamics of international collaborations within this domain over time, showcasing how different organizations and countries contribute to advancing the field. This research utilizes publications and data from Scopus and employs VOSviewer software to create graphical representations that examine keyword co-occurrences, citation patterns, bibliographic links, and co-authorship relationships. These findings can help the researchers with effective strategies and innovations in sustainable WM.

This study is organized as follows: Section 2 reviews the specialized literature on machine learning in waste management, highlighting key advancements and methodologies used in recent research. Section 3 outlines the methodology used for this bibliometric analysis, detailing the criteria for selecting publications and the analytical tools applied. Section 4 presents the findings along with their interpretations, revealing significant trends in the application of machine learning technologies and their impact on WM practices. Drawing on the trends identified in the results section, Section 5 will engage in discussions regarding these trends, addressing the implications for future research directions. Finally, Section 6 will summarize the key conclusions and provide recommendations for further exploration in the field, emphasizing the importance of continuous innovation in sustainable WM practices.

Literature review

Effective WM is essential for environmental sustainability, resource conservation, and public health protection. WM encompasses a range of processes focused on the collection, transportation, treatment, reuse, and disposal of waste materials. As urban populations grow, the volume and complexity of waste generated have increased, creating a need for more efficient and effective WM strategies. ML, a branch of artificial intelligence (AI), focuses on developing algorithms that allow computers to learn from data and make informed predictions. Its application in WM has significant potential to optimize processes, enhance decision-making, and improve sustainability outcomes. A key application of ML in WM is the classification and segregation of waste materials. Traditional sorting methods often rely on manual labor, which can be time-consuming, error-prone, and inefficient. For example, Nnamoko et al. (2022) introduced an optimized five-layer convolutional neural network (CNN) for classifying organic and recyclable waste, which reduces computational demands by using lower-resolution images, ultimately outperforming both higher-resolution models and baseline classifiers. Recent literature (Al Duhayyim et al., 2023; Ali et al., 2024; Nezerka et al., 2024) highlights substantial advancements in WM through machine learning, employing sophisticated algorithms such as custom CNNs, K-nearest neighbors (KNN), and ensemble learning models to achieve greater classification accuracy and efficiency. These studies emphasize ML's transformative role in automating sorting processes, reducing errors, and supporting a more sustainable future. Additionally, studies (Gondal et al., 2021; Carrera et al., 2022; Mohammed et al., 2023; Jin et al., 2023) address various waste types for improved classification and recycling. Techniques include using infrared spectrums for plastic identification, applying artificial neural networks (ANN) to urban waste sorting, deploying hybrid CNN models for real-time metal and non-metal sorting, and enhancing

MobileNetV2 models with attention mechanisms to improve classification accuracy. ML-driven predictive analytics has become an essential tool for anticipating waste generation patterns. By examining historical data, these models can detect trends and forecast future waste production. Namoun et al. (2022) discussed an optimized ensemble learning model for predicting urban household waste generation, which supports more effective waste management in smart cities. In the literature (Cha et al., 2020; Cha et al., 2022; Cha et al., 2022; Cha et al., 2024), advanced machine learning models, including ANN, support vector machines (SVM), and random forests (RF), have been applied to accurately predict construction and demolition waste production. Furthermore, ML models enhance the forecasting of municipal waste production by leveraging socioeconomic data, with optimization techniques improving accuracy. Many researchers (Oguz-Ekim et al., 2021; Yang et al., 2021; Zhang et al., 2022; Munir et al., 2023; Singh et al., 2023) utilize ML algorithms like XGBoost, and RF to predict municipal solid waste (MSW), highlighting population and gross domestic product (GDP) as key indicators.

Huang and Koroteev (2021) analyzed an ML framework to optimize waste and energy management, achieving a 90% reduction in waste processing time, a 40% decrease in landfill dependency, and a 15% reduction in transportation costs by predicting waste volumes and adapting to fluctuations in energy markets. Altarazi F. (2024) explores EcoEfficientNet, an advanced ML tool for sustainable manufacturing that uses deep learning to analyze production data and identify waste reduction opportunities. Through continuous learning, EcoEfficientNet adapts to new data and evolving production conditions, achieving up to a 30% reduction in waste generation. ML models are increasingly essential for enhancing waste-to-energy (WTE) processes by reliably forecasting the energy potential and volume of MSW based on diverse factors. Studies indicate that advanced techniques, including ANNs, SVMs, and ensemble approaches, improve WM efficiency and support the strategic siting of WTE facilities, as shown in the literature (Kaya et al., 2021; Al-Ruzouq et al., 2022; Taki & Rohani, 2022; Yatim et al., 2022).

In references (Mookkaiah et al., 2022; Belsare et al., 2024; Chavhan et al., 2024), artificial intelligence (AI), IoT, and ML have driven innovative solutions, utilizing CNN models like ResNet for precise automated classification of MSW, thereby improving sorting accuracy and promoting sustainable WTE practices. Moreover, numerous scholars (Mudannayake et al., 2022; Zia et al., 2022; AlJamal et al., 2024; Hossen et al., 2024; Mishra et al., 2024) have implemented AI and ML models such as GCDN-Net and DenseNet-121 - SVM to achieve highly accurate automated waste classification, enhancing recycling processes and supporting sustainable WM amid the challenges of urbanization.

Literature (Medina-Mijangos & Seguí-Amórtegui, 2020) offers a comprehensive bibliometric analysis of the economic dimensions of MSW management. This methodology has gained substantial traction across various disciplines, primarily due to its capacity to deliver intricate scientific mappings over specified temporal frameworks. Such analyses illuminate emerging trends that decision-makers can strategically utilize in diverse contexts (Tamala et al., 2022; Oladinrin et al., 2023; Martins et al.,2024). Recent studies (Negrete-Cardoso et al., 2022; Sohail et al., 2023) highlight, through bibliometric analyses, waste management strategies based on multi-criteria decision-making methods and circular economy principles, emphasizing current research trends in the field.

MATERIALS AND METHODS

In this study, data from the Scopus (Elsevier, accessed 17 October 2024). database is utilized. Scopus is a multidisciplinary citation database managed by Elsevier, widely recognized, and commonly used for analyzing research output. The database includes content from various subjects, including science, technology, medicine, and social sciences. Scopus provides detailed statistics and visualizations for assessing data on research areas, document types, countries, authors, institutions, publication timelines, and universities. Additionally, it allows users to export

publication records in formats such as CSV or Excel, which are compatible with data visualization and analysis tools like VOSviewer or Bibliometrix. Besides journal articles, Scopus also indexes conference proceedings, book series, and patents, offering a comprehensive view of the global research landscape.

A key challenge in bibliometric research is defining the boundaries of the specific field being analyzed. To gain a broader perspective on publications related to ML in waste management systems, searches were conducted using the key words: "waste", "management", and "machine", "learning." The search was limited to publications from 2014 to 2024, and the data was collected on 17 October 2024. The objective of this search was to identify articles that explored the application of ML in waste management. A total of 217 results were found. To map and analyze the network, the full records which primarily included the titles, sources, authors, affiliations, abstracts of the research articles, and the cited references were downloaded in CSV format. Figure 1 illustrates the methodology employed for searching, data collection, and information processing.

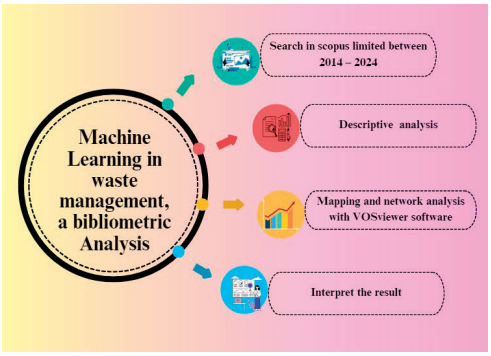

Figure 1. Methodology employed in this study

An exploratory analysis was conducted to examine and highlight the most impactful journals, authors, countries, and articles within the database. In reference (Seguí-Amortegui et al., 2019), the research employed bibliometric measures, including (i) productivity, determined by the total count of publications (Reuters, 2008); (ii) impact, analyzed by the total citation count (Reuters, 2008); (iii) the H-index (Hirsch index), which indicates that N publications have received at least N citations, providing a combined measure of both productivity and impact in a single figure (Reuters, 2008; Hirsch, 2005); and (iv) the impact factor (IF), a metric used to evaluate journals by calculating the average number of citations for articles published within a two-year period (Reuters, 2008).

The research employed VOSviewer software, developed by Leiden University, to map and analyze networks of scientific publications, including journals, institutions, countries, authors, and keywords (Van Eck & Waltman, 2016). Analyzing these networks creates a graphical representation that visualizes the relationships within the data (Ji, 2018). These networks allow for the viewing and exploration of maps by connecting the articles through citations, authorship, co-occurrence, bibliographic links, or co-citation connections (Van Eck & Waltman, 2016).

VOSviewer software represents the interest of items, such as publications, authors, sources, or keywords, using nodes; larger nodes indicate greater weight or significance of the item. A link refers to the connection between two objects, displaying the count of articles where one particular object is found alongside another. The thickest lines exhibit more frequent co-occurrence or higher levels of cooperation (Seguí-Amortegui et al., 2019; Van Eck & Waltman, 2016). The distance between the nodes also reflects their co-occurrence. Elements are grouped by colour to signify their connection to research topics, with elements sharing the same colour referred to as clusters (Van Eck & Waltman, 2016).

RESULTS AND DISCUSSIONS

First, we highlighted key research trends, including annual publication numbers, citation rates per article and field, leading countries in publication output, and the most prominent authors (Seguí-Amortegui et al., 2019). Next, we examined the current state and evolution of research on ML in waste management, analyzing 217 articles. In the second section, we focused on the most cited articles on ML in waste management. The third section examined the leading journals in this area. The fourth

section investigated the overlap of authors' keywords in ML within waste management. The article then analyzed the co-citation patterns of references, sources, and authors related to ML in waste management. Finally, it explored the networks of co-authorship among countries and organizations involved in ML in waste management research.

Significant trends

In 2014 and 2015, no articles were published in Scopus on ML in waste management. However, from 2016 to 2024, the number of publications shows a significant increase, beginning with one publication in 2016 and rising to 62 in 2024. Despite a slight decline in 2024, with the number dropping to around 60, the overall trend indicates a substantial rise in research activity during this period, totalling 217 publications. This growth highlights the growing interest and contributions to the field over the years. Figure 2 illustrates the yearly publication count on ML in waste management as indexed in Scopus.

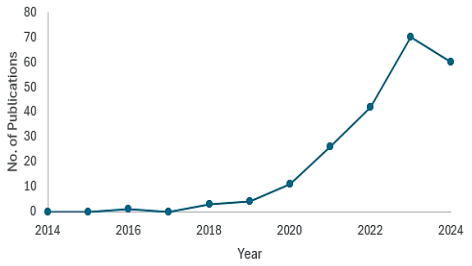

Figure 2. Yearly publication counts on ML in waste management

The bar chart in Figure 3 highlights the countries with the highest number of publications focused on ML in waste management. The x-axis represents the number of publications, ranging from 0 to 45, while the y-axis lists the countries involved. The analysis shows that China leads with 42 articles, followed by India with 34 and South Korea with 23. Iran has the fewest publications among the listed countries. In total, 62 countries have contributed to the production of 217 publications, corresponding to 19.35%, 15.67%, and 10.60% of the total publications on the topic, respectively. This visual representation effectively demonstrates the comparative research contributions of different nations.

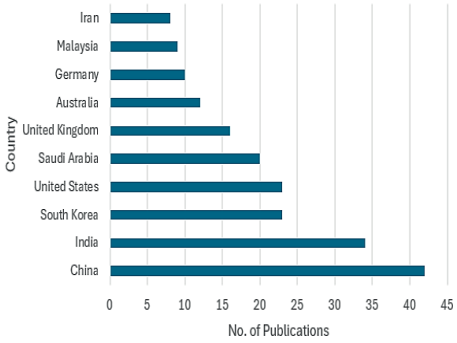

Figure 3. Publications in Scopus on ML in waste management, categorized by country

The horizontal bar chart visually represents the number of publications by different authors in the field. The x-axis indicates the number of publications, ranging from 0 to 8, while the y-axis lists the authors' names. Figure 4 shows that the top authors in ML research in waste management are Cha, G.W. with 8 publications, Kim, Y.C. with 6 publications, and Hong, W.H. with 5 publications. These figures represent 3.69%, 2.76%, and 2.30% of the 217 total publications in this area, respectively.

Figure 4. Publications in Scopus on ML in waste management, categorized by author

Citation counts provide a clear measure of an article's impact. Table 1 provides a detailed breakdown of articles based on their citation count, offering insights into the citation performance of publications related to ML in

waste management. Only 1 article (0.46%) has more than 251 citations, and articles with 151 to 250 citations represent 0.92% of the total. Moderately cited articles (51 to 100 citations) account for 6.45%, while a larger portion has fewer citations: 12.91% (26 to 50 citations) and 17.06% (11 to 25 citations). Notably, 44.23% of the articles have fewer than 11 citations, and 16.12% have not been cited at all, indicating that many publications have relatively low visibility and impact in the academic community. Overall, this highlights a significant opportunity for increased recognition and dissemination of research in this field.

Table 1. Overview of Citation Distribution on ML in waste management

Citation Count	Number of Articles	Accumulated Articles	% Articles	% Accumulated Articles
≥251	1	1	0.46%	0.46%
≥201	0	1	0%	0.46%
≥151	2	3	0.92%	1.38%
≥101	4	7	1.84%	3.22%
≥51	14	21	6.45%	9.66%
≥26	28	49	12.91%	22.61%
≥11	37	86	17.06%	39.63%
<11	96	182	44.23%	83.89%
0	35	217	16.12%	100%

Most-cited publications on ML in waste management

Table 2 provides a ranking of influential articles that apply ML to waste management, detailing important factors such as the reference, year of publication, country of origin, journal source, article title, and the number of citations each work has received. This ranking helps to highlight the most impactful contributions in this research area. At the top of the list is the work by Abbasi & El Hanandeh (2016) from Australia, which has garnered 276 citations. Following closely is the study by Palansooriya et al. (2022) from South Korea, with 195 citations. Another notable contribution comes from Yuan et al. (2021) from South Korea, which has received 173 citations. These top-cited articles illustrate the critical role of ML in addressing global waste management challenges, with each contributing to advancements in predictive modeling and sustainable practices within the field.

Table 2. Most-Cited Articles

Rank	Reference	Country	Journal source	Title	Citations
1	Abbasi & El Hanandeh (2016)	Australia	*Waste Management*	Forecasting municipal solid waste generation using artificial intelligence modelling approaches	276
2	Palansooriya et al. (2022)	South Korea	*Environmental Science and Technology*	Prediction of soil heavy metal immobilization by biochar using machine learning	195
3	Yuan et al. (2021)	South Korea	*Environmental Science and Technology*	Applied machine learning for prediction of CO 2 adsorption on biomass waste-derived porous carbons	173

8	Nguyen et al. (2021)	Vietnam	*Resources, Conservation and Recycling*	Development of machine learning - based models to forecast solid waste generation in residential areas: a case study from Vietnam	95
9	Vu et al. (2019)	Canada	*Waste Management*	Time-lagged effects of weekly climatic and socio-economic factors on ANN municipal yard waste prediction models	90
10	Lu et al. (2021)	Australia	*Waste Management*	Estimating construction waste generation in the Greater Bay Area, China using machine learning	77

Analysis of the Research Journals in ML in Waste Management

In this bibliometric analysis, Table 3 highlights the top 10 local sources that play a significant role in assessing the influence and relevance of research in the field of ML in waste management. Among these, the *Journal of Cleaner Production* stands out as a particularly impactful source. With an H-index of 9 and a G-index of 14, this journal demonstrates a strong influence in the domain, reflecting that many of its articles have significantly contributed to the research community. Its M-index of 1.5 suggests an average of 1.5 citations per article, further emphasizing its academic value. Since 2019, this journal has published 14 papers on ML in waste management, contributing a total of 302 citations to the field. Next in line is the *Waste Management Journal*, with an H-index of 9 and a G-index of 12. It has been a prominent contributor since 2016, with 12 articles accumulating an impressive 714 total citations, making it a highly referenced source in the field, even though its M-index is slightly lower at 1.

The *Journal of Environmental Management*, active in this area since 2021, also makes a notable contribution with an H-index of 6 and a G-index of 9, featuring an M-index of 1.5. Despite having published only 9 papers, it has garnered 177 citations, indicating that the work published here is also well-regarded in the academic community.

Table 3. Influence of Research Journal

Source	H_index	G_index	M_index	TC	NP	PY_start
Journal of Cleaner Production	9	14	1.5	302	14	2019
Waste Management	9	12	1	714	12	2016
Journal of Environmental Management	6	9	1.5	177	9	2021
Sustainability (Switzerland)	5	6	1.667	48	9	2022
International Journal of Environmental Research and Public Health	4	4	0.8	119	4	2020
Sensors	4	5	1	122	5	2021
Environmental Science and Technology	3	4	0.75	393	4	2021

Keyword analysis

Keywords typically signify the main topics and themes of a research article, highlighting key trends and essential subjects within a particular field (Segui-Amortegui et al., 2019). An analysis of 217 articles on ML in waste management identified 779 unique keywords. Figure 5 illustrates the network map of keywords in ML for waste management. The central node, machine learning (blue), connects to several related terms, such as artificial intelligence (red), deep learning (green), solid waste management (yellow), municipal solid waste (orange), sustainability (purple), and artificial neural network (teal).

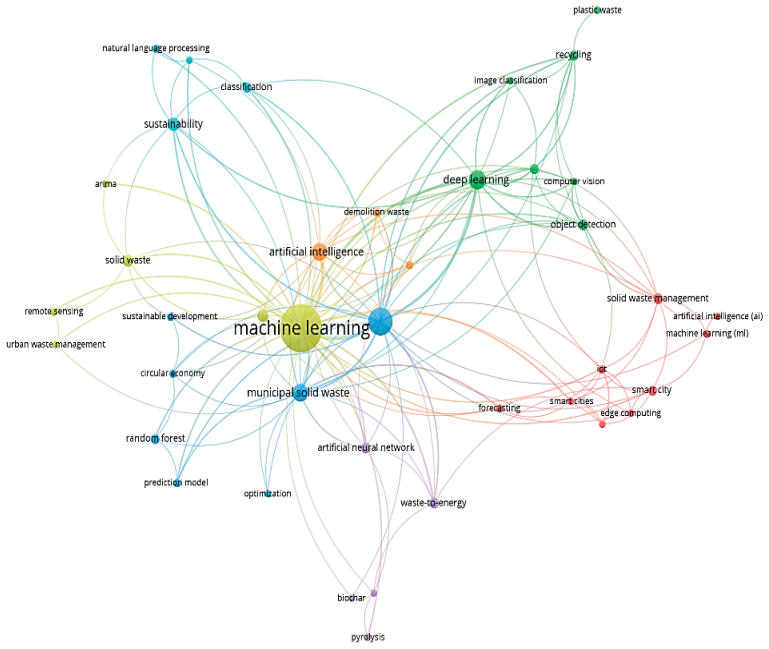

Figure 5. Author keywords network of co-occurrence. The figure showcases the 41 most frequently occurring keywords out of a total of 779 keywords, each meeting a minimum occurrence threshold of 3

The top 10 keywords highlighted in this analysis emphasize the integration of ML within waste management. Keywords such as machine learning, deep learning, and artificial intelligence underscore the role of advanced algorithms in improving waste processing systems. Terms like municipal solid waste and waste classification reflect efforts to optimize waste handling and categorization through technology. Additionally, the inclusion of object detection and recycling highlights the importance of automation in enhancing sorting processes, while sustainability and prediction emphasize the commitment to sustainable practices and the anticipation of waste trends to inform better management strategies.

Table 4 presents the 10 most prominent keywords, along with their occurrences and link strengths.

VOSviewer offers powerful density visualizations, as shown in Figure 4. In the keyword density plot, each node is colored according to the concentration of elements around it, making patterns in the data easily identifiable.

Table 4. The top 10 keywords of the ML in waste management

Rank	Keywords	Occurrences	Link strength
1	Machine learning	109	121
2	Waste management	37	67
3	Deep learning	19	36
4	Municipal solid waste	15	35
5	Artificial intelligence	15	27
6	Object detection	6	15
7	Recycling	5	15
8	Sustainability	9	15
9	Prediction	8	14
10	Waste classification	5	14

In other words, a node's color reflects the number of surrounding objects, with denser areas showing higher concentrations of keywords. Keywords highlighted in red occur more frequently, indicating major areas of focus, while those in yellow are less common and represent peripheral topics. Density visualizations are particularly useful for gaining a quick overview of the distribution of research trends, identifying clusters, and detecting key themes.

As demonstrated in Figure 6, this method provides a clear and intuitive view of the primary research areas in machine learning within WM systems. Keywords such as "machine learning", "waste management", "deep learning", "municipal solid waste", and "artificial intelligence" emerge as significant.

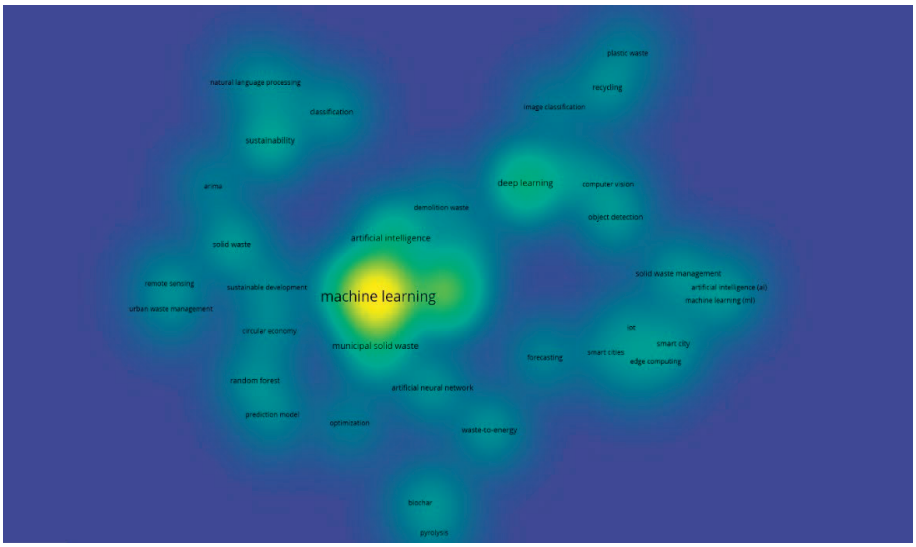

Figure 6. A density map illustrating the keyword distribution in publications related to ML in waste management

Analysis of co-citations for authors, references, and research journals

This section focused on the concept of co-citation among authors, references, and research journals. Co-citation occurs when two documents are cited in tandem by a third source, reflecting how frequently these items (authors, research journals, or references) are jointly referenced, thus forming a co-citation link between them (Small, 1973). A co-citation link connects two elements that are cited within the same document. Here, the proximity between two authors, references, or research journals indicates the strength of their relationship based on shared citation links. Generally, nodes that are closer together indicate a stronger relationship. Connections between nodes are also depicted with lines, highlighting the strongest co-citation (Van Eck & Waltman, 2016).

The initial analysis focused on author co-citation patterns. The network of author co-citations illustrated in Figure 7 identifies three main clusters: a red cluster, which is the largest, containing 70 authors; a green cluster with 46 authors; and a blue cluster with 7 authors. Key authors include Li J., who has 109 citations along with a link strength of 6,425; Wang X., who has 105 citations along with a link strength of 5,622; and Wang Y., who has 102 citations along with a link strength of 4,796.

The network of reference co-citations presented in (Figure 8) reveals three primary clusters: a red cluster, the most extensive, which includes 8 references; a green cluster comprising 7 references; and a blue cluster featuring 3 references. The red cluster may represent the most influential or foundational works in the field, while the green and blue clusters highlight additional areas of research that are interconnected but perhaps less frequently cited. This visualization aids in understanding the relationships between key references and their contributions to the overall scholarly discourse.

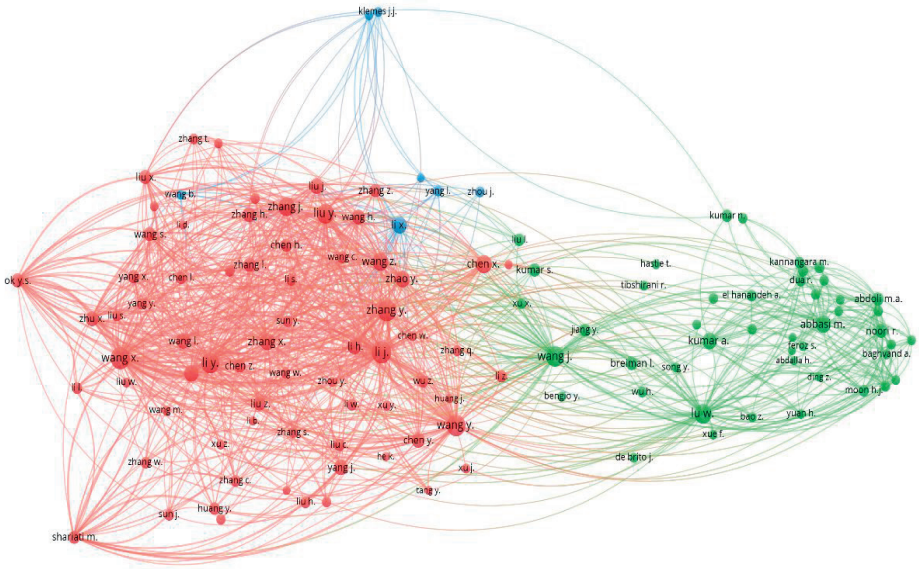

Figure 7. Network of author co-citations, highlighting 123 authors out of 25,398 cited authors who meet the minimum threshold of 20 citations each

Figure 8. Co-citation of references, 19 references from a total of 11,490 that meet the minimum citation threshold of 5

Concerning journal co-citation patterns, the network discussed in Figure 9 identifies seven clusters. The first three clusters are as follows: The red cluster, the largest, includes 10 research journals, with the *Journal of Cleaner Production* as the most prominent source, having 223 citations and a link strength of 5,875. This cluster consists of interdisciplinary journals addressing topics related to environmental sustainability. The second cluster is green, also containing 10 research journals, with *Waste Management* as the leading source, having 181 citations and a link strength of 3,755. This cluster covers journals on various aspects of WM, including generation, features, reduction, gathering, sorting, treatment, and disposal. The third cluster is blue and includes 8 research journals, with *Sustainability* as a key source, showing 104 citations and a link strength of 2,090. This cluster features journals that publish research on sustainability, including topics such as energy production, conversion, and utilization. The remaining clusters include yellow and purple with 7 journals, light blue with 5 journals, and orange with 2 journals.

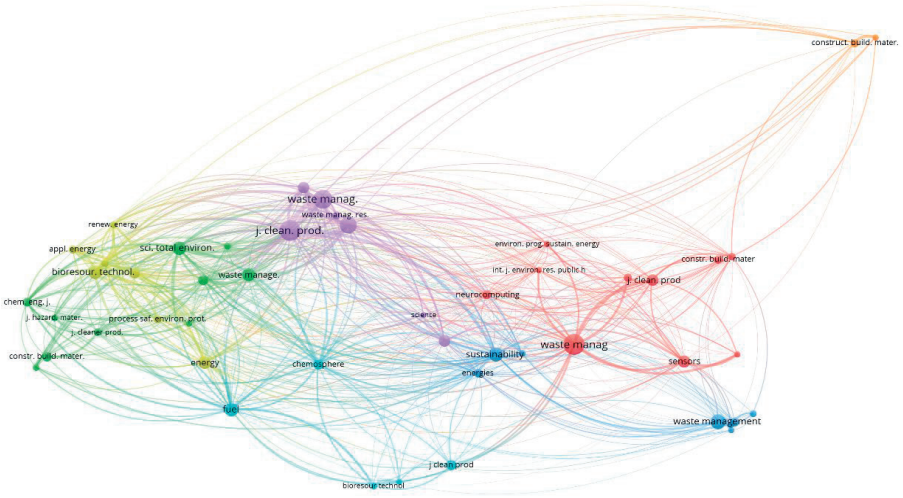

Figure 9. Network of journal co-citations 49 core journals from a total of 5,262 that meet the minimum citation threshold of 20

Authors' bibliographical coupling

The analysis of bibliographic coupling among authors enabled us to determine whether authors A and B reference the works of author C. This means that two authors sharing common citations are more interconnected and likely have comparable research interests (Gazni & Didegah, 2016). The bibliographic coupling of authors (Figure 10) revealed two clusters consisting of 10 authors in total. The primary cluster is red, featuring 6 authors, with the most notable being Cha, Gi-Wook. The green cluster contains 4 authors, with Li, Jie being the most prominent. The authors with the highest number of publications include Cha, Gi-Wook (155 citations), who has 8 publications in Scopus; Kim, Young-Chan (136 citations), who has 6 publications; and Hong, Won-Hwa (72 citations) has 5 publications.

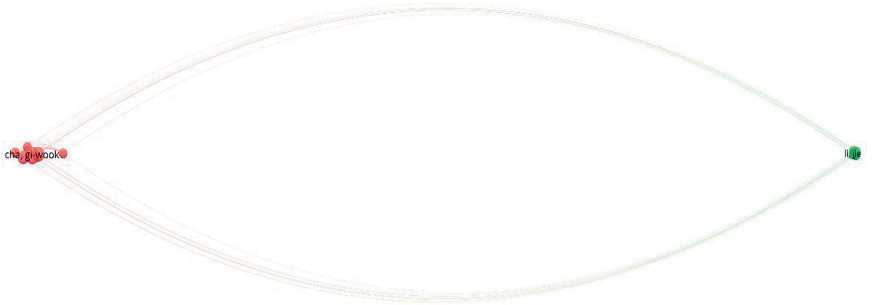

Figure 10. Authors' bibliographical coupling: 10 authors out of 928 meet the minimum threshold of 3 documents per author

Analysis of co-authors by country and institution

Co-authorship among cities and Institution was examined, with node size representing the importance of Institution or countries and the spacing indicates the extent of their collaboration.

Examining the co-authorship connections among countries reveals a network of 20 countries divided into 5 clusters (Figure 11). The cluster of red includes 7 countries, with China as the most prominent (42 documents, 745 citations), followed by Hong Kong (7 documents, 323 citations) and South Korea (23 documents, 842 citations). The cluster of green comprises 4 countries, with Saudi Arabia as the leading country (20 documents, 210 citations), along with Pakistan (8 documents, 135 citations) and Poland (8 documents, 166 citations). In the cluster of blue, which includes 3 countries, the United States is the primary contributor (23 documents, 426 citations), followed by Bangladesh (5 documents, 67 citations) and Canada (6 documents, 121 citations). The cluster of yellow is made up of 3 countries, led by India (35 documents, 516 citations), while the cluster of purple also contains 3 countries, led by the United Kingdom (16 documents, 59 citations). The countries with the highest number of publications and citations are China, Saudi Arabia, and the United Kingdom.

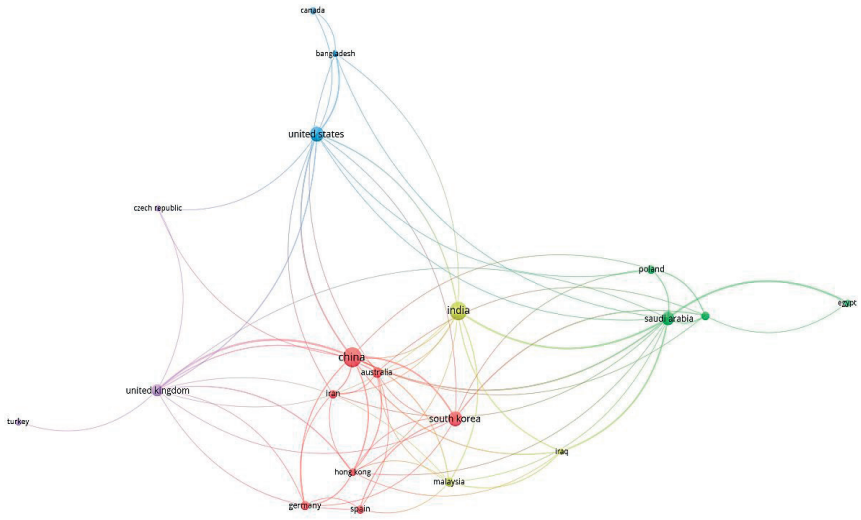

Figure 11. Co-authorship network of countries: 20 countries out of 63 meet the minimum threshold of 5 papers per country

Finally, the co-authorship network of institutions Figure 12 reveals that there is limited collaboration among different organizations that satisfy the threshold of having at least 2 published documents. Out of the 608 universities listed, the largest group comprises only 5, divided into two clusters: the cluster of red consists of 3 organizations, while the cluster of green includes 2 organizations. A notable organization is the School of Science and Technology in Acceleration Engineering at Kyungpook, National University in Daegu, South Korea, which has 4 documents and 27 citations.

Figure 12. Co-authorship network of organizations: 5 organizations out of 608 meet the minimum threshold of 2 documents

This study examined the application of ML in waste management to understand how these advanced algorithms can enhance decision-making processes and improve WM outcomes. The results highlight several critical factors that could advance the field and help scholars make more informed decisions. This paper also explores how ML integration impacts current practices and influences future developments in waste management. China, India, and South Korea lead in the highest number of publications in this area. Keyword analysis indicates a strong focus on specific waste types, including "solid waste", "demolition waste", and "organic waste". Research on these types of waste is essential, as they represent the most generated waste worldwide and pose multiple potential negative impacts (economic, sustainability, and environmental) if not managed properly.

In general, there is a noticeable rise in publications focused on WTE. Recovering energy from waste through incineration plants offers a way to reduce the volume of waste directed to landfills. Moreover, it can aid in decreasing reliance on energy produced from fossil fuels, which are often imported. However, the increase in publications does not align with the waste hierarchy outlined by organizations like the European Parliament. This hierarchy emphasizes the importance of implementing strategies to minimize waste generation, enhance efforts for recycling and reuse, and discourage reliance on landfills and incinerators, which remain common in certain areas of Europe and other parts of the world. Evaluating WM systems (collection and processing) is crucial because they can help minimize waste generation and enhance opportunities for recycling and reuse instead of relying on landfills and incineration.

The present study can help researchers identify various concepts and their interconnections, paving the way for further research opportunities. In this context, the article reveals several trends within the research landscape. The first trend is the growing importance of machine learning in waste management, as demonstrated by the increase of publications in Scopus. Additionally, there is heightened interest in researching WTE technologies. Another significant point is the need for collaboration among various universities across different countries, as limited cooperation has been observed. Such collaboration would facilitate knowledge sharing and the development of improved WM systems. Ultimately, there is a pressing need for increased research in this area on a global scale.

CONCLUSIONS

This bibliometric analysis highlights the application of ML in waste management from 2014 to 2024, covering trends and developments that underscore the growing importance of ML in this field. The significance of this study lies in its being the first bibliometric analysis to examine the role of ML in waste management. The data reveals substantial growth in ML-related studies within waste management, increasing from a single publication in 2016 to 62 in 2024, culminating in 217 publications. China, India, and South Korea have emerged as leading contributors to global research, driving significant advancements in the application of ML to waste management. The recognition of key journals, including the Journal of Cleaner Production and Waste Management, further underscores the academic significance of research in this domain. We also analyzed the evolution of research by examining highly cited papers, top journals, authors' keywords, co-citation patterns, and co-authorship networks among countries and organisation. This analysis highlights the ongoing need for further exploration and application of ML in waste management. VOSviewer visualizations revealed extensive international collaboration, emphasizing a robust research framework. However, the study has limitations. The use of broad keywords like "machine learning in waste management" could be refined to focus more specifically on waste-related topics. Additionally, the reliance on the Scopus database, while favored for its wide coverage and credibility in bibliometric studies, limits the study’s overall scope. Overall, this bibliometric analysis provides a comprehensive overview of the evolving role of ML within waste management, it highlights the field's rapid growth, the strength of international collaborations, and the rising significance of

ML techniques in enhancing waste management processes. In the near future, research could investigate a comparison between conventional bibliometric methods and machine learning-driven bibliometric models in waste management. Expanding this comparison over several decades may reveal trends in the development and effectiveness of these approaches. This approach helps researchers identify various concepts and their connections, paving the way for new research directions.

Abstract

This study evaluates the success of Scots pine sapling plantings conducted in 2023 on the waste deposits at the Recea Șuncuiuș Quarry in Bihor County. Four experimental plots were established, divided into two slope categories. Half of the saplings received fertilizer, and for all saplings, survival rates were assessed, along with measurements of diameter and height growth. The findings indicate no significant differences in sapling growth between the slopes, and the application of fertilizer did not notably affect their development in the first year after planting. However, in the second year, significant changes were observed. The slope became a negative factor, while fertilization had a significant positive impact on growth in terms of diameter and height, particularly under the harsh conditions of the exceptionally dry and hot summer of 2024.

Key words*: diameter, height, pine, Pinus, survival rate.*

INTRODUCTION

Over the past century, the global population has increased from 2 billion to over 8 billion, placing significant strain on natural resources. Growing demand for products has intensified landscape impacts, particularly through the extraction of underground resources, leading to a considerable expansion of degraded lands in recent years. In this context, restoring ecosystems has become a key responsibility for foresters, with afforestation widely recognized as an essential component of this effort (Huang et al., 2024).

Afforestation offers a practical solution for the ecological restoration of degraded lands, providing a foundation for their sustainable use and development in the medium and long term (Constandache et al., 2020). Additionally, afforestation efforts are widely acknowledged as effective measures for combating climate change by sequestering carbon (Zhiyanski et al., 2016).

One of the most used worldwide tree species for afforestation is the Scots pine (*Pinus sylvestris* L.). It has the largest natural range of any pine species, extending across both Europe and Asia (Przybylski et al., 2015; Bonciu et al., 2023). Latitudinally, it ranges from northern Scandinavia (70°N) to the Sierra Nevada mountains in southern Spain (37°N) (Houston Durrant et al., 2016).

During the twentieth century, Scots pine forests saw significant expansion throughout Europe, currently accounting for over 20 percent of the EU's forest area. Although the initial focus of this expansion was to enhance timber production, recent decades have shifted towards a broader set of management goals (Mason & Alia, 2000). Scots pine exhibits significant morphological and genetic diversity due to its wide distribution (Stoica et al., 2022; Sheller et al., 2023), with several varieties, including *Pinus sylvestris* "Glauca", *Pinus sylvestris* var. *hamata* Stev, and *Pinus sylvestris* var. *mongolica* Litvin (Budău et al., 2024). Scots pine is a pioneer species with a wide range of uses, including in the wood and chemical industries, household applications, decoration, ecological restoration, as well as in medicinal and cosmetic products (Papp et al., 2022; Gurău,

2024; Szanto et al., 2025). Particularly, it is recognized for its resilience to frost and drought, as well as its capacity to grow in nutrient-poor soils, allowing it to inhabit a variety of ecologically diverse environments (Enescu, 2015). It forms a deep root system, allowing it to tap into water from deeper soil layers and stabilize land prone to erosion. Its rapid growth supports the restoration of vegetation in degraded areas. Scots pine can thrive in both lowland and mountainous regions due to its adaptability to diverse climatic conditions and its ability to grow in nutrient-poor soils, making it an important resource for ecosystem restoration and the fight against desertification (Kelly and Conolly, 2000; Doniță et al., 2004; Pietrzykowski et al., 2013). Through the decomposition of its needles, *P. sylvestris* contributes to the formation of raw humus (Traci et al., 1981), thereby enhancing biodiversity in the soil's upper layer (Xue et al., 2022).

In many European countries, Scots pine is one of the primary coniferous species used for afforestation and is often considered the dominant species for forest formation (Oszako et al., 2023; Okon et al., 2024). For example, Scots pine has been successfully planted in the Czech Republic, where it ranks as the second most important tree species for industrial wood production (Brichta et al., 2023), and has been established in various terrains, including post-mining sites (Zeidler et al., 2024). In Latvia, Scots pine has been successfully used for afforestation of abandoned peat extraction sites (Skrastiņa et al., 2021), while in Ukraine, it has been planted to establish forest plantations resilient to environmental factors in the northern steppe region (Gritsan et al., 2019). Positive results have also been reported in Russia (Belan et al., 2024) and Mongolia (Sukhbaatar et al., 2018).

In Romania, Scots pine has been planted in a variety of site conditions, including the sandy soils of the Oltenia region in southwestern Romania (Nuță, 2005), abandoned mining lands in the northwestern part of Transylvania (Buta et al., 2019), and degraded terrains in eastern part of the country (Vlad et al., 2019). In most cases, Scots pine exhibited a rapid growth rate, particularly during the initial years of vegetation (Batsaikhan et al., 2018; Colișar et al., 2024).

This study aimed to evaluate the growth in diameter and height of Scots pine saplings planted in 2023 on sterile dumps at the Recea Șuncuiuș Quarry in Bihor County.

MATERIALS AND METHODS

The experiments were conducted within the 2.89 km² Recea perimeter, situated in the Șuncuiuș refractory clay deposit in the northern part of the Pădurea Craiului Mountains, Bihor County (46°55'11"N, 22°30'34"E), where the first afforestation experiments were made in 2008-2009 (Bodea et al., 2023).

According to Ministerial Order no. 2533/2022 (MMAP, 2022), the landfill site in this case is classified as YD1B (Y - landfill; D - hill region; 1 - for raw waste dumps or terrigenous materials from mining and B - anthropogenic materials composed of small materials such as sand, gravel, loess, and clay). The planting materials were sourced locally, and 4 experimental plots, 50 m^2 each, noted with E, F, G and H, were established (Figure 1).

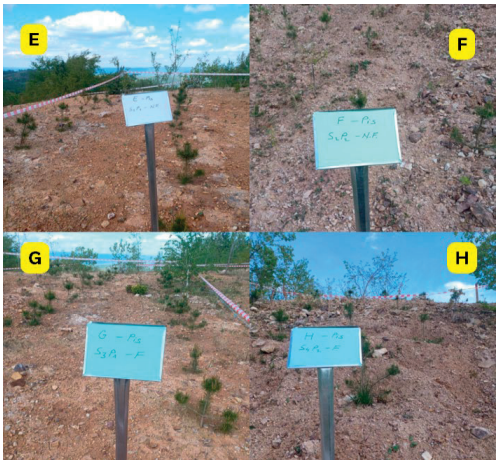

Figure 1. The 4 experimental plots

In the four experimental plots, 3-year-old Scots pine seedlings, averaging 30 cm in height, were planted using a 2x1 m spacing arrangement, with 25 seedlings in each plot. During the spring and autumn of 2023 and 2024, the following characteristics were measured:

- the survival rate after planting in the field, expressed as a percentage;

- the survival rate of seedlings, recorded at the end of the first vegetation period, expressed as a percentage;
- seedling height (cm), measured from ground level to the top of the main stem;
- seedling diameter at the root collar (mm) at the end of the first vegetation year in the field;
- the number of whorls;
- the number of branches per whorl.

The four experimental plots were labelled as follows:

- Variant E, code Pi.s. S_1P_1N: small slope P1≤10°, N - unfertilized substrate;
- Variant F, code Pi.s. S_2P_2N: large slope P2>10°, N - unfertilized substrate;
- Variant G, code Pi.s. S_3P_1F: small slope P1≤10°, F - fertilized substrate;
- Variant D, code Pi.s. S_4P_2F: large slope P2>10°, H - fertilized substrate.

The saplings' height was measured with a height measuring tape (Figure 2a), and the trunk diameter at the base was measured using a digital caliper (Figure 2b).

Figure 2. Measuring the height and the collar diameter of the saplings

Fertilization was applied in experimental plots G and H using a chemical fertilizer specifically formulated for softwood seedlings, containing 14% N, 7% P_2O_5, 17% K_2O, 2% MgO, 9% S, 0.02% B, and 0.01% Zn. The fertilizer was distributed around the seedlings at a rate of 15–20 grams per plant (Figure 3).

For most of the analyzed characteristics (degree of survival after planting, degree of survival after the first year, plant height, diameter at the root collar, number of whorls, and number of branches per whorl), the arithmetic mean was calculated using the standard formula: $x = \sum x/n$.

Figure 3. Applying fertilizers

For the number of branches per first whorl, as each sample contained groups of plants with varying numbers of branches (ranging from 0 to 6 branches per whorl per plant), the weighted arithmetic mean was used, calculated with the following formula:

$$X_{med.pond.} = \frac{\bar{x}_1 n_1 + \bar{x}_2 n_2 + \ldots + \bar{x}_k n_k}{N},$$

where:

$N = n_1 + n_2 + \ldots + n_k$;

$\bar{x}_1 \ldots \bar{x}_k$ = group averages.

To determine the degree of survival after planting in the field, the following formula was used:

$$Gp(\%) = \frac{Pveg}{Pplant}\ 100,$$

where:

- P_{veg} represents seedlings started in vegetation on April 20, 2023;
- P_{plant} accounts for planted seedlings.

To determine the degree of survival after planting in the field, the following formula was used:

$$Gm(\%) = \frac{Pviab}{Pveg}\ 100$$

where:

- Pviab represents viable seedlings at the time of determination;
- Pveg represents the number of seedlings that started growing on April 20, 2023.

The results from the biometric measurements were statistically analyzed using analysis of variance, appropriate for monofactorial experiments conducted in randomized blocks. The significance of differences between the two tested varieties was assessed using the DL test or the multiple comparisons test (DS5%). For certain characteristics, the Student's *t* test was also applied (Ardelean et al., 2005; Ardelean, 2011).

The coefficients of variability (s%) were calculated using data from the series of measurements taken on the 25 individuals in each variant, following the formula described by Ardelean (2011):

$$s\% = \frac{s}{\bar{x}}\ 100,\%$$

where:

- s represents the standard deviation;
- x is the average of the series.

Simple correlation coefficients were calculated using Microsoft Excel, with their significance assessed at the 5% and 1% levels.

RESULTS AND DISCUSSIONS

The data presented in Tables 1 and 2 confirm the uniformity of the planted material, indicating that at the time of planting, there were no significant differences in seedling height or diameter within the parcel.

Tables 3 and 4 present the mean diameters and heights of *P. sylvestris* measured in spring and autumn of 2023 and 2024 across the four experimental plots.

Table 1. Mean collar diameter (mm) in the 4 plots

Var	Initial diameter, mm $\bar{X} \pm s_x$	± d, cm	t	Significance of difference	s%
E	12.66 ± 0.63	-	-	-	21.9
F	10.81 ± 0.44	-1.85	-0.84	n.s.	17.7
G	14.57 ± 0.53	1.91	0.79	n.s.	13.8
H	11.22 ± 0.34	-1.44	-0.70	n.s.	27.9
$t_{calc} < t_{P5\%} = 1.9$					

Table 2. Mean height (cm) in the 4 plots

Var	Initial height, cm $\bar{X} \pm s_x$	± d, cm	t	Significance of difference	s%
E	28.90 ± 1.26	-	-	-	24.9
F	29.54 ± 1.04	0.64	0.07	n.s.	20.1
G	31.58 ± 0.87	2.68	0.30	n.s.	18.1
H	30.48 ± 1.70	1.58	0.10	n.s.	15.3
$t_{calc} < t_{P5\%} = 1.9$					

In terms of survival rate after planting, it was observed that losses were minimal, with only 1% in the first year and an additional 1% (one dried seedling in experimental plot H) in 2024.

Table 3. Mean diameters and heights measured in spring and autumn 2023 for *P. sylvestris* in the 4 experimental plots

Code	Variant	Collar diameter, mm		Diameter growth, mm	Height, cm		Height growth, cm
		03.2023	11.2023		03.2023	11.2023	
Pi.s. - S1P1N	E	12.66	12.95	0.28	28.90	45.60	16.70
Pi.s. - S2P2N	F	10.81	11.10	0.24	29.54	46.50	16.73
Pi.s. - S3P1F	G	14.57	14.99	0.42	31.58	45.70	14.12
Pi.s. - S4P2F	H	11.22	11.71	0.49	30.48	46.10	15.62

Table 4. Mean diameters and heights measured in spring and autumn 2024 for *P. sylvestris* in the 4 experimental plots

Code	Variant	Collar diameter, mm		Diameter growth, mm	Height, cm		Height growth, cm
		03.2024	11.2024		03.2024	11.2024	
Pi.s. - S1P1N	E	12.95	19.85	6.90	45.60	57.53	11.94
Pi.s. - S2P2N	F	11.10	17.34	6.24	46.50	59.94	13.44
Pi.s. - S3P1F	G	14.99	26.75	11.75	45.70	66.79	21.08
Pi.s. - S4P2F	H	11.71	20.36	8.65	46.10	63.94	17.84

An analysis of the 25 seedlings from the first variant (E; no slope, unfertilized) revealed that, at the end of the first year of growth, the seedlings' height ranged from 25 to 67.5 cm, with a variability coefficient of 23.8% (high variability).

The calculation and interpretation of results from the bifactorial experiments involve the following factors:

- Factor A: fertilization method, with two levels: N (unfertilized) and F (fertilized);
- Factor B: slope, with two levels: P1 (0-10°) and P2 (>10°).

The experiment was carried out using a randomized block design with 25 replications (n = b = 25). The total number of experimental variants (v = 4) was determined by the combination of the two factors at two levels each (2 × 2 = 4). Each experimental plot contained 25 seedlings, and the average height growth for each replication area was calculated as the mean of the measurements from all 25 seedlings within the plot. The analysis of variance for the bifactorial experiment (2 × 2), considering slope and fertilization method, is presented in Table 5.

Table 5. Analysis of variance for the bifactorial experiment (2 x 2) with slope and fertilization mode

Source of variation	Sum of squares (SS)	Degrees of freedom (DF)	Mean square (MS)	F-Statistic (F)			
Total	3892.70	99					
blocks	872.0596	24				5%	1%
fertilization	56.7009	1	56.70	1.39	<	3.98	7.01
slope	502.7481204	1	502.75	12.35	>	3.98	7.01
fertilization x slope	-469.80	1	-469.80	-11.54	>	3.98	7.01
Error	2930.99	72	40.708				

According to the data in Table 5, the calculated *F* values for the slope factor exceed the theoretical *F* values at the 5% significance level (P5%), indicating that slope has a significant influence on seedling height growth during the first year after planting.

The significance of differences between variants is assessed below. Given the potential for multiple types of comparisons, the analysis of variance method was used to calculate the standard deviation (sd) and least significant difference (LSD) values for each comparison.

a) In Table 6, the variants are compared to the control variant:

- sd = 1.80 cm
- $LSD_{5\%}$ = 3.59 cm
- $LSD_{1\%}$ = 4.78 cm
- $LSD_{0.1\%}$ = 6.19 cm

Table 6. Summary of the results

Var.	Variant name	hm, cm	h rel, %	±d, cm	Significance of difference
11	NP1 (Control variant)	16.70	100.0	-	-
12	NP2	16.73	100.2	0.0	-
21	FP1	14.12	84.6	-2.6	-
22	FP2	15.62	93.5	-1.1	-
	LSD 5%=	3.59			
	1%=	4.78			
	0.1%=	6.19			

b) The influence of fertilization on height growth was evaluated relative to the unfertilized variant, which served as the control. The error and least significant difference (LSD) values corresponding to the fertilization factor were as follows:

- sd (fertilization) = 11.51 cm;
- $LSD_{5\%}$ = 22.91 cm;
- $LSD_{1\%}$ = 30.51 cm;
- $LSD_{0.1\%}$ = 39.49 cm.

The results are given in Table 7.

Table 7. The influence of fertilization on hm

Variant name	hm, cm	h rel, %	±d, cm	Significance of difference
unfertilized (Mt)	16.4	100.0	-	-
fertilized	14.9	90.8	-1.8	-
LSD 5%=	22.9			
1%=	30.51			
0.1%=	39.49			

It can be observed that regardless of the slope, the applied fertilization does not result in significant growth in the seedlings.

c) The influence of slope on growth height is compared to the variant without slope as a control. The results are given in Table 8. Regardless of the fertilization applied, slope negatively influences seedling growth, but insignificantly.

d) Comparing all variants with each other using the Duncan test (multiple comparisons method). It is applied when the interaction of the 2 factors is significant.

d1) To compare the influence of fertilization on height growth, regardless of slope:

- sx = 0.90 cm
- Degrees of freedom for error = 72

The $DS_{5\%}$ values for different comparison limits between the mean effects of the fertilization factor were calculated as follows:

- Number of variants within the comparison limits: 2
- q5%, (for DF = 72) = 2.82
- sx = 0.90 cm
- $DS_{5\%}$ = 2.54 cm

The $DS_{5\%}$ values for the different comparison limits between variants are presented in Table 9.
d2) The same as variant d1) - All non-significant.

Table 8. The influence of slope on hm

Variant name	hm, cm	h rel, %	±d, cm	Significance of difference
P1 (Mt)	15.41	100	-	-
P2	15.836	102.7644	-0.86	-
LSD 5%=	22.91			
1%=	30.51			
0.1%=	39.49			

Table 9. The $DS_{5\%}$ values for different comparison limits between variants

Variant	hm	1	4	3
2	16.73	0.03	1.11	2.61
1	16.7	-	1.08	2.58
4	15.62		-	1.5
3	14.12			-

All non-significant

d3) To compare the influence of fertilization on the same or different slopes, as well as the effect of slope under the same or different conditions on height growth: sx = 1.28 cm. The DS5% values for the different comparison limits between variants are presented in Table 10. Table 11 presents the seedling height growth (cm) one year after planting, under the influence of two slope categories and two fertilization methods. Differences between two variants followed by the same letter in the table are not statistically significant.
The same procedure was applied for the year 2024. The average increases in collar diameters in the first 2 years in all 4 experimental plots are given in Figure 4. The average increase in height in the first 2 years in all 4 experimental plots are given in Figure 5.

Table 10. The DS5% values for different comparison limits

The number of variants within the comparison limits.	2	3	4
$q_{5\%}$ for DF= 72	2.82	2.97	3.07
s_x in cm	1.28		
$DS_{5\%}$	3.60	3.79	3.92

Table 11. Seedling height growth (cm) one year after planting by slope category and fertilization method. Variants sharing the same letter do not differ significantly

Fertilization \ Slope	P1	P2	Fertilization average
N - Unfertilized	16.7 b	16.7 b	16.7 A
F - Fertilized	14.1 a	15.6 a	14.9 A
Average slope	15.4 M	16.2 M	

$DS_{5\%}$ to compare two averages fertilization =2.5
$DS_{5\%}$ to compare two averages slope =2.5
$DS_{5\%}$ to compare two averages: fertilization x slope =3.6-3.9

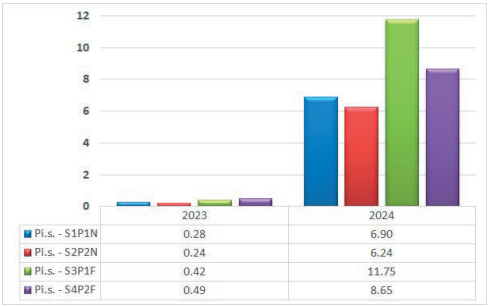

Figure 4. The average increase in collar diameters (mm) in the first 2 years in all 4 experimental plots

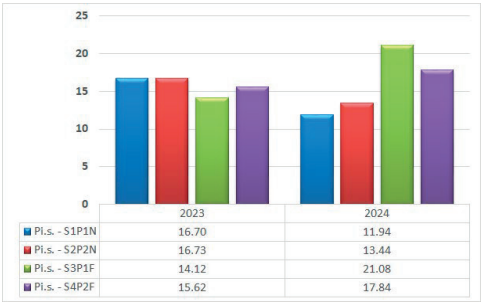

Figure 5. The average increase in height (cm) in the first 2 years in all 4 experimental plots

CONCLUSIONS

Scots pine seedlings of local origin (Șuncuiuș nursery, Bihor County), planted in 2023, demonstrated a high survival rate of 98% during the first two years after planting.
The 3-year-old seedlings, planted in large planting holes (40 × 40 × 40 cm), showed no significant differences in diameter and height growth during the first year, regardless of fertilization, due to prior nursery growth and initial site conditions. However, in the second year, seedlings in plot G, where fertilizers were

applied on a gradual slope, exhibited significantly higher growth, with height increases 70.2% greater than in the unfertilized plot E. On steeper slopes, diameter growth was 26.3% lower compared to flat or gently sloping areas.

In 2024, height growth was lower than in 2023 for unfertilized seedlings. In contrast, fertilized seedlings on gradual slopes achieved height increases 49.2% higher than in the first year and 76.5% higher than unfertilized seedlings on the same slope in the second year. Overall, fertilization significantly enhanced height and diameter growth in 2024 compared to 2023. However, due to exceptional climatic conditions in 2024, including three months of severe drought, growth increments were lower in unfertilized seedlings compared to the previous year.

During the first year after planting, slope had a clear and significant influence on height growth. Scots pine has proven to be a valuable species for afforesting degraded lands due to its exceptional adaptability to challenging conditions. It has demonstrated effectiveness in restoring areas impacted by vegetation removal and excavation, particularly in high clay content soils where other species struggle to establish. With its capacity to stabilize soil and support ecosystem recovery, Scots pine plays a critical role in ecological restoration projects, contributing to vegetation recovery, biodiversity enhancement, and long-term environmental protection.

Corresponding author email: b.pesheva@ltu.bg

Abstract

Some sentences are overly long or repetitive. Consider: Forest fires induce significant environmental changes, with long-term impacts on forest ecosystems and soil properties. These changes affect soil temperature, chemical composition, organic matter content, and microbial communities. This study investigates the alterations in silvicultural properties of Gray Forest soils (Gray Luvisols) in Northwestern Bulgaria following forest fires, considering key variables such as fire type and intensity, time since fire, forest type, and stand density. The results show that forest fires generally reduce soil organic matter and total nitrogen content, alter soil acidity, and affect soil microbial abundance. In particular, low-intensity fires may stimulate microbial activity, whereas high-intensity fires tend to suppress it. These findings provide insights into the mechanisms of post-fire soil transformation and offer a scientific basis for afforestation and land reclamation planning in fire-affected forest areas.

Key words*: forest fires, soil fertility, silvicultural properties, soil microflora, Gray Luvisols, soil recovery, post-fire management.*

INTRODUCTION

Forest fires, whether natural or anthropogenic in origin, represent a major ecological disturbance with both immediate and long-term consequences for forest ecosystems. One of the most significant effects is the alteration of soil properties, which play a critical role in supporting vegetation recovery and maintaining ecosystem functions.

Soil characteristics are closely tied to vegetation cover and organic matter inputs both of which are drastically altered by fire. The extent and nature of these changes depend on multiple factors, including the type and intensity of the fire, the amount and distribution of combustible material, fuel moisture content, and prevailing weather conditions. These variables introduce considerable variability, making it challenging to generalize the effects of forest fires across different landscapes (Barnes et al., 1998; Kimmins, 1996; DeBano et al., 1998; Bogdanov, 2023a).

Post-fire changes in soils occur on both short- and long-term timescales. Immediately after a fire, the release of energy alters soil temperature regimes and may lead to the combustion of organic matter, volatilization of nutrients, and disruption of soil structure and microbial habitats (Jiménez Esquilín et al., 2008; Neary et al., 1999). Long-term impacts are often associated with increased solar absorption due to surface darkening and reduced organic matter, which can further influence soil temperature and moisture regimes (Molla et al., 2014).

The increase in the concentration of nutrients after a fire is associated with the increase or recovery of the soil microflora. The initial impact of fires usually leads to a decrease in the total amount of microorganisms in the soil, and this is often followed by their increase, which is beneficially affected by the increase in soil temperature (Bogdanov, 2023b).

Microbial communities in soil are particularly sensitive to fire. Initially, fire often results in a decline in microbial abundance and diversity due to elevated temperatures and loss of organic substrates. However, recovery dynamics vary widely. In some cases, microbial populations rebound quickly, facilitated by increased nutrient availability and warmer soil temperatures (Bogdanov, 2023b). The extent of microbial recovery is influenced by both the physical-chemical properties of the soil and the intensity and duration of the fire (Mataix-Solera et al., 2002; Barreiro & Diaz-Ravina, 2021).

In forest management, fires are classified based on the location of fuel consumption (crown,

surface, or ground fires) and by their spread and severity. These classifications are important for evaluating the degree of ecological damage and planning appropriate restoration strategies (Bogdanov, 2023a). One of the key post-fire challenges in forestry is the restoration of burned stands, which often cannot regenerate naturally and require targeted afforestation efforts. These efforts depend on a thorough understanding of the soil's silvicultural properties - factors such as organic matter content, nutrient status, and microbial health that determine soil fertility for tree growth (Bogdanov, 2023b).

The present study aims to assess the changes in the silvicultural properties of soils affected by forest fires in Northwestern Bulgaria. Specifically, it analyzes how different factors - fire type and intensity, time elapsed since the fire, forest type, and stand density - affect soil properties such as organic matter, total nitrogen, pH, and microbial abundance. By identifying these relationships, the study contributes to improved understanding of post-fire soil dynamics and supports science-based forest restoration planning.

MATERIALS AND METHODS

Study area and soil classification

The study was conducted in Northwestern Bulgaria, within the territory of the Belogradchik State Forestry. According to Bulgaria's forest-vegetation zoning system (Zahariev et al., 1979), the area is situated in the Lower Forest Vegetation Belt (700-2000 m above sea level) of the Misian Forest Zone.

The soils under investigation are classified as Gray Forest soils (Gray Luvisols), based on the classification system of Penkov et al. (1992). These correspond to the Luvisols soil group in the World Reference Base for Soil Resources (WRB) (IUSS, 2022), with dominant qualifiers being Haplic and Albic (Bogdanov, 2024).

Plot design and sampling procedure

To assess the effects of forest fires, nine paired sample plots (100 m² each) were established - each including a burned area and a corresponding unburned control plot. The plots were selected based on fire history, fire characteristics (type and intensity), forest type (deciduous or coniferous), and stand density (Table 1). Table 1 provides an overview of the plot characteristics, including year of fire occurrence, type and strength of fire, altitude, forest type, and stand density.

Soil samples were collected from the 0-5 cm surface layer, which is known to exhibit the most pronounced post-fire changes (Barnes et al., 1998; Bogdanov, 2023a). For microbiological analysis, all soil samples were collected using sterile tools, placed in sterile bags, and processed within 48 hours to preserve microbial integrity.

Table 1. Characteristics of the sample plots

Sample plots (SP)	Year of the fire	Fire type/strength	Area (1000 m^2)	Altitude (m)	Forest group	Stand density
1	2020	Surface/ Middle	8.0	150	D	0.2
2	2020	Surface/ Middle	4.2	180	D	0.5
3	2020	Surface/ Middle	3.2	200	D	0.5
4	2021	Surface/ Middle	4.4	170	D	0.5
5	2021	Surface/ Middle	1.8	180	C	0.6
6	2022	Crown/ Middle	1.6	180	D	0.5
7	2022	Surface/ Middle	6.0	170	D	0.4
8	2022	Surface/ Strong	2.0	200	D	0.5
9	2022	Surface/ Weak	1.5	200	D	0.4

*D - deciduous; C - coniferous

Fire classification

Within the scope of this study, forest fires were classified based on the visible intensity of their impact on vegetation, following the approach of Bogdanov (2023b). This classification distinguishes between crown fires and surface fires, with further categorization into three levels of severity - weak, medium, and strong.

A strong crown fire involves complete combustion of the tree canopy and stems, corresponding to what is commonly referred to as a "total fire," resulting in the complete destruction of the stand. A medium crown fire also affects the tree crowns but typically results

in full stand mortality without complete combustion of all stems. In contrast, a weak crown fire affects the upper canopy more sporadically, causing partial or mosaic mortality within the stand.

Surface fires were characterized by stem scorching at heights ranging from 0.5 to 1.5 meters. A strong surface fire results in significant stem damage and the eventual destruction of the stand. A medium surface fire causes variable mortality within the stand, leading to a mosaic pattern of tree survival. A weak surface fire, while still affecting stem bases within the same height range, does not result in substantial tree mortality.

Laboratory analyses

To analyze the changes in the silvicultural properties of the soil following forest fire events, both primary and supplementary indicators were assessed. The primary indicators included the content of soil organic matter and total nitrogen, which are key determinants of soil fertility. Supplementary indicators - such as soil pH, the carbon-to-nitrogen (C:N) ratio, and the abundance of total soil microflora - were also evaluated, as these parameters are critical to soil biological functioning and are known to undergo significant changes under the influence of fire (Bogdanov, 2023a; Bogdanov, 2023c; Donov, 1976).

Laboratory analyses were conducted using standardized methods. Soil organic matter was determined using the modified Turin method (Filcheva & Tsadilas, 2002). Total nitrogen content was measured using a modified version of the classic Kjeldahl method (ISO 11261:2002). Soil pH was assessed potentiometrically in a water extract. The C:N ratio was calculated based on measured concentrations of carbon and nitrogen, following the method outlined by Bogdanov (2023c). The abundance of total soil microflora was quantified through the method of serial dilutions and inoculation on selective solid nutrient media, followed by incubation (Gousterov et al., 1977). Microbial abundance was expressed in colony-forming units (CFU) per gram of oven-dry soil.

RESULTS AND DISCUSSION

Effects of forest fires on soil organic matter, total Nitrogen, and pH

The analysis of soil samples from burned and corresponding unburned control plots revealed certain changes in the key indicators of soil fertility following forest fires (Table 2).

Table 2. Properties of soils influenced by forest fires

Sample plot (SP)	SOM % M ± SD	Total N % M ± SD	C: N	pH M ± SD
FP 1	2.11 ± 0.02	0.142 ± 0.003	8.6	5.7 ± 0.007
Contro l	2.35 ± 0.04	0.135 ± 0.006	10.1	5.4 ± 0.005
FP 2	2.26 ± 0.05	0.121 ± 0.007	10.8	5.9 ± 0.004
Control	2.77 ± 0.04	0.117 ± 0.007	13.7	5.2 ±0.005

Control	2.47 ± 0.06	0.126 ± 0.005	11.4	5.0 ± 0.007

Note: FP- fire plot, SOM - soil organic matter, M - Mean, SD - Standard Deviation, Amount of soil microflora - 103/g absolutely dry soil

One of the most immediate and pronounced effects observed was the reduction in organic soil matter (SOM). This decline was especially evident in plots affected by moderate to high-intensity fires. The combustion of organic matter during fire events not only reduces humus content but also disrupts soil structure and affects water retention, aeration, and nutrient availability - factors critical to tree growth and regeneration.

Changes in SOM are inherently complex due to the variable composition of organic compounds and the influence of multiple environmental factors, such as topography, microclimate, and vegetation type.

Nevertheless, the consistent decline in SOM across multiple fire-affected plots underscores its vulnerability to fire disturbance and its central role in post-fire soil degradation.

Similarly, total nitrogen content showed a general decrease in the burned plots compared to the control plots. This reduction is attributed to increased soil temperatures during fires, which accelerate volatilization and intensify nitrification processes (Barnes et al., 1998). Furthermore, although microbial populations often recover after fire, the initial microbial decline can lead to immobilization and limited availability of nitrogen in both ammonium and nitrate forms (Bogdanov, 2023a).

The data also indicate an increase in soil pH following fire exposure, suggesting a reduction in acidity. This is commonly observed in post-fire soils and is primarily due to the accumulation of ashes and basic cations such as calcium, magnesium, and potassium. These cations are released during the combustion of organic matter and contribute to an alkaline reaction in the soil solution (Kimmins, 1996). The increase in pH can have both beneficial and detrimental effects depending on the species-specific requirements of the vegetation and microbial communities. High pH levels tend to inhibit the development of micromycetes while favoring the proliferation of non-spore-forming bacteria (Lauber et al., 2009; Ammitzbøll et al., 2022).

These findings clearly demonstrate that forest fires disrupt the balance of key soil properties that are essential for maintaining silvicultural productivity and soil ecological health.

Microbial community responses to fire

The influence of forest fires on soil microbial abundance was assessed by comparing total microbial counts in fire-affected plots and their respective control areas (Figure 1).

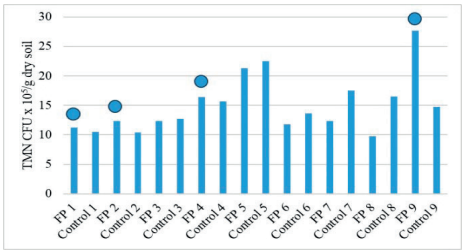

Figure 1. Total microbial number
Samples with increased TMN compared to controls

The results reveal a heterogeneous response, with no uniform trend across all sites. In some plots - specifically FP1, FP2, FP4, and FP9 - the total microbial number (TMN) was higher in the burned soils than in the control soils. This trend was most pronounced in FP9, where microbial abundance nearly doubled following a low-intensity surface fire. These findings suggest that weak surface fires may not significantly disrupt microbial communities and, under certain conditions, may even stimulate microbial activity due to increased nutrient availability and elevated soil temperatures. In contrast, in the remaining plots, microbial abundance was consistently lower in burned areas compared to controls. The most notable reduction occurred in FP8, which experienced a strong surface fire. Here, microbial counts in the control plot were approximately 40% higher than in the corresponding burned area. This pattern indicates that high-intensity fires exert a stronger suppressive effect on microbial communities, likely due to lethal temperatures and the destruction of habitat and organic substrates. On average, across all other sites (excluding FP8), microbial abundance in control plots was approximately 12.5% higher than in the burned plots. A parallel trend was observed in the population of ammonifying bacteria, which play a vital role in nitrogen cycling (Figure 2). As with total microflora, elevated counts of ammonifying bacteria were recorded in FP1, FP2, and FP9. A marginal increase (approximately 4%) was also observed in FP4. This pattern confirms that ammonifying bacteria constitute a substantial proportion of the total microbial community and respond similarly to fire-induced changes in the soil environment.

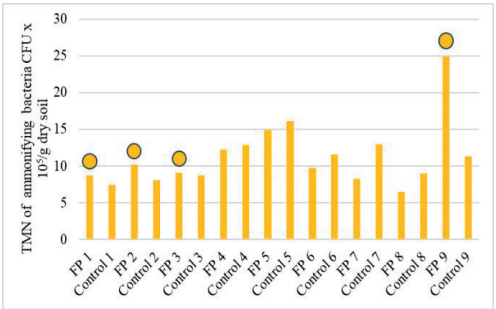

Figure 2. TMN of ammonifying bacteria
Samples with increased TMN of ammonifying bacteria compared to controls

The variability of microbial responses was further analyzed through the standard distribution of microbial abundance across all sample plots (Figure 3).

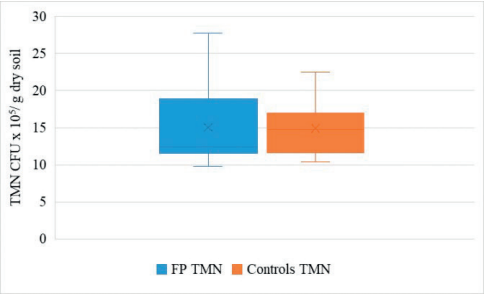

Figure 3. Standard distribution of FPs and Controls

The data show that in the control plots, the mean value closely aligns with the median, indicating a symmetrical distribution of microbial abundance. In contrast, in the burned plots, the mean and median values differ significantly, suggesting a more skewed distribution. In both control and burned areas, the values in the first quartile display a narrow range. However, in the second quartile, the control plots exhibit a wider range (11.5×10^5 to 12.4×10^5 CFU/g of dry soil) compared to the burned plots. This pattern reverses in the third quartile. In the burned plots, 25% of the values fall within a broader range - from 12.4×10^5 to 18.9×10^5 CFU/g - while in the control plots the corresponding range is narrower, from 14.8×10^5 to 17×10^5 CFU/g. A similar trend is observed in the fourth quartile: burned plots exhibit greater variability (18.9×10^5 to 27.8×10^5 CFU/g) than control plots (17×10^5 to 22.5×10^5 CFU/g).

These findings indicate that microbial abundance in burned soils is more variable, reflecting the heterogeneous impact of fire depending on its type and intensity. Such variability underscores the complex influence of fire on soil microbial communities, which play a fundamental role in ecosystem processes in forest environments.

Changes in soil microbial communities resulting from both the direct and indirect effects of forest fires can lead to significant disruptions in ecosystem functions, particularly by slowing the transformation and cycling of nutrients (Mataix-Solera et al., 2009). The impact of fire on soil microbial communities is highly variable and depends on several factors, including fire intensity, duration, and depth of penetration into the soil (Yeager et al., 2005). In some cases, high-intensity fires can lead to near-complete sterilization of the soil, whereas in other instances, fires may have minimal long-term effects on microbial populations (Vázquez et al., 1993).

Zhou et al. (2014) emphasized that the loss of soil microbial life following a fire is not only due to elevated temperatures but also to post-fire conditions that inhibit microbial recovery. In a more recent study, Zhou et al. (2024) further noted that the strength of a fire's impact on microbial communities is influenced by multiple factors, including its intensity, duration, and the depth of soil affected.

The findings of the present study support the idea that, although there is an initial decline in microbial populations after fire, in some cases, microbial abundance may increase beyond control levels in the post-fire environment. This pattern was observed in plots FP1, FP2, FP4, and FP9 (Figure 1). The observed increase in microbial abundance is likely driven by elevated soil temperatures and the enhanced availability of nutrients released during the combustion of organic matter - conditions that can temporarily boost the biogenicity of soils in fire-affected areas (Bogdanov, 2023a; 2023b).

Correlation analysis between microbiological and soil properties

To better understand the relationships between microbial parameters and the physicochemical properties of fire-affected soils, a correlation analysis was conducted. The focus was on examining how total microbial number (TMN) and ammonifying bacteria relate to key soil indicators, including soil organic matter, total nitrogen, and pH. A strong positive correlation was found between the abundance of ammonifying bacteria and the total microbial number in both burned and control plots. However, this relationship was notably stronger in burned areas, where the correlation coefficient reached $r = 0.97$ (Figure 4), compared to $r = 0.87$ in control plots (Figure 5). These results suggest that ammonifying bacteria constitute a substantial proportion of the total microbial community, especially under post-fire conditions. This observation is consistent with previous research indicating that fire-altered environments can

accelerate nitrogen cycling by enhancing the conversion of ammonium to nitrate (Duran et al., 2008; Ball et al., 2010).

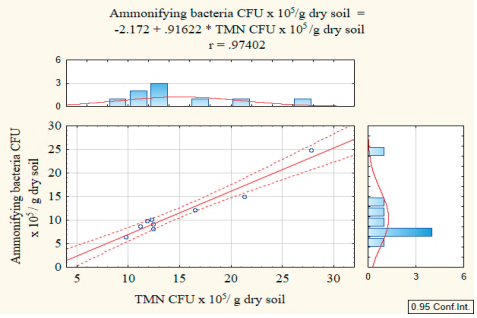

Figure 4. Correlation between TMN and number of ammonifying bacteria in Fire

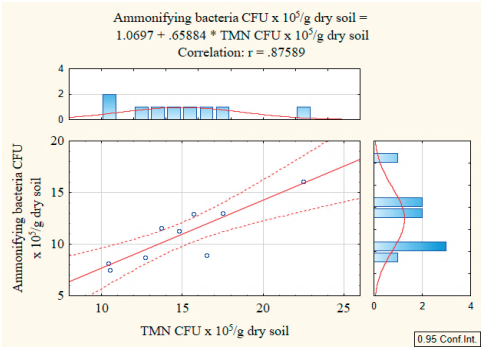

Figure 5. Correlation between TMN and number of ammonifying bacteria in Control Plots

Further analysis explored the relationship between microbial abundance and environmental factors. In unburned control plots, no statistically significant correlations were found between TMN and the soil's organic matter content (r = 0.05), total nitrogen (r = 0.26), or pH (r = –0.09). Similarly, no meaningful correlations were observed between ammonifying bacteria and these soil parameters in the control areas.

In contrast, several noteworthy correlations emerged in burned plots. A moderate positive correlation was identified between TMN and organic matter content (r = 0.48; Figure 6), suggesting that soils with higher residual organic content support a more robust microbial community even after fire. This indicates that partial retention of organic matter can buffer microbial populations against fire-induced decline.

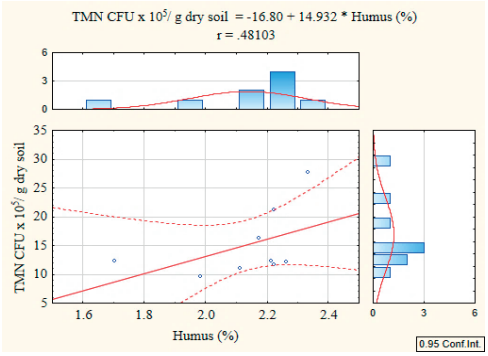

Figure 6. Correlation between total microbial number and humus (%) in fire plots

No significant correlation was found between total nitrogen content and total microbial number (TMN), with a correlation coefficient of r = 0.16, indicating a weak and statistically insignificant relationship. In contrast, the correlation between soil pH and TMN revealed a moderate negative association (r = –0.51, Figure 7), similar to the relationship observed between TMN and soil organic matter.

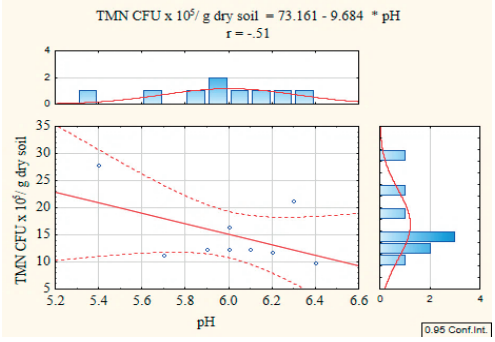

Figure 7. Correlation between total microbial number and pH in fire plots

This inverse correlation suggests that microbial abundance tends to be higher in more acidic soils. This pattern may be attributed to the high sensitivity of soil microbial communities to variations in pH following fire. Even slight deviations from pre-fire acidity levels, when compared to those in control plots, appear to have a positive influence on microbial activity. In such transitional conditions, reduced environmental stress may promote microbial adaptation and facilitate recovery.

These observations highlight the need for more nuanced, multifactorial investigations into the

complex interactions between post-fire soil chemistry and microbial dynamics. Notably, previous studies have identified soil pH as a key determinant in structuring the composition and diversity of microbial communities, especially in ecosystems subjected to disturbance events such as wildfires (Lauber et al., 2009).

The strongest correlation observed was between soil pH and the abundance of ammonifying bacteria, with a correlation coefficient of r = –0.63 (Figure 8).

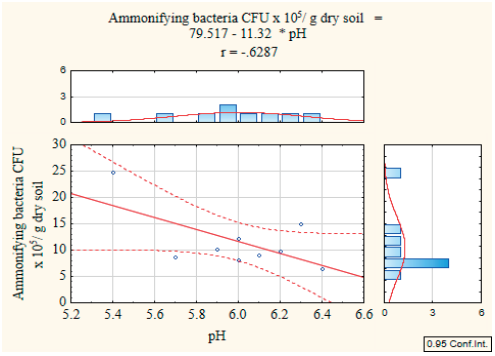

Figure 8. Correlation between number of ammonifying bacteria and pH in fire plots

This significant inverse relationship indicates that the activity of ammonifying bacteria is closely influenced by soil acidity. The findings suggest that microbial communities are particularly responsive to shifts in pH, with greater abundance occurring in soils where acidity levels remain closer to pre-fire conditions.

It is likely that in environments where pH changes are minimal, microbial stress is reduced, allowing for better survival and function of sensitive groups such as ammonifiers. However, to fully understand the thresholds and resilience of microbial communities under more extreme conditions, further research is required, particularly in sites that experience substantial post-fire shifts in soil pH.

Influence of stand density on soil properties after fire

Soil properties are strongly influenced by vegetation cover and the accumulation of organic matter, both of which are significantly altered by fire. The extent of these changes depends largely on the intensity of the fire and the volume of biomass consumed during combustion (Kimmins, 1996). As fire affects vegetation structure and organic inputs, it can lead to substantial modifications in soil chemical and biological characteristics.

In this context, it is particularly important to examine how stand density influences post-fire soil dynamics, as it determines both the amount and spatial distribution of combustible material. In the present study, soils beneath stands of differing densities - 0.2 and 0.5 - were analyzed. Both stands experienced fires of comparable type and intensity, allowing for a focused comparison of density-related effects. The changes in key soil properties, expressed as percentage differences relative to unburned control plots, are illustrated in Figure 9.

Although differences in total nitrogen content remained relatively minor three years after the fire, the stand with higher density exhibited notably higher pH values compared to the unburned control. This increase can be attributed to the combustion of a larger volume of organic matter and the subsequent release of base cations (e.g., Ca^{2+}, Mg^{2+}, K^{+}), which contribute to soil alkalization (Figure 9).

The soil organic matter content in the denser stand was significantly lower, reflecting a higher degree of fire impact due to the increased volume of biomass consumed. This trend was consistent with observed differences in both the C:N ratio and the abundance of total microflora. Following a fire, elevated soil temperatures and enhanced nutrient solubility can stimulate microbial growth in some cases; however, intense fires may lead to the near-complete destruction of microbial communities (Bogdanov, 2023a).

In line with this, the carbon-to-nitrogen (C:N) ratio - an indicator of the rate of organic matter decomposition - was significantly lower in the denser stand. This suggests more rapid mineralization of organic residues, likely driven by post-fire microbial activity and favorable thermal and chemical conditions resulting from a more severe fire impact (Figure 9).

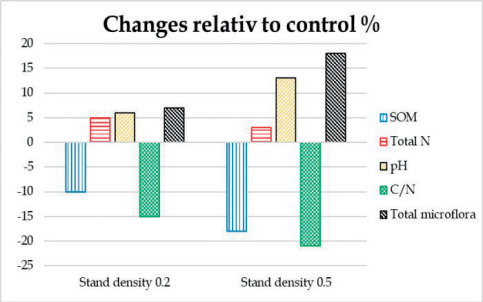

Figure 9. Change in the studied indicators in burned soils compared to control plots depending on the stand density

Influence of forest type on post-fire changes in soil silvicultural properties

To evaluate the influence of forest type on soil response to fire, soil samples were analyzed from both coniferous and deciduous stands affected by moderate-intensity surface fires in 2021, along with samples from their corresponding unburned control plots. The aim was to determine how forest composition affects post-fire changes in silvicultural soil properties. The results indicate that fire-induced changes were more substantial and persistent in soils under coniferous stands. This finding is consistent with previous studies and can be attributed to the higher combustibility of coniferous litter, which results in more intense and longer-lasting fires compared to those in deciduous forests (Bogdanov, 2023b; Velizarova, 2011). The most significant difference was observed in total nitrogen content, where the largest reduction, relative to the control, occurred in the coniferous stand (Figure 10).

Similar trends were observed for organic soil matter, pH, and the C:N ratio. In all cases, greater deviations from the control were recorded under coniferous stands, indicating more intense alteration of soil chemistry. These changes reflect both the severity of the fire and the nature of the organic material present in coniferous ecosystems, which tends to burn more thoroughly and penetrate deeper into the soil profile. In contrast, the total microbial abundance showed an inverse pattern, though within a narrow margin of 5%. In the deciduous stand, microbial numbers slightly increased post-fire, while in the coniferous stand, they slightly decreased. This discrepancy may be explained by the deeper thermal impact under conifers, which likely caused a greater initial decline in microbial populations. In deciduous forests, the fire's effects appear to have been more superficial, allowing microbial communities to recover more quickly or even benefit from short-term post-fire conditions.

These findings underscore the importance of forest composition as a key factor influencing soil resilience and recovery after fire. From a silvicultural perspective, deciduous stands may offer a degree of natural protection against severe soil degradation, supporting more stable post-fire ecosystem recovery.

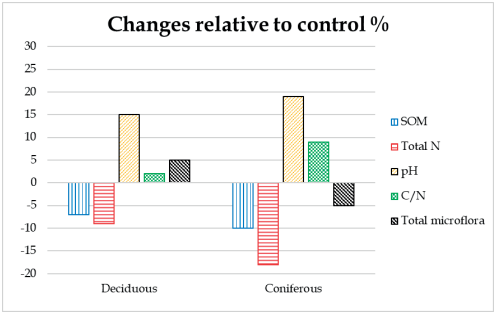

Figure 10. Changes in the studied soil indicators in burned plots compared to control plots, grouped by forest type

Effects of fire type on silvicultural properties of soil

The spatial characteristics of a forest fire - whether it is a surface fire or a crown fire - significantly influence the degree and depth of soil disturbance. These fire types differ in terms of fuel consumption patterns, heat transfer to the soil, and post-fire ecological consequences. In this study, changes in soil properties were analyzed in two forest stands with similar silvicultural characteristics that experienced medium-intensity crown and surface fires in 2022 (SP6 and SP7, respectively), along with their corresponding control plots.

The comparative analysis revealed notable differences in the response of silvicultural soil indicators based on fire type (Figure 11). More pronounced changes were observed in the surface fire-affected plot, particularly in terms of total microflora abundance, total nitrogen content, and the C:N ratio. In this case, microbial populations and nitrogen content decreased more significantly, likely due to more intense

heat transfer into the upper soil layers and increased combustion of surface organic matter. The C:N ratio increased in soils affected by crown fires, while it decreased in those affected by surface fires. This suggests that in the case of crown fires, the decomposition of organic matter slowed down, a finding further supported by the observed reduction in total nitrogen content. In contrast, the soil affected by the surface fire exhibited an accelerated rate of organic matter mineralization, as indicated by the lower C:N ratio - even though total nitrogen levels also declined (Figure 11). These opposing trends reflect the distinct thermal and biological impacts associated with each fire type.

This contrasting pattern can be explained by the differing ecological consequences of the two fire types. Moderate-intensity surface fires typically result in mosaic tree mortality, allowing partial canopy retention and less drastic alteration of microclimatic conditions. In contrast, moderate-intensity crown fires often lead to complete stand mortality, causing more abrupt and extensive changes in light, temperature, and moisture regimes. These environmental shifts have a significant influence on the intensity and direction of organic matter transformation in the soil. These findings suggest that the type of forest fire, determined by the spatial distribution of combustible materials, exerts an indirect yet significant impact on the silvicultural properties of soil - primarily through its influence on the rate and dynamics of organic matter decomposition.

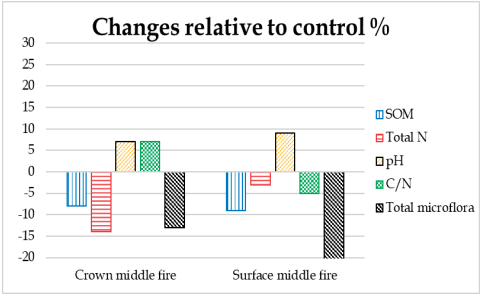

Figure 11. Change of the studied indicators in burnt soils compared to control plots depending on the type of fire

Effects of fire intensity on silvicultural soil properties

The intensity or strength of a forest fire plays a crucial role in determining the extent of its impact on soil properties. To examine this effect, soil samples were analyzed from areas affected by a weak surface fire and a strong surface fire, both occurring in 2022, along with their respective unburned control plots. The results, presented as percentage changes relative to the controls, are summarized in Figure 12.

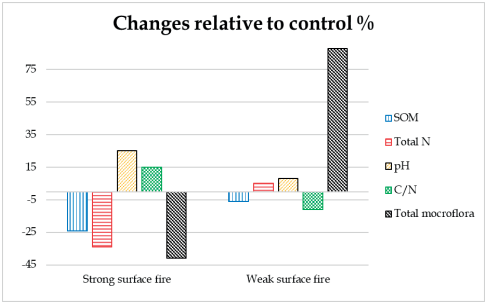

Figure 12. Change of the studied indicators in burnt soils compared to control plots depending on the strength of the fire impact

The analysis revealed that all soil indicators were influenced by fire strength, with the most pronounced changes observed in the strongly burned plots. In areas affected by weak surface fires, the combustion of organic matter was relatively limited, resulting in a slight increase in total nitrogen and minimal changes in pH. In this case, a moderate rise in soil temperature likely stimulated microbial activity, which led to a decrease in the C:N ratio, indicating enhanced decomposition and mineralization of organic material.

Conversely, strong surface fires caused more substantial degradation of silvicultural soil properties. A significant reduction in soil organic matter was observed, accompanied by a decline in total nitrogen content. The more intense combustion released higher quantities of base cations, resulting in elevated soil pH, while simultaneously creating conditions less favorable for microbial recovery. This was reflected in the lower abundance of soil microflora and a higher C:N ratio, suggesting that microbial processes related to organic matter turnover were suppressed.

These findings underscore the fact that fire severity amplifies the disruption of soil fertility, not only by physically consuming organic substrates, but also by altering the chemical and biological environment essential for post-fire

recovery. Understanding these variations is critical for predicting the resilience of forest soils and planning appropriate post-fire management strategies.

Temporal changes in silvicultural soil properties following forest fire

Changes in the silvicultural properties of soil following forest fires were examined as a function of time since the disturbance, based on the analysis of soil samples collected from areas affected by fires of similar characteristics in 2020 and 2022.

The results indicate that all studied soil indicators exhibited more pronounced deviations from control values in the more recently burned plots (2022), while the soils affected by the 2020 fire showed changes of reduced magnitude (Figure 13). This trend suggests a gradual recovery of silvicultural soil properties over time.

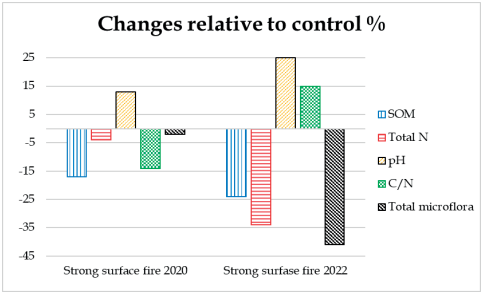

Figure 13. Change of the studied indicators in burnt soils compared to control plots depending on the time after the fire impact

These findings demonstrate that the impact of forest fires on soil silvicultural properties is not necessarily permanent, and that recovery processes can begin within a few years, depending on fire severity and site conditions. However, the rate and completeness of recovery are strongly influenced by factors such as vegetation type, post-fire management, and climatic conditions. This underscores the importance of timing in the implementation of restoration measures, which should consider the post-fire developmental stage of the soil ecosystem to align with periods of optimal nutrient availability and biological activity.

CONCLUSIONS

Forest fires have a pronounced negative impact on the silvicultural properties of soils, primarily through the reduction of soil organic matter and, in most cases, total nitrogen content. Additionally, fires often alter soil pH, creating conditions that may be incompatible with the ecological requirements of dominant tree species.

The response of soil microflora is strongly influenced by fire intensity. While low-intensity fires can stimulate microbial development by increasing soil temperature and releasing readily available nutrients from burned organic matter, high-intensity fires may lead to near-complete microbial destruction and hinder community recovery. In several sampled sites - particularly those affected by weak surface fires - microbial abundance exceeded that of the unburned controls, highlighting the potential for short-term biological enrichment under mild fire conditions. Furthermore, correlations between environmental factors and microbial abundance were observed in burned areas, whereas such relationships were absent in control soils. Notably, microbial suppression was more severe in coniferous stands than in deciduous stands under equivalent fire conditions, likely due to the higher combustibility of coniferous biomass. Stand density was also found to be a critical factor. Higher density forests tend to accumulate more biomass, which, when burned, leads to more severe and longer-lasting impacts on soil properties. Similarly, fires in coniferous forests resulted in more significant and persistent changes than those in deciduous stands, again linked to differences in fuel load and combustibility.

The type of fire - whether surface or crown - was shown to influence soil conditions indirectly, primarily through its effects on the rate and nature of organic matter transformation. In contrast, fire intensity and the time elapsed since the fire had a direct and measurable effect on all assessed soil indicators. These results demonstrate that the changes induced by forest fires are not irreversible; recovery is possible under favorable conditions, especially if supported by appropriate post-fire management.

Restoration efforts in burned areas should be tailored to specific changes in soil composition and fertility, considering the time since the fire and the temporary increase in nutrient availability. Special attention should be given to coniferous plantations in the Lower Forest Vegetation Belt, which are particularly vulnerable to fire. In these areas, afforestation using native deciduous species, along with timely silvicultural interventions, is essential for reducing long-term fire risk and promoting ecological stability.

This study provides a valuable reference for future in-depth investigations on the topic and offers a practical foundation for developing forest restoration and afforestation strategies in fire-affected regions.

Abstract

The attitudes of students toward the European Green Deal were assessed through a survey involving master's and doctoral students from four European universities: Universitat Autònoma de Barcelona (Spain), University of Porto (Portugal), University of Agronomic Science and Veterinary Medicine of Bucharest (Romania), and Uzhhorod University (Ukraine). Results revealed strong overall support among students for actions promoting environmental sustainability and reducing carbon footprints. Significant variations were observed across countries, with students from Spain, Portugal, and Romania demonstrating particularly high agreement regarding the importance of balancing economic growth with environmental protection. While respondents generally recognized the long-term benefits of the Green Deal, concerns regarding implementation costs were notably higher among students from Romania and Ukraine. Additionally, a vast majority expressed interest in tools to monitor personal carbon footprints, highlighting growing awareness of individual environmental responsibilities. These findings suggest a positive attitude among European university students toward environmental sustainability initiatives, though addressing concerns about economic implications could enhance broader support.

Key words*: European Green Deal, environmental sustainability, students attitude, higher education, comparative study.*

INTRODUCTION

Anthropogenic climate change is an undeniable reality that requires immediate and coordinated action. In response, the European Union has established ambitious targets to reduce carbon emissions by 55% by 2030 compared to 1990 levels (European Commission, 2019; 2021). Achieving these goals demands broad societal engagement, including the active participation of educational institutions. To support this transition and improve understanding of climate-related challenges, universities across the EU are revising and adapting their curricula. This educational shift aims to equip students with the knowledge and skills essential for effectively addressing environmental concerns.

A growing body of research suggests that higher education plays a significant role in shaping environmental attitudes and policy preferences. For example, survey studies by Harring & Jaegers (2017) demonstrated that university education influences students' support for environmental policies. Their findings highlighted that economics students were more inclined to support market-based environmental policies, illustrating the impact of academic discipline on environmental perspectives. Subsequent studies have expanded on these insights by exploring the roles of education, socioeconomic background, and cultural context. Mónus (2022) examined the effects of environmental education policies and ocioeconomic factors on secondary school

students' attitudes and behaviors. The study concluded that schools with robust environmental education programs more effectively foster pro-environmental behaviors. Similarly, Concina & Frate (2023) analyzed university students' beliefs and attitudes toward sustainability in various countries. Their results showed that while students were generally aware of sustainability issues, this awareness did not always translate into environmentally responsible behaviors.

In alignment with these trends, the present study was designed to assess the attitudes of master's and doctoral students toward the European Green Deal. The research was conducted among students from universities in Spain, Portugal, Romania, and Ukraine - the latter currently a candidate for EU membership. By evaluating students' perceptions and perspectives on this major policy initiative, the study aims to provide valuable insights into how higher education contributes to shaping future leaders' environmental commitments.

MATERIALS AND METHODS

This study assessed the attitudes of master's and doctoral students toward the European Green Deal through a survey-based approach, building on previous research frameworks (Radu et al., 2019; Radu et al., 2020). The participants were selected from four European universities: Universitat Autònoma de Barcelona (Spain), University of Porto (Portugal), University of Agronomic Sciences and Veterinary Medicine of Bucharest (Romania), and Uzhhorod National University (Ukraine).

Participant selection

The target population consisted of students enrolled in engineering sciences at the master's and doctoral levels. This group was selected for several reasons:

1. *Advanced knowledge:* graduate students possess a deeper understanding of complex topics such as environmental policy, sustainability, and European legislative initiatives, allowing them to critically assess the implications of the European Green Deal.

2. *Relevant training:* due to their academic backgrounds and involvement in research related to environmental issues and public policy, these students are capable of providing more informed and nuanced responses.

3. *Future policy influence:* as potential future decision-makers, graduate students often engage more readily in academic research and are motivated by the opportunity to contribute to scientific understanding and policy development.

Participants were recruited via email invitations, and responses were collected anonymously through an online questionnaire. All participants were informed of the study's objectives prior to participation, and their involvement was entirely voluntary. No personally identifiable information - such as names, contact details, or addresses - was collected, ensuring full anonymity and compliance with ethical research standards.

Survey design

The survey consisted of six closed-ended questions designed to evaluate students' attitudes toward the principles and implementation of the European Green Deal. These questions addressed the following core dimensions:

1. *Individual responsibility*: "I believe that my actions can contribute to solving environmental problems."
2. *Willingness to act:* "I am willing to reduce my personal carbon footprint to support the European Green Deal."
3. *Sustainability and growth:* "Economic growth should not occur at the expense of the environment."
4. *Perceived value:* "The cost of implementing the European Green Deal is justified by its long-term benefits."
5. *Self-assessment tools:* "It is appropriate for students to calculate their carbon footprint through their regular daily activities."
6. *Engagement through tools:* "Do you consider that you would pay more attention to your carbon footprint if you had an appropriate tool to quantify it?"

Responses were rated using a 5-point Likert scale, where: 1 = Not Important, 2 = Low Importance, 3 = Medium Importance, 4 = High Importance, and 5 = Very High Importance.

Data collection and analysis

By September 2024, a total of 40 valid responses had been received. The geographic distribution of participants was as follows: 28% from Ukraine, 28% from Romania, 26% from Portugal, and

18% from Spain. Although the sample size is modest, the random selection of participants from each institution helped minimize selection bias and offered a degree of representativeness within the target population.
Given the exploratory nature of the study and the limited sample size, data analysis was primarily descriptive. No inferential statistical tests were applied. The goal was to identify prevailing trends and general patterns in student perceptions of and attitudes toward the European Green Deal and related environmental policies.

RESULTS AND DISCUSSIONS

Regarding the first statement, "I believe that my actions can contribute to solving environmental problems", fewer than 30% of respondents from each university strongly agreed (Figure 1a). Specifically, 29% of respondents from Spain, 27% from Romania, and only 10% each from Portugal and Ukraine expressed strong agreement. However, a higher proportion of respondents expressed high agreement: 70% from Portugal, 50% from Ukraine, 43% from Spain, and 19% from Romania (Figure 1a). Overall, 66% of respondents either highly agreed (44%) or strongly agreed (22%) with this statement, while only 13% considered it of low importance or not important (Figure 1b).

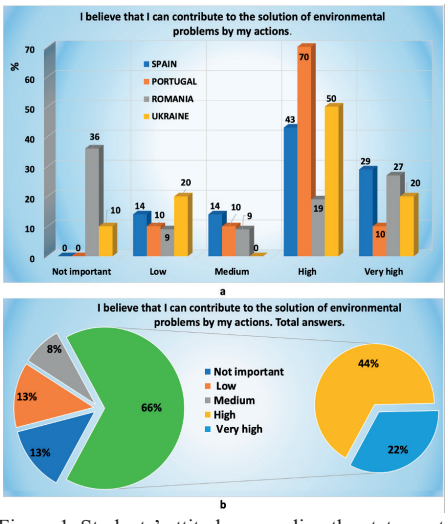

Figure 1. Students' attitudes regarding the statement: *"I believe that I can contribute to solving environmental problems through my actions."*
a) Distribution of responses by country; b) Overall distribution of responses across all participants

In response to the statement, "I am willing to reduce my personal carbon footprint to support the European Green Deal", a high level of strong agreement was observed among students: 60% from Portugal, 64% from Romania, and 57% from Spain (Figure 2a).
In Ukraine, strong agreement was slightly lower at 30%, but a significant proportion expressed high agreement (60%). Overall, 92% of respondents strongly agreed (53%) or highly agreed (39%) with the statement, while only 2% rated it as medium importance, and 3% considered it unimportant (Figure 2b).

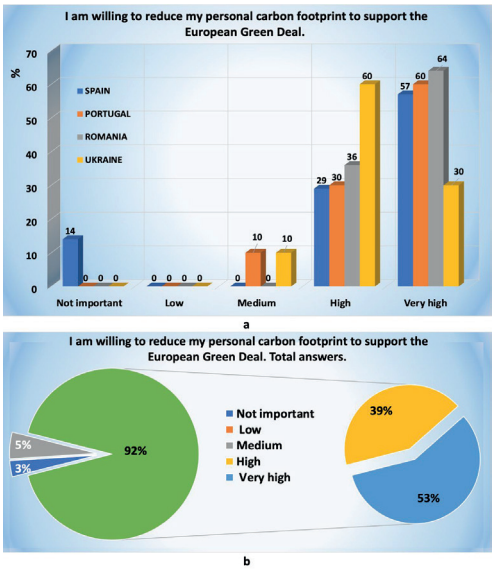

Figure 2. Students' attitudes regarding the statement: *"I am willing to reduce my personal carbon footprint to support the European Green Deal."*
a) Responses categorized by country; b) Overall distribution of responses across all participants

Concerning the statement, "Economic growth should not occur at the expense of the environment," students showed substantial consensus, with 100% from Spain, 82% from Romania, 80% from Portugal, and 60% from Ukraine strongly agreeing (Figure 3a).
Less than 30% from each university expressed high agreement. Overall, 97% of respondents either strongly agreed (79%) or highly agreed (18%), and only 3% viewed this as of low importance (Figure 3b).

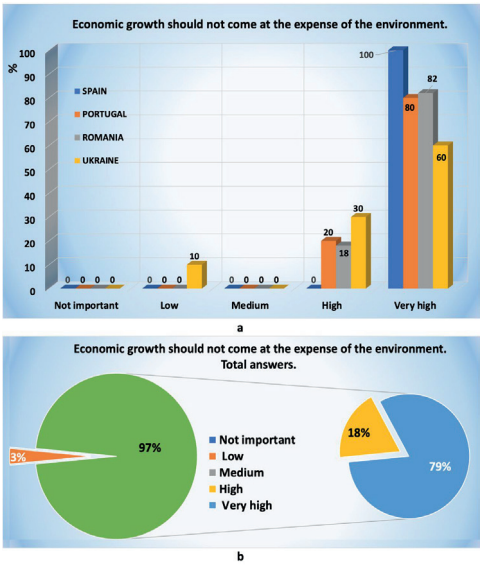

Figure 3. Students' attitudes regarding the statement: *"Economic growth should not come at the expense of the environment."* a) Responses categorized by country; b) Overall distribution of responses across all participants

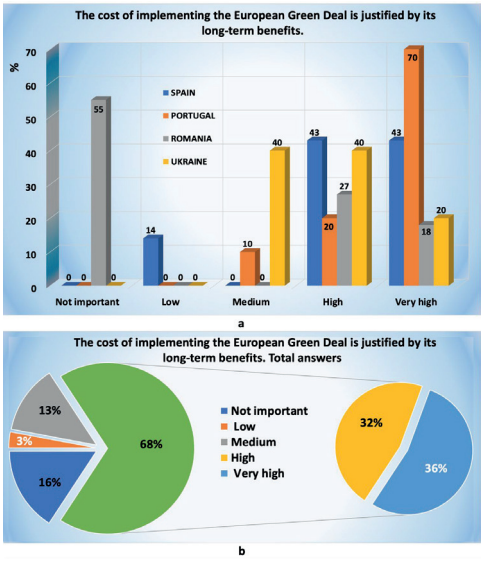

Figure 4. Students' attitudes regarding the statement: *"The cost of implementing the European Green Deal is justified by its long-term benefits."* a) Responses categorized by country; b) Overall distribution of responses across all participants

When evaluating the statement, "The cost of implementing the European Green Deal is justified by its long-term benefits", 70% of respondents from Portugal strongly agreed, followed by 43% from Spain, 20% from Ukraine, and 18% from Romania (Figure 4a). High agreement ranged from 20% to 43% across universities.

Overall, 68% of respondents either strongly agreed (36%) or highly agreed (32%), while 16% considered this statement of no importance, 13% as medium importance, and 3% as low importance (Figure 4b).

Regarding the appropriateness of calculating personal carbon footprints in daily activities, strong agreement was high in Romania (82%) and Spain (57%), while lower in Portugal and Ukraine (20% each) (Figure 5a). High agreement was substantial, especially in Portugal (70%). Overall, 77% of respondents either strongly agreed (45%) or highly agreed (32%), while 13% considered it of medium importance and 10% as low importance (Figure 5b).

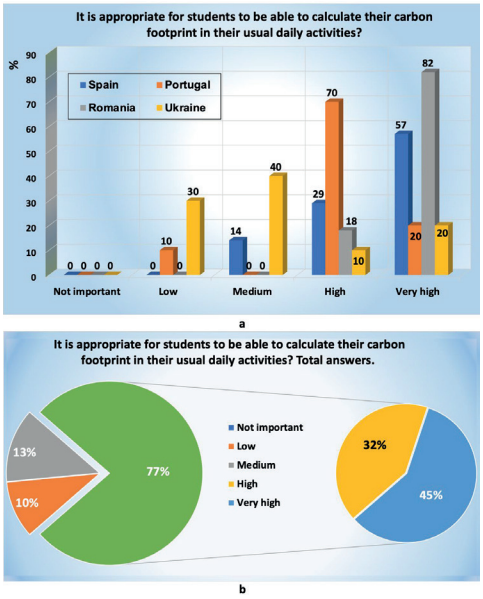

Figure 5. Students' attitudes regarding the statement: *"It is appropriate for students to calculate their carbon footprint in their regular daily activities."* a) Responses categorized by country; b) Overall distribution of responses across all participants

In response to the question about whether using an appropriate tool to quantify carbon footprints would increase personal awareness, 91% of students from Romania, 71% from Spain, 50% from Portugal, and only 10% from Ukraine expressed strong agreement (Figure 6a). High

agreement varied, with notable percentages from Ukraine (50%) and Portugal (40%).
Overall, 87% of respondents strongly agreed (55%) or highly agreed (32%) with this statement, with only 5% rating it as medium importance and 8% as low importance (Figure 6b).

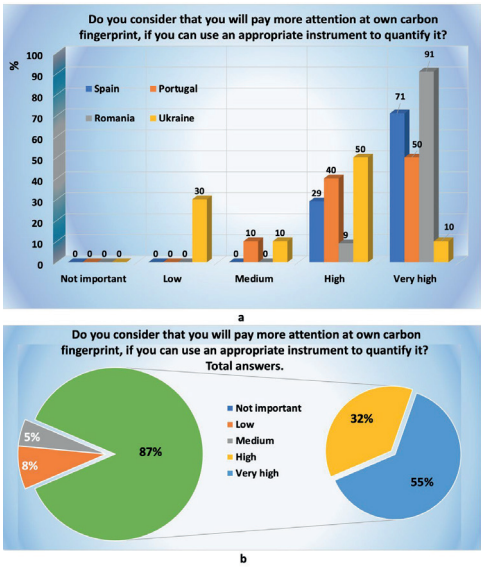

Figure 6. Students' attitudes regarding the statement: *"Do you consider that you will pay more attention to your own carbon footprint if you had an appropriate tool to quantify it?"* a) Responses categorized by country; b) Overall distribution of responses across all participants

Respondents from these European universities generally showed strong support for environmental sustainability, expressing high levels of agreement on the importance of reducing personal carbon footprints, supporting the European Green Deal, and prioritizing environmental protection over economic growth.
While the level of support varies among the different countries, there is a consistent preference for environmentally conscious actions and initiatives. Students expressed significant interest in tools designed to track their carbon footprints, reflecting a growing awareness of their individual environmental impacts. The majority of respondents from the four European universities believe that individual actions can effectively contribute to solving environmental problems. Nevertheless, the strength of agreement varies by country, with students from Portugal and Ukraine more frequently expressing strong agreement compared to those from Spain and Romania. Overall, a substantial proportion of respondents (66%) strongly agree about the importance of individual actions in addressing environmental issues. Additionally, students from all universities indicated high agreement with reducing their personal carbon footprints in support of the European Green Deal, with the highest levels observed in Romania (64%) and Portugal (60%), followed by Spain (57%) and Ukraine (30%). Collectively, 92% of respondents support the Green Deal, demonstrating strong endorsement for this environmental initiative among European students.
The statement "Economic growth should not come at the expense of the environment" received nearly unanimous support, with the highest levels of strong agreement in Spain (100%) and Romania (82%). This suggests that European students strongly prioritize environmental sustainability over economic growth, with 97% of respondents overall agreeing that economic growth should not harm the environment.
Respondents expressed mixed feelings about the cost of implementing the European Green Deal about its long-term benefits. Students from Portugal are the most supportive (70%), while Ukraine and Romania show lower levels of agreement (20% and 18%, respectively). However, a majority (68%) agree that the Green Deal's long-term benefits justify its costs, though a notable portion still considers these costs a problem.
A significant number of respondents believe it is important for students to calculate their carbon footprint. Romania shows the highest agreement (82%), followed by Spain (57%). While a lower percentage of respondents from Portugal and Ukraine agree with this idea, overall, 77% of respondents express the importance of tracking personal carbon footprints, signalling an awareness of individual environmental impact.
There is strong support among students for using tools to calculate and track their carbon footprints. Romania leads again with 91% of respondents very highly agreeing, while Spain (71%) and Portugal (50%) show notable support as well.

Ukraine lags with only 10% agreeing strongly. Nevertheless, 87% of all respondents believe that having the right tools would encourage them to be more conscious of their carbon footprint. The data obtained in this study are in agreement with those reported by other scientific publication.

Economic growth should not come at the expense of the environment," received nearly unanimous support among respondents, with the highest levels of strong agreement observed in Spain (100%) and Romania (82%). This indicates that European students strongly prioritize environmental sustainability over purely economic growth, as 97% of all respondents agreed that economic development should not compromise environmental health.

Respondents expressed mixed opinions regarding whether the long-term benefits of the European Green Deal justify its implementation costs. Students from Portugal showed the strongest agreement (70%), whereas agreement levels were lower among students from Ukraine (20%) and Romania (18%). Nevertheless, the majority (68%) concurred that the Green Deal's long-term advantages justify the associated costs, although a notable proportion remained concerned about the financial implications.

A considerable number of respondents acknowledged the importance of enabling students to calculate their personal carbon footprints. The highest level of strong agreement was recorded in Romania (82%), followed by Spain (57%). Although agreement was lower among respondents from Portugal and Ukraine, overall, 77% recognized the significance of monitoring personal carbon footprints, reflecting increased awareness of individual environmental impacts.

Furthermore, respondents widely supported the use of tools designed to calculate and track carbon footprints. Romanian students again expressed the highest level of strong agreement (91%), followed by students from Spain (71%) and Portugal (50%). Ukrainian students showed less enthusiasm, with only 10% strongly agreeing. Overall, however, 87% of respondents indicated that having appropriate tools available would encourage greater awareness and management of their personal carbon footprints. These findings align well with previous studies reported in the scientific literature.

A survey study conducted by Cernicova-Buca et al. (2023) among Romanian students revealed a high level of interest and readiness to engage in basic sustainable behaviors concerning environmental issues. Similarly, Khanam et al. (2022), in a survey-based analysis conducted across four European countries, found that nations in Central and South-Eastern Europe recorded the highest willingness to reduce their carbon footprints, indicating strong regional support for climate change mitigation.

Bassi (2023) also confirmed that attitudes toward the environment significantly influence ecological behavior, based on research into European consumers' perspectives on climate change.

Predictive studies by Smith et al. (2013), Mielcarek-Bocheńska et al. (2021), and Panchasara et al. (2021) have shown that greenhouse gas emissions are largely produced through agricultural waste and sector-specific processes. Research by Li et al. (2025) emphasized that integrating both nature-based and technological solutions is crucial for sustainable agricultural development. Such integration is essential not only for mitigating climate change but also for ensuring long-term global food security.

CONCLUSIONS

This study reveals that European university students exhibit strong support for the European Green Deal and show high levels of environmental awareness and willingness to adopt sustainable behaviors. The findings highlight that while support for reducing personal carbon footprints is consistently strong across all countries, notable differences emerge regarding economic concerns. Students from Portugal and Romania demonstrate the highest levels of agreement with sustainability goals, whereas respondents from Ukraine show comparatively more apprehension, particularly regarding the financial costs associated with implementing the Green Deal. The results suggest that educational initiatives and policy communication strategies should be tailored to address these national differences. For policymakers, the findings underline the importance of transparent and context-sensitive communication about the costs and long-term

benefits of environmental policies. For educators, integrating practical tools for calculating carbon footprints into university curricula could foster greater personal responsibility and engagement in climate action among students. However, the study is not without limitations. The sample size is relatively small and limited to master's and doctoral students from only four universities, which may not fully represent the broader student population across Europe. Additionally, the survey's reliance on self-reported attitudes introduces the possibility of social desirability bias. Future research should consider expanding the study to include undergraduate students and a more diverse range of universities across different EU regions. Longitudinal studies could also explore how student attitudes evolve over time, particularly in response to policy changes or increased climate-related education. This expanded scope would provide deeper insights into the effectiveness of the European Green Deal's outreach and implementation strategies at the academic level.

ACKNOWLEDGEMENTS

This research was conducted with the support of the project 2023-1-RO01-KA220-HED-000154433, entitled *"Gender, Digitization, Green: Ensuring a Sustainable Future for All in Europe"*, co-funded by the European Union.

Abstract

The winter season, characterized by unfavorable conditions for aquatic biota, determined by low temperatures, instigates a series of ecological shifts that intricately shape the phytoplankton and zooplankton communities' structure and function. Our study in Văcărești Lake focuses on the effect of the winter season on plankton communities, highlighting structural and functional changes in these communities. During the winter, environmental parameters significantly changed indicating organic matter decomposition and eutrophic conditions. The winter conditions functioned as ecological stressors on plankton communities. Phytoplankton responded by changing composition, with green algae and diatoms becoming prominent as cyanobacteria declined. Zooplankton, especially Rotifera and Cladocera, showed increased diversity and abundance, while Ciliata and Copepoda decreased. The RDA analysis highlighted phytoplankton's responsiveness to TDS, conductivity, turbidity, pH, and zooplankton's correlation with oxygen and temperature. The Diversity t-test indicated significant changes in both phytoplankton and zooplankton communities in terms of diversity. Zooplankton diversity was higher than phytoplankton, with moderate species composition changes, reflecting cold-tolerant species development and the ecosystem's resilience and adaptability to winter conditions.

Key words: *abundance, cold-season changes, phytoplankton, zooplankton structure, Văcărești Natural Park.*

INTRODUCTION

Winter poses numerous challenges to the biotic components of aquatic ecosystems, particularly the so structurally diverse communities of the zooplankton. The cold season starting with November heralds a multitude of physicochemical transformations determined by temperature and light that shape the dynamics of these vital processes (Molles, 2016). Water temperature undergoes a significant drop, significantly impacting the metabolic activities of plankton. In tandem with temperature, light emerges as another critical factor, its diminishing intensity intricately linked to the seasonal changes in aquatic ecosystems. The reduced light availability during winter precipitates a decline in phytoplankton production, the primary food source for many zooplankton species. The interaction between temperature and light dynamics makes the biotic response of phytoplankton and zooplankton to winter conditions crucial. This scarcity of food resources can influence the composition and abundance of zooplankton communities, as some species may exhibit adaptations to low food availability. In contrast, others may struggle to find sufficient food. Furthermore, changes in winter conditions in temperate zones have significantly impacted the ice and snow regime. During winter, chlorophyll-a content can reach an average of only 43% of its summer level (Negrete-Garcia et al., 2024). Grazing by zooplankton is responsible for phytoplankton losses and changes in community composition. Due to ongoing climate change, warmer winters may also influence the development of overwintering phytoplankton (Hrycik & Stockwell, 2021). Fott et al., 2020 consider that light regime and water temperature significantly positively influence chlorophyll-a concentrations in the cold season. Instead, zooplankton tend to slow down, influencing their growth rates, feeding behaviors, and overall life cycles. Within the diverse structure of zooplankton, many species show pronounced sensitivity to temperature fluctuations, prompting the evolution of adaptive strategies for survival during winter. These strategies manifest through various forms of resistance, allowing certain zooplankton species to endure harsh conditions. According to Litchman et al., 2013,

zooplankton exhibits a high diversity of traits and ecological strategies that impact other trophic levels and the cycles of matter and energy.

Understanding these seasonal shifts provides invaluable insights into the adaptive mechanisms, resilience, and ecological aspects of phytoplankton and zooplankton communities, underscoring the significance of comprehending their responses to the challenges posed by the cold season (Wollschläger et al., 2021; Bramm et al., 2009; Davis & Baird, 2022).

In the seasonal dynamics, the winter period is not only an inactive period of rest but also defines the plankton dynamics of the following year. In temperate eutrophic lakes, there are usually two or more peaks of zooplankton activity during the warm season, typically following the spring and summer/autumn phytoplankton blooms.

Warming climate conditions have led to biodiversity loss, the proliferation of opportunistic and resistant species, and the emergence of invasive species, negatively impacting ecosystems. Ecosystems in temperate zones are particularly affected due to complex seasonal regulation processes and a diminished capacity for resilience (Lenard et al., 2019). However, mild winter temperatures and nutrient availability influence phytoplankton development, demonstrating their temperature sensitivity, which can increase productivity. In urban areas, lakes are exposed to heightened nutrient loading and temperatures, leading to severe phytoplankton blooms. Understanding the role of urbanization and its interaction with climate change in producing these blooms is crucial to preventing negative effects on urban water sources (Li et al., 2023). Consequently, zooplankton peak numbers may vary seasonally and annually, reflecting fluctuations in environmental conditions and food web interactions (Sutton et al., 2021; Jensen, 2019). Our study aimed to identify changes in the structural composition of phyto- and zooplankton, highlighting key species such as *Moina* spp. and *Daphnia* spp., and their potential cascading effects on the overall aquatic food webs. It is known that the winter period directly influences the structure and diversity at the plankton level. Due to the low temperatures, the phytoplankton undergoes significant changes in species composition and density. The changes at this level together with other environmental factors, define the traits of the zooplankton consumers. Our study hypothesizes that winter is a period of decline in plankton communities, characterized by a poor representation of species, even in urban areas, where temperatures are slightly higher as a result of heat islands. We assume that in November, when the cold season starts, we will encounter a higher diversity, with species that have accumulated during the year, while in February both the density and richness of species are much more reduced. This was a pilot study testing the structural changes of the phyto- and zooplankton evaluated at the end of the growing season, late autumn, followed by an evaluation during the cold period of winter and the beginning of the next growing season.

In this aim, we proposed the following (1) to identify the changes in the water physicochemical parameters throughout the cold period, (2) to describe the structure and diversity of phytoplankton and zooplankton communities, (3) to establish the relationships between phyto- and zooplankton and environmental variables and (4) to identify which factors defined the structure of these communities.

MATERIALS AND METHODS

Sample Collection and Laboratory Analyses

The Văcărești Natural Park has its origins in an unfinished hydrological project, initially conceived as a component of the development of the Dâmbovița River. Before 1989, Ceaușescu planned to turn the area into a recreational place with a lake and sports facilities. The project failed, due to the risk of flooding and the lake basin remained unused thus the area became known as "Văcărești Wetlands". Over the previous 20 years, the abandoned area has been transformed into a unique lacustrine ecosystem that appeared in the former Văcărești Pit. The area has become a habitat for various species of birds, reptiles, and mammals. The place attracted the attention of NGOs and the Ministry of the Environment so, in 2016, "Văcărești Wetlands " was declared a Natural Park. The Văcărești Natural Park became Romania's first urban natural park and the only protected area in Bucharest. This initiative has been supported and recognized by international environmental organizations, considering the project as an outstanding

example of cohabitation between urban and wild nature (Atanasiu et al., 2017; Manea et al., 2013). Văcărești Natural Park (Figure 1) has an area of approximately 200 hectares and is located at an altitude of 60-80 meters (Merciu et al., 2017).

Figure 1. The Văcărești Park map with the sampling points (Google Earth app, 2022)

The park is fed primarily by springs from the Dâmbovița River, which support its aquatic ecosystem. This includes lakes, marshes, extensive reed beds, and areas with rich vegetation such as meadows, willows, and various aquatic plants (Danta, 1993).

Bucharest's climate is characterized by hot summers, cold winters, moderate precipitation, and occasional cold snaps. Văcărești experiences typical urban climate effects, including the urban heat island phenomenon. Under these conditions, the wetlands play a crucial role in moderating temperatures, maintaining local humidity, and creating a more favorable microclimate, despite variability caused by urbanization and seasonal changes. These meteorological factors can influence species distribution within the wetland and affect water quality (Legutko-Kobus et al., 2023).

The park is surrounded by residential areas, commercial zones, and busy roads. However, due to the remnants of old communist-era constructions, the wetland remains relatively isolated. Despite its proximity to urban development, Văcărești has become a wildlife sanctuary, supporting over 100 bird species as well as various mammals and reptiles (Manea et al., 2016).

The area is exposed to urban runoff, including contaminants from roads and waste from surrounding areas, which poses a challenge to the park's water quality, noise, and light pollution.

The sampling took place in November 2021 and February 2022 in six stations to cover a representative proportion of the lake in the evaluation of zooplankton communities (Table 1).

Table 1. The GPS coordinates of the sampling points

Sampling points	Latitude	Longitude
S1	44°24'7.82"N	26° 8'18.26"E
S2	44°24'4.19"N	26° 8'20.58"E
S3	44°24'6.48"N	26° 8'13.76"E
S4	44°24'9.99"N	26° 8'13.09"E
S5	44°24'8.38"N	26° 8'11.19"E
S6	4°24'6.58"N	26° 8'9.71"E

Environmental data

The measurements of the water physicochemical factors were done using a Hanna Instruments HI 9829 multiparameter. The device is equipped with sensors for temperature - °C, pH, ORP (Oxidation-reduction potential) - mV, % DO (Dissolved Oxygen Saturation); DO (Dissolved Oxygen) - mg/L; Conductivity - µS/cm; TDS (Total Dissolved Solids) - mg/L, Salinity, and turbidity - NTU. In addition, the Secchi disc was used for Depth and Transparency (m) assessment.

Phytoplankton sampling

The phytoplankton sampling was done on the water column using a Schindler-Patalas device (4 L) and mixed into a 10 L bucket. In 500 mL plastic bottles samples were fixed with formaldehyde (4%) and stored for a period of sedimentation. The taxonomical identification was done using a Zeiss inverted microscope for *Cyanobacteria* (Komárek & Anagnostidis, 1998; Komárek & Anagnostidis, 2005*), Chlorophyceae* (Ettl & Gärtner, 1983; Ettl & Gärtner, 1988), *Bacillariophyceae* (Krammer & Lange-Bertalot, 1986; Krammer & Lange-Bertalot, 1988; Krammer & Lange-Bertalot, 1991a; Krammer & Lange-Bertalot, 1991b) *Dinophyceae* (Huber-Pestalozzi, 1950), and *Xanthophyceae* (Gottfried, 1976) with an additional check on https://www.algaebase.org 2019). Cell densities (cells/L) were determined at the species or genus level using the Utermöhl method (Edler & Elbrächter, 2010). Three aliquots were analyzed microscopically for each sample.

Zooplankton sampling

The samples were taken on a water column, using a Patalas - Schindler plankton trap (4 L) device, and filtered through a standard plankton net (mesh size 50 μm Ø). The filtered samples were collected in 10 ml bottles, preserved in 4% formalin, kept for 2 weeks for sedimentation, and later filtered for the second time to reduce the excess water. Using a Kolkwitz counting chamber, three aliquots (1 mL) from the final sample were analyzed using a Zeiss inverted microscope for taxonomic determination and counting of individuals for abundance as individuals per liter (ind. L^{-1}) estimation according to the Edmonson & Winberg (1971) method. The taxonomic determinations were made using the following taxonomic keys *Ciliata* (Foissner et al., 1991; Foissner et al., 1992; Foissner et al. 1994; Foissner et al., 1995), *Testate Amoeba* or *Testacea* (Bartoš, 1954; Grospietsch, 1972), *Rotifera* (Rudescu, 1960), *Cladocera* (Negrea, 1983). *Copepoda* were identified as the main groups. The juvenile stages were counted together and the adult individuals were classified into *Cyclopida* g. sp.; *Harpacticoida* g. sp. and *Calanoida* g. sp. For both, phytoplankton and zooplankton in the microscopic analyses, three sample aliquots were performed.

Statistical analysis

Descriptive statistics were used to analyze and summarize the data. For this purpose, Minimum (Min), Maximum (Max) Mean, and Standard deviation (n-1) were selected.

The ***IndVal*** measures the strength of the association of a species with period environment conditions, based on abundance and frequency depending on the site and period.

The results include: ***IndVal %*** - is the percentage representation of the IndVal, revealing the relative importance of the species in the ecosystem context. The mathematical formula:

$$IndVal\ \% = \frac{\text{INDVALij}}{\sum \text{INDVAL}} \text{ x } 100$$

IndVal is calculated from the following formula:

$$INDVAL_{ij} = 100 A_{ij} B_{ij}$$

The indicator value of species *i* in group *j*, values range from 0 to 100 (percentage). ***p -*** indicates the statistical significance of the association. A value under $p < 0.05$ suggests a strong significant association, while a higher value indicates no significance. The p-value (statistical significance) of the indicator values is assessed through 9999 permutations of sites across groups.

Specificity (A) - refers to how exclusively a species is found in a particular habitat. The mathematical formula:

$$A_{ij} = N_{ij}/N$$

where:

- Nij - is the mean of individuals of species *i* across sites in group *j*;
- Ni is the sum of the mean numbers of individuals of species *i* over all groups.

A value of 1.00 indicates that the species is only found in that habitat, while lower values indicate broader habitat use.

Fidelity (B) represents the reliability of the species as an indicator of the habitat.

The mathematical formula:

$$B_{ij} = Nsites_i/Nsites_j$$

where:

- $Nsites_{ij}$ - is the number of sites in group j where species *i* is present;
- $Nsites_j$ is the total number of sites in group j. A value of 1.00 indicates the species is consistently found in that habitat when it is present.

The analysis was performed using Past 4.13 software (Hammer & Harper, 2024).

Diversity indices, such as Species richness (SR), Shannon index (H), Evenness (E), and Simpson index (D) are commonly applied measures for biodiversity and are crucial to quantifying the variety and distribution of species within a community. ***Species richness*** refers to the total number of different taxa (species).

Simpson's Dominance Index quantifies how dominant certain species are within a community. A higher value indicates lower diversity and one or a few species dominate the population.

$$D = \sum_i \left(\frac{ni}{n}\right)^2$$

where *ni* is the number of individuals of taxon *i*. The index ranges from 0 (infinite diversity) to 1 (no diversity).

The ***Shannon Index (H)*** measures the uncertainty in predicting the species identity of

a randomly chosen individual from a community. It takes into account both the number of species and their relative abundances:

$$H = -\sum_i \frac{ni}{n} \ln \frac{ni}{n}$$

where:

- ni is the number of individuals of taxon I;
- n is the sum of all ni.

Buzas and Gibson's Evenness Index (E) is a measure of species' evenness derived from the Shannon diversity index. It quantifies how evenly individuals are distributed among the species in a community, providing insights into biodiversity beyond mere species richness.

$$E = \frac{e^H}{S}$$

where:

- e - is Euler's number, approximately equal to 2.71;
- H - is the Shannon index;
- S is the total number of taxa.

The evenness index ranges from 0 to 1, where 0 indicates that all individuals belong to one species (complete dominance) and 1 indicates that all species have equal abundance (maximum evenness).

The ***Diversity t-test (Hutcheson's t-test)*** is based on an adapted variant of the classic t-test, allowing for the comparison of Shannon and Simpson indices values between two samples. This test provides an assessment of the statistical significance of observed differences. The formula used in Hutcheson's t-test is similar to that of the standard t-test but includes adjustments for the variance of the Shannon and Simpson indices (Hammer & Harper, 2006).

Redundancy Analysis (RDA) is a multivariate statistical technique used to evaluate the relationships between plankton groups and physicochemical parameters. Before analysis, data were log-transformed to meet the assumptions of the method. The graphical output of RDA includes quantitative environmental variables represented by lines (vectors) and plankton group variables represented by squares. The first two axes, F1 and F2, explain the data's total variation, providing a robust representation of the explanatory variables. The environmental predictors, shown by red arrows, indicate the magnitude and direction of the parameters. The positioning of the squares (representing plankton groups) and the environmental predictors along the different axes illustrate the strength and direction of the relationships between the variables. This visual representation enables the identification of key environmental factors influencing the distribution and composition of plankton communities. The length and orientation of the arrows in the plot signify the magnitude and direction of the environmental gradients, aiding in interpreting complex ecological interactions (Legendre & Legendre, 2012). XLSTAT pro was used for statistical analysis (XLSTAT pro. 2013; PAST software (Hammer et al., 2001).

RESULTS AND DISCUSSIONS

Abiotic parameters

Environmental parameters showed increasing trends from November to February, except for temperature, oxygen saturation, and ORP. During this period, depth ranged from 1 to 2.35 meters, transparency from 1 to 2 meters, and temperature from 6 to 10.44°C. A redox potential (ORP) variation was also observed, indicating unfavorable ecological conditions. In November, the ORP was positive but low (29.2 mV - 54.3 mV), reflecting organic matter decomposition processes, eutrophic conditions, and high oxygen consumption. By February, the decrease in oxygen content was associated with negative ORP values (Table 2), suggesting ongoing decomposition processes through reducing mechanisms. These conditions can negatively affect both biota and natural nutrient cycling processes.

Table 2. Descriptive statistics, mean, variance, and standard deviation of the measured water environmental parameters

Statistic	Min	Max	Mean	Standard deviation (n-1)
	November			
Depth (m)	1.00	2.00	1.48	0.50

Phytoplankton community structure

A total of 43 phytoplankton species were recorded, including *Cyanobacteria* (2 species), *Dinophyceae* (1 species), *Xanthophyceae* (1 species), *Bacillariophyceae* (29 species), and *Chlorophyceae* (10 species). While the number of species remained constant during the winter (Table 2), their taxonomic composition and abundance changed. For instance, 2 species of *Cyanobacteria* were present in November (*Chroococcus turgidus* Nägeli, 1849, and *Gomphosphaeria aponina* Kützing, 1836) and no longer found in February. By February, new green algae and diatom species appeared alongside *Dinophyceae* (*Peridinium* sp.) and *Xanthophyceae* (*Tribonema affine* (Kütz.) G.S.West, 1904). The variability in the taxonomic composition and abundance of species like *Chroococcus turgidus* and *Gomphosphaeria aponina* during winter is influenced by several factors. Winter temperatures can reduce the growth of *Cyanobacteria*, which prefer warmer conditions. Reduced daylight limits photosynthesis, impacting phytoplankton. Seasonal nutrient changes and cooler temperatures can favor the growth of species like *Peridinium* and *Tribonema affine*, which appear in February.

In November, the *Cyanobacteria species* reached the algal bloom (1.04×10^7 cells L^{-1}) threshold, followed by diatoms ($9.67Ex10^5$ cells L^{-1}). During the winter, *Bacillariophyceae* and *Chlorophyceae* dominated in species richness and abundance, showing significant increases in density until February (Table 3).

Table 3. The species richness and density of the phytoplankton groups

	Species richness		Density (cells L^{-1})	
	Nov.	Feb.	Nov.	Feb.
Total phytoplankton	27.0	27.0	$1.15 x10^7$	$6.97 x10^6$
Cyanobacteria	2.0	0.0	$1.04 x10^7$	0
Dinophyceae	0.0	1.0	0	$9.10 x10^3$
Xanthophyceae	0.0	1.0	0	$2.19 x10^6$
Bacillariophyceae	19.0	19.0	$9.67 x10^5$	$3.85 x10^6$
Chlorophyceae	6.0	6.0	$1.19 x10^5$	$9.20 x10^5$

Based on IndVal analysis, February generally exhibits a stronger association and higher indicator values for species, suggesting distinct ecological conditions compared to November. In November, *Epithemia zebra* and *Cocconeis placentula* had high IndVal values (72.97 and 70.23, respectively), indicating the species were strongly associated with the period ecological conditions.

In February, a higher number of species presented elevated IndVal values, most of them diatoms thus highlighting the capacity to exhibit several specific adaptations that enable them to thrive in cold periods (Table 4). These adaptations are crucial for their survival and competitive success during winter months when temperatures drop and light conditions change.

Table 4. Significant results of Indicator Species analysis (IndVal) of phytoplankton assemblage

	Group	IndVal%	p
November			
Epithemia zebra (Ehr.) Kütz.	*Bacillariophyceae*	72.97	0.03
Cocconeis placentula Ehrenberg, 1838	*Bacillariophyceae*	70.23	0.04
Gomphosphaeria aponina Kützing 1836	*Cyanobacteria*	66.67	0.03
February			
Synedra ulna (Nitzsch.) Ehrenberg, 1832	*Bacillariophyceae*	100.00	0.00
Gomphonema ventricosum W.Gregory, 1856	*Bacillariophyceae*	96.67	0.00
Fragillaria intermedia (Grunow) Grunow, 1881	*Bacillariophyceae*	89.92	0.00
Synedra affinis Kützing, 1844	*Bacillariophyceae*	83.33	0.01
Mougeotia sp.	*Chlorophyceae*	76.34	0.00
Gomphonema constrictum Ehrenberg, 1832	*Bacillariophyceae*	66.67	0.03
Navicula pupula Kützing, 1844	*Bacillariophyceae*	66.67	0.03
Synedra acus Kützing, 1844	*Bacillariophyceae*	66.67	0.03
Neidium dubium (Ehr.) Cleve, 1894	*Bacillariophyceae*	66.67	0.03
Navicula longirostris Hustedt, 1930	*Bacillariophyceae*	66.67	0.03

Zooplankton community structure

The zooplankton assemblage consisted of 40 taxa, with *Rotifera* (20 species) and *Cladocera* (14 species) being the most representative, both showing an increase from November to February (Table 5).

Ciliata (1 species) and *Testacea* (2 species) were less representative, while *Copepoda* (comprising three groups: *Calanoida*, *Harpacticoida*, and *Cyclopoida*) was present with a high proportion of juvenile stages. In terms of abundance, the zooplankton in November was characterized by few species with high abundance. Total Zooplankton species richness and densities indicate an important increase from November (521.32 ind. L^{-1}) to February (1025.65 ind. L^{-1}), reflecting cold-tolerant species development. *Ciliata* and *Testacea* showed low densities, with *Ciliata* absent in February and *Testacea* exhibited a significant increase during the winter (from 0.10 to 9.97 ind. L^{-1}). *Rotifera* was the dominant group, with an important growth from November (207.20 ind. L^{-1}) to February (764.20 ind. L^{-1}), indicating favorable conditions for their proliferation during this period. *Cladocera* densities increased slightly from November (64.35 ind. L^{-1}) to February (89.17 ind. L^{-1}), while *Copepoda* densities saw a decrease from November (249.43 ind. L^{-1}) to February (162.31 ind. L^{-1}), suggesting varying ecological responses among different taxa (Table 5).

Table 5. Zooplankton composition in Văcărești Natural Park Lake

	Nov.	Feb.	Nov.	Feb.
	Species richness		Density (ind. L^{-1})	
Total zooplankton	23.0	32.0	521.32	1025.65
Ciliata	1.0	0.0	0.25	0.00
Testacea	1.0	2.0	0.10	9.97
Rotifera	10.0	18.0	207.20	764.20
Cladocera	8.0	11.0	64.35	89.17
Copepoda	3.0	1.0	249.43	162.31

Among the species that formed zooplankton assemblages, few exhibited significant specificity ($p < 0.05$) for a particular study period. In November, the highest IndVal index percentages (Table 6) were observed for the cladocerans *Daphnia* sp. and *Moina* sp., as well as the *Calanoida* copepod group. In contrast, only rotifers were found in February. During this month, environmental conditions favored the proliferation of *Synchaeta oblonga* Ehrenberg, 1832, which attained the highest IndVal index percentage (98.90%), followed by *Ascomorpha* sp. (66.67%).

Plankton diversity

The Diversity t-test highlights significant changes in both the phytoplankton and zooplankton communities in terms of diversity during the winter. Of both indices (Shannon and Simpson), t-values and p-values indicate significant differences between the two periods (Table 7).

Table 6. Significant results of Indicator Species analysis (IndVal) of zooplankton assemblage

	Group	IndVal%	p(raw)
November			
Moina spp.	*Cladocera*	62.09	0.03
Calanoida	*Copepoda*	91.18	0.00
Daphnia spp.	*Cladocera*	100.00	0.00
February			
Synchaeta oblonga Ehrenberg, 1832	*Rotifera*	98.90	0.00
Ascomorpha sp.	*Rotifera*	66.67	0.03

Table 7. Diversity t-test ($p < 0.05$) for phytoplankton and zooplankton communities during the study period

	Phytoplankton		Zooplankton	
	Nov.	Feb.	Nov.	Feb.
Shannon index	0.56	1.80	1.69	2.17
Variance	1.81×10^{-7}		0.0023	
t	-1845.30		-7.83	
df	1.53×10^{7}		1142.50	
p	0.00	2.71×10^{-7}	0.00	0.0014
Simpson index	0.82	0.27	0.25	0.18
Variance	2.40×10^{-8}		0.0001	
t	2.83×10^{3}		5.72	
df	1.85×10^{7}		956.32	5.08×10^{-5}
p	0.00	1.35×10^{-8}	0.00	

The phytoplankton Shannon Index showed a significant increase from November (0.56) to February (1.80), indicating a rise in diversity. Conversely, the Simpson Index decreased from November (0.82) to February (0.27), further supporting the observed increase in diversity. On the other hand, the zooplankton showed a higher diversity, compared with phytoplankton, with moderate changes regarding the species composition.

The results of the Diversity t-test indicate that there have been changes in the structure and diversity of the two planktonic components. However, to obtain a complete overview, it is necessary to identify the response of the

communities that form them. Diversity indices, such as Shannon - H; Evenness - E, and Dominance - D are interconnected and provide a robust framework for assessing the health of aquatic ecosystems. These indices not only reflect the state of biological communities but also indicate their trends. Plankton diversity was assessed based on component groups, characterized by various traits related to species richness and abundance.

Shannon index showed that the most diverse were *Bacillariophyceae* (H = 2.26) and *Chlorophyceae* (H = 0.94), while *Cyanobacteria* showed very low diversity (H = 0.01). Until February, all mentioned groups showed a decline (Table 8).

Table 8. Diversity indices Shannon - H; Evenness – E and Dominance – D of phytoplankton and zooplankton groups

	November			February		
	H	E	D	H	E	D
Phytoplankton						
Bacillariophyceae	2.26	0.50	0.15	1.27	0.19	0.54
Chlorophyceae	1.17	0.54	0.44	0.97	0.44	0.43
Cyanobacteria	0.01	0.51	1.00	NA	NA	NA
Dinophyceae	NA	NA	NA	ND	ND	ND
Xanthophyceae	NA	NA	NA	ND	ND	ND
Zooplankton						
Ciliata	ND	ND	ND	NA	NA	NA
Testacea	0.00	1.00	1.00	0.55	0.87	0.64
Rotifera	0.36	0.14	0.88	1.57	0.27	0.29
Cladocera	0.94	0.32	0.61	1.11	0.28	0.44
Copepoda	0.35	0.48	0.83			

NA - Not applicable - no species found; ND - not determined – insufficient data to perform the analysis.

At the zooplankton level, the taxonomic groups were characterized by different traits in diversity. *Protozoa* were poorly represented. Notably, *Testacea* shows an interesting trend where its Shannon value increases from near zero to moderate levels (from H = 0 to H = 0.55), while its dominance decreases significantly from D = 1 to D = 0.64, indicating an increase in diversity. Instead, *Rotifera* demonstrates a development highlighted by the increase of the Shannon Index from November (H = 0.36) to February (H = 1.57), with a corresponding decrease in dominance (from D = 0.88 to D = 0.29). *Cladocera* shows slight improvement in both months but remains relatively low in Evenness and high in Dominance. *Copepoda* indicates a decline during the period (Table 8). The Evenness index varies significantly across categories and periods.

Species groups with low diversity showed high evenness values (Table 8), whereas groups with high Shannon values exhibited low evenness values. This indicates that communities with higher diversity were dominated by one or a few species.

The response of plankton communities to environmental conditions

The environmental conditions during the two periods functioned as ecological stressors on plankton communities. The relationships between environmental variables and plankton communities were established through RDA analysis.

Axes F1 (56.67%) and F2 (21.97%) together explain 78.63% of the total variation in the data. In Redundancy Analysis (RDA), F1 (56.67%) and F2 (21.97%) represent the first two *constrained canonical axes* that capture most of the variation in the biological response variables (species communities) explained by the environmental predictors in the model. Phytoplankton groups, including *Cyanobacteria*, *Chlorophyceae*, *Bacillariophyceae*, and *Xanthophyceae*, exhibited a dispersed distribution in the plot, contrasting with the more cohesive grouping of zooplankton (such as *Cladocera*, *Copepoda*, and *Rotifera*). This difference in dispersion may suggest that phytoplankton and zooplankton employ distinct ecological strategies in response to environmental pressures.

Phytoplankton were more responsive to variations in parameters such as TDS, conductivity, turbidity, and pH, reflecting nutrient availability. Zooplankton (*Cladocera*, *Copepoda*, and *Ciliata*) were closely correlated with oxygen and temperature conditions, indicating a preference for well-oxygenated waters and higher temperatures.

In the RDA biplot, the distribution of physico-chemical parameters highlights an inverse relationship between turbidity and dissolved oxygen (DO%), suggesting that higher turbidity coincides with lower oxygen availability. Conversely, these conditions were unfavorable for *Ciliata*, *Cladocera*, and *Copepoda*. Increases in conductivity, turbidity, and TDS were tolerated by diatoms, green algae, *Dinophyceae* (dino-flagellates), and *Xanthophyceae* (yellow-green

algae). The association of *Rotifera* and *Testacea* (testate amoebae) with these parameters reflects the availability of food resources (phytoplankton and detritus) and a negative response to cyanobacterial blooms. Organisms such as *Cladocera* and *Copepoda* could indicate well-oxygenated and good-quality water, while the presence of *Cyanobacteria* may indicate water quality degradation.

Environmental controlling factors of plankton

Winter conditions significantly affect phytoplankton and zooplankton communities. Seasonal changes, driven by temperature, light, and nutrient fluctuations, also impact water quality parameters. The evaluated physicochemical parameters (Table 2) indicated active organic matter decomposition. Temperature declines during winter significantly alter environmental conditions, affecting biotic components through interconnected chemical processes. In this period, correlations of TDS, conductivity, turbidity, transparency, and depth with plankton reflected nutrient access for primary producers.

Simultaneously, under these conditions, the zooplanktonic components that demonstrated tolerance, such as rotifers and testate amoebae, were observed (Figure 2). On the other hand, the decrease in oxygen saturation showed negative effects on both phytoplankton and zooplankton communities.

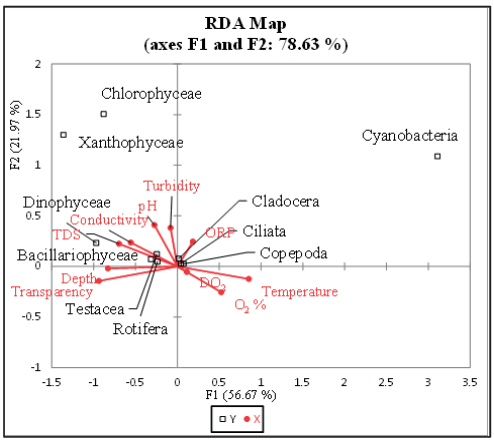

Figure 2. Redundancy analysis (RDA) for the relationship among the phytoplankton and zooplankton groups' abundance and environmental variables in Văcărești Lake

Plankton diversity

The dynamics of plankton communities can exhibit distinct patterns throughout the seasons, often characterized by shifts in species composition and abundance. Previous studies in the Văcărești Natural Park, during the growing warm period, have reported the presence of 80 species in phytoplankton and 89 species in zooplankton structure. Shannon's diversity index for phytoplankton was 1.78 and for zooplankton - 3.48 (Florescu et al., 2022). Thus, our results reveal a decline in diversity; species richness, and abundance of planktonic communities (Table 3; Table 5; Table 7; Table 8) during the winter reflecting the different conditions compared with the vegetation period.

Other studies confirm the critical role of these factors during colder months with a negative impact on both phytoplankton and zooplankton communities, leading to reduced biodiversity and altered community structures (Dokulil & Herzig, 2009). Contrary to expected trends, certain species within the planktonic assemblage exhibited tolerance to winter conditions. As a result, with the shift in community composition during the winter, an increase in diversity was observed (Table 7). The increasing species diversity can be due to the reduction in competition from less tolerant species may allow more resilient species to thrive (Geng et al., 2022).

In urban environments like Văcăresti, anthropogenic pressures have led to eutrophication and algal blooms. Previous studies emphasized that the phytoplankton in Văcăresti Natural Park exhibited seasonal variations with eutrophic and hiper-eutrophic conditions, especially during the autumn The composition of the algal blooms primarily consisted of *Cyanobacteria* and *Chlorophyceae* species (Florescu et al., 2022). The decline of *Cyanobacteria* during the winter period showcased the ecosystem's resilience. This decline could allow other groups like *Dinophyceae* and *Xanthophyceae* to develop, thus maintaining the overall biodiversity and functional stability of the ecosystem. Furthermore, the reduction in cyanobacterial blooms can prevent potential negative effects common during cyanobacteria-dominated periods. The shift in community composition

during the winter underscores the ecosystem's ability to self-regulate and support a diverse range of species, despite the adverse conditions.

The shift of the phytoplankton species during the cold season

Because phytoplankton assemblages play a crucial role in aquatic ecosystems, species that are strongly associated with particular conditions, make them indicators of an ecological state. Identifying key indicator species and their associations with environmental conditions offers a better understanding of ecological dynamics (Sidding et al., 2016). Given these practical applications, the general utility of IndVal for the analysis of phytoplankton assemblages becomes apparent and highly valuable. Conversely, the presence or absence of a particular single species of organism might be used to indicate chemical or physical attributes of the biotope. The data reflects the shifts in phytoplankton assemblages, with different species dominating. The distinction between November and February groups was determined by driven factors such as temperature, light availability, or nutrient dynamics (Figure 2). Thereby, *Epithemia zebra* (IndVal 72.97, p = 0.030), *Cocconeis placentula* preferred, nutrient-rich conditions typical of November (Table 4). The IndVal results of *Gomphosphaeria aponina* (IndVal 66.67, p = 0.03) confirm their role in cyanobacterial blooms from November (Table 4). Instead, species like *Synedra ulna* (IndVal 100.00, p = 0.00) and *Gomphonema ventricosum* (IndVal 96.67, p = 0.00), were highly indicative of February, pointing to the ecological relevance as strong indicators of winter-specific ecological conditions. The higher number of significant species in the IndVal analysis in February compared to November suggests a distinct phytoplankton community that defines the end of the winter.

The dominance of *Bacillariophyceae* in winter is a complex interplay of ecological adaptations, nutrient dynamics, and climatic influences. The group is generally well-adapted to lower temperatures, allowing the species to thrive even in the cold winter months. Diatoms' contribution to the plankton assemblage was also reflected in the highest species diversity in response to environmental changes during the winter season (Table 8). Their ability to develop in cold conditions allowed them to show their ecological importance as most numerous as significant IndVal species in both periods of investigation (Tabel 4) (Zepernick et al., 2024; Zang et al, 2018).

The *Chlorophyceae* was the second group after *Bacillariophyceae* present in phytoplankton during the entire study. Green algae are often abundant in urban lakes during the cold season. This abundance can be attributed to several factors, including reduced competition from other phytoplankton groups, lower grazing rates, and their ability to thrive (Tapolczai et al., 2015). Similar to other studies, the filamentous green algae *Mougeotia* spp. showed a proliferation. *Mougeotia* spp. tends to bloom earlier in the year when conditions are favorable, such as stable water columns and sufficient nutrient availability. The species is adapted to access the light by the water's surface utilizing its buoyant structures. Consequently, its growth can outcompete other phytoplankton species, leading to its dominance in urban lakes during the cold season and impacting the overall plankton community structure (Tapolczai et al., 2015).

During the study, the temperature dropped along with oxygen levels and redox potential (ORP) inhibited cyanobacteria, leading to their decline (Figure 2; Table 3). The cumulative effect of these factors significantly impacts cyanobacterial populations during the winter months, changing the overall composition and dynamics of the aquatic ecosystem. Most cyanobacterial taxa become less active or enter dormancy during winter, producing specialized cells (akinetes) that can survive adverse conditions until warmer temperatures return (Cottingham et al., 2021; Mânica & de Lima Isaac, 2023).

The shift of zooplankton species during the cold season

The changes in structure and composition in the main zooplankton groups depended on the adaptation strategies to the pressures of the winter conditions, their life cycle patterns, and physiological traits. Also, the quality and accessibility of food were important factors (Varpe, 2012). During the study, zooplankton abundance and species richness increased, indicating favorable conditions and

opportunities for some species development. Late warm autumn, without ice cover, has significant hints in aquatic organisms with dormant stages, as temperature stimulates production or release from the overwintering stages. The thermal responses of different species vary and are correlated with their seasonal abundance and distribution. Thus, periods of prolonged warm periods have different effects depending on the thermal tolerance limits and could influence survival and wintering strategies to the advantage of some species and the disadvantages of others (Chen & Folt, 1996).

The structural changes observed in the zooplankton communities in urban lakes during winter, leading to improved diversity, can be attributed to the prevalent environmental conditions. In February, the species richness of *Rotifera* and *Cladocera* showed an increase compared cu November. Thus, this period was opportune for other species to grow and distribute more evenly. This phenomenon underscores the intricate relationship between the ecological factors and zooplankton community dynamics. In addition, the capacity for rapid responses to environmental pressures makes the zooplankton a valuable indicator for evaluating the consequences of anthropogenic impacts (Umi et al., 2024). According to Haberman & Haldna (2017), water temperature in temperate shallow lakes has a significant impact on the abundance and composition of zooplankton. The communities have high dynamics of abundance, with a seasonal trend, such as, in spring with higher values than autumn. In addition, the approximately 10°C water temperature was considered "*a critical time window*" for generating a shift in species composition and abundance.

In the Văcărești Lake, the recorded abundance of rotifers during the winter can be explained by the resilience capacity of these communities to the pressure of unfavorable conditions. Rotifers are versatile organisms characterized by a great diversity of survival strategies, that include tolerance to eutrophication and pollutants, a fast reproductive cycle, and a change in feeding regime depending on the trophic resources. The responses of rotifers can be attributed to various factors (Figure 2) that highlight the species' food availability and cosmopolitan features. Rotifers have shown sensitivity to decreased oxygen saturation and ORP but tolerate fluctuations in water turbidity, pH, conductivity, or depth.

The cladoceran life history strategy is more complex and dependent on selective food availability. Also, cladocerans, are generally more sensitive to lower temperatures (Figure 2). Their metabolic rates slow down, and their reproductive rates decrease in colder conditions, leading to lower overall abundance (May & Wallace, 2019; Jensen, 2019). Also, most copepod species exhibit seasonal diapause in winter to avoid unfavorable conditions. This behavior can contribute to our study's observed decrease in adult copepod abundance. However, water temperature (ranged 6 and 10°C) maintained the presence of juvenile stages in Văcărești. Under these conditions, copepods may exhibit a range of responses to changes in temperature and food availability. Some species might adjust the timing of their life cycle to better align with the new environmental conditions.

The response of copepod assemblages to environmental changes was significantly influenced by temperature. Similar to *Cladocera*, copepods' life-history traits, such as reproductive strategy and generation length, are crucial for understanding how these microcrustaceans adjust their life cycles to align with environmental conditions, including temperature shifts. Research indicates that life-history traits, such as reproductive strategy and generation length, are critical for understanding how copepods adjust their life cycles in response to environmental conditions, including temperature shifts. Studies show that temperature variations and food availability interact to influence copepod life stages, which can contribute to observed changes in adult abundance in specific environments such as urban temperate shallow lakes. These factors differentially affect the naupliar and copepodite stages. For instance, nauplii showed reduced survival at elevated temperatures unless provided with phosphorus-replete food, emphasizing the importance of nutrient quality alongside temperature in shaping copepod life stage dynamics. In our study, after autumn phytoplankton growth, nauplii benefit longer from an abundant food source, favoring high

development. Thus, they were able to develop in the following stages as well. The interaction of these factors may explain the dynamics of the young stages of the copepods in Văcărești Lake. These findings suggest that climate-driven alterations in microplankton communities could affect copepod survival, particularly during periods of food scarcity, thus influencing overall abundance (Banas et al, 2016; Haberman & Haldna, 2017; Mathews et al, 2018; Halsband-Lenk et al., 2002; El-Sherbiny & Al-Aidaroos, 2021).

Regarding the decline of ciliata, low temperatures significantly decreased their growth rates, with effects on their abundance. The development of heterotrophic protists is affected by a decrease in temperature. Numerous studies have claimed that low temperatures have a strong negative impact on herbivorous protozoa; for example, ciliates prefer higher temperatures (20-25°C) (Rose & Caron, 2007). From this point of view, in our study, it was noted that the low representation of ciliates and testate amoeboids may indicate changes in environmental conditions or population dynamics in the ecosystem.

Thereby, the winter compositional patterns in zooplankton were driven by the fitness of rotifers and copepods juveniles to colder temperatures and their ability to exploit available food resources, whereas other communities as cladocerans, adult copepods, and protozoa were less able to cope with the harsh conditions.

The diversity increases were associated with a change in the key species in the ecosystem. Of the species that showed a significant response in abundance during winter (Table 6), some were advantaged by environmental conditions, such as *Ascomorpha* sp. (November – 0; February – 315.44 indv. L^{-1}); *Synchaeta oblonga* (November – 0.42; February – 37.48 indv. L^{-1}); while others such as *Calanoida* adults (November – 29.80; February– 2.88); *Daphnia* spp. (November – 50.25; February – 0.00 indv. L^{-1}) have gone through a decline. The zooplankton the taxonomic composition and diversity traits during the cold period in our study reflected mainly the known responses to a moderate winter. According to these conditions, Goździejewska & Kruk (2023) emphasized a weak interspecific relationship between rotifers, cladocera, and protozoa during moderate winters. Also, the authors mention that *Ascomorpha* spp., and *Synchaeta* spp. were the representatives that outlined the typical features of the period. Stressors such as temperature and phytoplankton availability significantly influence these dynamics. The interplay between the warming effects, nutrient supply, and grazing varies with seasonality and the ecosystems' long-term history. Concerning temperature and grazing, the decrease in temperature is due to modifications in species composition, and the predominance of smaller species (Goździejewska & Kruk, 2023). Also, the research by paleolimnological analyses based on sediment cores indicated a significant negative correlation between *Daphnia* abundance and winter temperature series (Nevalainen et al., 2013). The mild temperatures and the absence of ice on the surface of the lakes during the winter period would be advantageous for some species and allow them to increase.

In Lake Văcărești during winter, limited food sources shape zooplankton structure by quality and quantity. For copepods, size and abundance were linked, with juveniles driving population numbers and adults contributing to biomass despite lower abundance. As part of zooplankton communities, there are taxonomic groups like *Protozoa*, *Rotifera* and *Crustacea* with distinct features that, through their availability through biomass, can decisively influence the feeding behavior of higher consumers. The seasonal succession of the plankton community described by Sommer et al., 1986 as the PEG model, is found in numerous freshwater ecology studies, focused especially on the growth periods, and less on the winter season. Because winter for many species of zooplankton is a period of dormancy, the season was considered less important. Because of the interest in climate change, this period has gained crucial importance for the seasonal dynamics of plankton communities. Thus, is necessary to understand the dynamics of zooplankton under winter conditions (Jensen, 2019).

CONCLUSIONS

Winter conditions led to significant changes in environmental parameters, indicating organic matter decomposition and eutrophic conditions. The phytoplankton responded to the environmental changes: green algae and diatoms became more prominent, while cyanobacteria declined. Zooplankton responded with increased diversity and abundance of *Rotifera* and *Cladocera*, while *Ciliata* and *Copepoda* decreased. Phytoplankton showed responsiveness to TDS, conductivity, turbidity, and pH, while zooplankton correlated with oxygen and temperature. There were significant changes in diversity for both phytoplankton and zooplankton, with zooplankton showing higher diversity and moderate species composition changes. Winter conditions acted as ecological stressors, leading to structural and functional changes in plankton communities.

The development of cold-tolerant species and moderate species composition changes reflected the ecosystem's resilience and adaptability to winter conditions.

The urban lake environment appears to mitigate some of the harsh effects of winter, supporting higher abundance and species richness of zooplankton, while the phytoplankton assemblage showed a decline in abundance but with recovery effects after autumn algal blooms.

These findings underscore the importance of long-term monitoring and comparisons with other urban lakes to gain broader insights into urban aquatic ecosystems.

ACKNOWLEDGEMENTS

This research work was carried out with the support of Institute of Biology Bucharest, Romanian Academy, grant number RO1567-IBB02/2024 and RO1567-IBB08/2024. The authors thank Stela Sofa for the technical assistance received during the development of the study.

Abstract

Lithium-ion batteries dominate electrochemical energy storage due to their high charge–discharge efficiency, thermal stability, and safety. With an average lifespan of 3-5 years, their growing end-of-life volume poses environmental and resource management challenges. While recycling efforts have focused on high-value metals, electrolyte recovery remains underdeveloped. This review compares pyrometallurgy, hydrometallurgy, and direct recycling based on literature from 2015–2025, evaluating metal recovery efficiency, energy demand, CO_2 emissions, environmental impact, and technological readiness. Hydrometallurgy emerges as the most viable current method (>90% recovery, ~800 kWh/ton energy use), while pyrometallurgy, though industrially established, has high energy requirements (~2,200 kg CO_2/ton) and poor lithium recovery. Direct recycling shows strong sustainability potential by preserving active material structures yet faces scalability challenges from feedstock variability and process standardization. Advancing sustainable recycling will require innovation in automation, standardized materials, and robust policy frameworks to support a circular economy for critical raw materials.

Key words*: battery, direct recycling, hydrometallurgy, pyrometallurgy.*

INTRODUCTION

In the context of the global transition toward sustainable technologies and electric mobility, lithium-ion batteries (Li-Ion) have become the cornerstone of energy storage for applications such as electric vehicles (EVs), portable electronics, and stationary storage systems. As this sector rapidly expands, the generation of waste from spent Li-Ion batteries has grown exponentially, exerting pressure on both the environment and the supply chains of critical materials such as lithium, cobalt, and nickel.

Recycling Li-Ion batteries is not only an ecological necessity but also a strategic opportunity to reduce dependence on primary resources, enhance the security of critical raw materials, and close the materials loop within a circular economy framework. However, not all recycling methods offer the same level of efficiency, sustainability, or industrial feasibility. Currently, three major technologies are employed or under investigation for battery recycling: pyrometallurgy, hydrometallurgy, and direct recycling. Each of these presents specific advantages and limitations, both from a technical standpoint and in terms of environmental impact and operational costs.

The objective of this study is to provide a comparative evaluation of the three primary recycling technologies, focusing on material recovery efficiency, greenhouse gas emissions (CO_2), energy consumption, and practical applicability within the European and Asian contexts, with particular emphasis on China. This paper offers a critical appraisal of the current landscape of battery-recycling technologies and maps plausible development pathways, emphasizing implications for environmental policy and industrial practice. It addresses three questions: (1) Which recycling method offers the best balance between efficiency, cost, and environmental impact? (2) What are the differences in application between the EU and China? (3) What is the long-term potential of emerging technologies?

The article is structured as follows: Section 2 outlines the methodology used for selecting the

reviewed studies; Section 3 provides a detailed overview of each recycling technology; Section 4 presents the comparative and regional analysis; Section 5 discusses the implications for policy and industry; and Section 6 includes the conclusions and future research directions.

MATERIALS AND METHODS

This review paper was conducted based on a systematic selection of scientific articles from the Scopus, Web of Science, and ScienceDirect databases, covering the period 2015-2025.

The selection criteria included technological relevance, the presence of quantitative data on recovery efficiency, emissions, and technological maturity. Articles without comparable data or those focusing solely on battery reuse were excluded.

The comparative analysis was performed according to five criteria: metal recovery efficiency, energy consumption, CO_2 emissions, environmental impact, and level of industrial maturity.

Li-Ion battery recycling methods

Pyrometallurgical Recycling

Pyrometallurgy represents one of the most established and industrially applied methods for the recycling of spent lithium-ion batteries (LIBs), particularly in the European Union. This technique involves high-temperature processing, typically above 1,200°C, to smelt battery materials and recover valuable metals. The process generally includes thermal pre-treatment (e.g., drying, deactivation), followed by smelting in a furnace where the electrode materials decompose and separate based on their physical and chemical properties.

During smelting, organic components such as electrolytes, binders, and separator materials are combusted, while transition metals like cobalt (Co), nickel (Ni), and copper (Cu) are recovered in a metallic alloy or slag phase. These metals can then be refined through additional hydrometallurgical steps to meet battery-grade purity levels.

One of the primary advantages of pyrometallurgical recycling lies in its process simplicity and robustness, making it suitable for mixed and unclassified battery waste streams. Moreover, the technique ensures relatively high recovery rates for cobalt and nickel, which are among the most economically valuable elements in LIBs.

However, this approach also presents several notable disadvantages. Most importantly, lithium is largely lost during the process, often ending up in the slag and becoming unrecoverable without additional complex treatments. In addition, the high energy demand of the smelting process contributes to significant greenhouse gas emissions, particularly when fossil fuels are used as the energy source. The combustion of electrolyte components can also release toxic gases, such as hydrogen fluoride (HF), which necessitates strict environmental controls and gas scrubbing systems.

Despite these limitations, pyrometallurgy continues to be widely used due to its maturity, scalability, and compatibility with existing metallurgical infrastructure. Nevertheless, in light of increasing environmental regulations and the need to recover lithium and other light elements more efficiently, this method is gradually being complemented or replaced by alternative recycling strategies, such as hydrometallurgy and direct recycling.

We have the following chemical reactions that take place during melting:

Cobalt reduction: $CoO + C \rightarrow Co + CO \uparrow$

Nickel reduction: $NiO + C \rightarrow Ni + CO \uparrow$

Decomposition of $LiPF_6$ from electrolyte:

$LiPF_6 \rightarrow LiF + PF_5 \uparrow$ (at > 60°C).

At high temperatures, PF_5 turns into HF (extremely toxic), and LiF ends up in the slag.

Depending on the chosen pyrometallurgical recycling method, batteries may require a pretreatment stage to extract the active cathode material for subsequent recovery, or they can be directly fed into a furnace, as in smelting processes. Thermal pretreatment techniques used for recovering cathode materials include incineration, calcination, and pyrolysis. The resulting metal-rich fraction is then processed through roasting or smelting. A major technical challenge in these pyrometallurgical processes has been the emission of toxic gases. However, recent advancements in pyrometallurgy have led to the development of integrated gas treatment systems such as the one implemented by Umicore which ensure the complete

removal of volatile organic compounds, effective dust capture, and a significant reduction in gas emissions.

Depending on the chosen pyrometallurgical recycling method, batteries may require a pretreatment stage to extract the active cathode material for subsequent recovery, or they can be directly fed into a furnace, as in smelting processes. Thermal pretreatment techniques used for recovering cathode materials include incineration, calcination, and pyrolysis. The resulting metal-rich fraction is then processed through roasting or smelting.

Regarding pyrometallurgy, its advantages consist of: mature technology that is already used on an industrial scale (e.g. Umicore, Glencore), high tolerance to mixtures where precise sorting of batteries is not necessary, but also efficient recovery of Co, Ni and Cu (over 85-90%).

Analyzing the disadvantages, there are certain limitations such as: lithium losses: Li ends up in the slag and is not economically recovered, high energy consumption: >4,000 kWh/ton processed in some cases, significant CO_2 and HF emissions: high climate impact and need for advanced gas treatment, requires advanced metallurgical infrastructure and large initial investments.

Hydrometallurgical recycling

Hydrometallurgy is an advanced method for recycling lithium-ion batteries that involves the chemical transformation of solid electrode materials into soluble forms, followed by the selective recovery of valuable metals. This process is structured in several stages: leaching (dissolution), separation of metal ions, purification and final recovery of salts or metals in solid form.

Acid leaching stage

The active materials (e.g. $LiCoO_2$, $LiNi_{1-x-y}Mn_xCo_yO_2$) are treated in an acidic solution, usually sulfuric acid (H_2SO_4) or hydrochloric acid (HCl), in the presence of a reducing agent (usually hydrogen peroxide, H_2O_2), which helps to oxidize the transition metals and solubilize them in the form of ions.

Typical dissolution reactions:

- $LiCoO_2 + 2H^+ + H_2O_2 \rightarrow Li^+ + Co^{2+} + O_2 + 2H_2O$
- $LiNiO_2 + 2H^+ + H_2O_2 \rightarrow Li^+ + Ni^{2+} + O_2 + 2H_2O$
- $MnO_2 + 4H^+ + 2e^- \rightarrow Mn^{2+} + 2H_2O$

Li^+ remains dissolved as a soluble ion, without further redox reaction.

The leaching process is generally carried out at temperatures between 60-90°C, for a time of 1–3 hours, in a slightly agitated environment, with a pH < 2.

Metal separation and recovery stage

After complete dissolution, the metal ions (Co^{2+}, Ni^{2+}, Mn^{2+}, Li^+) are separated by sequential techniques such as:

Selective precipitation – e.g. $Co(OH)_2$, CoC_2O_4;

Solvent extraction – D2EHPA, Cyanex 272;

Lithium recovery – e.g. $Li^+ + CO_3^{2-} \rightarrow Li_2CO_3 \downarrow$

The yields are over 90-95% for Co and Ni and between 80-90% for Li, depending on the cathode formulation and process conditions.

The limitations and challenges of this method would be: the generation of liquid waste rich in non-recoverable ions, significant consumption of acidic reagents, the need for rigorous control of process parameters.

The method is applied by companies such as Fortum (Finland), Li-Cycle (Canada), Recupyl (France), all using hydrometallurgical variants adapted for the efficient recovery of strategic metals.

Direct recycling

Direct recycling is an emerging technology with significant potential in the field of circular economy, which aims to recover and directly reuse active materials from used lithium-ion batteries, especially cathode ones, without completely decomposing them into basic chemical elements. Unlike pyrometallurgical and hydrometallurgical methods, which involve the complete destruction of the material structure, direct recycling preserves or regenerates the crystalline structure of transition metal oxides (e.g. $LiCoO_2$, NMC), allowing their direct reuse in the manufacture of new cells.

During charge-discharge cycles, the active material undergoes electrochemical and structural degradation caused by: interstitial lithium loss; phase changes and distortions of the crystal lattice; surface contamination. However, the basic structure of the cathode often remains relatively intact, especially in the

case of post-industrial waste or batteries with a low number of cycles.

Stages of the direct recycling technological process:

1. Battery deactivation and disassembly;
2. Mechanical separation of the active material;
3. Binder and contaminant removal (thermal or chemical);
4. Stoichiometric replenishment with Li_2CO_3 or LiOH;
5. Recrystallization at 700-900°C;
6. Testing and characterization (XRD, SEM, electrochemical cycling).

Representative reaction: $Li_{1-x}MO_2 + xLi_2CO_3 + \Delta T \rightarrow LiMO_2 + xCO_2\uparrow$.

Performance and efficiency:

Material recovery efficiency is up to 95%;

Electrochemical capacity restoration: 85-95%;

Costs: 30–50% lower than in classical methods;

CO_2 emissions: reduced by up to 90%.

Limitations for this method are represented by: the need to sort materials; the lack of a mature industrial infrastructure; sensitivity to contaminants; the need for automation and standardization.

RESULTS AND DISCUSSIONS

Pyrometallurgy is widely adopted due to its simplicity and robustness but suffers from high emissions and energy consumption, with poor lithium recovery. Hydrometallurgy offers a more environmentally friendly alternative with high recovery rates, though it generates liquid waste and involves complex chemical separation. Direct recycling, while still emerging, shows the greatest potential for low-impact, high-efficiency recovery by preserving cathode materials, yet it requires high feedstock purity and standardized battery formats (Table 1).

Table 1. Comparative analysis of Lithium-Ion battery recycling technologies

Criteria	Pyrometallurgy	Hydrometallurgy	Direct Recycling
Recovery Efficiency	~60%	~90%	~95%
Materials Recovered	Co, Ni, Cu (Li, Al lost in slag)	Co, Ni, Li, Mn, Cu	Intact cathode material (e.g., NMC, LFP)
CO_2 Emissions	~2200 kg/ton	~1200 kg/ton	~300 kg/ton
Energy Consumption	~1500 kWh/ton	~800 kWh/ton	~500 kWh/ton
Process Temperature	>1500°C	<100°C	Room temperature to 150°C
Technology Maturity	Industrial	Commercial	Emerging
Feedstock Flexibility	High	Medium	Low
Capital & Operating Costs	High	Medium	Low (with automation)
Environmental Impact	High	Medium	Low
Challenges	Low Li recovery, high CO_2	Chemical waste, separation complexity	Sorting, disassembly, standardization

The European Union and China are the two leading regions implementing large-scale lithium-ion battery recycling programs, each reflecting unique industrial strategies and regulatory frameworks.

In the EU, the recycling landscape is shaped by strong environmental directives such as the EU Battery Regulation (2023), which mandates minimum recycled content and high recovery targets for lithium (35%), cobalt (95%), and nickel (90%) by 2030.

The EU supports direct recycling research through initiatives like the Horizon Europe program, but most commercial plants still use hydrometallurgical techniques, balancing efficiency and sustainability.

China, in contrast, leads the world in both battery production and recycling volume, processing over 600,000 tons of spent LIBs annually. Chinese companies leverage vertical integration and economies of scale, with a strong emphasis on hydrometallurgical recovery.

Recent pilot projects also explore direct recycling, driven by the government's 2021 guideline on battery recycling and reuse, which supports second-life applications and material loop closure. Key differences lie in the policy focus: the EU prioritizes sustainability and traceability, while China emphasizes scale, speed, and economic return. Technologically, both regions are advancing direct recycling, but

with different paces of standardization and investment.

Figure 1 illustrates a comparative assessment between the European Union and China regarding lithium-ion battery recycling, based on key indicators such as recycling volume, recovery efficiency, CO_2 emissions, regulatory strength, and investment in direct recycling technologies.

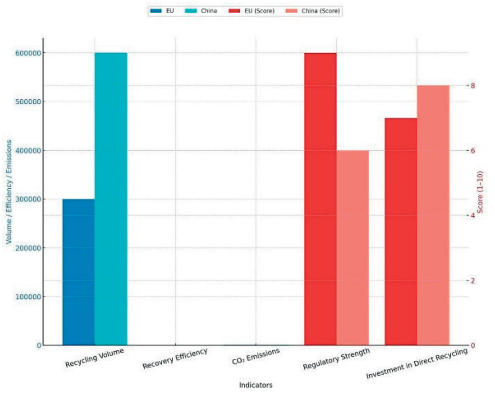

Figure 1. UE vs China in Li-Ion battery recycling (Source: European Commission (2023). Regulation (EU) 2023/1542 of the European Parliament and of the Council on batteries and waste batteries. Official Journal of the European Union. https://eur-lex.europa.eu)

China processes approximately 600,000 tons of lithium-ion batteries annually - about twice the EU's recycling volume of 300,000 tons - reflecting its significant industrial capacity and the high domestic demand for battery reuse and material recovery. In terms of efficiency, the EU achieves an estimated 90%, slightly surpassing China's 85%, a performance advantage attributable to stringent environmental regulations that mandate elevated recovery standards for critical raw materials such as lithium, cobalt, and nickel. From an environmental impact perspective, the EU generates lower carbon emissions, averaging around 800 kg per ton, compared to China's approximately 1,000 kg per ton, largely due to its reliance on cleaner hydrometallurgical processes, while China employs a broader range of technologies, including more carbon-intensive methods. Regarding governance, the EU attains a regulatory strength score of 9/10, underpinned by comprehensive legislative frameworks such as Regulation (EU) 2023/1542, whereas China scores 6/10, with a still-developing and more flexible regulatory environment that prioritizes industrial agility and rapid execution. Finally, in the domain of technological investment, China leads with a score of 8/10, driven by substantial funding for direct recycling initiatives from major industrial actors such as CATL and GEM, while the EU follows with 7/10, primarily through Horizon Europe programs, focusing on scientific validation and regulatory harmonization but progressing more slowly in large-scale commercial deployment.

Table 2 presents a comparative analysis of the three major Li-Ion battery recycling methods: pyrometallurgy, hydrometallurgy and direct recycling, based on energy efficiency, metal recovery yield, environmental impact, costs and technological maturity.

Table 2. Comparative analysis of Li-Ion battery recycling methods

Criterion	Pyrometallurgy	Hydrometallurgy	Direct Recycling
Energy efficiency	Low – requires very high temperatures (>1000°C)	Medium – energy needed for chemical processes and separation	High – low-temperature processes, more efficient
Metal recovery rate	Low–medium – recovers only valuable metals	High – can recover most metals (Li, Co, Ni, Mn)	Very high – preserves the structure of active materials
Environmental impact	High – CO_2 and other toxic gas emissions	Medium – uses acidic chemical substances	Low – fewer emissions and waste
Costs	High – significant energy costs	Medium – chemicals can be reused	Potentially low – but technology is still developing
Technological maturity	Very mature – used at industrial scale	Mature – being optimized for large-scale application	Immature – still under research, limited applications

The comparative analysis of the three primary methods for recycling Li-Ion batteries - pyrometallurgy, hydrometallurgy, and direct recycling indicates that there is no universally optimal solution. Rather, the selection of the recycling method should be guided by specific process objectives, including energy efficiency, cost-effectiveness, environmental sustainability, and scalability. Nevertheless, an integrated assessment of the key criteria yields the following insights:

From the perspective of energy efficiency and environmental impact, direct recycling appears to be the most promising approach. This method enables the preservation of active materials with minimal energy consumption and produces significantly lower amounts of hazardous waste. However, its limited technological maturity and the absence of a well-established industrial infrastructure currently constrain its large-scale deployment.

Direct recycling stands out for its low energy consumption and minimal CO_2 emissions, as it preserves active cathode materials without fully breaking them down. Recovery rates can exceed 90% for certain materials, and the environmental footprint is significantly lower than that of other methods. However, its industrial application is currently limited due to low technological maturity and the lack of a standardized recycling infrastructure.

Hydrometallurgy offers a balanced trade-off between performance and sustainability. It enables high recovery rates - often above 95% - for critical metals such as lithium, cobalt, nickel, and manganese. The energy demand is moderate, and the technology is already being implemented in pilot and commercial-scale facilities. Its adaptability to different battery chemistries makes it the most viable and scalable solution in the medium term.

Pyrometallurgy, while technologically mature and widely industrialized, presents several drawbacks: high energy requirements (often exceeding 5–8 MJ/kg), relatively low lithium recovery (below 50%), and significant CO_2 emissions. These limitations increasingly position it as a transitional or last-resort method, better suited for mixed or contaminated battery waste streams but misaligned with future regulatory and sustainability goals.

The comparative performance chart (Figure 2) clearly illustrates the strengths and limitations of each method across five key criteria: energy efficiency, metal recovery rate, environmental impact, cost-effectiveness, and technological maturity. This multidimensional evaluation supports the discussion and highlights where each method currently stands and what future developments may be needed.

Hydrometallurgy is therefore increasingly favored by researchers and industry stakeholders for integration into large-scale circular economy initiatives.

Although pyrometallurgy is a well-established and industrialized recycling method, it presents significant disadvantages, including high energy consumption, relatively low recovery rates for certain elements (particularly lithium), and major environmental concerns. As a result, pyrometallurgy is increasingly regarded as a transitional or last-resort option, especially in the context of tightening environmental regulations in the European Union and other regions.

In summary, hydrometallurgy currently represents the most efficient and balanced approach for Li-Ion battery recycling, combining high metal recovery rates with proven technical feasibility. However, direct recycling holds substantial long-term potential to become the industry standard, provided that future technological advancements improve its scalability and standardization.

Accelerating the transition toward sustainable battery recycling requires coordinated action from both policymakers and the industry. On the policy side, investments in research, fiscal incentives for emerging technologies, and clear regulations on battery ecodesign (such as standardization of formats and materials) are essential. From an industrial perspective, companies are encouraged to adopt circular business models, develop local recycling infrastructure, and establish strategic partnerships to facilitate the transition from innovation to commercial deployment. International cooperation, particularly between the EU and China, can further support the harmonization of standards and accelerate widespread adoption.

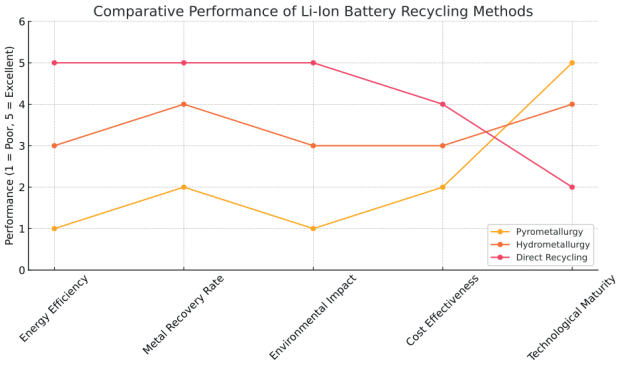

Figure 2. Comparative performance of Li-Ion battery recycling methods
(Source: Data compiled from Gaines, 2018; Xu et al., 2020; Fan et al., 2021; Harper et al., 2019; Zhao et al., 2021; Liu et al., 2021; Cornelio et al., 2024; Makuza et al., 2021)

CONCLUSIONS

As demand for Li-Ion batteries continues to rise - driven by the transition to electric mobility and renewable energy - the development of efficient recycling solutions has become a critical priority. Currently, three main technologies are emerging as viable options for recovering valuable materials from spent batteries: pyrometallurgy, hydrometallurgy, and direct recycling. Each method offers distinct advantages and limitations, and the optimal choice depends on balancing technical performance, environmental impact, and industrial readiness.

Among these, hydrometallurgy stands out as the most balanced and practical option at present. With recovery efficiencies of over 90% for critical metals such as lithium, cobalt, nickel, and manganese, moderate energy consumption (approximately 800 kWh per ton of processed batteries), and proven scalability, this method is already being deployed in commercial facilities. However, the intensive use of chemical reagents and the generation of liquid waste require advanced wastewater treatment solutions to mitigate environmental impact.

Pyrometallurgy, a long-established industrial method used by companies like Umicore and Glencore, offers the advantage of processing entire batteries without prior dismantling. Yet, it performs poorly from an environmental perspective: high CO_2 emissions (~2200 kg/ton), high energy demand (~1500 kWh/ton), and relatively low metal recovery (~60%), with significant lithium losses in the slag.

In contrast, direct recycling is increasingly viewed as the most promising long-term solution. By preserving the chemical structure of active materials - such as $LiCoO_2$ or NMC - it enables their reuse at lower costs and energy requirements. It also delivers excellent performance in key areas: up to 95% recovery efficiency, minimal CO_2 emissions (~300 kg/ton), and low-temperature processing. However, it is still in the early stages of development, facing major challenges such as material variability, the need for precise dismantling and separation processes, and the lack of industrial infrastructure.

To accelerate the advancement of direct recycling, research and innovation efforts should focus on battery standardization, the development of automated dismantling technologies, efficient separation and regeneration methods for cathode materials, and increasing tolerance to the variability of spent batteries. Additionally, integrating direct recycling into existing supply chains through public-private partnerships will be crucial.

From a policy perspective, accelerating the transition toward sustainable battery recycling requires coordinated action between authorities and industry. Key measures include investment in local recycling infrastructure, fiscal incentives for companies adopting emerging technologies, and clear regulations on battery ecodesign - especially regarding material and component standardization. Setting ambitious

material recovery targets and fostering international cooperation - particularly between the European Union and China - could further harmonize technical standards and support the rapid deployment of the most efficient technologies globally.

In conclusion, hydrometallurgy currently offers the best trade-off between environmental responsibility, material recovery, and industrial feasibility, while direct recycling holds strong long-term potential. Unlocking this potential, however, will require a sustained, cross-sectoral effort in research, innovation, and policy development.

STUDY OF MICROBIOLOGICAL STATUS OF SOILS IN BEECH PLANTATIONS

Bilyana GRIGOROVA-PESHEVA, Yordan IVANOV

University of Forestry, 10 Kliment Ohridski Blvd, Sofia, Bulgaria

Corresponding author email: b.pesheva@ltu.bg

Abstract

The main objective of the study is to investigate the microbiological status of soils in beech plantations of the first and second site index. Ten soil profiles were established in ten test areas with beech plantations. The study includes an analysis of the main physico-chemical and microbiological parameters of the ten soil profiles. In each test area, the site index, relative stocking and the average volume (m^3/ha) of the plantation was determined. The studied soils are of the Cambisols, Regosols and Rendzinas type. Soil samples were taken from the A and B (C) horizons. Basic indicators related to soil microorganisms were studied - humus (%), org.C mg/kg^{-1}, pH and mechanical composition. For determination of total microbial number and the amount of individual microbiological groups (bacteria, actinomycetes and fungi), the standard method of serial dilutions and subsequent inoculation was used. The results are reported in Colony-forming unit. A horizon has a greater microbial abundance than the underlying soil horizons, regardless of the considered soil type. There are no clear dynamics in the redistribution of the percentage participation of microbial groups at depth. There is no clear correlation between the microbial abundance and site index of the plantations. The highest microbial abundance was observed at an altitude above 1300 m (TA9 and TA10). Brown forest soils stand out with the highest average biogenicity. It was found that the percentage of microscopic fungi increases in acidic soils, while their amount in Rendzinas decreases below 1.0 × 10^5 CFU/g dry soil.

Key words*: soil, soil microorganism, forest ecosystems, total microbial number.*

INTRODUCTION

Forest ecosystems are of great importance for the Earth's biosphere, covering more than 1/4 of the land (Keenan et al., 2015). When determining the quality (site index) of the plantation, a number of factors are taken into account: the biological characteristics of the tree species, the rank of the tree in the plantation, the rate of growth, soil conditions, soil microorganisms, climatic conditions, growth space - expressed by the density and fullness of the stand, etc. (Callesen et al., 2006; Uroz et al., 2007; Packham et al., 2012; Kirchen et al., 2017). Tree species have specific requirements for environmental conditions and for soils. Growth and productivity of tree species depend on soil fertility, on the activity and abundance of soil microorganisms (Graham et al., 2016). Microorganisms participate in a number of complex processes of organic decomposition and humus synthesis, which determines their important role in the development and stability of forest ecosystems (Paul & Clark, 1989). Without their active participation, the circulation of substances and providing the ecosystem services by the forests is impossible (Strickland et al., 2009). There are studies that highlight the possibility of microorganisms being used as bioindicators for the state of forest ecosystems, given their rapid response to environmental changes. (Turco et al., 1994; Kennedy & Papendick, 1995; Dick, 1997.) Although there are several studies that consider ecosystem services considering the activity and abundance of soil microorganisms (Fonseca, 1990; Staddon et al., 1999; Zhang et al., 2020), there are still no sufficiently in-depth studies on the interrelationships between the condition of the plantation as reflected by its site index and the microbiological status of the soils, as their main characteristic.

The present study represents the pioneering analysis of main characteristics and microbiological status of the soils and the site index of beech plantations from the Vitosha Nature Park region.

MATERIALS AND METHODS

For the study, ten test areas (TA) were laid out on the territory of Vitosha Nature Park, Sofia

region, Bulgaria. The selection of Vitosha Natural Park was prompted by the available information on its background levels of pollution despite its proximity to the capital Sofia, making it a suitable site for studies in an ecologically clean environment (Kadinov, 2019; Kadinov, 2021a; Kadinov, 2021b).

In each test area, the tree stand was surveyed, and its site index, relative stocking (RS) and the average volume (AV) (m^3/ha) were determined was determined. Characterization of the soil type was carried out by making a soil profile. The main microbiological parameters of the soil were studied. The TAs are located at an altitude of 910 to 1445 m.

Soil samples were collected from each of the soil profiles for analysis. The samples were collected from the average depth for each of the investigated horizons. An average sample was formed from five points taken horizontally, at the selected depth of the soil horizon. An approximate amount of 1.5 kg was collected for each sample taken.

The soil analysis includes the study of soil parameters related to the microbiological characteristics of the soil and the assessment of site index of the tree plantations. The following soil parameters were studied: org. C content (kg/mg^{-1}) and humus (%) - according to Turin's method; Mechanical composition - Kaczynski's method; pH - potentiometric.

Microbiological analyzes were performed according to all sterility rules. The microbial abundance of each of the investigated samples was determined by determining the total microbial number (TMN) for all horizons. Microbiological analyzes include determination of the main microbiological groups in the soil related to its biogenicity and to the site index of tree plantations - bacteria, actinomycetes and fungi (micromycetes). Inoculation was carried out on appropriate nutrient media: (Nutrient agar for bacteria, Starch ammonia agar for actinomycetes, Čapek dox agar for fungi). Incubation was carried out at a certain temperature and duration for each of the studied groups (for bacteria 48 hours at 24°C, for actinomycetes 7 days at 35°C and for micromycetes - Czapek-Dox agar for 7 days at 30°C. The number of sprouted colonies was determined. The data are presented in colony forming units (CFUs) per gram of dry soil.

Results were statistically analyzed using the StatSoft Statistica 12 software program at 95% significance thresholds. The program was used to compare and search for correlations between the individual parameters studied, based on direct and inverse correlations.

RESULTS AND DISCUSSIONS

All of the studied tree stands have a 100% participation of *Fagus sylvatica*, with the exception of TA1, in which there is 94% participation of *Fagus sylvatica* and a minimum participation of *Carpinus betulus* - 6%. The stand relative stocking (RS) and the average volume (AV) (m^3/ha) were determined, as follows:

- TA1-1.49 relative stocking; 628 m^3/ha average volume;
- TA2-0.90 relative stocking; 375 m^3/ha average volume;
- TA3-0.99 relative stocking; 493 m^3/ha average volume;
- TA4-1.19 relative stocking; 580 m^3/ha average volume;
- TA5-0.82 relative stocking; 422 m^3/ha average volume;
- TA6-1.07 relative stocking; 619 m^3/ha average volume;
- TA7-1.26 relative stocking; 569 m^3/ha average volume;
- TA8-1.29 relative stocking; 565 m^3/ha average volume;
- TA9-1.11 relative stocking; 472 m^3/ha average volume;
- TA10-1.09 relative stocking;618 m^3/ha average volume.

Table 1 and Table 2 present the results of the conducted research. A total of 10 soil profiles were investigated. Of them, TA7 and TA1 were defined as Regosoli, TA 2 and TA 6 as Rendzini, and TA3, TA4, TA5, TA8, TA9 and TA10 as Cambisols. The main microbiological groups - and the total microbial number was calculated (Table 2).

Data was statistically processed, and the standard deviation is presented. A statistical analysis of the relationship between the TMN of the upper soil horizon and the underlying soil horizon with respect to altitude was performed

without considering soil type (Figure 1 and Figure 2).

Correlation was performed to follow the dynamics of microbial communities in height. Statistical processing of results was also performed to detect potential interrelationships between microbial abundance and environmental factors.

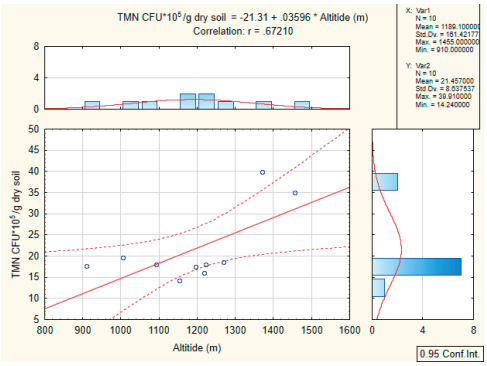

Figure 1. Correlation TMN of A horizon and altitude

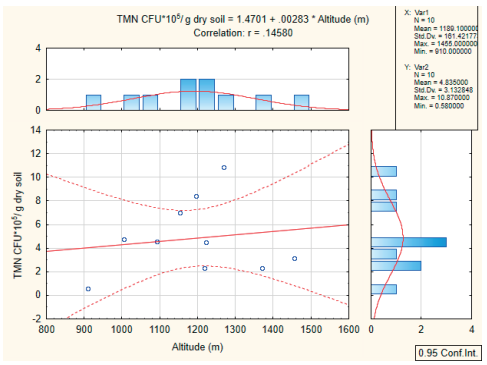

Figure 2. Correlation TMN of B horizon and altitude

Soils from TA1 and TA7 are defined as Regosols. The soil of TA7 is highly acidic, and that of TA1 is moderately acidic. According to the specified levels of Org. C, the considered A horizon of soils of the Regosols type are defined as moderately stocked with organic matter. With an increase in the depth of the soil profile, however, at TA7, a sharp drop in the humus content, respectively, in the amount of org. C and the stock is determined to be very low. In contrast to TA7, in TA1 in the depth of the soil profile, the amount of organic matter does not decrease so sharply, although it falls to class II - low stocking according to the Vanmechelen scale (Vanmechelen et al., 1997). In terms of mechanical composition, both considered profiles have a predominant dust fraction. The soils have a reduced volume of pore spaces and a lack of well-formed aggregates, which leads to a lack of an optimal water-air regime.

Soils from soil profiles TA2 and TA6 are classified as Rendzinas. In these soils, the pH is much higher, and in TA2 soil has a neutral reaction, and in TA6 it has an alkaline reaction. The humus content in the A horizon is lower than the considered Regosols (TA7 and TA1), but in contrast to them, it decreases smoothly in the depth of the soil profile. According to the content of organic carbon, the soils of TA2 are averagely stocked throughout the depth of the soil profile. At TA6, in the humus accumulative horizon, the quantities of organic matter are of class 3 (medium stock), while in depth they pass into class two (low stock). These soils are defined as fine dust. This mechanical composition characterizes the studied Rendzinas, as soils with poor plasticity and stickiness that cannot form stable soil aggregates. In these soils, the pore space is

reduced, leading to a reduction in the air content of the soil.

The remaining soil profiles (TA3, TA4, TA5, TA8, TA9 and TA10) are defined as Cambisols. All soils are defined as acidic, and with increasing altitude there is an increase in acidity due to natural acidification processes. In the overlying humus accumulative horizon, there is an average amount of organic matter for all studied profiles, except for TA9, where the organic matter has a lower content and defines the soil as class two (low amount of organic C) according to Vanmechelen scale. The mechanical composition is diverse. Soil from TA3 is dusty. The soil of TA5 is defined as a fine dusty A horizon and a clayey dusty Bw horizon. The soil of TA8 is defined as fine dust. The soils of TA9 and TA10 are sandy-dusty. The diversity in the mechanical composition of the studied Cambisols shows the influence of the environment and the soil-forming rock on the formation of these soils.

In all soils studied, the microbial abundance decreases in depth of the soil profile. This decrease in total microbial abundance at depth is due to reduced levels of organics as well as altered water–air regimes, as found in the studies of Fierer et al., 2003 and Tripathi et al., 2018. In their study, Taylor et al., 2002 indicates that in the deeper soil horizon there is an absence of microscopic fungi. No such trend was found in the present study. The present study found varying degrees of reduction in microbial abundance in different soil types. Thus, in Regosols and Rendzinas the decrease is much sharper than in Cambisols.

The soils of the Cambisols type stand out as the richest in microorganisms, with an average total microbial number 23 x 10^5. Soils with a sandy-dusty mechanical composition are characterized by greater microbial abundance. No correlation was established between the mechanical composition of the soils and the site index of the stands. There is no clear statistical correlation between humus content and pH. Like the current research, Cho et al., 2016 found that pH, as the only factor considered, did not significantly affect microorganisms' diversity. Furthermore, Lauber et al., 2009 proved that pH is not a sufficient factor to assess the status and diversity of soil microorganisms.

A high correlation coefficient was observed between the increase in total microbial numbers and the increase in altitude ($r = 0.70$), and similar conclusions were generated in the study of Siles & Margesin 2016. In all studied soil profiles, regardless of soil type, the dominant group is bacteria. In highly acidic soils (TA4 and TA7), the percentage participation of the group of fungi increases and reaches over 30% of the total microflora. Looking again at the pH data, the influence of this parameter on the number of microscopic fungi is clearly seen. The neutral and slightly alkaline pH of Rendzinas encourages the development of microscopic fungi, with their levels falling below $1*10^5$. There is no relationship between total microbial number and site index of the stands. No correlation was found between the percentage distribution of microbial groups and the quality site index of the stands.

Further studies of soil parameters are needed to determine which parameters influence the site index of the stands.

CONCLUSIONS

The present study aimed to investigate the microbiological status of soils in beech plantations. There is no clear dynamic between the site index of the stands and the studied soil parameters. No direct correlations were found between stand quality and microbiological characteristics. A decrease in microbial abundance in depth was found in all studied soil profiles. The soils of the Cambisols type stand out as the richest in soil microorganisms. There is no clear correlation between soil characteristics and microbial abundance, regardless of the horizon considered. A positive correlation ($r = 0.70$) was found between increasing total microbial numbers and increasing altitude. Soils above 1,300 meters are characterized by a higher number of microorganisms per gram of soil. The forest and the soil as an element of forest ecosystems are a specific complex, for the understanding and tracking of its functioning, in-depth studies are necessary. We recommend investigating the average content of the total microflora for the entire depth of the soil profile and to look for interrelationships between the microbial abundance and the condition of the stands,

expressed by their site index. We recommend surveying an average sample of the entire stand area, by sampling at least 20-25 points at a depth of 1 m, because soil profiles are likely to reflect the local situation. Microorganisms are a fundamental part of forest ecosystems. Their study and the new information generated can be used to develop strategies and practices for sustainable forest management. Given the important role that soil microorganisms play in the cycling of substances in forest ecosystems, it is necessary to conduct in-depth studies of soil microflora in order to maintain forest massifs in an environmentally friendly manner. Further studies are needed to establish possible interrelationships between environmental factors, soil characteristics, stands site index and soil microbial abundance. The present study can serve as a baseline for future studies.

Abstract

Hydrogen Sulfide (H2S) gas leaks are a serious threat to communities near industrial sites, endangering health and the environment. While safety technology has improved, a community's ability to respond effectively depends on how well-prepared people are. This review dives into what shapes community behavior during H2S emergencies, drawing from global research and a study in Assaluyeh and Nakhl Taghi, Iran. We found that understanding risks, trusting local authorities, and clear communication are key to safe responses. Our data shows notable differences in safety behaviors, especially tied to where people live, revealing gaps in awareness and training. We call for community-focused plans with better education, open communication, and practical training to empower people, reduce risks, and build stronger, safer communities worldwide.

Key words: *H_2S gas leak, emergency preparedness, community safety, behavioral factors, risk communication.*

INTRODUCTION

The pervasive threat of H_2S in industrialized regions

Hydrogen sulfide (H_2S) is a colorless, toxic, and flammable gas recognized as one of the most significant industrial pollutants and environmental health hazards (Talebi, 2020). At low concentrations, it produces a distinct "rotten egg" odor that serves as a simple warning; however, at higher and more dangerous concentrations, olfactory fatigue occurs rapidly, making H_2S a true "silent killer" (Beauchamp et al., 2020; Public Services and Procurement Canada, 2023).

H_2S is primarily produced through the anaerobic decomposition of organic matter and is commonly present in industries such as crude oil and natural gas extraction and refining, wastewater treatment, and geothermal energy production (OSHA, 2015; Talebi, 2020).

Accidental or chronic releases of H_2S pose serious health risks, ranging from acute respiratory and neurological symptoms to rapid death at high concentrations (Beauchamp et al., 2020; Ng et al., 2019).

Beyond its direct health impacts, H_2S also contributes to environmental acidification and the deterioration of infrastructure and ecosystems (WHO, 2003). The global expansion of carbon-based energy industries and infrastructure, particularly in resource-rich regions, has further increased community exposure risks, underscoring the urgent need for robust emergency preparedness and effective community-based response strategies (Brahmia & Mannai, 2025).

The indispensable role of community preparedness in disaster mitigation

Although advanced engineering controls and strict industrial safety practices are the primary strategies for mitigating H_2S risks, the readiness and resilience of local communities ultimately determine the success of disaster management efforts (Batterman et al., 2023). Contemporary approaches to disaster management increasingly draw on sociotechnical systems theory, which emphasizes that human behaviors, attitudes, and interactions within a system are as critical as technological safety measures (Legator et al., 2001; Leveson, 2012). Community preparedness is a proactive, multilayered process that includes understanding risk and vulnerability factors, interpreting complex warning systems, identifying safe evacuation sites, and acquiring basic first aid and self-protection knowledge

(Lacher, 2024). Rapid and effective behavioral responses to alarms during an H_2S release are crucial and can significantly reduce exposure, injuries, and fatalities (Woodcock & Au, 2013). This paper emphasizes that community safety behaviors are not passive outcomes but active, dynamic components of industrial disaster resilience, requiring targeted interventions and continuous engagement with human factors (Siegrist, 2000; Wyche Etheridge et al., 2022).

Aim and scope of this critical review

This review aims to synthesize recent, comprehensive insights into community safety behavior in the context of H_2S gas leak emergencies. It focuses on the multifaceted determinants that shape how individuals and communities perceive, anticipate, and respond to such hazardous incidents. The review systematically integrates evidence from the broader scientific literature, including industrial safety, environmental health, behavioral psychology, human factors engineering, and disaster management. Additionally, it is enriched by empirical evidence from a study examining safety behavior in the local populations of Nakhl Taghi and Assaluyeh counties in Bushehr Province, Iran, regions characterized by extensive oil and gas industry activities and associated H_2S risks (Talebi, 2020). By identifying common challenges, evaluating effective practices, and highlighting persistent gaps in preparedness and response systems, this article seeks to provide practical recommendations to enhance public health safety and strengthen emergency response capacities in industrial environments vulnerable to H_2S hazards worldwide.

MATERIALS AND METHODS

Study Design and Scope

This critical review employed a dual-method approach to synthesize evidence on community behavioral responses to H_2S gas leaks:

1. A systematic literature analysis of peer-reviewed studies (2000–2025) focusing on H_2S preparedness, risk perception, and community behavior.
2. Empirical validation using region-specific survey data from high-risk industrial zones in Assaluyeh and Nakhl Taghi counties, Iran.

Literature searches were conducted using Scopus, Web of Science, PubMed, and Google Scholar with the keywords: "H_2S leak," "emergency preparedness," "community behavior," "risk perception," and "industrial disasters" (Table 1). Inclusion criteria prioritized studies examining human behavioral factors, sociodemographic influences, and the effectiveness of communication in H_2S emergency contexts.

Table 1. Literature search keywords and strategy

Database	Keywords	Search fields	Filters applied	Results retrieved
Scopus	"H_2S leak" OR "hydrogen sulfide leak" AND "emergency preparedness"	Title, Abstract, Keywords	Peer-reviewed articles, English language, 2000-2025	142
Web of Science	("hydrogen sulfide" OR H2S) AND ("community behavior" OR "risk perception")	Topic (Title, Abstract, Keywords)	Articles, Reviews, English language, 2000-2025	98
PubMed	("H2S" OR "hydrogen sulfide") AND ("industrial disasters" OR "disaster management")	Title, Abstract	Human studies, English language, 2000-2025	76
Google Scholar	"H2S gas leak" AND ("community preparedness" OR "behavioral factors")	All fields	Exclude patents, citations; English language, 2000-2025	96

Notes:

- Search was conducted in January 2025.
- Boolean operators (AND, OR) were used to combine terms for precision and recall.
- Inclusion criteria: Studies focusing on H2S-related emergencies, community behavior, risk perception, or disaster management.
- Exclusion criteria: Non-peer-reviewed sources, studies unrelated to H2S or community response, pre-2000 publications.
- Total unique records after duplication: 412, with 127 meeting inclusion criteria after screening.

Data Collection and Sources

Literature Review

- **Screening**: a total of 412 records were identified, with 127 studies meeting the inclusion criteria after deduplication and relevance assessment (Figure 1).
- **Quality appraisal**: The included studies were evaluated for methodological rigor, risk of bias, and applicability using the Critical Appraisal Skills Programme (CASP) checklists (CASP, 2023).

Empirical Study

- **Survey instrument**: A validated questionnaire assessed safety behavior determinants, including:
  - Risk perception (5-point Likert scale; adapted from Siegrist & Zingg, 2014).
  - Trust in authorities (items derived from Siegrist, 2000).
  - Preparedness actions (e.g., evacuation plans, kit availability; Perry & Lindell, 2003).
  - Sociodemographic variables (age, education, occupation, health status).
- **Sampling**: Stratified random sampling of 680 residents in Assaluyeh (n=350) and Nakhl Taghi (n=330), ensuring proportional representation by distance from industrial sites (<5 km, 5-10 km, >10 km).
- **Ethics**: Approved by University of Tehran IRB (Ref: UT/ENV/2020-87). Written informed consent was obtained.

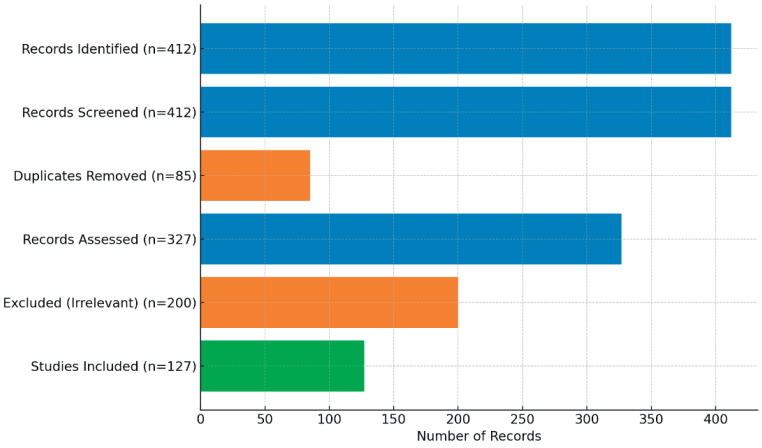

Figure 1. PRISMA flow diagram for literature screening

Data Analysis

- **Quantitative analysis**: survey data were analyzed using multiple linear regression to identify predictors of safety behavior (SPSS v28). The key model was specified as in eq. 1. Covariates included age, education, occupation, and health status. Multicollinearity was assessed using variance inflation factors (VIF), with all values below 2.5 indicating acceptable levels.

$$\text{Safety Behavior} = \beta_0 + \beta_1(\text{City}) + \beta_2(\text{Distance}) + \beta_3(\text{Risk Perception}) + \cdots + \epsilon \quad (1)$$

- **Qualitative synthesis**: a thematic analysis of the literature was conducted using NVivo 12 to identify recurring gaps, including training deficits and communication barriers, within the context of community preparedness and H_2S emergency response.

Integration Framework

Findings from literature and empirical data were triangulated using a **sociotechnical systems lens** (Sasou et al., 1996), evaluating interactions between:

1. *Technical factors* (warning systems, monitoring tools).

2. *Human factors* (risk perception, trust, demographics).
3. *Organizational factors* (policy, community engagement).

Limitations and Mitigation

- **Cross-sectional design** limits causal inference; future work should adopt longitudinal tracking (Barnett et al., 2023).
- **Geographical specificity**: Findings from Assaluyeh/Nakhl Taghi may not generalize globally; contextual factors were explicitly discussed (Keshmiri et al., 2018).
- **Self-reported data**: Potential recall bias was mitigated via pilot-testing instruments and anchoring responses to recent drills.

RESULTS AND DISCUSSIONS

1. Understanding H_2S Exposure and Its Multifaceted Health Impacts

1.1. Characteristics, exposure pathways, and mechanisms of toxicity on H_2S

Characteristics: hydrogen sulfide (H_2S) is a colorless, flammable, and toxic gas that emits a distinct "rotten egg" odor at low concentrations. At higher concentrations (>100 ppm), olfactory fatigue occurs rapidly, leading to an inability to detect its odor, which is why H_2S is often referred to as a "silent killer" (Beauchamp et al., 2020; Public Services and Procurement Canada, 2023).

Physical properties: H_2S is denser than air, allowing it to accumulate in low-lying areas and enclosed spaces, such as trenches and industrial environments, thereby increasing the risk of exposure (Public Services and Procurement Canada, 2023).

Exposure pathway: the primary route of exposure is inhalation, through which H_2S is rapidly absorbed across alveolar membranes into the bloodstream (Beauchamp et al., 2020).

Toxicity mechanism: once absorbed, H_2S inhibits cytochrome c oxidase (Complex IV) in the mitochondrial respiratory chain, disrupting cellular respiration and leading to cellular hypoxia. This mechanism causes rapid systemic effects, particularly in organs with high oxygen demands, such as the brain, heart, and lungs, potentially resulting in critical organ failure (Batterman et al., 2023; Ng et al., 2019; Lewis & Copley, 2015).

Long-Term effects: prolonged or sub-lethal exposure to H_2S can induce oxidative stress, inflammation, and cell death, which may contribute to long-term adverse health outcomes (Rumbeiha et al., 2016).

1.2. Health risks, dose-response relationships, and vulnerable populations

Exposure to H_2S has detrimental health effects that correlate directly with the concentration and duration of exposure (Ng et al., 2019).

- *Low-level chronic exposure* (as low as 0.3 parts per billion) has been associated with mild neurological and respiratory symptoms, including headaches, nausea, and eye and nasal irritation (Legator et al., 2001).
- *Acute moderate exposure* (50-100 ppm) can rapidly induce chest pain, coughing, shortness of breath, conjunctivitis, and keratitis (Beauchamp et al., 2020; Santana Maldonado et al., 2023).
- *High-level exposure* (>500 ppm) may cause severe central nervous system depression, convulsions, unconsciousness, and respiratory arrest, potentially resulting in death (Beauchamp et al., 2020; Lewis & Copley, 2015; Ng et al., 2019).

Certain demographic groups and individuals with pre-existing conditions are particularly vulnerable to H_2S exposure and require targeted protective measures (Talebi, 2020):

- *Children* are more susceptible due to smaller lung capacities, higher metabolic rates, and proportionally larger alveolar surface areas (Talebi, 2020).
- *Elderly people* often have neurological, cardiovascular, or respiratory comorbidities that can be exacerbated by H_2S exposure (ATSDR, 2016; Legator et al., 2001).
- *Individuals with pre-existing conditions*, such as cardiovascular disease, asthma, or chronic obstructive pulmonary disease (COPD), may experience more severe symptoms even at lower exposure levels, as highlighted in studies from Assaluyeh and Nakhl Taghi (Talebi, 2020).
- *Occupational groups* working in high-risk industries with potential H_2S exposure are particularly vulnerable, and their workplace experiences can influence overall community safety practices and perceptions (OSHA, 2005). Developing accurate emergency alerts and preventative measures that are inclusive and

successful across various community segments requires an understanding of these particular vulnerabilities (Ogie et al., 2018).

2. Factors Influencing Community Safety Behavior in Emergencies

Effective community safety behavior in response to H_2S leaks results from a complex interplay of individual cognitive processes, social dynamics, and environmental factors. The empirical study conducted in Assaluyeh and Nakhl Taghi offered valuable real-world insights by systematically examining various demographic and situational factors that influence safety behavior in high-risk industrial contexts (Talebi, 2020).

2.1. Risk perceptions and knowledge

Accurate knowledge of hazards and the subjective estimation of associated risks are central drivers of safety behavior (Siegrist & Zingg, 2014). In the context of H_2S, this includes understanding its odorless nature at hazardous concentrations, its specific health effects, the limitations of odor detection due to olfactory fatigue, and awareness of appropriate first-line protective actions (e.g., moving upwind or uphill, seeking shelter indoors and sealing openings, and activating personal warning systems) (Morgan et al., 2001).

Empirical findings from Nakhl Taghi and Assaluyeh indicate varying levels of knowledge among residents regarding H_2S properties and emergency response strategies (Talebi, 2020). Notably, the significant correlation between “city of residence” and safety behavior suggests variability in risk perception and knowledge distribution, potentially influenced by proximity to industrial areas, prior exposure to industrial incidents, and differing historical exposure levels between the two districts (Talebi, 2020). Groups with a clearer and more precise understanding of specific hazards are more likely to exhibit appropriate and anticipatory safety behaviors during emergencies (Santoro et al., 2023; Siegrist & Zingg, 2014). However, over-reliance on the “rotten egg” odor as an indicator of danger can lead to fatal complacency, highlighting a critical knowledge gap regarding the limitations of sensory detection of H_2S at dangerous concentrations (Public Services and Procurement Canada, 2023).

2.2. Emergency communication and warning systems

Clear, prompt, consistent, and credible communication is the key to effective emergency response (Ogie et al., 2022). Warning systems must be robust, stable, and accessible to all population groups, including vulnerable populations (Karimiziarani & Moradkhani, 2023). Effective strategies necessitate multi-channel communication techniques (e.g., sirens, SMS, local radio/TV, social media, door-to-door warning, community alarm systems) to ensure message penetration and redundancy (Ogie et al., 2022; Tzioutzios et al., 2024). The coherence, specificity, and concision of messages, conveying clear-cut instructions on "what to do", "where to go", and "who to contact", are crucial for triggering appropriate action (Hinsberg & Lamanna, 2024; Woodcock & Au, 2013). Risk communication must also be recognized as an iterative, integrative process throughout the entire risk management stages - preparedness, response, and recovery - calling for openness, participation, and two-way communication to enable informed decision-making and adaptive capacity building (Hinsberg & Lamanna, 2024; Pidgeon & O'Leary, 2000). The variable safety behavior present in the thesis between the two cities could have implicitly shown differences in communication effectiveness or public acceptance of warnings in the two cities (Talebi, 2020).

2.3. Trust in authorities and industry

The baseline level of the community's trust in the government agencies and the nearby industrial sector is an understated but profound determinant of safety behaviour (Siegrist, 2000). High levels of such trust in the community make them much more likely to respond to official warnings, quickly obey evacuation orders, and take voluntary courses in preparedness (Frewer et al., 1996; Siegrist, 2000). Contributing to the development and sustenance of trust are open communication of information, perceived expertise and responsiveness of emergency departments, sustained interaction with the population, and established accountability for past errors or

incidents (Health and Safety Executive (HSE), 2013; Siegrist, 2000). Conversely, prior experience with unresolved problems, expectation of privacy, lack of transparency, or inadequate response to prior incidents can destroy trust, leading to cynicism, delayed responses, or self-imposed non-compliance in a real emergency (Renn & Levine, 1991; Siegrist, 2000). The diversified safety behavior in Assaluyeh and Nakhl Taghi indirectly represents the differences in community-industry/government relations and trust levels in those regions, which reinforce the important role of social capital in crisis management (Behera, 2023; Talebi, 2020).

2.4. Preparedness actions and evacuation behavior

Personal and family preparedness actions are at the heart of community resilience (Lacher, 2024). This includes emergency kit preparations, having family communication plans, establishing safe meeting points, and being familiar with prearranged evacuation routes (Perry & Lindell, 2003). Evacuation decisions are decided by a multidimensional array of factors, including perceived threat severity and proximity, clarity and credibility of directions to evacuate, presence and influence of social networks, and personal resources (Lewis & and Copley, 2015; Shrivastava, 2005). These are barriers to evacuation success and include the absence of transport, caregiving responsibilities (e.g., children or elderly), physical disability, socioeconomic constraints, as well as psychological aspects such as "normalcy bias," where the affected person underestimates the threat and is certain that all would go back to normal (Lewis & and Copley, 2015; Rumbeiha et al., 2016). The thesis, in its general "safety behavior" indicator, indirectly encompasses the dimensions of preparedness behaviors and mentions the role of demographic variables like "number of dependents" and "age" in one's ability or willingness to prepare and evacuate. For instance, individuals with a greater number of dependents will find it more challenging to quickly evacuate, and elderly people will have different mobility problems, which indicates the necessity of inclusive disaster planning (Akama et al., 2014; Talebi, 2020).

2.5. Socioeconomic and demographic factors

Socioeconomic and demographic factors significantly influence individual and collective safety behavior by conditioning access to information, resources, and social networks (Cutter et al., 2003; Legator et al., 2001). Your thesis particularly tested the influence of several such factors, adding empirical validation from the regional context (Talebi, 2020):

- *Gender and age:* both emerged as variables influencing safety behavior, with implications for age- and gender-sensitive communication and training programs (Talebi, 2020).
- *Education level:* a significant influence, with higher levels of education generally linked to better risk understanding, heightened critical thinking, and adherence to safety protocols and emergency instructions (Becker, 2009; Legator et al., 2001).
- *Health status (smoking, chronic illness, medication use):* such health conditions can have direct impacts on one's physical capacity and psychological ability to act effectively in an emergency and demand special planning measures (Ogie et al., 2018; Talebi, 2020).
- *Occupation type, work experience, shift work, second job:* these work-related variables suggest an exploration of whether occupational exposure or experience would translate into general safety awareness and behavior in the broader community. Individuals who work in hazardous industries might have a higher perception of risk or suitable safety awareness that would influence their household's preparedness (Occupational Safety and Health Administration (OSHA), 2005; Talebi, 2020).
- *City of residence (Nakhl Taghi vs. Assaluyeh):* this was the variable most strongly associated with safety behavior (Talebi, 2020). This robust finding highlights that immediate geographical proximity to the industrial complex, coupled with special local policies, community outreach activities, historical exposure to incidents, and socio-economic status within each city, has a dominant and highly localized impact on safety behavior. This highlights the context-dependent nature of preparedness.

3. H_2S Emergency Preparedness and Response Gaps and Challenges

Despite ongoing advancements in industrial safety and emergency management, there are still ongoing and pertinent gaps in fully preparing and enabling communities to respond most effectively to H2S gas releases and other chemical threats.

3.1. Absence of standardized training and drills

The majority of communities residing near chemical hazard sites are seriously short of exposure to routine, standardized, and realistic emergency training exercises specifically targeting chemical releases like H_2S (Santana Maldonado et al., 2023; United Nations Office for Disaster Risk Reduction (UNDRR), 2015). Bystander disaster preparedness training is typically not satisfactory in meeting the unique features of H_2S (e.g., odorlessness in high concentrations, quick onset of bad symptoms, specific ventilation requirements) (Santana Maldonado et al., 2023). Further, the absence of proper public training on H_2S hazards and related protective precautions also increases extensive knowledge gaps, directly hurting proper safety performance (Mileti, 1999). Drills should include escape procedures, shelter-in-place drills, and realistic scenarios in order to create muscle memory and self-assurance (Centers for Disease Control and Prevention (U.S). Center for Preparedness and Response, 2018).

3.2. Inadequate use of local knowledge and participatory approaches

Traditional top-down emergency planning tends to overlook or insufficiently incorporate valuable local knowledge, accessible community social networks, and unique vulnerabilities and assets of affected groups (Atlanta (GA): Agency for Toxic Substances and Disease Registry (US), 2016). This can lead to technically competent but operationally worthless, culturally insensitive, and even unimplementable state plans on the ground (Perry et al., 2001). Effective preparedness demands genuinely participatory approaches where active involvement of community members is made in the risk identification, collaborative plan development, dissemination of information, and feedback so that strategies are feasible to implement, culturally appropriate, and sensitive (Atlanta (GA): Agency for Toxic Substances and Disease Registry (US), 2016; Paton & Johnston, 2006). Disregard of local knowledge can also enhance psychosocial risks among communities who reside in toxic pollution (Couch & Coles, 2011).

3.3. Technological limitations in detection and distribution systems

Although sophisticated H_2S detection systems exist, challenges persist in creating real-time, widespread, and detailed localized monitoring, especially across vast industrial and adjacent residential areas (Morgan et al., 2001; WHO, 2003). Also, providing real-time and focused warning to all at risk, taking into account multiple communication barriers (e.g., language, illiteracy, digital divide, disability), is a significant challenge (Comfort & Haase, 2006; Karimiziarani & Moradkhani, 2023). Obscure warning systems, overreliance on a single mode of communication, or lack of harmonization with smart city systems may lead to vulnerable groups being uninformed or misinformed at moments of high demand (Comfort & Haase, 2006; Elvas et al., 2021).

3.4. Persevering psychological and behavioral barriers

Even with proper knowledge and timely notification, basic human psychological responses can interfere with best safety practice (Rumbeiha et al., 2016). "Normalcy bias" (denial or minimizing of threat), "optimism bias" (sensing personal probability of being harmed as low), "bystander effect," or "panic" (while actual panic is rare, improper conduct can occur) can lead to response delay, maladaptive conduct, or non-compliance (Rumbeiha et al., 2016; Shrivastava, 2005). Neutralizing such widespread behavioral barriers involves not just provision of information but also realistic practice under stress, psychological preparation techniques, and training that aims at the likely exposure to emotional and mental responses to an unexpected, unseen, and lethal threat (Perry & Quarantelli, 2005).

3.5. Policy and regulatory framework gaps

Although industrial emissions, workplace safety, and general disaster management are regulated by law in most nations, policy frameworks specifically addressing general

community emergency preparedness for H_2S and other chemical hazards can have significant gaps (Santana Maldonado et al., 2023; UNEP, 2025). These include the absence of clear mandates for industries to get actively engaged and make financial contributions towards community preparedness activities, defined roles and responsibilities for inter-agency coordination (e.g., between industrial operators, local government, emergency services, and public health agencies), and enforceable standards for risk communication and public education (Santana Maldonado et al., 2023; Tierney, 2025). Moreover, there is sparse scientific monitoring and assessment of environmental and health impacts in communities around long-established industrial facilities, reflecting significant knowledge and policy gaps at national and regional levels (Willis et al., 2018). Inadequate land-use planning around dangerous industrial factories can also exacerbate community vulnerability (Walker, 1991).

4. Future Perspectives and Conclusion

4.1. Towards integrated, community-centric preparedness paradigms

Future effective emergency preparedness for H2S will demand a paradigm shift to synergistic, genuinely community-oriented solutions. This demands integrated synergism of robust technical solutions (e.g., advanced, comprehensive H_2S monitoring networks, hybrid early warning systems), sophisticated human factors analysis (e.g., cognitive ergonomics of signals, behavior-based training on psychological principles), and sophisticated socio-ecological knowledge (e.g., linking to community networks, interpreting cultural matters, reducing social vulnerability) (Legator et al., 2001; Leveson, 2012; Siegrist & Zingg, 2014). Multi-stakeholder collaboration, comprising industry, government departments, emergency services, academia, and not least of all the local communities themselves, is required in a bid to establish common responsibility for resilience and safety (Paton & Johnston, 2006; Siegrist, 2000). Pre-emergent activities like joint drills, scenario planning in unison, and unfettered information sharing can build needed trust and significantly enhance collective response capacities, thus overall preparedness and adaptive capacity of a community (Pidgeon & O'Leary, 2000).

4.2. Leveraging emerging digital technologies for enhanced response

Emerging digital technologies offer game-changing possibilities for transforming H_2S emergency preparedness and response:

- *Predictive analytics & real-time monitoring:* IoT sensors deployed for widespread H_2S sensing, combined with advanced atmospheric dispersion modeling and AI for predictive analytics, have the potential to provide real-time, highly localized risk assessment and hazard mapping (Morgan et al., 2001; Prasad et al., 2024).
- *Customized alerts & communication:* Mobile applications and geo-fencing technologies enable rapid, hyper-targeted alerts to individuals in affected areas, with customized directions based on their precise real-time location and known vulnerabilities (Morgan et al., 2001; Mota et al., 2023).
- *Immersive training & simulation:* Virtual Reality (VR) and Augmented Reality (AR) technologies can offer realistic, safe, and repeatable environments for community members to practice complex emergency response behaviors, e.g., evacuation and shelter-in-place. This addresses the limitations of traditional drills via immersive experiential learning (Perry & Quarantelli, 2005; Srinivasan et al., 2022).
- *Social media & crowdsourcing for situational awareness*: While unofficial, social media can also offer valuable sources of real-time information, citizen reporting, and community sentiment during an emergency. Advanced data analytics can allow emergency managers to rapidly identify emerging needs, identify gaps in resource deployment, and refute misinformation (Elvas et al., 2021; Ogie et al., 2022).

4.3. Imperative research priorities for future advancement

Future research efforts in this critical field should be directed towards:

- *Longitudinal studies:* Investigating the long-term psychosocial and physical health consequences of H2S exposure on residents and the sustainability of safety behavior changes following various interventions (Couch & Coles, 2011; Legator et al., 2001).

- *Culturally sensitive communication:* Developing and rigorously testing communication strategies and warning systems that are not only technologically advanced but also culturally sensitive, linguistically appropriate, and actually resonate with multicultural community segments in H2S-risk zones (Ogie et al., 2018; Tzioutzios et al., 2024).
- *Behavioral economics in safety:* Applying findings from behavioral economics and nudge theory to better comprehend and actively influence pro-safety behaviors and compliance with emergency procedures in high-risk environments (Perry & Quarantelli, 2005).
- *In-depth resilience measurement:* Exhaustively measuring the performance of comprehensive community resilience-building initiatives that are specific to industrial chemical threats, extending beyond preparedness actions (Brahmia & Mannai, 2025; Gisela van et al., 2025).
- *Chronic threat psychological effect:* In-depth exploration of the psychosocial stress and mental health consequences for communities under constant threat of H2S exposure, and the development of community-level coping mechanisms and support systems (Couch & Coles, 2011; Galea et al., 2002).
- *Cost-Benefit analysis of preparedness:* Quantifying the economic and social benefits of robust community preparedness programs versus the cost of inaction in industrial disaster scenarios (Botzen et al., 2019).

CONCLUSIONS

Empirical evidence, supported by findings from Assaluyeh and Nakhl Taghi, demonstrates that adaptive and conscious community safety behavior is a critical pillar for effective emergency response to H_2S gas leaks. The observed variations in safety behavior, particularly influenced by the city of residence, underscore the highly localized, context-dependent, and complex nature of preparedness challenges.

Addressing existing gaps in knowledge, trust, communication, and training requires coordinated, multidisciplinary, and multi-stakeholder efforts. By embracing integrated planning, leveraging advanced digital technologies, and fostering genuine community participation and empowerment, it is possible to create environments where communities near H_2S sources are not only safeguarded by industrial systems but are also equipped to respond promptly and effectively during emergencies.

The overarching goal is to build resilient communities capable of mitigating the human, environmental, and economic impacts of H_2S incidents, thereby ensuring public health safety and promoting sustainable industrial development in high-risk regions globally.

ACKNOWLEDGEMENTS

Abstract

The Stupini mire, proposed as a new Natura 2000 site, is a wetland located in Romania's Bârsa Depression. The site hosts a diverse range of habitats, including alkaline fens (7230), calcareous fens (7210), Molinia meadows (6410), hygrophilous tall herb communities (6430), and alluvial forests (91E0*). This study highlights the ecological importance of the mire and evaluates the impact of recent restoration efforts. Vegetation surveys conducted between 2022 and 2024 confirmed the presence of rare and protected species, such as Swertia perennis and Primula farinose as well as the glacial relict Ligularia sibirica, a species protected under European legislation. However, the rare orchid Liparis loeselii was not detected, raising concerns about its possible local extinction due to drought and habitat degradation. To counteract these threats, restoration efforts focused on reestablishing the hydrological balance and removing invasive species. These measures resulted in a notable increase in the water table, with levels rising by up to 10 cm. The findings underscore the urgency of continued conservation efforts and formal designation of the site under Natura 2000 to prevent further biodiversity loss.*

Key words*: anthropic pressure, climate change, invasive species, rare species, biodiversity conservation.*

INTRODUCTION

At the United Nations Climate Change Conference held in Paris (COP21) the Intergovernmental Panel on Climate Change (IPCC) concluded the need for carbon neutrality by 2050, in order to prevent the rise of global temperatures beyond 2°C. In this respect, several nature-based solutions for climate change mitigation have been proposed, such as sustainable use of forest lands, croplands, wetlands, and grasslands to enhance their potential to store carbon (IPCC, 2021). The proposed solutions align with Aichi Target 15 from Convention on Biological Diversity, committed to restore at least 15% of degraded ecosystems by 2020 (CBD, 2013). They also correspond with the most recent Kunming-Montreal Global Biodiversity, Framework Target 2, which focuses on the restoration of degraded land to enhance biodiversity and ecosystem functions and services (CBD Secretariat, 2022). According to Bossio et al. (2020), soil carbon represents 25% of the potential of natural climate solutions (total potential, 23.8 Gt of CO_2-equivalent per year) and comprises 72% of the mitigation potential of wetlands. As part of the wetland category, peatlands cover only 3% of the global land area but store more carbon than that contained in the world's tropical rainforest biomass (Page & Baird, 2016). Unfortunately, through degradation, peatland carbon sinks are turned into carbon sources (Erkens et al., 2016).

During the past 150 years extensive peatland areas in the temperate and boreal zones have been drained mainly for agriculture. Over 70% of peatlands in Europe have been lost due to agricultural expansion, forestry, and urban development (Raeymaekers et al., 2000). It is

estimated that peatland drainage contributes to 10% of global annual anthropogenic greenhouse gas emissions (Page & Baird, 2016). Thus, a reliable nature-based solution for climate change mitigation is the restoration of natural carbon sinks, such as degraded peatlands. Peatlands are strategic areas for climate change mitigation as their restoration results in safeguarding existing soil carbon stocks (Günther et al., 2020). Apart from their role in carbon storage and sequestration, peatlands deliver a range of ecosystem services, including water regulation, biodiversity protection, natural risk mitigation, food and fuel, and recreation opportunities (Page & Baird, 2016). Only 17% of peatlands are protected worldwide, according to Austin et al. (2025), which is much less than the percentage for many other high-value ecosystems. Thus, we consider it a pressing need to enhance the efforts made for this purpose, in Romania as well.

In order to restore peatland ecosystems services, the Institute of Biology Bucharest of Romanian Academy implemented a range of projects starting in 2015 (with *PeatRo* acronym), financed through the EEA Grants (https://www.ibiol.ro/). Within one of these projects entitled *Degraded mires and peatlands restoration of North-East 1 region of Romania (PeatRO2)* a series of restoration activities were performed in Stupini mire.

Currently, peatlands in Romania lack biodiversity assessment, habitat restoration strategies and a legal framework to protect these sensitive ecosystems. The present study aims to address these gaps for the Stupini mire. Assessment of the reference state of the site, showed an unfavorable conservation status, resulting from a significant decline in the water table, alterations of the characteristic vegetation with the presence of invasive species, and other anthropic pressures. As a result, a comprehensive restoration plan addressing all these factors was made.

In order to preserve in time and space the results of restoration activities, the Stupini mire was proposed as a Special Area of Conservation (SAC) under Natura 2000 Network. The current work first describes the study site and methods, then presents preliminary results on biodiversity and hydrological restoration and provides perspectives to strengthen conservation efforts of the site by including it in the Natura 2000 Network.

MATERIALS AND METHODS

Study site

The mire is situated in the Bârsa Depression, between the Bârsa and Ghimbășel valleys (45º42′3.04″N, 25º32′37.49″E), at an altitude of 560 m a.s.l. with a slight inclination to the north (Figure 1).

The site extends over 9.257 ha and hosts a meso-eutrophic marsh, being a complex formed by meso-eutrophic marshes, reedbeds and sedge communities, alluvial forests and wet meadows.

Vegetation monitoring and data collection

Between 2022 and 2024, botanical surveys were conducted in order to identify plant species, characterize the vegetation, and evaluate the site's conservation potential. For a comprehensive assessment of the site's ecological integrity and long-term vegetation trends, multiple field investigations were carried out throughout the vegetation seasons, providing complementary data on floristic composition and habitat conditions. Transects were made to capture the variability of all habitat types, with at least one transect established for each habitat type. The number and length of transects varied depending on the size and distribution of each habitat within the site.

In April 2022 we surveyed the springs in the floodplain and primarily the aestival aspect of vegetation, taking GPS coordinates and photo documentation at the springs and traces of previous drainage or other anthropic impact. In addition, we listed the flowering species. In July, homogeneous vegetation patches were delineated based on a preliminary map, which allowed us to determine the size of the habitat patches. We also completed the list of plant species.

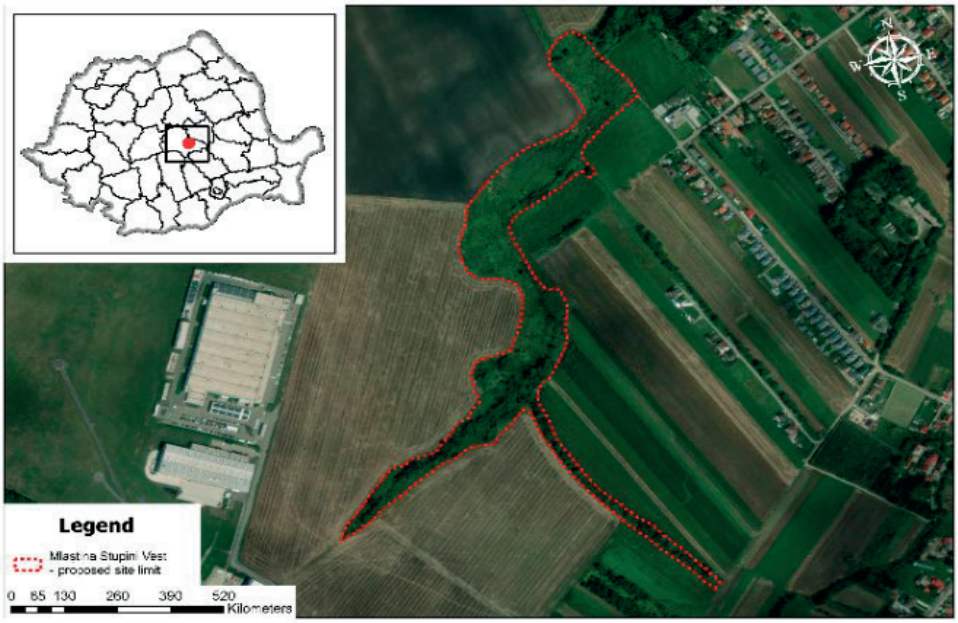

Figure 1. Satellite image of the proposed Stupini mire SAC

In July 2023 and April 2024, further field surveys were carried out to confirm the previously identified species.

Nomenclature for cormophyte taxa follows the Plants of the World Online (POWO) online database published by the Royal Botanic Gardens, Kew, while habitat types and plant associations are given according to Gafta and Mountford (2008).

Restoration Activities

The primary cause of degradation at Stupini mire is water loss due to artificial drainage, which has led to significant habitat alteration. To mitigate this, restoration activities focused on two main objectives: (1) reestablishing water balance and (2) controlling invasive species.

Hydrological restoration

In April 2024, a dam was constructed over the main drainage channel to reduce water loss and restore natural hydrological conditions (Figure 2). The channel, originally straightened and deepened for land drainage, significantly lowered groundwater levels. The dam was designed using a combination of wooden beams, soil, and plant material to mimic natural hydrological barriers. It measured 130 cm in length, 60 cm in width, and 50 cm in depth.

Figure 2. Dam over the main water drainage channel from Stupini mire
(photo by Ana-Maria Moroșanu, 08.04.2024)

Invasive species control

A secondary but equally critical restoration measure involved the removal of invasive species, particularly *Solidago canadensis*, which poses a major threat to native

biodiversity. Invasive plants were manually uprooted along with their root systems to prevent recolonization.

In order to lay the groundwork for creating a legislative framework for the conservation and protection of the Stupini mire, the restoration efforts aimed to improve the site's hydric characteristics. Identification of important species and a continued and improved monitoring strategy will be essential for assessing the stability and effectiveness of long-term restoration initiatives.

Monitoring activities

To assess the effect of restoration activities special devices were placed on site, as follows:

- two Data Loggers (EasyLog EL-USB 2 type), to monitor temperature, relative humidity, and dew point, measured every 30 minutes;
- 5 piezometers (one central and 4 in peripheral position), measured in July 2023 and April 2024.

One of the two data loggers was lost, likely due to its proximity to an urban area, where increased human activity and recreational use make monitoring instruments more susceptible to disturbance. This contrasts with our Norwegian project partner's experience in remote regions of Norway, where such interference with peatland restoration and monitoring is significantly less.

RESULTS AND DISCUSSIONS

Site quality and importance

A vestigial part of the vast marshy areas that covered the Bârsa depression in the past (Pop, 1960), the Stupini mire, although occupying a small area, represents one of the few remaining areas that shelter plant communities of particular scientific importance.

Vegetation surveys revealed that the site hosts several habitats of community importance, included in Annex I of the Habitat Directive, and require special conservation area designation. These habitats are:

- 7230 Alkaline fens, with the plant associations *Orchido-Schoenetum nigricantis,* Oberdorfer 1957, *Caricetum davallianae,* Dutoit 1924 and *Seslerietum uliginosae* (Palongy 1915) Soó 1941 (Figure 3) with an area of 1.2 ha. Their ecological importance lies in their role in sustaining wetland hydrology and providing habitat for rare and specialized plant species and communities, adapted to nutrient-poor, base-rich wetland conditions and dependent upon a constant hydrological regime. These fens act as refuges for numerous orchids, sedges, and bryophytes, contributing to overall ecosystem stability and resilience (Šefferová et al., 2008).
- 7210* Calcareous fens with *Cladium mariscus* (L.) Pohl and species of *Caricion davallianae* Klika 1934 (Figure 4), present on an area of 0.2 ha, forming a rare wetland habitat that depends on stable groundwater levels (Frink et al., 2013).
- 6410 *Molinia* meadows on calcareous, peaty or clayey soils, with the *Molinietum coeruleae* Koch 1926 plant association, with an area of 1.5 ha. *Molinia* meadows are species-rich semi-natural grasslands that support a high diversity of plants; their conservation depends on traditional management, such as mowing or light grazing, to prevent shrub encroachment and maintain their biodiversity value (Ziaja, 2017).
- 6430 Hydrophilous tall herb fringe communities of plains and of the montane to alpine levels with an area of 1.5 ha. This habitat is a species-rich, tall herb community that acts as a biodiversity hotspot along water bodies and offers essential resources for pollinators and wetland species (Joint Nature Conservation Committee, 2013).
- 91E0* Alluvial forests of *Alnus glutinosa* (L.) Gaertn. and *Fraxinus excelsior* L. (*Alno-Padion* ex Medwecka-Kornaś in W. Matuszkiewicz et Borowik 1957*, Alnion incanae,* Pawłowski et al. 1928, *Salicion albae* Soó 1951) with an area of 2 ha. This priority floodplain forest dominated by *Alnus glutinosa* plays a key role in flood regulation and soil stabilisation, and functions as an ecological corridor that supports habitat connectivity within riparian ecosystems (Danci, 2015).

The Stupini site is rich in rare and/or relict plant species such as felwort (*Swertia perennis* L.), the bird's eye primrose (*Primula farinosa* L.), several species of sedge (*Carex davalliana* Sm., *Carex paniculata* L., *Carex lepidocarpa* Tausch, *Carex panicea* J.Carey, and *Carex hostiana* DC.), the black bog-rush (*Schoenus*

nigricans Hoppe), and the brown bog-rush (*Schoenus ferrugineus* Huds.). Also, several species of orchids can be admired in June-July, such as the early marsh-orchid (*Dactylorhiza incarnata* (L.) Soó) (Figure 5), the marsh helleborine (*Epipactis palustris* (L.) Crantz) (Figure 6), and the marsh fragrant-orchid (*Gymnadenia densiflora* (Wahlenb.) A. Dietr.) (Figure 7).

Another important plant species identified in site is *Ligularia sibirica* (L.) Cass., a glacial relict protected under the Habitats Directive, Annex II (Figure 8).

The identified population is relatively small and consists of 15-20 well developed individuals, all in the flowering stage at the end of July. The presence of this glacial relict confirms that Stupini mire functions as a glacial refugia. Fed by cold springs, the site has created conditions for the perpetuation of glacial relict plant species.

During the period 11-14.07.2022, the rare and declining species *Liparis loeselii* (L.) Rich. (fen orchid or yellow widelip orchid, Natura 2000 species code: 1903 was reassessed). The species of community interest was previously identified by one of us at Stupini mire, in 2013 with a population of at least 15 flowering specimens.

Figure 4. Habitat **7210*** with the characteristic swamp sawgrass (*Cladium mariscus*), a priority conservation habitat that persists on only 0.2 ha, making it highly vulnerable to groundwater decline, which threatens its long-term stability and biodiversity
(photo by Attila Mátis, 22.06.2022)

(photo by Anna Szabó, 22.06.2022)

Figure 5. *Dactylorhiza incarnata*, a moisture-dependent orchid, now restricted to the few remaining wet areas as the fen habitat continues to degrade
(photo by Attila Mátis, 14.07.2022)

Figure 6. *Epipactis palustris*, a wetland orchid species that endures in isolated refuges where groundwater flow is still high, but where it faces increasing pressure due to drying habitat
(photo by Attila Mátis, 14.07.2022)

Figure 7. *Gymnadenia densiflora*, an orchid species that persists in the last patches where the groundwater level remains high, threatened by habitat desiccation. It occurs in the habitat 7230 Alkaline fens, within the plant association *Orchido-Schoenetum nigricantis*
(photo by Attila Mátis, 14.07.2022)

Figure 8. *Ligularia sibirica*
(photo by Anca Manole, 25.07.2023)

Unfortunately, not a single specimen of *Liparis loeselii* could be detected in any of the three small fragments of habitat 7230, represented mainly by the plant association *Orchido-Schoenetum nigricantis* Oberdorfer 1957. The absence of the species may be due to the exceptional drought of the year 2022, but there is a bleak possibility that the species completely disappeared because of the continuous drainage activities, and because of water capture from the Lauterbach tributary upstream of the mire.

Unfortunately, because of habitat degradation other rare plant species that require humidity, such as: *Drosera anglica* Huds.*, Pinguicula vulgaris* L.*, Menyanthes trifoliata* L. and *Saxifraga mutata* L. could not be reconfirmed in site.

During the survey, an expansion of the eutrophic species *Carex acutiformis* Brot. was observed consequently with a regression of the *Carex* species characteristic of type 7230 habitat. Thus, only a few bushes of *Carex davalliana* Sm. and *Carex paniculata* L. were detected. In alkaline marshes, the species *Carex lepidocarpa* Tausch and *Carex hostiana* DC. are often abundant, but in this area, they were suppressed by a hybrid between the two mentioned species, *Carex* x *leutzii* Kneuck., a

taxon that has not been reported so far from the Romanian flora (Attila Mátis, Anna Szabó - personal communication, 22 June 2022). This sterile hybrid has pronounced vegetative reproduction, becoming the dominant sedge in the *Orchido-Schoenetum nigricantis* plant association.

Habitats of type 7230 and 7210* are also threatened by the expansion of reed (*Phragmites australis* (Cav.) Trin. ex Steud.), which, facilitated by the lowering of the water table, invades and shrinks habitats characterized by sedge species (Figure 9).

Drought, due to climate change, accentuates the negative impact of drainage channels, water captured from the Lauterbach tributary upstream of the Stupini mire, and the presence of invasive species. These are the main causes of lowering the water level in the substratum and ongoing habitat degradation. As a result, rare species that depend on a high water level in the substratum, such as *Liparis loeselii*, *Drosera anglica*, *Pinguicula vulgaris*, *Menyanthes trifoliata*, and *Saxifraga mutata*, are disappearing.

Figure 9. Habitat 7230 invaded by reed
(photo by Attila Mátis, 22.06.2022)

Although no extensive faunistic inventory was carried out, the house snake (*Natrix natrix* L.) was identified on site and should also be considered for conservation because the species was recently reclassified, according to the study carried out by Kindler et al. (2017). Thus, the range of the house snakes has suffered a significant reduction, and the impact of this change on the conservation of the species has not been assessed.

Preliminary effects of restoration activities

Even though the period between measurements was relatively short (between 20.09.2023, and 08.04.2024), the data from all five piezometers showed that the water table raised 1.5, 3.5, 4.5, 7.5, and 10 cm, respectively. Within the same interval, the maximum temperature value (31ºC) was recorded on 23.09.2023, and the minimum value (-17ºC) on 10.01.2024, with an average of 6.1ºC, during the measurement period. The air humidity recorded a maximum of 97% on 11.08.2023, and a minimum of 25%, on 21.07.2023, with an average of 75.8%. The dew point recorded a maximum of 18.4ºC on 1.08.2023, and a minimum of -18.8ºC, on 10.12.2023, with an average of 1.7ºC (Figure 10).

With implications for comprehending the impact of climatic conditions on water table oscillations and general ecosystem function, these data offer insightful information about the site's environmental dynamics. A warmer climate and altered precipitation patterns are driving changes in peatlands` vegetation, resulting in an increase in vascular plant cover, a decrease in peat moss abundance and an earlier onset of the growing season (Antala et al., 2022). Moreover, shifts in plant phenology result from climate change and can serve as indicators of environmental transformation and species adaptation to evolving conditions (Parmesan & Yohe, 2003; Visser and Both, 2005).

Restoring flooding is the first step in maintaining and conserving specific marsh species that depend on water levels. The importance of water levels is highlighted by Lou et al. (2020). In their survey, they found that over 40 years, water levels decreased, leading to a substantial decline in the abundance of species with higher optimal water levels.

The need for improved monitoring strategies is just as pressing even though Romania's peatlands cover a significantly smaller area compared to those in Norway, for example, which have utilized more complex monitoring methodology. According to Kyrkjeeide et al. (2024), current monitoring efforts in Norway

are limited in geographical and hydro morphological diversity hampering a thorough knowledge of restoration outcomes.

In a comparative study of eight national initiatives, Nordbeck & Hogl (2024) indicates that these strategies are making significant progress in raising awareness and building capacity. However, integrating policies across different sectors remains the main obstacle to effective implementation. The experiences of trailblazing nations provide important insights and a solid basis for developing their own effective, integrated approaches to peatland management and restoration for nations that have not yet established a national peatland policy.

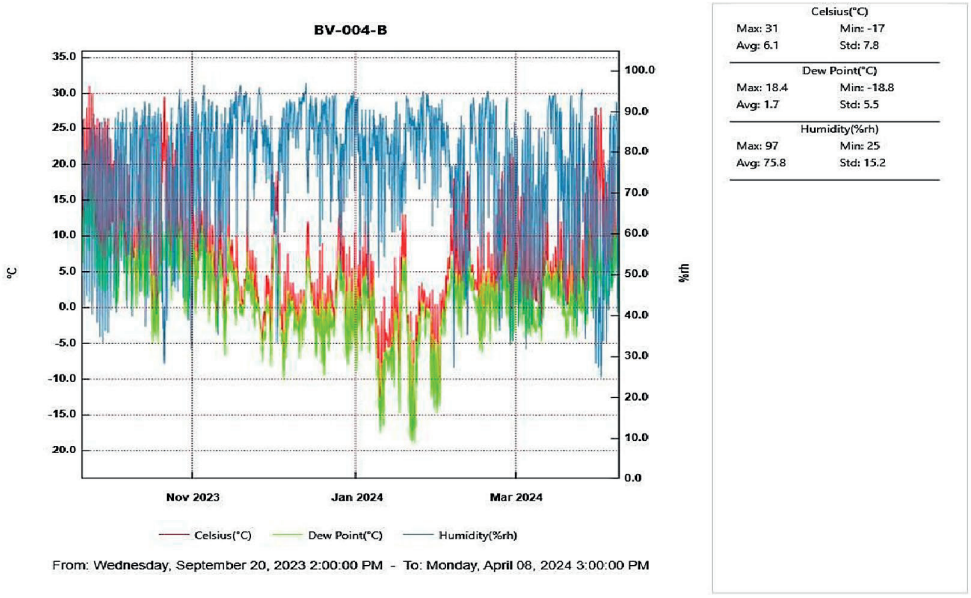

Figure 10. Abiotic parameters of the air recorded in Stupini mire. Most temperatures fall between 0.5°C (25th percentile) and 11.0°C (75th percentile), indicating a predominance of cooler conditions. Humidity values range from 25% to 97%, suggesting significant variation, though most values are above 67.5%. The interquartile range is -1.55°C to 5.3°C, showing that dew points are mostly positive but can drop significantly

CONCLUSIONS

The restoration measures undertaken have contributed to an increase of water table levels, but in order to preserve this result, the Stupini mire must be subjected to additional protection. Assessing the long-term success of the restoration process through continued monitoring of the water table, along with further vegetation surveys, will be essential. The success of future peatland conservation activities will be aided by developing a more comprehensive and varied monitoring strategy, which will guarantee more accurate data and allow future restoration projects to be conducted in an efficient manner.

Considering the species richness of the site, Stupini mire could be considered a biodiversity sink that requires specific conservation measures.

The Natura 2000 Network, composed of SACs designated under the Habitats Directive and the SPAs classified under the Birds Directive, is the central pillar of the Union's conservation policy. Because of their rarity and continuing decline, 13 mire habitat types are included in Annex I of the Habitats Directive. From these, 5 types of habitats were identified on Stupini mire. Also, the presence in Stupini mire of two plant species protected under EU Habitats Directive (*Liparis loeselii* and *Ligularia sibirica*) along with other rare species of the Romanian flora, gives the opportunity to designate this site as SAC under Natura 2000 Network, in order to assure complete legal protection.

THE DEGREE OF THE ROOTING AND ADAPTABILITY OF CORMOFLORA ON THE WASTE DUMPS OF THE BAIA NOUĂ QUARRY (MEHEDINȚI COUNTY)

Mariana NICULESCU, Florina GRECU

University of Craiova, 19 Libertății Street, 200583, Craiova, Romania

Corresponding author email: florina.grecu@edu.ucv.ro

Abstract

The studied area includes the former Baia Nouă quarry mining, which belongs to the Dubova locality, Mehedinți County, an integral part of the Banat Mountains. As part of this work, we tried to carry out an ecological rehabilitation study of the area where all mining operations have been closed for a very long time, the Baia Nouă quarry mining is a ruin, here you can find waste and garbage resulting from the abandonment and degradation of the administrative buildings in the quarry. In order to achieve a good rehabilitation of this area, we took into account the type of native vegetation, existing here and in the immediate vicinity, in order to avoid fragmentation of habitats, as well as the existence of an obvious "desire" of some species to establish themselves and conquer new territories in this area.

Key words*: Baia Nouă, quarry, waste dumps, adaptability, cormoflora.*

INTRODUCTION

Mining activity was known and practised worldwide since ancient times. Human impact exerted in a mining career on biodiversity is smaller or greater and it depends on many factors (Niculescu, 2019). Mining environment issues require a systematic approach and sustainable environmental management techniques must be applied correctly in the mining areas around the world. It is very important to establish principles and strategic elements to ensure sustainable development in a mining quarry. For good ecological rehabilitation in a mining quarry, we must first know the biodiversity existing in that area in all its complexity, including the substrate on which it grows (Niculescu, 2019).

Following mining operations, the so-called mining dumps are formed, consisting of the waste material brought to the surface from underground galleries, which over time require the restoration of the land to useful destinations from an ecological, economic and social point of view through a process of improving the natural capital in the mining pits (Niculescu, 2015).

The ecological rehabilitation of degraded lands and the establishment of a vegetal carpet on waste dumps also play an important role in stabilizing and "greening" these dumps, consolidating the resulting coarse deposits, and restoring the natural landscapes of a mining area.

The restoration of biodiversity from a mining quarry, on the dumps left after exploitation, is indispensable, regardless of where it is located.

The studied area includes the former Baia Nouă mine, which belongs to the commune of Dubova, Mehedinți County, an integral part of the Banat Mountains. This area is particularly important from a geographical, floristic and faunal, landscape, cultural and economic point of view, as the "Portile de Fier" Natural Park is located in this area. As part of this work, I tried to carry out an ecological rehabilitation study of the area where all mining operations have been closed for a very long time, the Baia Nouă mine is a ruin, here you can find waste and garbage resulting from the abandonment and degradation of the administrative buildings in the quarry (Figures 1 and 2).

As a result of mining activity in the perimeter of the former Baia Nouă mining pit, an important area has resulted in which the entire biodiversity has suffered. At the same time, there are still waste dumps made up of course materials (gravel, sand), in the form of mounds on which a pioneer vegetation has settled in a continuous expansion and adapted to the current eco-pedo-climatic conditions, as well as with a favourable coenotic and syndamic

evolution for the restoration of the ecological, bio-conservative balance in the studied area.
The study and knowledge of the degree of restoration and regeneration of the cormoflora and implicitly of the entire biodiversity within the perimeter of the former Baia Nouă mining quarry, where they have undergone profound changes due to anthropo-zoogenic factors resulting both during exploitation and after the quarry's closure, in an area of bioconservative interest, responds to a need of great interest.

MATERIALS AND METHODS

Study area

As mentioned, the studied territory is located within the perimeter of the former Baia Nouă mining quarry in the village of the same name belonging to Dubova locality, Mehedinți County, Romania. During the period 2021-2024, studies were carried out in this area that falls between the following geographical coordinates: 44°56′73,4″N-22°11′59,4″E and 44°56′73,1″N -22°11′58,8″E, the altitude being between 523-517 m (using Geo Tracker – GPS traker application).
Geographically, the former mining quarry is located in the Banat Mountains, in a narrow valley of the Tisovița River, bordered by forest vegetation often installed on quite steep slopes, which extends to the mines exploited in Baia Nouă. The Baia Nouă village is located approximately 10 km from the Danube basin, namely the Porțile de Fier Gorge, being an integral part, as we mentioned, of the "Porțile de Fier" Natural Park (Figure 3).

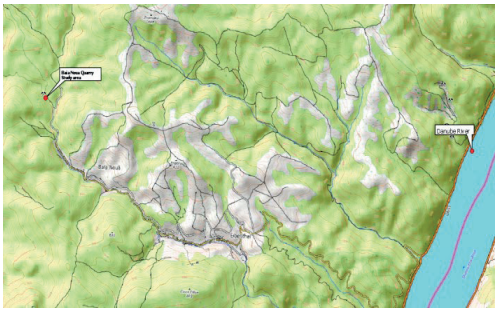

Figure 3. Map of the studied territory - Baia Nouă mining quarry (Mehedinți County)

Floristic and phytosociological analysis

The identification of taxa was based on Illustrated Flora of Romania: *Pteridophyta* and *Spermatophyta* (Ciocârlan, 2000), Romanian Flora (Săvulescu, coord., 1952-1976) and Flora Europaea (Tutin et al., 1964-1980).
For the coenotaxonomic study we used synthesis studies of the following authors Coldea (1991, 1997), Sanda et al. (1997), as well as Oberdorfer (1992), Mucina et al. (1997, 2016), Rodwell (2002).

RESULTS AND DISCUSSIONS

To ensure effective rehabilitation of the area, we considered the native vegetation present locally and in the surrounding vicinity to avoid habitat fragmentation. We also observed the clear tendency of certain species to establish and expand into new territories within the quarry. Field research across the quarry, particularly on the remaining waste heaps, revealed that some plant species exhibited a high degree of rooting ability and adaptability, enabling them to rapidly colonize new areas.

Given these observations, we deemed it essential to conduct a study focusing on these species with high colonization capacity. We classified the identified species based on their rooting ability and adaptability within the former quarry, assigning each species a score from 1 to 10 according to the number of individuals, species ecology, and, most importantly, their rooting, regeneration, and adaptation capacities, as well as the land area occupied (Table 1). These species demonstrated excellent development and vitality on the waste dumps, showing robust growth and successful fruiting without issues. This confirms the area's strong potential for ecological rehabilitation using native species, with natural regeneration holding significant promise. However, realizing this potential requires implementing a green management plan, particularly now that anthropogenic pressures and pollution have decreased following the quarry's closure.

Overall, the conditions within the former quarry are favorable for restoring natural habitats, which can contribute to reducing pollution levels with minimal intervention.

Among the species with notable rooting and regeneration capacities, three are particularly important: *Scleranthus perennis*, *Calamagrostis epigeios*, and *Elymus repens* (syn. *Agropyron repens*).

Scleranthus perennis is a pioneer species that has readily established itself in the area, thriving on skeletal soils.

Calamagrostis epigeios is a perennial species that prefers sandy soils and areas that have experienced disturbance, establishing easily at the base of the dumps or on flat lands surrounding the former constructions of the Baia Nouă mining quarry.

Elymus repens (syn. *Agropyron repens)* is characterized by a broad ecological tolerance, readily colonizing disturbed land surfaces.

A vine species, *Clematis vitalba,* is frequently found within the quarry perimeter, where it is locally dominant as a pioneer species (Figure 4). It primarily establishes on the upper parts of the remaining tailings dumps, occupying significant areas within the study site (Figure 5).

Invasive species have also established within the quarry, with frequent occurrences of *Ambrosia artemisiifolia, Erigeron annuus* (Figure 6), *Galinsoga ciliata,* and *Ailanthus altissima.*

Figure 4. *Clematis vitalba* in the former Baia Nouă mining quarry (photo: M. Niculescu)

Figure 5. *Clematis vitalba* on a waste dump in the former Baia Noua mining quarry (photo: M. Niculescu)

These species demonstrated excellent development and vitality on both soil types, successfully flowering and fruiting without issues. This further confirms the area's strong potential for ecological rehabilitation using native species, with natural regeneration showing great promise. Additionally, anthropogenic pressures and pollution have decreased in intensity within the site.

From a syndynamic perspective, studies indicate that the vegetation on the remaining quarry dumps is progressing towards the establishment of the following plant communities: *Medicagini lupulinae-Agropyretum repentis* Popescu et al. 1980 (Figure 7) and *Medicagini-Festucetum valesiacae* Wagner 1941 (Figure 8).

Figure 6. *Erigeron annuus* in the former Baia Noua mining quarry (photo: M. Niculescu)

The first plant community began to settle in the southern part of the quarry at the base of the dumps, here several phytocoenoses ranging between 10-100 m^2 were observed. The second plant community has settled in the quarry on smaller surfaces, *Medicago minima* as an edifying species frequently occurring alongside *Festuca valesiaca* on stony soils, alongside a well-defined core of species characteristic of this plant community, frequently found in the Tisovița Valley.

Figure 7. *Medicagini lupulinae-Agropyretum repenti s*Popescu et al. 1980 plant community in the former Baia Nouă mining quarry (photo: M. Niculescu)

Figure 8. *Medicagini-Festucetum valesiacae* Wagner 1941 plant community in the former Baia Noua mining quarry (photo: M. Niculescu)

Some species settle at the edge of the forest, next to abandoned buildings in ruins, or within meadow communities with a secondary character, in the floristic structure of ruderal communities, settling on skeletal, on more or less oligotrophic soils, among which we can mention *Teucrium chamaedrys* (Figure 9), *Lysimachia punctata* (Figure 10), *Hypericum perforatum*.

In Tabel 1 the following abbreviations were used:

- Bioforms: Ch – chamaephytes; MPh – megaphanerophytes; H – hemicryptophytes; N – lianas; Th – annual therophytes; TH – biennial therophytes; Hh – helophytes; G – geophytes.
- Floristic elements: Cosm – cosmopolitan; Adv – adventive; Eua – Eurasian; E – European; Ec – Central European; Atl – Atlantic; Med – Mediterranean; Cont – continental; Pont – Pontic; Pan – Pannonian; End – endemic; Balc – Balkan; Carp – Carpathian.
- Ecological indices: U – humidity; T – temperature; R – soil reaction.

CONCLUSIONS

Mining operations result in the formation of mining dumps, composed of waste material brought to the surface from underground galleries. Over time, these areas require restoration to ecologically, economically, and socially beneficial uses through the improvement of natural capital within mining pits.

The perimeter of the former Baia Nouă mining quarry is characterized by significant Anthropogenic impacts, including waste, abandoned structures, and tailings dumps. However, studies on the bio-ecological rehabilitation of this area have shown that it has gradually undergone natural restoration over several years.

Ruderal vegetation and native plant communities have established on the waste dumps, demonstrating good dynamics and progression. Surveys identified 49 cormophyte species with high capacity and affinity for colonizing and stabilizing these disturbed areas. Among these, several species can form primary or secondary plant communities within the mining landscape.

Two meadow-specific plant communities have developed a well-defined coenotic structure and strong synanthropic relationships, allowing them to expand into larger areas. Given that the study area is part of the "Iron Gates" Natural Park, the restoration of the plant communities *Medicagini-Festucetum valesiacae* Wagner 1941 and *Medicagini lupulinae-Agropyretum repentis* Popescu et al. 1980 holds particular importance for the recovery of natural meadow habitats and the conservation of biodiversity in this region.

Abstract

Leonardo Fibonacci (c. 1170 - c. 1240-1250), an Italian mathematician often regarded as the most gifted European mathematician of the Middle Ages, played a crucial role in introducing the Hindu–Arabic numeral system to Europe. His seminal work, Liber Abaci (1202), not only promoted this numerical framework but also featured the now-famous Fibonacci sequence - an integer series with deep mathematical properties and widespread applications. This paper explores the mathematical foundations of the Fibonacci sequence, including its recurrence relations, algebraic and matrix representations, and connections to continuous fractions. Furthermore, it examines the relationship between the sequence and the golden ratio (φ), an irrational number often referred to as the "divine proportion". The golden ratio is linked to aesthetically pleasing proportions and appears in various domains such as art, architecture, music, biology, and cosmology. Through historical analysis and illustrative examples, this work highlights the enduring influence of Fibonacci's legacy and the remarkable intersection between mathematical theory and patterns observed in the natural and cultural world.

Key words*: Fibonacci sequence, Fibonacci numbers, golden ratio, irrational numbers, recursive functions, mathematical modelling, patterns in nature, mathematical aesthetics, interdisciplinary applications.*

"Everything that is correct thinking is either mathematics or susceptible to mathematization"
Grigore Moisil

INTRODUCTION

Mathematics, logic, philosophy, astronomy, and cosmology form the foundation of many of the principles, calculations, and models used in contemporary science and daily life. These disciplines have shaped humanity's understanding of the world and continue to provide tools for discovery and innovation.

Among the great contributors to mathematical thought, names such as Pythagoras, Archimedes, Euler, and Fibonacci stand out. Their works laid the groundwork for theories and methods that remain relevant today. One particularly influential figure is Leonardo Fibonacci (c. 1170 - c. 1240-1250), also known as Leonardo of Pisa, a mathematician widely regarded as the most talented of the Western Middle Ages.

Fibonacci was the son of Guglielmo, an Italian merchant and customs official stationed in Bugia (modern-day Béjaïa, Algeria). Accompanying his father on commercial journeys throughout the Mediterranean, Fibonacci was exposed to diverse mathematical practices. It was in Bugia that he encountered the Hindu-Arabic numeral system - a revolutionary system far superior to the Roman numerals then used in Europe.

The name "Fibonacci" is derived from the Latin *filius Bonacci*, meaning "son of Bonacci". The word "Bonacci" likely comes from the Latin *bonus*, meaning "good," suggesting "fortunate son". This name would eventually become synonymous with one of the most elegant numerical sequences in mathematics.

This paper provides an overview of Fibonacci's mathematical legacy, focusing on his introduction of the Hindu–Arabic numeral system to Europe and the presentation of the Fibonacci sequence in his seminal work *Liber Abaci*. It also explores the mathematical properties of this sequence and its connection to the golden ratio - a number that has fascinated mathematicians, artists, and scientists for centuries due to its unique properties and surprising appearances in both natural and

human-made structures (Livio, 2003; Wang & Johnson, 2008; Choi et al., 2023).

FIBONACCI'S MATHEMATICAL HERITAGE

A pivotal milestone in Fibonacci's mathematical legacy was his role in introducing and promoting the Hindu–Arabic numeral system in Europe. This achievement was primarily realized through the publication of his influential work, *Liber Abaci* (The Book of Calculation), in the early 13th century (Beebe, 2009).

It is important to emphasize that Fibonacci's contributions were made in an era without modern computational tools such as calculators or computers. The introduction of an efficient numerical system was therefore revolutionary, facilitating arithmetic operations that were previously cumbersome under the Roman numeral system.

Among the many examples in *Liber Abaci*, Fibonacci included a now-famous problem involving the growth of a rabbit population. This example led to the popularization of the integer sequence that would later bear his name—the Fibonacci sequence. Although Fibonacci did not invent the sequence, his use of it in this context significantly contributed to its recognition and enduring legacy in mathematical literature.

Liber Abacci

Fibonacci employed a unique fractional notation in *Liber Abaci*, using composite fractions in which a sequence of numerators and denominators was written beneath a single fraction bar. A notable example is found in a manuscript preserved at the National Central Library, where Fibonacci lists the numbers 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144, 233, and 377—forming the well-known Fibonacci sequence (Boyer, 1968).

This page, shown in Figure 1, also illustrates how certain digits - particularly 2, 8, and 9 - bear a stronger resemblance to modern Arabic numerals than to their Eastern Arabic or Indian counterparts. While these early numbers are simple to compute or recall, the Fibonacci sequence extends far beyond its initial terms, revealing complex and profound mathematical properties (Sigler, 2002).

Liber Abaci - Latin for "The Book of Calculation" - was published in 1202 and remains one of the most influential arithmetic texts of the medieval period (Devlin, 2012). Although the original edition no longer survives, a revised version was completed in 1227 and dedicated to the scholar Michael Scot. At least nineteen manuscripts containing portions of this work still exist, including three complete versions from the 13th and 14th centuries and nine known incomplete copies dating from the 13th to 15th centuries (Mollin, 2002).

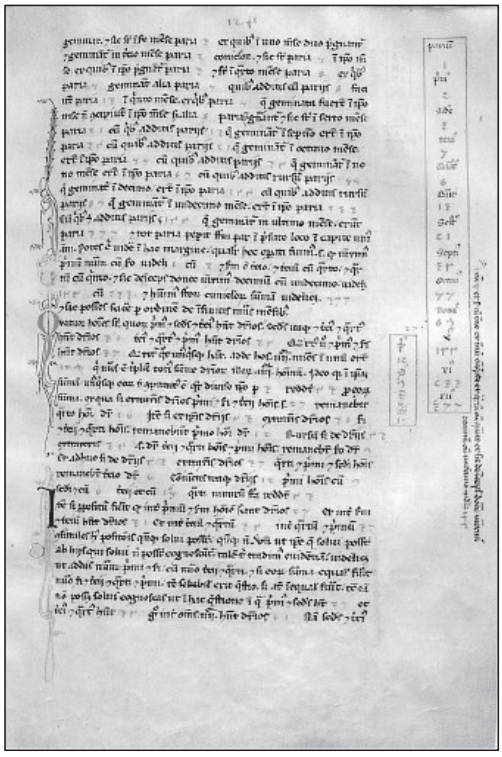

Figure 1. A page from *Liber Abaci*, displaying early use of the Fibonacci sequence and Arabic numeral forms (Pisano & Bussotti, 2015)

The first printed edition of *Liber Abaci* appeared in 1857, translated into Italian by Boncompagni. A complete English translation did not appear until the early 21st century, highlighting the enduring interest in Fibonacci's contributions.

This work is particularly renowned for introducing the base-10 positional system and Arabic numeral symbols to Europe, replacing the cumbersome Roman system. Fibonacci

emphasized the practical superiority of this approach throughout the text.

Beyond arithmetic, *Liber Abaci* demonstrated the widespread presence of Fibonacci numbers in nature. These numbers appear in spiraling arrangements of plant growth, such as sunflower seed patterns, pinecones, and other botanical structures. Similar spirals are observed in non-living systems such as hurricanes, water vortices, and galaxies. Additionally, biological structures like snail shells, nautilus spirals, the cochlea of the inner ear, and even goat horns often follow logarithmic spiral patterns aligned with the Fibonacci sequence.

Significantly, *Liber Abaci* was the first Western book to introduce and promote the Hindu–Arabic numeral system, including symbols resembling modern digits. The work made a compelling case for adopting this new system, explaining its advantages for both theoretical and practical calculations.

Although the title is sometimes mistranslated as *The Book of the Abacus*, Sigler (2002) clarifies that the term *abacus* during Fibonacci's time referred to "calculation" in general, not specifically to the counting device. In fact, in medieval Italy, the spelling *abbacus* (with two "b"s) denoted computations using Hindu–Arabic numerals, thus avoiding confusion.

Liber Abaci outlined techniques for performing arithmetic without relying on the traditional abacus. Ore (1948) noted a long-standing rivalry that persisted after the book's publication—between *algorists*, who promoted the new numerical system, and *abacists*, who remained loyal to the Roman numeral-based counting board.

Mathematics historian Carl Boyer emphasized that *Liber Abaci*, while not a treatise on the abacus itself, is "a very thorough treatise on algebraic methods and problems in which the use of the Hindu–Arabic numerals is strongly advocated" (Boyer, 1968).

The book is organized into four main sections:

- Section I introduces the Hindu–Arabic numeral system, arithmetic operations, and methods for converting between numerical representations. It also includes the earliest known use of trial division for identifying and factoring composite numbers.
- Section II applies arithmetic to commercial problems, including currency conversion, measurements, and interest calculations.
- Section III explores more advanced mathematical topics, such as the Chinese Remainder Theorem, perfect numbers, Mersenne primes, arithmetic series, and square pyramidal numbers. This section also presents the famous rabbit problem, which popularized the Fibonacci sequence.
- Section IV discusses numerical and geometric approximations of irrational numbers, such as square roots.

Notably, *Liber Abaci* contains several Euclidean geometric proofs, revealing Fibonacci's familiarity with classical Greek mathematics. Furthermore, his algebraic problem-solving methods suggest influence from earlier scholars such as the 10th-century Egyptian mathematician Abū Kāmil Shujāʿ ibn Aslam (Mollin, 2002).

Fibonacci's notation for fractions (Moyon et al., 2015)

In reading *Liber Abaci*, it is essential to understand Fibonacci's unique notation for rational numbers. His system represents a transitional form between ancient Egyptian fractions - commonly used up to that time - and the modern fractional notation still in use today. Fibonacci's approach differs from contemporary notation in several keyways:

1. *Order of mixed numbers:* modern notation typically places the fractional part to the right of the whole number (e.g., $2\frac{1}{5}$ for $\frac{11}{5}$). In contrast, Fibonacci wrote the fraction first, followed by the whole number: for instance, he would write "$\frac{1}{5}2$" to represent $2\frac{1}{5}$

2. *Composite fractions:* Fibonacci used a form of composite fraction notation in which a single fraction bar encompassed multiple numerators and denominators. Each term represented a separate fraction, where the numerator was divided by the product of all denominators to its right. For example:

$$\frac{b\ a}{d\ c} = \frac{a}{c} + \frac{b}{cd}, \text{ and } \frac{c\ b\ a}{f\ e\ d} = \frac{a}{d} + \frac{b}{de} + \frac{c}{def}.$$

As a specific example, the fraction, $\frac{27}{30}$ could be represented as $\frac{1\ 1\ 4}{2\ 3\ 5}$, which translates to:

$$\frac{4}{5} + \frac{1}{3{\cdot}5} + \frac{1}{2{\cdot}3{\cdot}5}.$$

This form of mixed radix notation was particularly useful for handling weights, measures, and currencies. Unlike traditional mixed-radix systems that often-omitted denominators, Fibonacci's notation explicitly included them, allowing more precision and adaptability for various practical contexts.

3. *Additive notation:* Fibonacci occasionally wrote multiple simple fractions side by side to indicate their sum. For example, since $\frac{1}{2}+\frac{1}{3}=\frac{5}{6}$, so a notation like $\frac{1}{2}\ \frac{1}{3}\ 4$ would represent the mixed number $4\frac{5}{6}$, or simply the ordinary fraction $\frac{29}{6}$.

This form of notation can be distinguished from composite fractions by a visual break in the fraction bar. Moreover, when all numerators are 1 and the denominators are distinct, the result corresponds to an *Egyptian fraction* - a sum of distinct unit fractions.

Fibonacci sometimes combined additive and composite notations to represent numbers more flexibly. His system allowed for multiple representations of the same value, and *Liber Abaci* includes several methods for converting between these forms.

Notably, Chapter II.7 of *Liber Abaci* features a collection of techniques for expressing improper fractions as sums of unit fractions. Among these is the *greedy algorithm* - a method later referred to as the *Fibonacci–Sylvester expansion* - which selects the largest possible unit fraction at each step to construct the sum (O'Connor et al., n.d.).

Modus Indorum – The Method of the Indians

In *Liber Abaci*, Fibonacci introduces the concept of the *Modus Indorum* - Latin for "method of the Indians" - which refers to what is now known as the Hindu–Arabic numeral system or base-10 positional notation. This system, developed in India and transmitted to the Islamic world, was recognized by Fibonacci for its superior efficiency in calculation and record-keeping.

The text includes a presentation of the nine Indian numerals: 1, 2, 3, 4, 5, 6, 7, 8, 9 and introduces the symbol 0, referred to by the Arabs as *zephyrum* (from the Arabic *ṣifr*), meaning "empty" or "zero". Using these ten symbols, any number can be written through positional value - a concept that was revolutionary in contrast to the Roman numeral system then prevalent in Europe.

Thus, *Liber Abaci* offers not only a practical guide to arithmetic but also a comprehensive introduction to the use of digits 0 through 9, along with the principles of place value, which lie at the core of modern number systems.

Prior to the adoption of this system, Europe relied on Roman numerals, which lacked a symbol of zero and made complex arithmetic operations - such as multiplication, division, and algebraic problem-solving - extremely difficult, if not impossible. As a result, the methods of modern mathematics could not fully develop.

Fibonacci's endorsement of the Hindu–Arabic system marked a turning point in European mathematics. Although *Liber Abaci* was instrumental in initiating this transition, the widespread adoption of the system was gradual and extended over several centuries. As Ore (1948) notes, the process was "long-drawn-out", and it was not until the end of the 16th century that the Hindu–Arabic numeral system became widely accepted across Europe.

Some Mathematical Properties of Fibonacci Numbers

The Fibonacci sequence is a sequence of natural numbers defined by the recurrence relation (Vorobiev et al., 2002):

$$F_1 = 1,\ F_2 = 1$$

$$F_n = F_{n-1} + F_{n-2}, \qquad n \geq 3$$

The recurrence relation has a characteristic equation:

$$r^2 = r + 1$$

Solving this quadratic yields the roots:

$$r_1 = \frac{1+\sqrt{5}}{2} \qquad \text{and} \qquad r_2 = \frac{1-\sqrt{5}}{2}$$

Remark, the first root,

$$\varphi = r_1 = \frac{1+\sqrt{5}}{2}$$

is known as the **Golden Ratio**.

Using these roots, the general term of the Fibonacci sequence can be expressed as:

$$F_n = c_1\left(\frac{1+\sqrt{5}}{2}\right)^n + c_2\left(\frac{1-\sqrt{5}}{2}\right)^n$$

where $c_1, c_2 \in \mathbb{R}$ are the constants.

Applying the initial conditions

$$F_1 = 1, \qquad F_2 = 1,$$

we find:

$c_1 = \frac{1}{\sqrt{5}}$ and $c_2 = -\frac{1}{\sqrt{5}}$,

so, the *general therm* of Fibonacci's sequence is:

$$F_n = \frac{1}{\sqrt{5}}\left(\frac{1+\sqrt{5}}{2}\right)^n - \frac{1}{\sqrt{5}}\left(\frac{1-\sqrt{5}}{2}\right)^n$$

Matrix form

The Fibonacci sequence can also be expressed in matrix form:

$$\begin{pmatrix} F_{n+2} \\ F_{n+1} \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} F_{n+1} \\ F_n \end{pmatrix}$$

If we denote:

$$A = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix},$$

we obtain

$$\begin{pmatrix} F_{n+2} \\ F_{n+1} \end{pmatrix} = A^n \begin{pmatrix} F_2 \\ F_1 \end{pmatrix}, n \geq 1.$$

then:

$$A^n = \begin{pmatrix} F_{n+1} & F_n \\ F_n & F_{n-1} \end{pmatrix}$$

Continuous fractions

The golden ratio can be represented as an infinite continued fraction:

$$\varphi = 1 + \frac{1}{\varphi} = \cdots$$

$$= 1 + \frac{1}{1 + \frac{1}{1 + \frac{1}{1+\cdots}}}$$

Selected identities and properties

1. Relation between φ and Fibonacci numbers:

$$\varphi^n = F_n\varphi + F_{n-1}, \qquad n \geq 1$$

Proof: by induction.

For *n = 2* the equality becomes:

$$\varphi^2 = F_2\varphi + F_1 \Leftrightarrow \varphi^2 = \varphi + 1 \text{ (true).}$$

$n \to n+1$

$$\varphi^n = F_n\varphi + F_{n-1} | \cdot \varphi \Longrightarrow$$

$$\varphi^{n+1} = F_n\varphi^2 + F_{n-1}\varphi =$$

$$F_n(\varphi + 1) + F_{n-1}\varphi = (F_n + F_{n-1})\varphi + F_n$$

$$= F_{n+1}\varphi + F_n$$

Inductive step follows by multiplying both sides by φ and simplifying.

2. Cassini's identity:

$$F_{n+1} \cdot F_{n-1} - F_n^2 = (-1)^n$$

Proof. We consider *m = 1* in the equality from below. A more elegant proof is via matrices.

We consider the matrix $A = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$ which characterizes Fibonacci's sequence and knowing $\det A = -1$ we obtain this identity.

$$A^n = \begin{pmatrix} F_{n+1} & F_n \\ F_n & F_{n-1} \end{pmatrix}$$

3. Catalan's Identity (Generalization of Cassini's):

$$F_{n+m} \cdot F_{n-m} - F_n^2 = (-1)^{n-m+1}F_m^2$$

Proof. By induction, we leave this to the reader.

4. Addition identity:

$$F_mF_{n+1} + F_{m-1}F_n = F_{m+n}$$

Proof. By induction on m,

Example cases:

- m = 2

$$F_2F_{n+1} + F_1F_n = F_{n+2} \Leftrightarrow F_{n+1} + F_n = F_{n+2}$$
(true)

- m = 3

$$F_3F_{n+1} + F_2F_n = 2F_{n+1} + F_n = F_{n+1} + F_{n+2} = F_{n+3} \text{ (true)}$$

$m - 1, m \to m + 1$

Adding the relations:

$$F_{m-1}F_{n+1} + F_{m-2}F_n = F_{m+n-1} \text{ and } F_mF_{n+1} + F_{m-1}F_n = F_{m+n}$$

we obtain:

$$(F_{m-1} + F_m)F_{n+1} + (F_{m-2} + F_{m-1})F_n = F_{m+n-1} + F_{m+n}$$

which gives:

$$F_{m+1}F_{n+1} + F_mF_n = F_{m+1+n}$$

5. Sum identity:

$$\sum_{k=1}^{n} F_k = F_{n+2} - 1$$

Proof. By induction.

For $n = 1$ the equality becomes $F_1 = F_2 = 1$ (true).
$n \to n+1$

$$\sum_{k=1}^{n+1} F_k = \sum_{k=1}^{n} F_k + F_{n+1} = F_{n+2} + F_{n+1} - 1$$
$$= F_{n+3} - 1$$

6. Pythagorean identity:
Every second term in the Fibonacci sequence starting from F_5 forms the hypotenuse of a right triangle:

$$(F_n F_{n+3})^2 + (2F_{n+1}F_{n+2})^2 = F_{2n+3}^2$$

Proof left to the reader.
7. Odd-Index Sum Identity:

$$\sum_{k=0}^{n-1} F_{2k+1} = F_{2n}$$

Proof. By induction. For n=1 the equality becomes $F_1 = F_2 = 1$ (true).
$n \to n+1$

$$\sum_{k=0}^{n} F_{2k+1} = \sum_{k=0}^{n-1} F_{2k+1} + F_{2n+1} = F_{2n} + F_{2n+1}$$
$$= F_{2n+2}$$

8.

$$\sum_{k=1}^{n} F_k^2 = F_n F_{n+1}$$

Proof. By induction. For $n = 1$ the equality becomes $F_1^2 = F_1 F_2 = 1$ (true).
$n \to n+1$

$$\sum_{k=0}^{n+1} F_k^2 = \sum_{k=0}^{n} F_k^2 + F_{n+1}^2 = F_n F_{n+1} + F_{n+1}^2$$
$$= F_{n+1}(F_n + F_{n+1}) = F_{n+1}F_{n+2}$$

EXAMPLES OF THE GOLDEN RATIO IN ARTS AND NATURE

Golden ratio

The *golden ratio* is a special irrational number, denoted by φ, and is defined by the division of a line into two parts (Figure 2), a and b, such that:

$$\frac{a}{b} = \frac{a+b}{a}$$

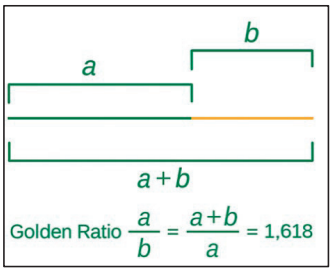

Figure 2. Golden Ratio

Golden Rectangle

A *Golden Rectangle* is a rectangle whose side lengths are in the golden ratio (Figure 3). That is, the ratio of the longer side to the shorter side equals φ.
This geometric figure is known for its aesthetic harmony and has been widely used in art, design, and architecture since antiquity.

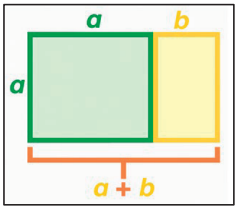

Figure 3. Golden Rectangle

Golden angle

In geometry, the *golden angle* arises when a circle is divided according to the golden ratio (Figure 4). Specifically, it is the smaller of the two angles formed when the circumference is split such that the ratio of the arc lengths is the golden ratio.
Its exact value is:

$$360^o\left(1 - \frac{1}{\varphi}\right) = (3 - \sqrt{5})180^o \approx 137{,}5^o$$
$$= 2\pi(3 - \sqrt{5})\, rad$$

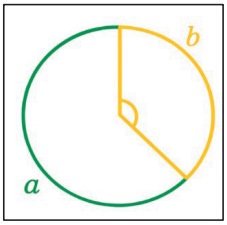

Figure 4. Golden Angle

Golden spiral

A *golden spiral* is a type of logarithmic spiral whose growth factor is equal to the golden ratio φ. Golden spirals are self-similar, meaning their shape remains unchanged under magnification (Figure 5).

The polar equation of a golden spiral is:

$$r = \varphi^{\frac{2\theta}{\pi}}$$

where:

- r is the radius;
- θ is the angle in radians;
- φ is the golden ratio.

More generally, a logarithmic spiral with growth factor B can be written as:

$$r = A\varphi^{B\theta}$$

which can be rewritten:

$$\theta = \frac{1}{B}\log\left(\frac{r}{A}\right)$$

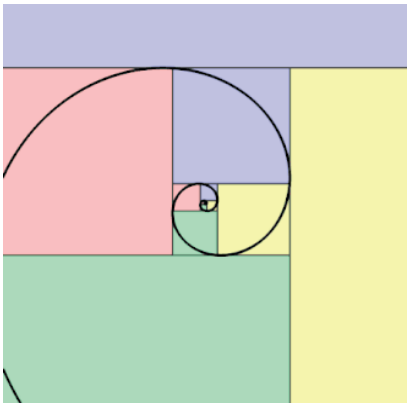

Figure 5. Golden Spiral
(https://en.wikipedia.org/wiki/Golden_spiral)

GOLDEN RATIO IN ARTS

Painting

The golden ratio has played a notable role in the composition of some of the most iconic works of art throughout history. Its presence is believed to enhance visual harmony, balance, and aesthetic appeal, contributing to the emotional and perceptual impact of a painting. Several masterpieces are often cited for their use of this proportion, including: "The Last Supper" and "The Mona Lisa" by Leonardo da Vinci (Figure 6), “The creation of Adam” by Michelangelo, "The Birth of Venus" by Botticelli, "The Starry Night" by Van Gogh, "The Persistence of Memory" by Salvador Dali. In these works, the golden ratio is thought to have guided the spatial arrangement of subjects and background elements, producing a visual equilibrium that resonates with the human sense of proportion and beauty. Artists throughout centuries have adopted the golden ratio, whether consciously or intuitively, as a compositional tool to create visual narratives that are pleasing and memorable. Alongside perspective, symmetry, and contrast, it remains one of the key elements used to achieve artistic coherence.

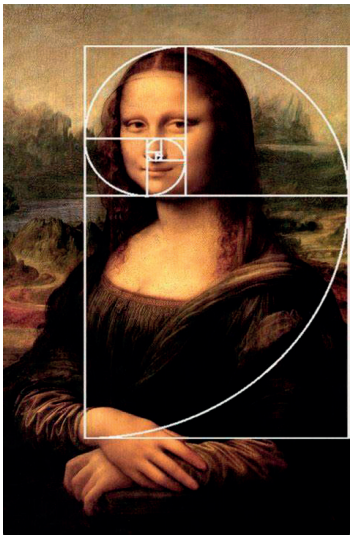

Figure 6. Mona Lisa - a painting frequently associated with golden ratio-based composition
(https://www.bing.com/images/)

Architecture

The golden ratio is also prevalent in architecture, appearing in both ancient monuments and contemporary structures. Long before Fibonacci’s time, this proportion was intuitively employed in designs that were considered naturally harmonious and aesthetically pleasing. Examples of structures often associated with the golden ratio include: The "Pantheon" in Rome (Figure 7), The "Great Pyramids" of Giza (Figure 8).

Architects and builders may have used the golden ratio not just for its beauty but also for structural balance and proportion. In modern times, it continues to inform architectural design

in buildings, bridges, and even furniture, reflecting humanity's enduring appreciation for mathematical harmony in physical space.

Figure 7. Pantheon - a classical Roman example often associated with golden proportions (https://www.bing.com/images/)

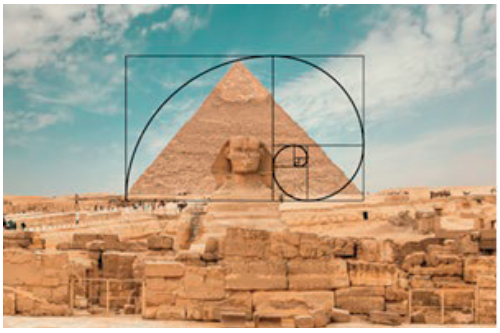

Figure 8. Pyramids - widely analyzed for golden ratio correlations in their dimensions (https://www.bing.com/images/)

Music

The golden ratio has also been observed in the structure and timing of musical compositions. Renowned composers such as Wolfgang Amadeus Mozart, Ludwig van Beethoven, and Claude Debussy are believed to have employed this proportion - either deliberately or intuitively - to shape the form and flow of their works.

For example, in Beethoven's Fifth Symphony, researchers have found structural divisions that align closely with the golden ratio, particularly in the placement of key climactic moments and thematic transitions (Figure 9).

Additionally, the golden ratio has been linked to the design of Stradivarius violins (Figure 10). Studies suggest that certain dimensional proportions in these famous instruments reflect golden ratio principles, potentially contributing to their visual elegance and acoustic excellence.

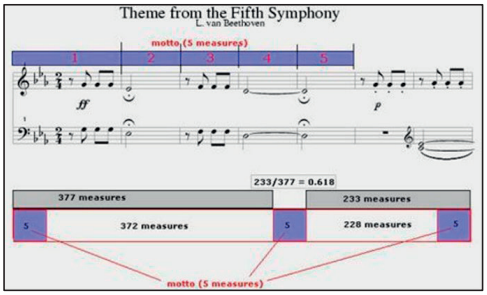

Figure 9. Beethoven's Fifth Symphony - noted for structural divisions consistent with the golden (https://www.bing.com/images/)

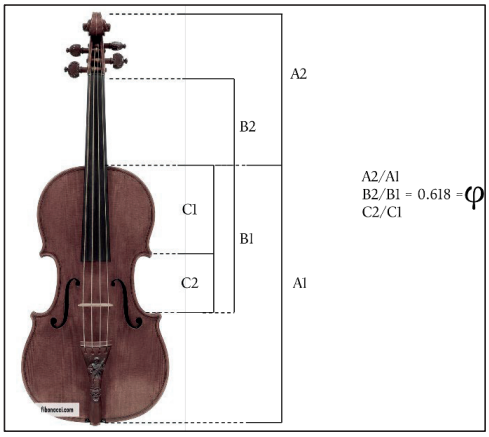

Figure 10. Stradivarius violine - exhibits golden proportions in design (https://www.bing.com/images/)

GOLDEN RATIO IN NATURE

Sunflower seeds

In sunflowers, the seeds located at the center are arranged in spiral patterns that follow Fibonacci numbers (Figure 11). These patterns allow for optimal packing and efficient use of space, maximizing the number of seeds that can fit in each area.

Pinecones

Pinecones frequently exhibit spirals in Fibonacci-related pairs, such as 3 and 5, 5 and 8, or 8 and 13. This form of natural arrangement is part of a broader phenomenon called phyllotaxis - the spiral pattern by which leaves, or other botanical elements are organized around a stem (Figure 12). Similar spiraling patterns are found in the outer petals of artichokes, succulents, and various flower buds.

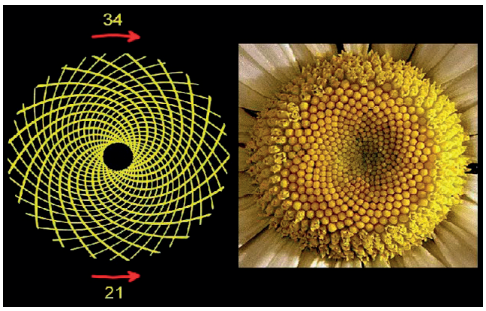

Figure 11. Sunflowers seeds - arranged in spirals that correspond to Fibonacci numbers (https://www.mathnasium.com/blog/golden-ratio-in-nature\)

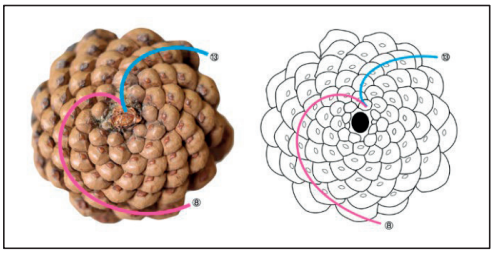

Figure 12. Pinecone with 8/13 configuration (https://craftofcoding.wordpress.com/2022/05/11/fibonacci-and-pinecones/)

Plant leaves

The golden ratio also manifests in the arrangement and structure of plant leaves. To maximize exposure to sunlight, many plants grow their leaves in spiral patterns, minimizing the shadow cast on lower leaves. This spiral spacing often aligns with the golden angle, which helps to optimize photosynthetic efficiency (Figure 13).

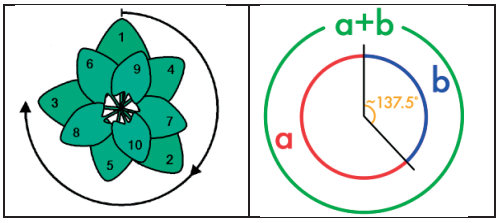

Figure 13. Leaves arrangement - successive leaves are separated by the golden angle (https://www.projectrhea.org/rhea/index.php/MA279Fall2018Topic1_Leaves)

Additionally, internal leaf structures show golden proportions. For instance, the vein spacing in some species approximates the golden ratio, and leaves of the Ginkgo tree often grow with dimensions reflecting this proportion (Figure 14).

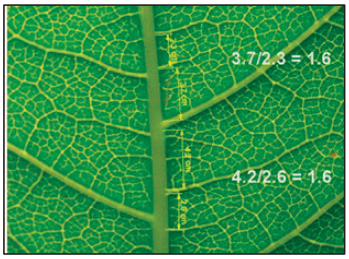

Figure 14. Venation of a leaf - illustrating golden ratio spacing (https://www.projectrhea.org/rhea/index.php/MA279Fall2018Topic1_Leaves)

Nautilus Shells

Nautilus shells are often cited as natural illustrations of the golden spiral, a logarithmic spiral whose growth factor is the golden ratio. As the shell grows, it maintains a consistent spiral shape, exemplifying self-similarity - a key characteristic of golden spirals (Figure 15).

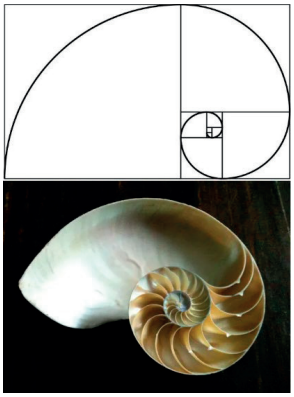

Figure 15. Nautilus shells - a classic example of the golden spiral in nature (https://www.mathnasium.com/blog/golden-ratio-in-nature\)

DNA

The golden ratio appears even at the molecular level. In the structure of DNA, relationships between its geometric features - including the length of a full turn of the helix and the width of the molecule - are often approximated by the golden ratio (Figure 16), suggesting an underlying harmony in the genetic blueprint of life.

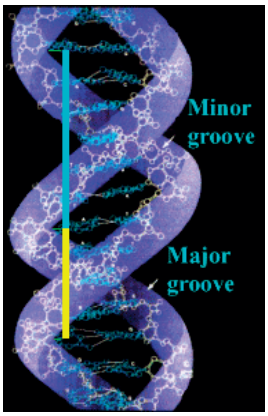

Figure 16. DNA - illustrating proportions that reflect the golden ratio
(https://www.goldennumber.net/dna/)

Fibonacci numbers in tornados, vortices or galaxies?

While many spiral shapes in nature arise from purely physical, non-biological processes - such as whirlpools, vortices in bodies of water, or the swirling formations of hurricane clouds and clear lanes - these spirals do not consistently follow Fibonacci-like patterns in their mathematical structure over time (Figure 17).

It may be possible to capture a snapshot where certain features temporarily exhibit ratios resembling those found in the Fibonacci sequence, but these patterns are neither sustained nor inherent to the structures themselves. In fact, the Fibonacci-like spirals observed in galaxies are more a result of human perception than a fundamental truth of the universe!

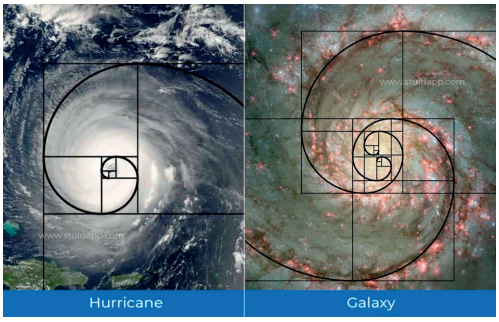

Figure 17. Hurricane and spiral galaxy – natural forms that appear Fibonacci-like, though not mathematically exact
(https://www.bing.com/images/)

CONCLUSIONS

The Fibonacci sequence and the associated golden ratio have long captivated mathematicians, scientists, and artists alike due to their mathematical elegance and their intriguing appearance in a wide range of natural and human-made phenomena.

While their mathematical foundations are firmly rooted in number theory and recurrence relations, their significance extends well beyond abstract theory. In fields such as biology, art, architecture, and music, these concepts often appear - sometimes as a matter of natural optimization, sometimes as a tool for achieving aesthetic harmony.

In nature, the Fibonacci sequence is often observed in plant growth patterns, leaf arrangements, pinecones, and flower petals, where the underlying spiral forms offer practical advantages such as sunlight exposure and space efficiency. The golden spiral appears in natural objects like nautilus shells and hurricanes, though its presence in large-scale phenomena like galaxies is often more interpretive than mathematically precise.

In art and architecture, the golden ratio has been consciously applied to design works that are balanced and pleasing to the eye, from Renaissance masterpieces to ancient monuments and modern constructions. Similarly, in music, some compositions reveal structural proportions aligning with the golden ratio, contributing to their rhythmic and thematic cohesion.

However, it is important to distinguish between intentional use and retrospective attribution. The golden ratio and Fibonacci numbers do not universally govern natural or artistic forms, and their presence is not always exact. In many cases, their appearance is approximate or coincidental and should be appreciated as part of a broader interplay between mathematics and the natural world - not as a universal design code.

In conclusion, the enduring fascination with Fibonacci numbers and the golden ratio lies in their ability to bridge pure mathematics with observable reality. Whether in a sunflower, a symphony, or a spiral staircase, they offer a compelling reminder of mathematical patterns that often underline beauty, function, and structure in both nature and human creativity.

Abstract

To ensure the realization and efficient technical and economic operation of an irrigation system, it is important that, from the design, a correct dimensioning of the network of underground sprinkler irrigation pipes and, respectively, of the pressure station to ensure the necessary flow and pressure on all sections of the network, starting from the calculation of the irrigation regime, is ensured. The paper presents a calculation model for the correct dimensioning of the network of underground pipes within an irrigation plot, applied to the case study of the Fântânele - Sagu plot, Arad County, which takes into account the determination of the diameter of the main, secondary pipes and the antennas in such a way as to ensure the transport of the necessary water flow in each point of the plot and respectively to ensure the pressure necessary for the operation of the mobile watering equipment at all existing hydrants on this network. In the case study, the project for the modernization and retechnology of the secondary irrigation infrastructure is presented of the SPP Fântânele - Sagu plot.

Key words*: antennas, hydrants, irrigation, pipe network.*

INTRODUCTION

Droughts, floods and other climate change-related threats have a significant impact on the stability of agricultural production and food security, and the lack of adequate infrastructure contributes to limiting opportunities for economic development despite the existence of potential in agriculture.

In order to adapt to the effects of climate change, for environmental protection and for reasons of competitiveness, it is necessary to modernize irrigation plots, which ensure the efficient use of water, through the correct technical and economic sizing of underground pipe networks, pressure pumping stations, by using new technologies that lead to a reduction in water and energy consumption at the level of investment.

This is proposed to be carried out within the National Strategic Program 2023-2027 - a program funded by the European Union and the Government of Romania through measures DR-25 (addressed to the OUAI for the rehabilitation and modernization of existing irrigation plots) and DR-26 (addressed to farmers for the realization of new local irrigation arrangements) - Modernization of irrigation infrastructure (AFIR, 2024).

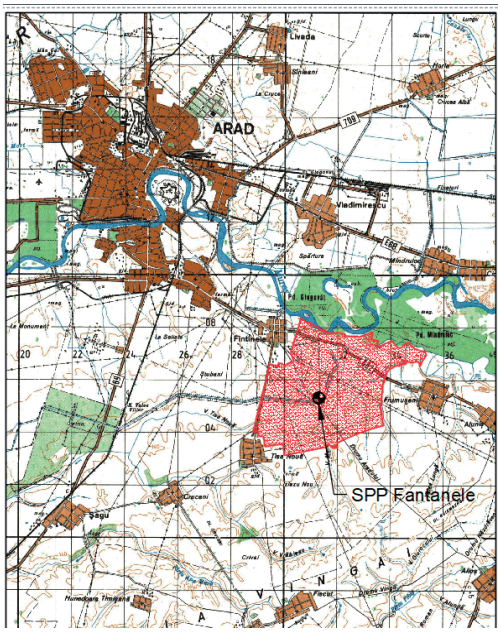

Figure 1. Map of SPP Fântânele, Arad County, Romania

In the process of carrying out these works, it is currently necessary to propose solutions for achieving intelligent irrigation using modern mobile irrigation equipment, as far as possible with automated operation and remote control (from the computer or even from the phone) (Cetin et al., 2023).

Currently worldwide (Biali et al., 2022) there are numerous pieces of equipment that, implemented in projects for the realization of new irrigation arrangements both by sprinkling and by dripping, or for the rehabilitation/ modernization of old arrangements degraded over time, lead to important benefits of labor, water and energy saving. The studied location is located on the administrative territory of Fântânele, Arad County (Figure 1). The plot of SPP Fântânele Sagu is part of the Irrigation Arrangement Sagu Fântânele Arad (Figure 2).

The design of the irrigation system was carried out between 1966 and 1968 on an area of 7154 ha, the entire area being connected to the unique hydrotechnical scheme for this system, with the connection to the Mureș river and served by the adduction channel. The irrigated area is served by means of a floating pumping station, SP floating, located on the left bank of the Mureș River, upstream from Fântânele (ANIF, 2024).

Fântânele pumping station (SPP Fântânele) is located at the downstream end of the Aducțiune I with a length of 2,984 m. It has an installed flow Q=1.45 mc/s and a head of H=70 m with water, necessary for the water supply of the SPP Fântânele plot arranged in the area of 1,914 ha.

Through the technical expertise carried out, it is necessary to replace the pump + drive motors assemblies and the electrical components for control, protection and automation, which present great wear, both physical and moral, due to the more than 50 years from the date of commissioning and non-operation of the irrigation system.

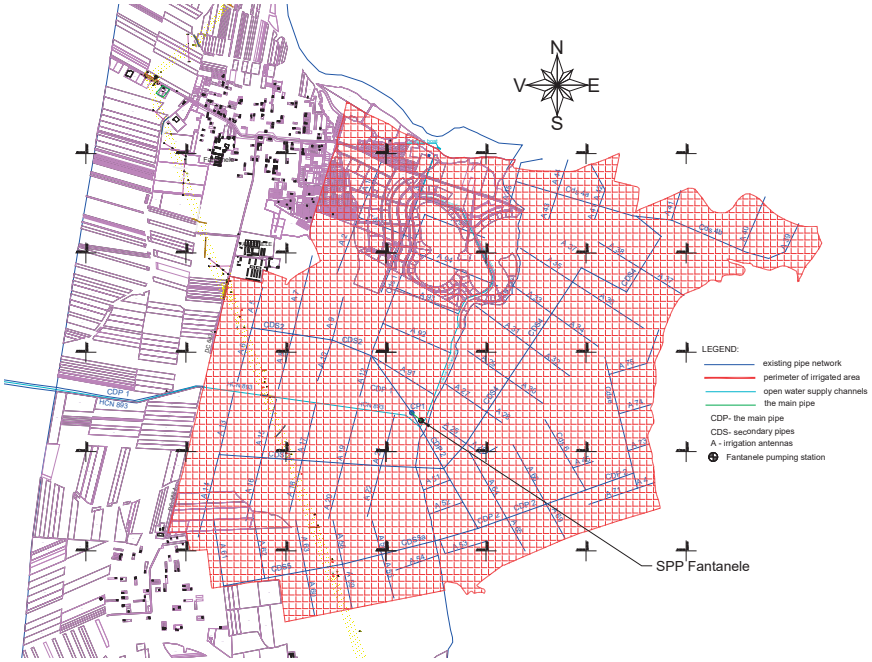

Figure 2. Map of existing irrigation system SPP Fântânele

MATERIALS AND METHODS

The elements of the irrigation regime include: Watering norm (m); Irrigation norm (Ni); Interval between waterings (T); Watering scheme; Irrigation hydromodule and uncoordinated and coordinated watering schedule chart. With these elements, the flow required for irrigation or the flow to be provided by the SPP (necessary to establish the time and number of pumping units) is calculated (Damian

et al., 2022). The calculation relationships of these elements are:

- Irrigation norm is calculated using:

$$m = \frac{N}{\sum n} \quad \left(m^3 / ha\right)$$

where:
N - irrigation norm in (m^3/ha);
n - number of waterings.

- Interval between waterings (or time to recover $T_{i,j}$) is determined using:

$$T_{i,j} = \frac{m}{Epz(luna)} \quad \left(m^3 / ha / day\right)$$

Epz - daily potential evapotranspiration (average water consumption of crops)

- Calculus of watering scheme requires external humidity values W_{min} and W_{max}

$$W_{\min} = 100 \cdot \gamma_v \cdot H \cdot P_{\min}$$
$$W_{\max} = 100 \cdot \gamma_v \cdot H \cdot C_c$$

where:
γ - volumetric weight of soil;
C_c - field capacity (m^3/ha);
P_{min} - minimum humidity ceiling;
H - depth of the active soil layer (m).

- The hydromodulus of irrigation for a rotation is determined with:

$$q_0 = \frac{n_i \cdot m_i}{3.6 \cdot T \cdot t} \ (l / s \times ha)$$

where:
n_i, m_i - the number of waterings, respectively the watering norm for the month of maximum consumption of the crop irrigation season (crop rotation) on the entire surface area (S_{pl});
T - 30 days the duration of surface watering the entire area with the maximum monthly irrigation norm;
T - 20 hours.
The required water flow rate is calculated with the ratio:

$$Q_i = q_i \times S_i \ \left(l / s\right)$$

where:
q_i - irrigation hydromodule (l/s/ha);
m_i - watering norm required by i crop;
T (8-10 days) - total watering time of crop;
t - 20 hours daily watering time;
S_i - i crop occupied area.

- Calculation ratio of the volume of water (V) required for each watering is given by:

$$V = \frac{m \cdot S}{1000 \cdot \eta} \quad \left(\text{k m}^3\right)$$

where:
m - watering norm (m^3/ha);
S - irrigated surface (ha);
η - (watering yield in the field) = (0.85 - 0.90).
The determination of the sizing flow rate of underground pipe networks is based on the theoretical calculation of pressure drops, where in general, Chezy's formulas are used:

$$V = C\sqrt{Ri}$$

Associating the continuity equation is obtained for the flow rate:

$$Q = VS = SC\sqrt{Ri}$$

The hydraulic radius is explained by $R = \frac{S}{P}$ and we obtain:

$$Q = SC\sqrt{\frac{S}{P}i} = \frac{S^{\frac{3}{2}}}{P}C\sqrt{i}$$

Associating the Chezy formula we obtain the flow rate:

$$Q=\text{SC}\sqrt{Ri} = S\frac{1}{n}R^y\sqrt{Ri} = S\frac{1}{n}R^{y+\frac{1}{2}}\sqrt{i} =$$

$$= S\frac{1}{n}\frac{S^{y+\frac{1}{2}}}{P^{y+\frac{1}{2}}}\sqrt{i} = \frac{1}{n}\frac{S^{y+\frac{3}{2}}}{P^{y+\frac{1}{2}}}\sqrt{i}$$

in other words:

$$Q = \frac{1}{n}\frac{S^{1,5+y}}{P^{0,5+y}}\sqrt{i}$$

by substituting with the Manning relation, we obtain:

$$Q = \frac{1}{n}\frac{S^{\frac{5}{3}}}{P^{\frac{2}{3}}}\sqrt{i}$$

For circular pipes we have:

$$Q=\frac{1}{n}\frac{\left(\frac{\pi D^2}{4}\right)^{\frac{5}{3}}}{(\pi D)^{\frac{2}{3}}}\sqrt{i}=\frac{\pi D^{\frac{8}{3}}}{n4^{\frac{5}{3}}}\sqrt{i}$$

flow module is noted:

$$\text{K}=\frac{\pi}{n}\frac{D^{\frac{8}{3}}}{4^{\frac{5}{3}}}$$

hydraulic resistance:

$$\text{M}=\frac{l}{K^2}$$

hence head loss is:

$$\text{h}_r=MQ^2$$

The study method is based on the use of Mike Urban software for hydraulic modeling of the underground irrigation pipeline network and the use of new / modern sprinkler irrigation equipment (DHI, 2024).

RESULTS AND DISCUSSIONS

The solution involves the rehabilitation of the pumping station building, with the replacement of the old pumping equipment with new ones with superior functional parameters, the rehabilitation of the underground network of transmission and distribution pipes with new HDPE pipes. The metering of consumption will be done entirely at the level of the pumping station, fencing (Figure 3)

Irrigation regime - was calculated for corn and wheat crop rotation. In Table 1 we find the calculation of the flow rate and the volume of water needed for sprinkler irrigation of 1857 ha during the vegetation period of one year (dry year). The entire area being cultivated with corn crop.

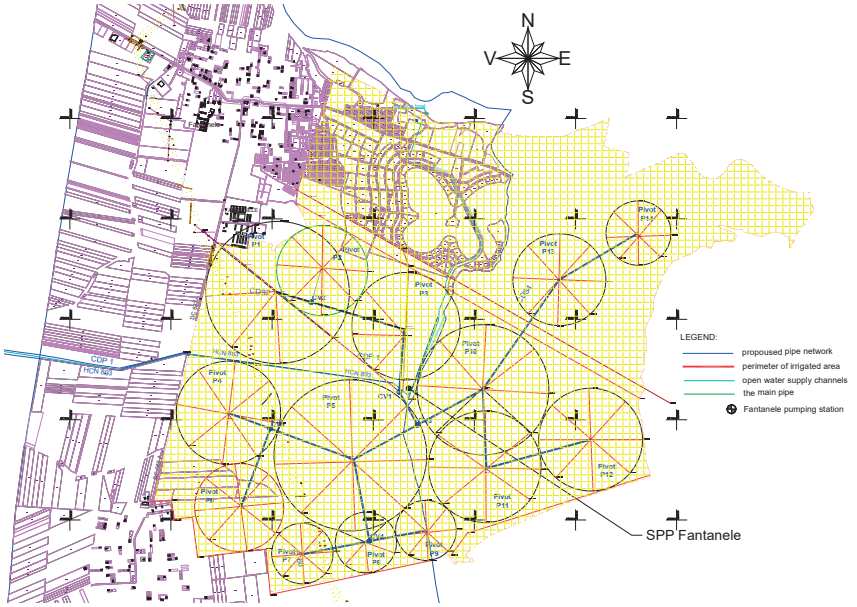

Figure 3. Map of proposed irrigation system SPP Fântânele

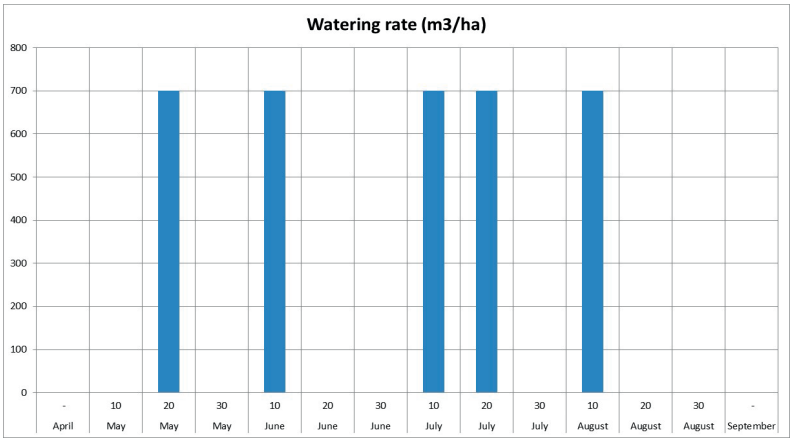

Figure 4. The annual and decadal watering charts

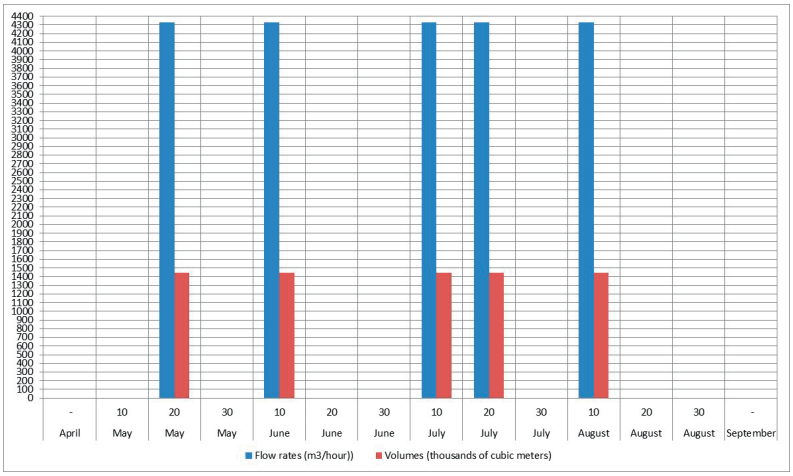

Figure 5. Uncoordinated watering schedule for a dry year

Figure 5 shows the water needs (flows and volumes) for decades, months and, the reference period (V-VIII) that the beneficiary must have a reference for watering.

To perform the modeling, the simulation model was developed by inputting coordinates in the Stereo 70 system, defining network nodes, and inserting pipe segments with specified materials and diameters. This process resulted in the layout plan illustrated in Figure 6. The SP Fântânele pumping station, which is supplied from the ANIF channel and has an installed flow capacity of 3991.9 m³/h, was integrated into the system. After calibrating and running the model, we obtained data on flow (Figure 7), velocity (Figure 8), headloss (Figure 9), and pressure (Figure 10) across all pipes and nodes, which were represented in corresponding diagrams.

Consequently, we were able to generate diagrams showing pressure, velocity, and headloss across all sections, specifically in the directions SP – A01 and SPP15 – P14, as shown in Figures 10 and 11.

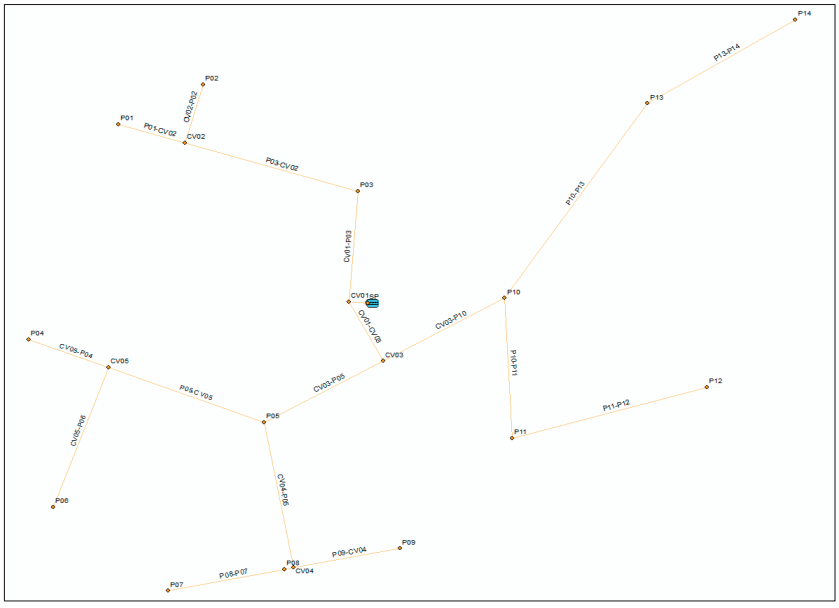

Figure 6. Plan view model

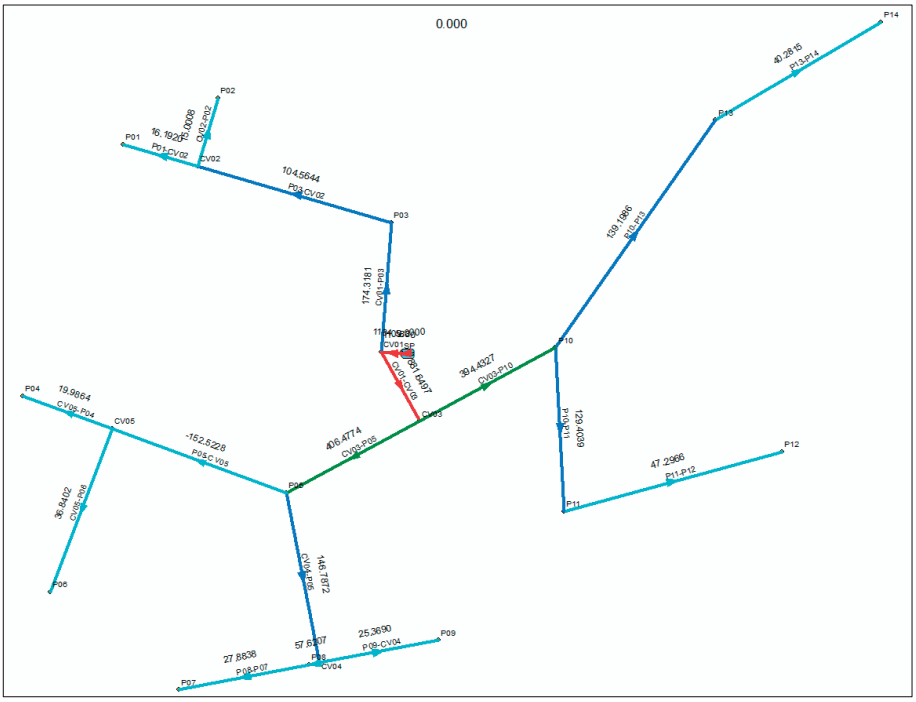

Figure 7. Pipe flows (l/s)

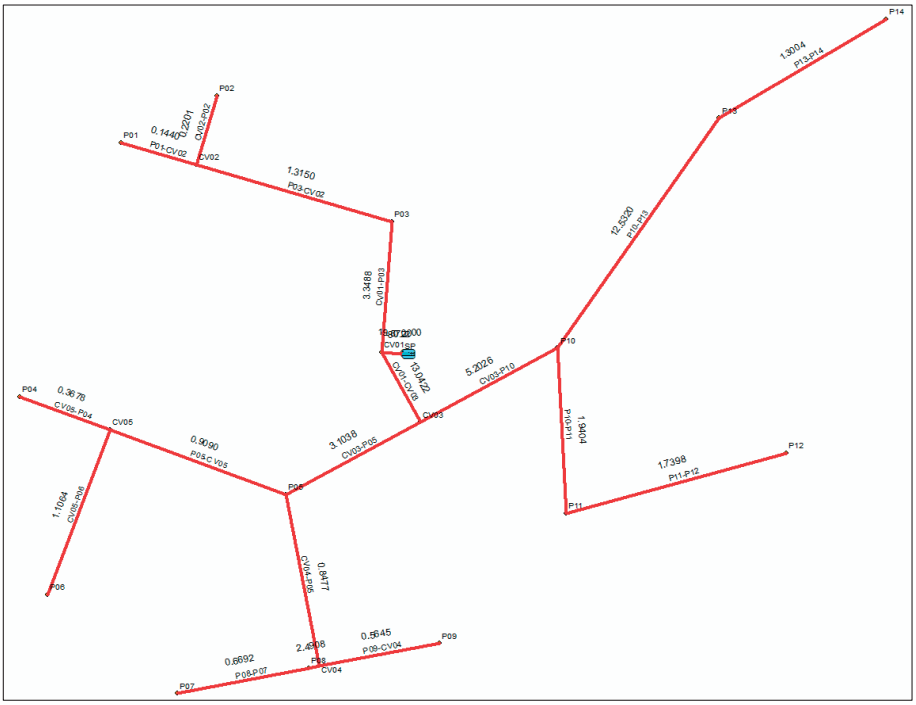

Figure 9. Pipe head-loss (m/km)

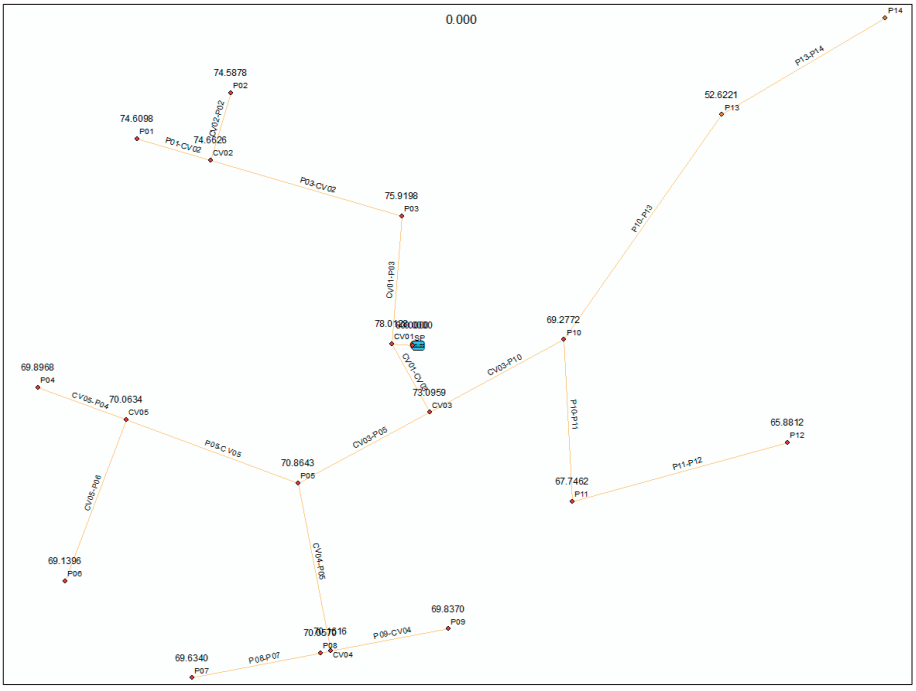

Figure 10. Node pressure (m)

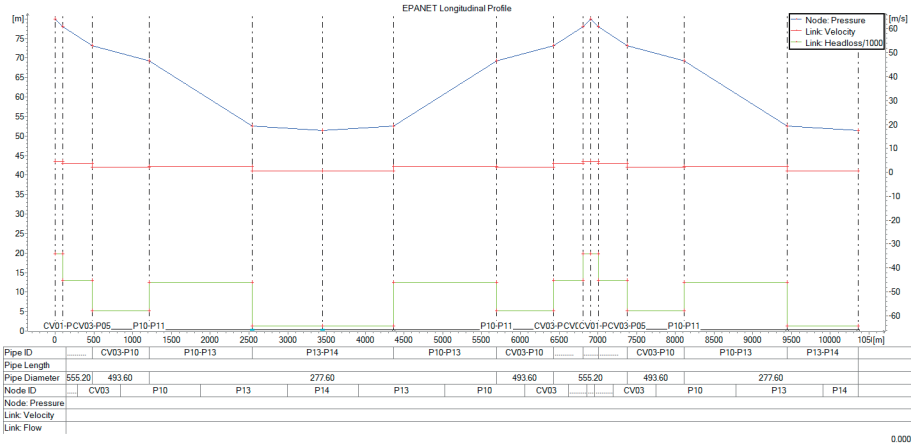

Figure 11. Section pressure diagram SP – P14

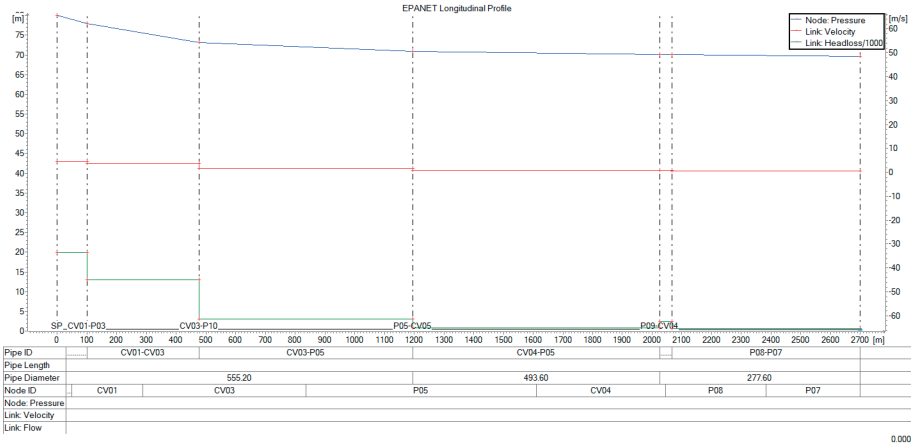

Figure 12. Section pressure diagram SP – P07

Without Project Scenario

Starting from the plant water requirement of 1600 m³/ha for 1198 ha, the total required volume is 1,916,800 m³. Assuming a field irrigation efficiency of 75%, the required volume at the hydrant is: 2,555,734 m³. To achieve this, with a pipeline network efficiency of 85%, the volume to be transported through the buried pipeline network must be 3,006,746 m³. Given the pump efficiency at the pressurization station is 65%, the volume to be extracted from the source (canal) is 4,625,763 m³.

Therefore, the water loss in the scenario WITHOUT the project is 2,708,963 m³.

With Project Scenario

Starting from the same plant water requirement of 1600 m³/ha for 1198 ha, the total needed volume remains 1,916,800 m³.

Assuming a field irrigation efficiency of 85% (due to new irrigation equipment acquired by the OUAI members), the required volume at the hydrant is 2,255,059 m³. To deliver this volume, with a modernized pipeline network efficiency of 95%, the volume to be transported is 2,373,746 m³.

With upgraded pumping units having an efficiency of 80%, the required intake from the source (canal) is 2,967,183 m³. Therefore, the water loss in the scenario WITH the project is 1,050,383 m³.

Water Loss Reduction

The reduction in water losses is calculated as the percentage difference between the losses in the "without project" and "with project" scenarios 61.22% Thus, the project implementation results in a 61.22% reduction in water losses.

The proposed technical solution ensures the functional safety of the entire irrigated area within the current irrigation system, starting from the distribution pipeline network required for water transport to the proper operation of the irrigation installations up to their terminal end.
The initial parameters of flow rate and discharge pressure are maintained to accommodate any crop plan with varying irrigation water requirements.
The new water distribution network, made of PE100 SDR17 PN10 polyethylene pipes, will lead to significant water savings.
Water losses in a pipeline network made of asbestos cement and pre-stressed concrete pipes older than 40 years, operating under a pressure regime of 6 bar, amount to approximately 25% of the volume of water pumped through the system. By replacing the old pipes with new HDPE (High-Density Polyethylene) pipes, these 25% losses can be eliminated.
In the case of the old hydrants, losses in the buried pipeline network are around 5% of the pumped water volume. Replacing the hydrants will eliminate this 5% loss as well.
For furrow and sprinkler irrigation methods, as originally designed for the buried pipeline system, the efficiency of this dual irrigation method is 0.8. By using new irrigation equipment such as boom and reel-type systems, irrigation efficiency increases to 0.9, thereby reducing water losses by approximately 10%.
Considering all three factors that influence water loss - replacement of the buried pipeline network with HDPE pipes, replacement of hydrants, and use of high-performance irrigation equipment - total water losses will be reduced by approximately 40%. Additionally, replacing the pumping units results in a further reduction of losses by around 15%, due to an increase in pump efficiency from 65% (old pumps) to 80% (new pumps).

CONCLUSIONS

The use of hydraulic modeling resulted in the pressure diagrams shown in Figures 11 and 12, which are essential for properly dimensioning the underground pipeline network used for irrigation. These diagrams ensure that both the pressure and flow rates are adequate for the efficient operation of sprinkler irrigation systems.
The proposed modernization scenarios focus primarily on optimizing the performance of the SP Fântânele pressure pumping station and the associated irrigation pipeline network responsible for delivering water to irrigated agricultural areas.
Installing new equipment to measure both water flow and volume distributed for irrigation will support transparent, contract-based operations between the water provider - ANIF Territorial Branch for Land Improvements Arad - and the beneficiary, OUAI Fântânele. This upgrade aims to prevent potential disputes arising from the absence of monitoring systems.
Additionally, the implementation of advanced automation technology is recommended to minimize staffing requirements at the pumping station during the system's operation period, thereby increasing operational efficiency.

Abstract

This study explores the attitudes of European students towards the role of advanced technologies in energy and industry in fostering a green environment, particularly in the context of climate change and the European Green Deal. Survey results highlight a strong recognition of the importance of sustainability-related knowledge, including topics such as Green Agriculture, Zero Pollution, Circular Economy, and Green Sustainable Energy. The findings suggest that while students across Europe acknowledge the transformative potential of advanced technologies in achieving environmental goals, national contexts and current events, such as the ongoing conflict in Ukraine, influence perceptions of climate-related education and policy priorities. The survey results underscore the importance of incorporating green technologies into academic curricula to support the objectives of the European Green Deal.

Key words*: green technology, zero pollution, European Green Deal (EDG), sustainability education.*

INTRODUCTION

The European Green Deal (EGD) is a strategic policy framework aimed at achieving sustainability, economic modernisation, and climate neutrality by 2050, focusing on the circular economy, biodiversity, and sustainable agriculture. Key initiatives - including the Bio-Based Industries Consortium and the integration of digital technologies, green innovation, and renewable energy - are central to achieving these objectives. However, existing studies reveal disparities in progress across EU nations, underscoring the need for a systemic approach combining policy, research, and technological innovation (Stefanidis et al., 2024). The transformation of the energy system is crucial for long-term sustainability, with industrial decarbonisation relying on strategies such as fuel substitution, carbon capture, and circular economy practices (Fernández Gómez, 2022). Other studies explore the EGD's impact on sustainable agriculture, noting that large farms are better positioned to maintain income levels, while small farms may face reduced production and income. This disparity calls for further research on farm incomes, subsidies, and food security across the EU (Pawłowski & Sołtysiak, 2024). Another approach suggests that to attain climate neutrality, the industrialised Member States are the most prepared, Southern/Eastern states have moderate capacity, and Central/Eastern states require targeted investment (Ciot, 2022). In this regard, three European universities (USAMV Bucharest, Romania; Politehnica Bucharest, Romania; UAB Barcelona, Spain; Porto, Porto, Portugal; Uzhhorod University, Uzhhorod,

Ukraine) have developed, since 2023, a study regarding graduates' opinions on the role of advanced technologies in energy and industry for a green environment in the context of climate change and the EGD.

MATERIALS AND METHODS

The study was conducted using a Survey Questionnaire sent online (Radu et al., 2018; Radu et al., 2019; Radu et al., 2020) to graduate students of five European universities involved in the study. A maximum of ten completed survey questionnaires were received from graduate students from each university. A maximum of ten completed Survey Questionnaires were received from graduate students at each university. As of the beginning of 2025, the distribution of respondents (graduate students) from the five universities was as follows: Romania 15%, Spain 27%, and Ukraine 42%.

In a specific questionnaire template distributed online, graduate students were asked to assign scores ranging from 1 to 5 to certain questions, which were interpreted in terms of relevance as follows: Score 1: Not important; Score 2: Low relevance; Score 3: Medium relevance; Score 4: High relevance; Score 5: Very high relevance. In this survey, the responses to six specific questions were chosen and analysed, as follows: 1. Do you appreciate as being important for you as a graduated student to have knowledge regarding Zero Pollution?

2. Do you consider that basic knowledge of climate change will impact your overall activity?

3. Do you consider that basic knowledge on Biodiversity will have a positive impact on your upcoming activity?

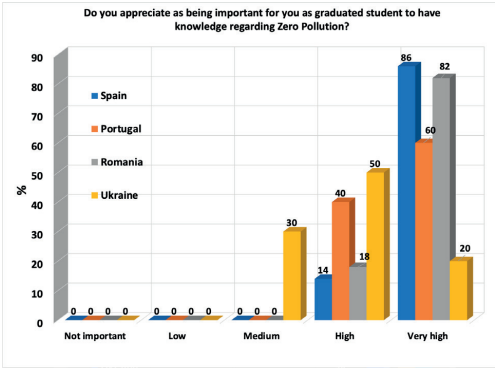
4. Do you agree that the understanding of the main issues of Green Agriculture will be fruitful for your future activity?

5. Do you consider it will be effective the graduate students can be able to use knowledge regarding Industrial Strategy for Circular Economy?

6. Do you agree you must be able to use and apply the principles of Green Sustainable Energy? The graduate students were previously informed about the aims of this study. Participation in the survey was voluntary. The Survey Questionnaires distributed and received did not contain personal information such as name, address, phone number, or email address.

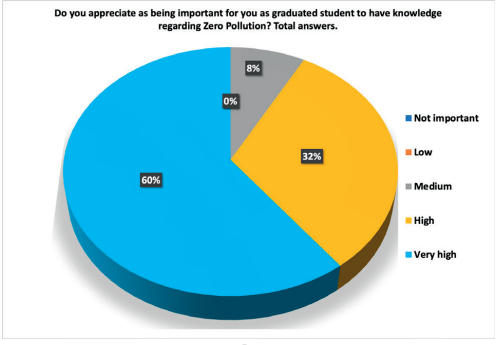
Data collection and analysis

Until September 2024, a total of 40 valid responses had been received. The geographic distribution of participants was as follows: 28% from Ukraine, 28% from Romania, 26% from Portugal, and 18% from Spain. Although the sample size is modest, the random selection of participants from each institution helped minimize selection bias and offered a degree of representativeness within the target population.



Given the exploratory nature of the study and the limited sample size, data analysis was primarily descriptive. No inferential statistical tests were applied. The goal was to identify prevailing trends and general patterns in student perceptions of and attitudes toward the role of advanced technologies in energy and industry for a green environment in the context of climate change and the European Green Deal.

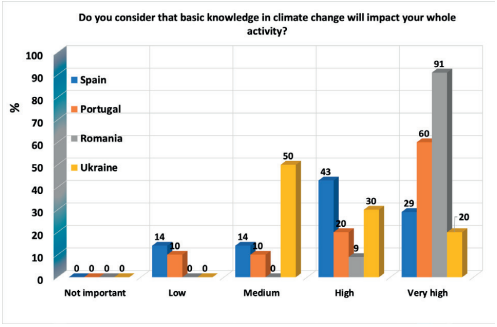
RESULTS AND DISCUSSIONS



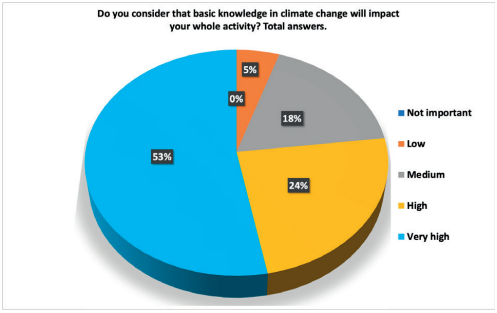
Regarding the statement, "Do you consider it important as a graduate student to have knowledge about Zero Pollution?" the majority of respondents from European countries gave the maximum score (Figure 1a), i.e., 86% of respondents from Spain, 82% from Romania, and 60% from Portugal. In contrast, only 20% of respondents from Ukraine gave the maximum score. Overall, 60% of all respondents considered it strongly important to know about Zero Pollution and assigned the highest score to this question. Additionally, 32% of respondents rated this statement as highly important, while only 8% provided an average rating (Figure 1b).

For the statement "Do you consider that basic knowledge of climate change will impact your entire activity?", 91% of Romanian respondents and 60% of Portuguese respondents stated that basic knowledge of climate change would have a very high impact on their overall activity (Fig. 2a). In contrast, only 29% of Spanish respondents considered this statement to have a very strong impact, as did 20% of Portuguese

respondents. Meanwhile, 43% of Spanish respondents believed that knowledge of climate change would have a high impact (Figure 2a).
Among Ukrainian respondents, 20% stated that basic knowledge of climate change would have a very strong impact on their entire activity, while 30% believed it would have a high impact. Responses indicating medium, low, or no importance did not exceed 15% in any country.
Overall, 53% of all respondents considered this statement to have a very strong impact (Figure 2b), while 24% believed it would have a high impact. Additionally, 18% of respondents rated the importance of this statement as medium, and only 5% considered it of low importance (Figure 2b).



a



b

Figure 1. Distribution of responses to the question: "*Do you appreciate as being important for you as graduated student to have knowledge regarding Zero Pollution*?"
a) Answer distribution by country; b) Overall answer distribution across all respondents

Regarding the response to the statement: "Do you consider that basic knowledge of biodiversity will have a positive impact on your upcoming activity?", the respondents from Romania strongly agree with this statement in proportion 82% (Figure 3a).

a

b

Figure 2. Distribution of responses to the question: "*Do you consider that basic knowledge of climate change will impact your overall activity?*"
a) Answer distribution by country; b) Overall answer distribution across all respondents

The respondents from Spain and Portugal strongly agree with the statement in proportions of 43% and 40%, respectively, and highly agree in proportions of 43% and 50%, respectively. The respondents from Ukraine moderately agree with this statement in a proportion of 50% (Figure 3a). Overall, 53% of all respondents strongly agree with this statement, while 24% highly agree (Figure 3b).
For the statement "Do you agree that understanding the main issues of Green Agriculture will be beneficial for your future activity?" 100% of Romanian respondents are very high agree that understanding the main issues of Green Agriculture will be beneficial for their future activities. Similarly, 57% of Spanish respondents and 40% of Portuguese respondents very highly agree with this statement (Figure 4a). Only 10% of

respondents from Ukraine very highly agree with this statement, while 40% highly agree, as do the Portuguese respondents (Figure 4a). The percentage of respondents who rated this aspect as low or not important does not exceed 10% for students from each country involved in this study. Overall, 53% of all respondents considered this statement to have a strong impact (Figure 4b), 24% considered that this statement had a high impact, 18% gave an average rating, and only 5% of all respondents considered that this statement had a low importance (Figure 4b).

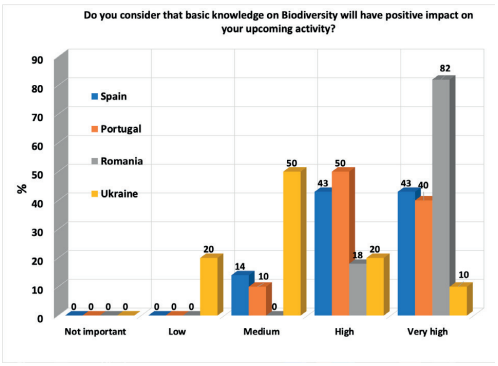


Figure 3. Distribution of responses to the question: "*Do you consider that basic knowledge on Biodiversity will have positive impact on your upcoming activity?*"
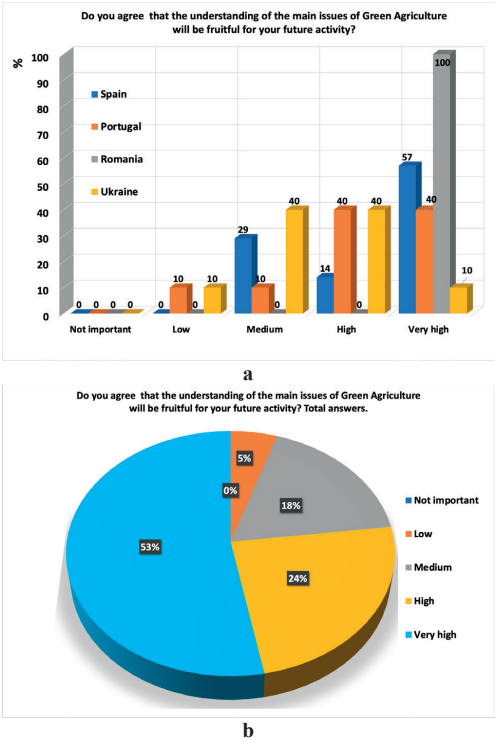
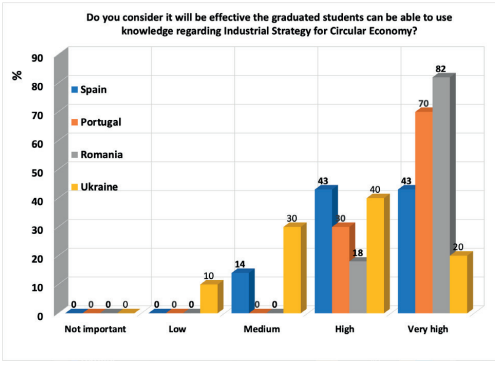
a) Answer distribution by country; b) Overall answer distribution across all respondents

In contrast, only 20% of Ukrainian respondents considered this statement to have a very strong impact. Additionally, 43% of Spanish respondents believed that this statement would have a high impact (Figure 5a). A per cent of 40% of Ukrainian respondents and 30% of Portuguese respondents considered it effective for graduates to be able to apply knowledge regarding the Industrial Strategy for the Circular Economy. Responses indicating medium, low, or no importance scores for this statement did not exceed 14% in any country (Figure 5a). Overall, 54% of all respondents considered this statement to have a very strong impact (Figure 5b), while 32% believed it would have a high impact. Additionally, 11% of respondents rated this statement as of medium importance, and only 3% considered it of low importance (Figure 5b).





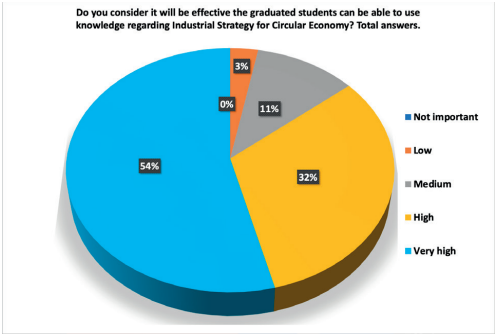


Figure 4. Distribution of responses to the question: "*Do you agree that the understanding of the main issues of Green Agriculture will be fruitful for your future activity?*" a) Answer distribution by country; b) Overall answer distribution across all respondents

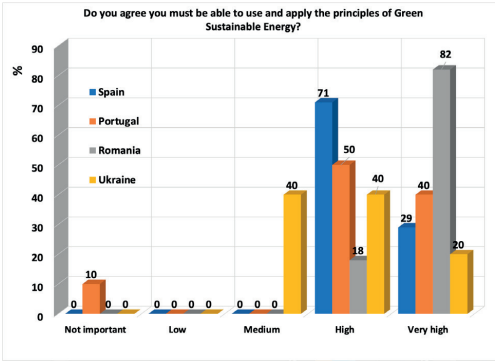
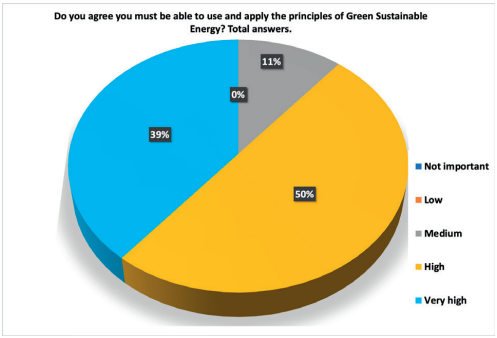
Regarding the statement "Do you agree that you must be able to use and apply the principles of Green Sustainable Energy?", 82% of Romanian respondents, 28% of Spanish respondents, and 40% of Portuguese respondents strongly agreed with this statement (Figure 6a). In contrast, only 20% of Ukrainian respondents strongly agreed. Additionally, 71%

of Spanish respondents and 50% of Portuguese respondents highly agreed with this statement (Figure 6a), along with 40% of Ukrainian respondents and 18% of Romanian respondents. Responses indicating medium, low, or no importance for this statement did not exceed 10% in any country (Figure 6a). Overall, 50% of all respondents very strongly agreed with this statement (Figure 6b), while 39% highly agreed. Only 11% of respondents rated this statement as of medium importance (Figure 6b).



a



b

Figure 5. Distribution of responses to the question: "*Do you consider it will be effective for graduate students to apply knowledge regarding Industrial Strategy for Circular Economy?*" a) Answer distribution by country; b) Overall answer distribution across all respondents

The survey analysis reveals significant regional differences in graduate students' views on environmental knowledge. Respondents from Romania showed the strongest support for environmental topics, with the highest ratings for Zero Pollution awareness, Green Agriculture, and Green Energy. Spanish and Portuguese respondents also expressed considerable interest, though with less intensity, while Ukrainian responses were notably lower, likely due to the ongoing conflict. Overall, there was strong consensus on the importance of climate change, biodiversity, and sustainability in shaping future careers, highlighting the need for increased emphasis on environmental education across Europe

a

b

Figure 6. Distribution of responses to the question: "*Do you agree you must be able to use and apply the principles of Green Sustainable Energy?*" a) Answer distribution by country; b) Overall answer distribution across all respondents

Yang et al. (2023) highlight that while the Circular Economy (CE) model offers significant environmental benefits by repurposing waste, its success requires a comprehensive approach, integrating economic and social factors alongside environmental considerations. Industrial eco-parks, offer a promising model for enhancing waste recovery, resource utilisation, and energy efficiency (Nyangchak, 2022; Yang et al., 2023; Glockow et al., 2024).

Other experts emphasise the need for stronger links between the bioeconomy and circular economy in the context of the Sustainable Development Goals (SDGs) (Shobande et al., 2024). The systematic review identifies significant gaps in the literature, including a lack of standardised methodologies, geographic imbalance with a focus on Europe and Asia, and insufficient attention to social dimensions like poverty and food security (Ferrez & Pyka, 2023; Niwalkar et al., 2023). The studies performed by Kumar et al. (2023) stress the critical role of Circular Economy (CE) and green energy in advancing environmental sustainability. Moreover, it underscores the importance of investing in renewable energy to reduce CO_2 emissions. By integrating CE with green energy, businesses can develop innovative models, create cross-industry value chains, and seize sustainable commercial opportunities. The adoption of a closed-loop system focused on waste reduction and resource efficiency fosters technological advancements, further contributing to ecological sustainability (Santeramo, 2022; Kumar et al., 2023; Paleari, 2024).

CONCLUSIONS

Based on the survey responses, the following key conclusions can be drawn regarding graduate students' perceptions of environmental and sustainability topics in the context of the European Green Deal. A high degree of awareness regarding Zero Pollution was observed, particularly in Spain, Romania, and Portugal. However, Ukrainian respondents showed less enthusiasm, likely due to the impact of the ongoing war. Overall, 60% of respondents viewed Zero Pollution as extremely important, signaling its relevance to future academic and professional pursuits. Climate change knowledge was seen as impactful by the majority of respondents, especially from Romania and Portugal, where 91% and 60%, respectively, viewed it as a critical factor for their future endeavours. While fewer Spanish respondents shared this view (29%), Ukrainian responses reflected a broader range of opinions, with 50% perceiving it as highly impactful. In total, 53% of respondents recognized the strong influence of climate change knowledge. Knowledge about biodiversity was especially valued by Romanian students, with 82% strongly agreeing that it would positively affect their careers. Spanish and Portuguese respondents demonstrated substantial support, with 43% and 40%, respectively. Across all respondents, 53% strongly agreed, showing consensus on the importance of biodiversity in shaping future professional paths. The importance of Green Agriculture was universally acknowledged in Romania (100%), with substantial support in Spain (57%) and Portugal (40%). On average, 53% of all respondents saw Green Agriculture as a crucial factor in shaping sustainable practices. Knowledge about the Circular Economy Industrial Strategy was viewed as important, particularly by Romanian and Spanish respondents (82% and 43%, respectively). Overall, 54% of all respondents considered it essential for sustainable industrial practices. Green Sustainable Energy knowledge was most strongly endorsed by Romanian respondents (82%), with somewhat less support from Spanish (28%) and Portuguese (40%) students. Nevertheless, 50% of respondents across Europe placed a high value on this knowledge.

Abstract

This study investigates expert opinions from five universities across Romania, Spain, Portugal, and Ukraine regarding the use of digital learning, gamification, and artificial intelligence (AI) in enhancing education aligned with the European Green Deal (EGD). Based on structured survey responses from academic professionals, the findings reveal that 65% of participants view online learning as a potential contributor to social isolation, highlighting the value of blended learning approaches. Gamification received broad support, with over 70% of experts agreeing it improves student engagement and comprehension, although concerns about cost and implementation persist. AI was acknowledged as a valuable tool for academic integrity and assessment, though its effectiveness in providing real-time personalized feedback remains inconclusive. These results suggest that a balanced integration of digital tools can support improved educational outcomes and better understanding of sustainability-related content.

Key words*: gamification, artificial intelligence, European Green Deal.*

INTRODUCTION

The integration of digital education and assessment techniques within the framework of the European Green Deal (EGD) presents both challenges and opportunities in reshaping higher education. The EGD, a strategic initiative by the European Union (EU), aims to achieve climate neutrality by 2050, requiring the transformation of multiple sectors - including education. Digital tools such as Moodle, Coursera, and other e-learning platforms contribute to this shift by facilitating access to educational content and promoting sustainable practices like cloud-based infrastructure and reduced material consumption (Aparisi-Torrijo et al., 2024; Oliveira et al., 2022; Torrez-Ruiz & Moreno Ibarra, 2019). These platforms are increasingly used to equip students with the knowledge and skills necessary to address climate change and sustainability challenges. Notable digital techniques include:

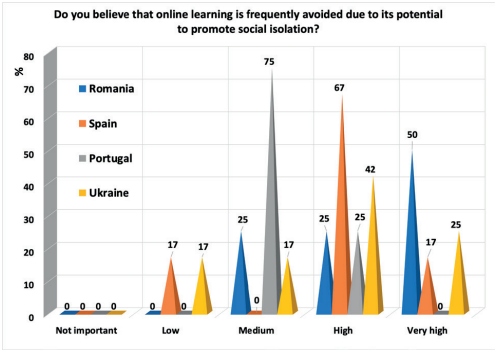
1) *Blended learning* – combining in-person teaching with digital platforms to enhance flexibility and inclusiveness.
2) *Gamification* – incorporating game-based elements into educational content to simulate real-world sustainability scenarios, making EGD-related topics more engaging.
3) *Collaborative learning* – leveraging online tools to support international teamwork on environmental and climate-related challenges (Elfert & Rubenson, 2022; Misra, 2012).

Assessment in digital education has also evolved to include:
1) *AI-Based Personalization* – tailoring learning and evaluation processes to individual student needs through adaptive technologies.
2) *Virtual simulations* – allowing students to interact with sustainability scenarios in realistic, consequence-driven environments.
3) *Digital assessment tools* – including online quizzes, virtual labs, and project-based evaluations (Frazão Santos et al., 2024; Reimers, 2021).
In this context, since 2023, five universities from four European countries and Ukraine have collaborated on a study examining expert perspectives on the most effective digital tools and teaching strategies for fostering a deeper understanding of EGD principles among Master's and Doctoral students. This paper presents the findings of that study, offering insights into current perceptions, regional differences, and key challenges in digital education for sustainability.

MATERIALS AND METHODS

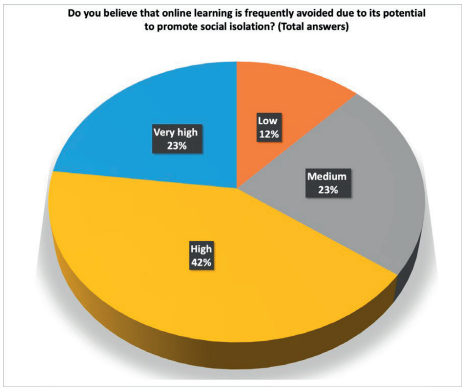
Between 2023 and 2025, a consortium of five universities conducted a structured survey aimed at evaluating expert opinions on digital education methodologies suitable for enhancing students' understanding of the European Green Deal. The study aimed to evaluate preferred learning and assessment strategies aligned with sustainability goals in higher education.
The survey analysis consisted of 20-30 questions, grouped into thematic sections, regarding learning and assessment techniques most appropriate for a digital learning approach. Pilot testing was conducted with a small number of experts from each university or country involved in the study (a maximum of 10 experts per university). Representatives from each participating university selected individuals with specialised knowledge in areas such as environmental policy, digital education, sustainability in education, and European policy development. The selection criteria for experts involved in this study were as follows: a minimum of 15 years of experience; involvement in EU-funded education or green projects; academic publications in relevant areas; and participation in working groups or policymaking bodies related to the European Green Deal or digital education. The experts selected were teachers, researchers, or policymakers in higher education. The participating institutions included: Universitat Autònoma de Barcelona (Spain), University of Porto (Portugal), University of Agronomic Sciences and Veterinary Medicine of Bucharest (Romania), National University of Sciences and Technologies Politehnica of Bucharest (Romania), Uzhhorod National University (Ukraine). The study targeted academic experts involved in Master's and Doctoral education, focusing on identifying the most effective digital learning and assessment strategies aligned with sustainability principles. The survey employed a structured questionnaire developed based on methodologies established in previous educational research by Radu et al. (2018; 2019; 2020). These earlier studies served as the foundation for question framing, relevance scoring, and data analysis. Respondents were drawn from the five partner universities, with the following country-level distribution recorded by early 2025:

- Romania (combined responses from two universities): 15%;
- Spain: 27%;
- Portugal: 15%;
- Ukraine: 42%.



Each question was rated by respondents on a five-point Likert-type scale, with scores interpreted as follows: Score 1 - Not important; Score 2 - Low; Score 3 - Medium; Score 4 - High; Score 5 - Very High.

RESULTS AND DISCUSSIONS



1. Online learning and social isolation

A key concern identified in the survey was the potential of online learning to contribute to social isolation among students. Experts were asked: *"Do you believe that online learning is frequently avoided due to its potential to promote social isolation?"*
The responses varied across countries. In Romania, 50% of experts rated this concern as *Very Important*. In Spain, 67% considered it *Important*, while in Portugal, the responses were more moderate, with most participants selecting *Medium* importance. In Ukraine, 42% of respondents rated it as *Very Important*, and an

additional 25% regarded it as *Important*. These results indicate that, apart from Portugal, most respondents viewed social isolation as a significant barrier to online education (Figure 1a). The overall distribution of responses confirms this pattern, with 42% of participants rating the issue as *Important* and 23% as *Very Important* (Figure 1b). This finding reinforces the value of blended learning models, which combine digital tools with face-to-face interaction to mitigate isolation while leveraging online flexibility.

a

b

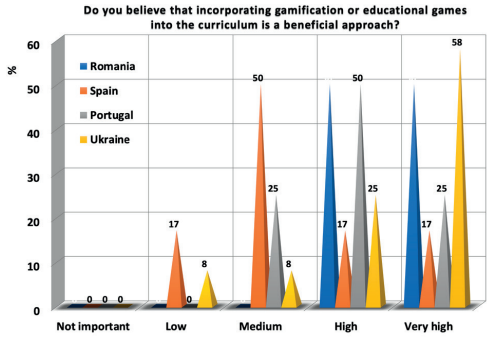


Figure 1. Expert perceptions of social isolation caused by online learning across four European countries:
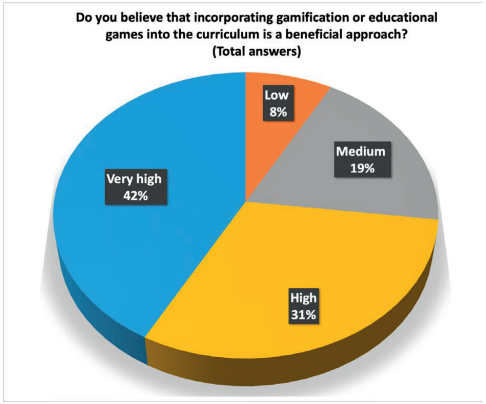
a) Country-level breakdown;
b) Combined overall results

2. Gamification in digital education

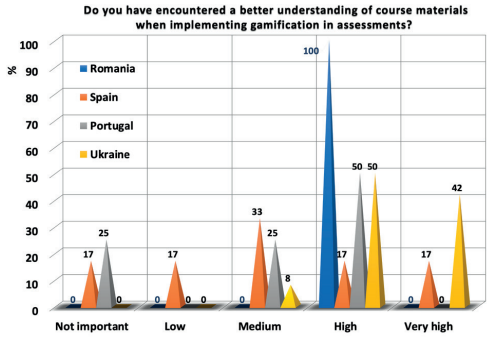


The effectiveness of gamification in supporting the understanding of EGD principles was explored through three distinct survey questions.

a) Perceived benefit of gamification

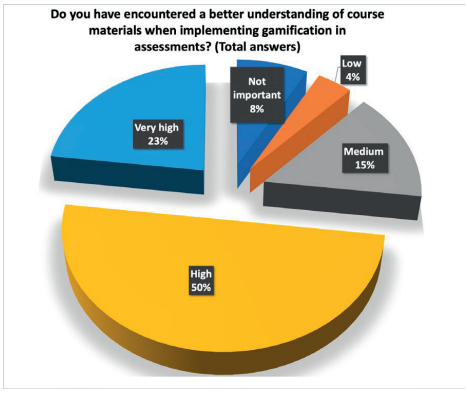
Responses to the question, *"Do you believe that incorporating gamification or educational games into the curriculum is a beneficial approach?"* indicated that experts from Ukraine and Romania rated this approach as *Very Important* in 58% and 50% of cases, respectively, while those from Portugal and Spain predominantly considered it *Important* (Figure 2a). The overall distribution showed 42% of respondents selected *Very Important*, and 31% selected *Important* (Figure 2b), indicating strong support for gamification as an engaging teaching method.

a



b

Figure 2. Expert perspectives on the educational value of gamification in the curriculum across four European countries: a) Responses by country; b) Overall response trends

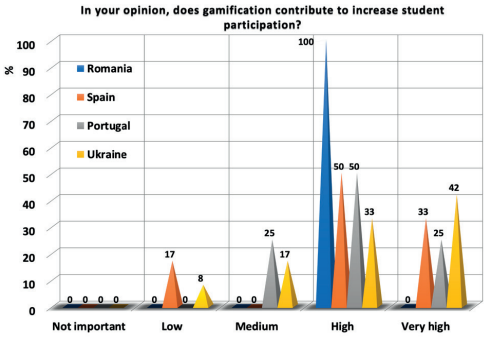


b) Effectiveness in enhancing understanding

The answers to the question: "*Have you observed a better understanding of course materials when implementing gamification in assessments?*" are more nuanced, likely due to practical limitations such as development cost and the need for technical expertise. As a result, 42% of experts from Ukraine rated this aspect as

Very Important. Meanwhile, all respondents from Romania and Portugal considered it *Important*, as did 50% of respondents from Ukraine. In contrast, experts from Spain provided more varied responses, generally leaning toward *Medium Importance* (Figure 3a). Overall, 50% considered gamification *Important*, and 23% *Very Important* (Figure 3b). This indicates a generally positive view, tempered by concerns about implementation feasibility.

a



b

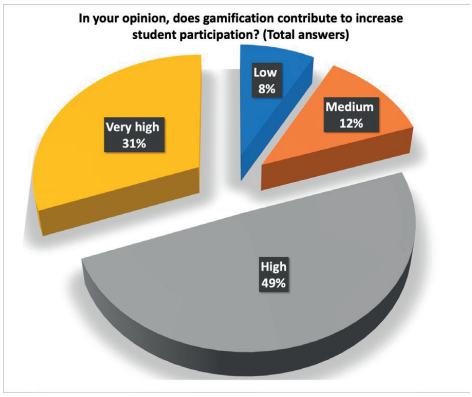


Figure 3. Expert opinions on whether gamification enhances student understanding of course materials: a) By country; b) Overall distribution

c) Impact on student participation

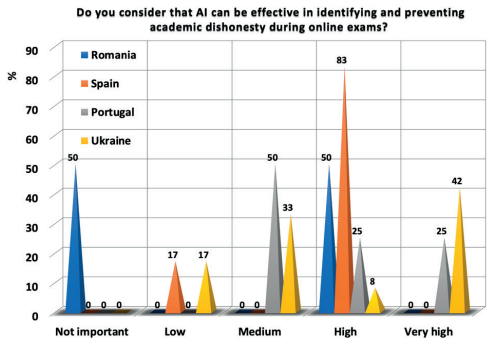
To gauge engagement, experts were asked: "*In your opinion, does gamification contribute to increased student participation?*" Experts from Romania, Spain, and Portugal rated this *Important* in 100% and 50% of responses, respectively. Ukraine: 42% rated it *Very Important* (Figure 4a). In total, 49% rated gamification as *Important* for increasing participation, and 31% as *Very Important* (Figure 4b), confirming its motivational potential.

a

b

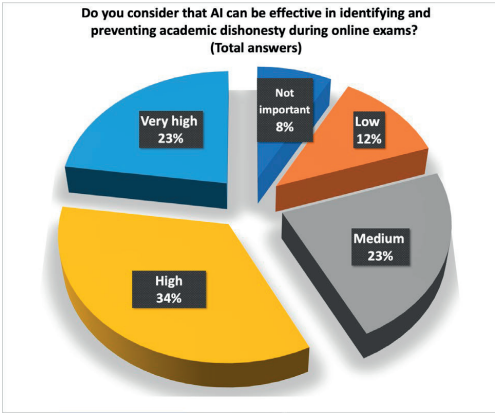
Figure 4. Expert views on whether gamification contributes to increased student participation, based on responses: a) Country-specific distribution; b) Overall response distribution

3. Artificial Intelligence (AI) in assessment and feedback



The survey also evaluated expert perspectives on the use of artificial intelligence in academic evaluation, particularly in two key areas: ensuring academic integrity and delivering real-time, personalized feedback.

a) AI for preventing academic dishonesty

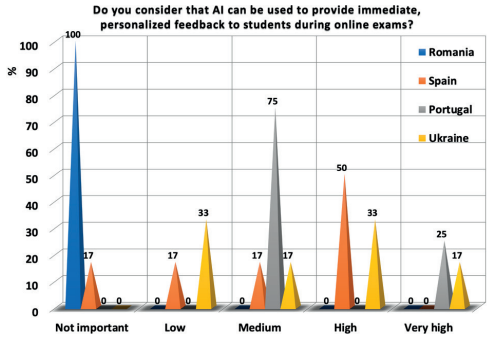


In response to the question: "*Do you consider that AI can be effective in identifying and preventing academic dishonesty during online exams?*", expert opinions reflected moderate to strong support. In Ukraine, 42% of respondents rated this aspect as *Very Important*. In Portugal, 25% of experts considered it either *Important* or *Very Important*. Meanwhile, the majority of respondents in Romania and Spain rated it as

Important, accounting for 50% and 83% of responses, respectively (Figure 5a). Overall, 34% of respondents considered the use of AI for detecting academic dishonesty as *Important*, while 23% rated it as *Very Important* or of *Medium* relevance (Figure 5b).

This indicates a generally positive outlook, though the level of support varied across countries.

a



b

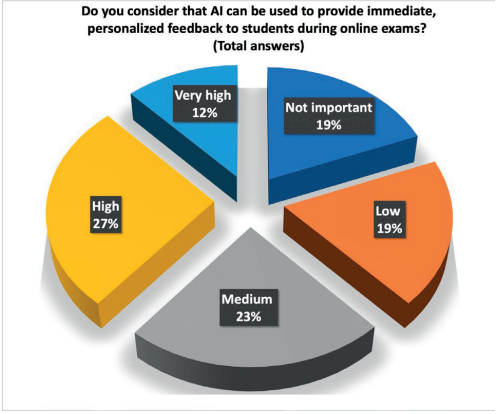


Figure 5. Distribution of expert responses to the question: *"Do you consider that AI can be effective in identifying and preventing academic dishonesty during online exams?"*: a) Responses by country; b) Overall response distribution

b) AI for providing personalized feedback

When asked, "*Do you consider that AI can be used to provide immediate, personalized feedback to students during online exams?*", responses were generally more reserved. In Spain, 50% of respondents rated this aspect as *Important*, while in Ukraine, 33% expressed a similar view. In Portugal, most responses leaned toward *Medium* importance. In contrast, all respondents from Romania considered this functionality *Not Important* (Figure 6a). Overall, only 27% of experts considered AI-based real-time feedback as Important, while 12% rated it as Very Important. A significant portion of the sample rated this function as Moderately Important or Unimportant, reflecting uncertainty about its practical value (Figure 6b).

a

b

Figure 6. Expert perspectives on the effectiveness of AI in providing immediate, personalized feedback to students during online exams: a) Distribution of responses by country; b) Overall response distribution

The survey identified a significant concern associated with fully online learning: the risk of social isolation. This issue was acknowledged by 65% of respondents, who rated it as either *important* or *very important*. In contrast, responses related to game-based learning experiences were largely positive. A substantial proportion of experts viewed gamification as a beneficial approach, highlighting its potential to enhance student engagement and improve the

overall learning experience. More than 70% of respondents agreed that incorporating game-based experiences into the curriculum is a beneficial approach that can enhance the understanding of scientific information. While respondents were in favour of using AI for knowledge assessment in EGD, it remained unclear whether its implementation in online exams could lead to immediate, personalised feedback. The survey results are consistent with recent studies. For instance, Khoshnoodifar et al. (2023) found that gamified learning improved medical students' attitudes toward statistics, making learning more engaging and efficient. Li and al. (2023) highlighted significant effects of gamification, particularly in science disciplines. Lampropoulos & Sidiropoulos (2024) confirmed gamification's superiority over traditional methods in higher education, with improvements in success rates and retention. Ortiz-Rojas et al. (2025) showed that leaderboards boosted learning performance but did not significantly affect self-efficacy. Effective implementation of gamification in education requires a tailored approach that addresses the diverse learning needs of students, particularly within STEM disciplines - science, technology, engineering, and mathematics (Ortiz-Rojas et al., 2025; Qudsi, 2024). Another study concludes that gamification represents a fundamental shift in pedagogical practice, emphasizing its potential to foster deeper learning and highlighting the need for further research to refine and assess its long-term effects (Li et al., 2023; McHenry & Makarius, 2023). According to Wulan et al. (2024), gamification offers several key advantages in the learning process. First, it *enhances student engagement and motivation* by making learning experiences more interactive and enjoyable. Second, it *promotes active learning*, encouraging deeper understanding through direct participation. Third, gamification helps *develop problem-solving and critical thinking skills* by fostering strategic thinking and informed decision-making. Fourth, it *encourages collaboration*, often through multiplayer or team-based activities that promote communication and cooperation. Finally, gamification can *personalize the learning experience,* adapting content and pace to meet the unique needs of individual learners.

CONCLUSIONS

The survey highlighted concerns and views on digital learning, gamification, and AI across four European countries. About 65% agreed that online learning can cause social isolation, seen as important by most experts except in Portugal. Over 70% supported game-based learning for improving understanding and engagement. AI was viewed as useful for reducing cheating and assessing knowledge, though opinions differed between countries. The use of AI for instant, personalised feedback was not supported, with all Romanian respondents finding it irrelevant. Future studies should examine how gamification preferences differ across disciplines and student groups. Differences in views on digital education tools among universities in Spain, Portugal, Ukraine, and Romania may stem from cultural, institutional, and technological factors unique to each country.

Cultural context: in some countries, the adoption of digital education tools is shaped by the local cultural approach to learning and technology. Countries with a strong tradition of face-to-face learning may be slower to adopt fully digital platforms, while others may be more open to innovation and remote learning.

Institutional digital readiness: different countries have varying levels of digital infrastructure and readiness. Spain and Portugal, as EU member states with substantial investment in digital education, may have more advanced systems in place compared to Ukraine and Romania, which may face challenges related to digital infrastructure or government support. These disparities may lead to differing opinions on the effectiveness and feasibility of certain digital education tools.

The digital readiness levels in these countries significantly influence the opinions of stakeholders (teachers, researchers, and policymakers). Countries with higher levels of digital readiness (such as Spain or Portugal) may be more confident in adopting advanced tools like AI-driven platforms or immersive technologies, while countries with lower digital infrastructure (such as Ukraine or Romania) may be more cautious or focused on basic digital tools and platforms. Limitations of this study are due to two factors:

- The maximum number of respondents, limited to 10 experts per country or university, is relatively small. This limits the ability to generalise the findings to the broader population of educators, policymakers, or researchers.
- The study included a maximum of two universities per country, which further restricts the diversity of perspectives. Different institutions may have different levels of digital readiness, and focusing on just a few may not fully reflect the variations that exist within each country's educational landscape,

Abstract

Grasslands are among the most widespread terrestrial ecosystems, covering over one-third of the Earth's surface. They play a pivotal role in carbon sequestration and the accumulation of soil organic matter (SOM), processes essential for soil fertility, biodiversity conservation, and climate regulation. The degradation and conversion of grasslands into croplands have historically contributed to significant soil organic carbon (SOC) losses, intensifying global warming. This hypothetical research paper proposes a comparative analysis of SOM dynamics between grasslands and arable lands worldwide. A standardized experimental design is outlined, involving soil sampling at two depths (0-20 cm and 20-40 cm), across three land-use types (natural grassland, degraded grassland, and arable land). Hypothetical results, based on existing literature, indicate that grassland soils retain 30-50% more SOM than arable soils, particularly in the upper soil layers. Findings emphasize the necessity of protecting grasslands through sustainable management practices such as controlled grazing, overseeding, and restoration programs. Global policies must prioritize grassland conservation to achieve soil health, food security, and climate change mitigation objectives.

Key words*: arable lands, biodiversity, carbon sequestration, grassland, soil organic matter.*

INTRODUCTION

Soil organic matter (SOM) is important for terrestrial ecosystem productivity, regulating essential functions such as nutrient cycling, water, soil structure stability and biodiversity support (Hussain et al., 2023). Globally, soils contain more than three times the amount of carbon stored in the atmosphere, and grasslands alone are estimated to store around 343 billion tons of carbon in the first meter of soil, surpassing forest ecosystems in terms of soil carbon stocks (FAO, 2015). Despite this, grasslands are among the most threatened ecosystems due to land-use conversion, overgrazing, and climate change (Bai et al., 2008; IPCC, 2021).

In recent decades, the expansion of arable land has occurred at the expense of grassland areas, confirming the ongoing trend of their transformation into cropland (FAO, 2015).

Over the past century, approximately 20% of natural grasslands have been converted to agricultural land (Ramankutty et al., 2008), leading to SOM losses of up to 60% (Paustian et al., 1997). This decline not only reduces soil fertility but also exacerbates atmospheric CO_2 concentrations. Understanding and quantifying the contribution of grasslands to SOM accumulation is therefore crucial for sustainable land management and climate change mitigation strategies (Paustian et al., 1997).

Globally, policies promoting grassland conservation are unequal. In Europe, agri-environmental schemes have provided incentives for sustainable grazing, while in developing regions, overgrazing and conversion continue to dominate (Elliott et al., 2023). Future research must focus on quantifying regional variations in SOM accumulation and integrating socio-economic

factors to ensure effective implementation of grassland management strategies.

In Romania, grasslands cover approximately 4.8 million hectares, representing nearly one third of the country's agricultural area (MADR, 2022). These ecosystems are highly diverse, ranging from alpine pastures in the Carpathians to lowland meadows in the Danube Plain, and they constitute a major reservoir of biodiversity and soil organic matter (SOM). However, their ecological and productive potential is often underutilized due to management challenges such as overgrazing, insufficient fertilization, and in some regions, land abandonment. Abandonment of pastures has become an increasingly widespread phenomenon, with negative consequences on biodiversity and the productive value of ecosystems. Studies conducted in the Apuseni Mountains show that grasslands go through distinct successional stages, in which floristic diversity decreases rapidly after the cessation of traditional use (Păcurar et al., 2015; Malinas et al., 2020).

Beyond their agronomic and ecological importance, Romanian grasslands also represent a basic principle for the transition to sustainable agriculture and the green economy. Natural grasslands and perennial crops are agricultural systems that are favourable for increasing the amount of organic matter in the soil. In the following paper, we will refer to natural grasslands in terms of their management to increase the amount of organic matter in the soil.

This study presents bibliographical research framework aimed at comparing the accumulation of soil accumulation in natural grasslands, degraded grasslands, and arable lands. The central hypothesis is that grasslands, due to their perennial root systems and reduced soil disturbance, accumulate and retain considerably more SOM than cultivated croplands.

MATERIALS AND METHODS

The bibliographical experimental design assumes a global comparative study after Guo and Gifford, 2002, involving three land-use types: (i) natural grasslands, (ii) degraded grasslands, and (iii) arable lands. Soil sampling is conducted at two standard depths: 0-20 cm (topsoil) and 20-40 cm (subsoil), with three replicates per site. Sites are assumed to represent diverse climatic zones, including temperate, tropical, and semi-arid regions, to capture the global variability of grassland ecosystems.

Soil organic matter is measured using the Walkley-Black method for organic carbon determination, with values converted to SOM by applying a factor of 1.724. Additional soil parameters include pH (measured in a 1:2.5 soil-to-water ratio), texture (hydrometer method), and bulk density (core method). Hypothetical values are derived from the synthesis of published literature (Guo & Gifford, 2002).

RESULTS AND DISCUSSIONS

The hypothetical results of Guo and Gifford, 2002 demonstrate clear differences in SOM content between land-use types and soil depths. Natural grasslands consistently show the highest SOM concentrations, followed by degraded grasslands, with arable lands having the lowest values. SOM content decreases with depth across all land uses (Figure 1).

The simulated results strongly support the hypothesis that grasslands serve as more effective carbon sinks compared to arable lands. The 30-50% higher SOM content observed in grasslands aligns with global meta-analyses (Guo & Gifford, 2002; Conant et al., 2017). Perennial grasses contribute continuous organic inputs through litterfall and extensive root systems, which penetrate deeper soil layers and enhance soil aggregation. Reduced soil disturbance in grasslands also minimizes carbon losses compared to frequently tilled croplands.

The comparative analysis between land-use types highlights not only quantitative differences in soil organic matter (SOM) levels, but also qualitative differences in the stability and turnover of organic fractions. These emphasize the role of grasslands in global climate strategies, reflecting the recommendations of the IPCC (2021) regarding nature-based solutions for carbon sequestration. In natural grasslands, the continuous input of root exudates and litter promotes the accumulation of stable humic substances,

whereas in arable systems, frequent tillage accelerates the decomposition of labile organic matter (Rotar & Pacurar, 2010). Thus, the vegetation specific to well-established steppe grasslands produces annually 10-20 t/ha of plant residues consisting of roots, stems, leaves, etc. It is worth noting that the majority is represented by roots that accumulate within the soil over a thickness greater than 100 cm with a higher concentration in the first 40-50 cm (Blaga et al., 2005). On the other hand, SOM in croplands is more dynamic and vulnerable to losses under climatic conditions.

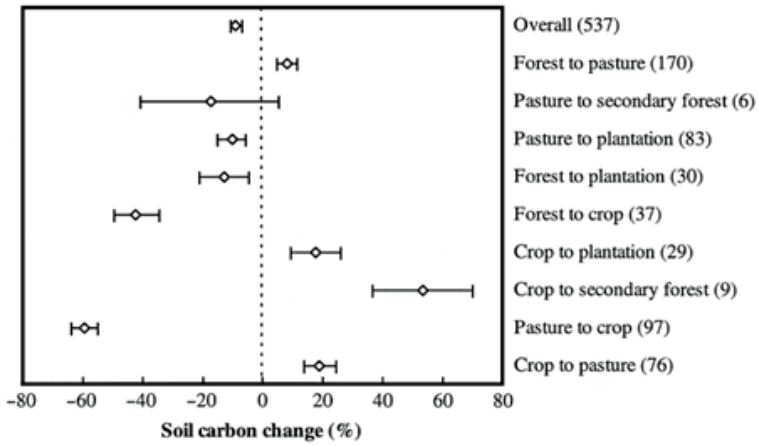

Figure 1. The presence of carbon in soil after different crop modification methods (after Guo & Gifford, 2002)

Recently, European strategies, such as the Biodiversity Strategy for 2030 and the Farm to Fork Strategy, emphasize the need to integrate semi-natural grasslands into more extensive sustainability objectives. In Romania, for example, these ecosystems contribute directly to the provision of public goods: clean water, pollination services, landscape preservation and important in preservation cultural heritage (Dragomir et al, 2023). Semi-natural pastures, many of which are Natura 2000 sites, host rare plant and animal species that cannot survive in intensive agricultural systems, that is the reason why from an economic point of view, grasslands offer opportunities for diversification, through the production of traditional dairy and meat products with high added value, as well as through the development of eco-tourism, species conservation and medicinal raw material. Certified products originating from extensive grassland systems can benefit from European quality schemes (e.g., Protected Designation of Origin-PDO, Protected Geographical Indication-PGI), linking environmental conservation with rural development (European Commission, 2023).

Nevertheless, challenges remain significant: land fragmentation, grassland's abandon and the effects of climate change (droughts, extreme weather) threaten the long-term sustainability of these natural ecosystems. Adaptive management, the integration of traditional practices with technological innovations, and the strengthening of farmer cooperatives are necessary measures to increase grassland resilience.

In this context, Romanian grasslands stand at the interface between tradition and innovation, offering both ecological stability and economic potential. By embedding them into national and European sustainability policies, they can play a decisive role in the transition towards a climate-neutral and resource-efficient agriculture.

Recent studies in Transylvania and the Subcarpathian hills highlight that permanent grasslands managed extensively (mowing and moderate grazing) store between 30-45% more SOM compared to adjacent arable lands (Blaga et al., 2005; Popovici & Ciubotariu, 1992). In contrast, grasslands subjected to frequent ploughing and reseeding exhibit accelerated organic matter mineralization, with losses

comparable to those observed in degraded pastures. The role of microbial communities in the stability and functionality of grassland ecosystems is increasingly recognized, and recent research highlights the link between long-term fertilizer application and changes in the soil microbiome (Stoian et al., 2022; Vidican et al., 2023).

Similar experiments conducted on high-natural value grasslands in the Apuseni Mountains have shown that long-term fertilization modifies colonization strategies at the root level of dominant species, with implications for microbial and plant biodiversity (Corcoz et al., 2022).

The Romanian case provides additional insights. Measurements from the Apuseni Mountains and Subcarpathian areas (Popovici & Ciubotariu, 1992; Blaga et al., 2005) confirm that permanent grasslands managed extensively contain significantly higher organic carbon stocks in the upper 40 cm of soil compared to adjacent arable fields.

At the same time, results suggest that the depth distribution of SOM is critical. In natural grasslands, up to 60% of the total SOM stock is concentrated in the first 20 cm of soil, largely due to dense root mats. However, the deeper layers (20-40 cm) also retain significant amounts, ensuring long-term stability (Lisec et al., 2025). This contrasts with arable systems, where SOM is predominantly surface-bound and more easily lost through erosion or oxidation. The role of deep root systems in perennial grasses is thus central to the long-term sequestration of carbon.

Climate change introduces new dynamics in SOM accumulation. Drying climate, droughts, increasingly frequent even in Romania, may affect plant production, but evidence suggests that root allocation increases under water stress, potentially enhancing belowground carbon inputs (Vörös et al., 2025).

Another important aspect revealed by the simulated results of Guo and Gifford, 2002 is the resilience of degraded grasslands. Although their SOM content is reduced compared to natural grasslands, they still maintain higher levels than arable lands. This indicates that even partially degraded systems retain a carbon sequestration potential that could be restored through interventions such as overseeding with legumes, controlled grazing, or organic fertilization. Case studies from Brașov and Cluj counties show that, after 5-7 years of improved management, SOM levels in degraded grasslands increased by 15-20%, approaching those of semi-natural systems (Dumitrescu et al., 1987).

Sustainable management practices are essential to maintain and enhance SOM in Romanian grasslands. Controlled grazing systems, periodic overseeding with legumes and valuable grasses, as well as organic fertilization with manure or compost have shown positive effects on soil structure and carbon sequestration (Dumitrescu et al., 1987). Moreover, agri-environmental measures supported under the Common Agricultural Policy (CAP) encourage farmers to preserve semi-natural grasslands, recognizing their role in climate change mitigation.

Measures to improve grasslands that contribute to increasing green mass yields and the quantity of roots in the soil are important, like harrowing and overseeding. The success of the work depends mainly on the quality of execution and the era, and in case of success it has a favourable effect on the properties of the soil.

Routine maintenance work (weed control, removal of woody vegetation, area modelling, weed control, etc.) has a favourable effect on soil properties, which has a positive impact on the harvest. Partial mobilization works considerably reduce soil erosion, favourably influence the water balance and protect the soil structure to a greater extent.

Favourable effects on production appear starting from the second year after sowing (Dumitrescu et al., 1987).

Total soil mobilization works on grasslands have a considerable influence on the decomposition and accumulation of organic matter in the soil and, through this, on the soil structure.

Soil organic matter plays an important role in healthy soil functions. Major soil functions such as primary production, water purification and regulation, carbon sequestration and regulation, biodiversity, and nutrient cycling depend largely on soil organic matter. Soil organic matter is made up of approximately 58% carbon, which has largely been taken up

from the atmosphere by plant photosynthesis (Grand & Michel, 2020).

Tillage works lead to rapid decomposition of the mobile fraction of the soil's organic matter, which thereby adversely influences the soil structure (the proportion of stable water aggregate decreases), processes is very rapid, occurring over a few years (Figure 2). Tillage has the opposite effect, leading to the accumulation of organic matter and, at the same time, to the improvement of soil structure. The process is very slow, with the balance between the amount of organic matter accumulated and the amount decomposed being achieved over decades (Dermatti, 1972).

At the opposite pole, increasing soil aeration through ploughing and stimulating the factors that determine its decline, especially in intensive agricultural systems, and over time exposes the soil to a series of degradation processes, sometimes irreversible.

The mineralization of organic matter in the soils of cleared meadows occurs at an accelerated rate in approximately 6 years, reaching the level of that in arable lands.

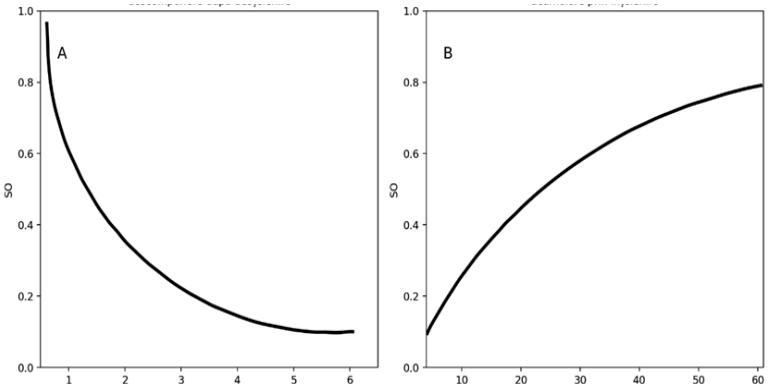

Figure 2. Scheme of the dynamics of organic matter (SO) in a grassland soil, after Dermatti, 1972 (A - the rate of decomposition of organic matter after tillage; mobile SO decomposes, for the most part, within a few years. B - the rate of accumulation of organic matter through tillage; the balance between accumulated SO and decomposed SO is achieved within a few decades

CONCLUSIONS

This bibliographical research emphasizes the role of grasslands in soil organic matter accumulation and carbon sequestration.

Grasslands contain 30-50% more SOM than arable lands, especially in the top 20 cm of soil.

Proper management of natural grasslands to increase harvest also implies an increase in the number of roots in the soil, making considerable progress in the accumulation of organic matter.

Sustainable management practices such as rotational grazing, overseeding, and reduced soil disturbance are essential to maintain SOM stocks.

Global policies must prioritize grassland conservation and restoration in soil health and climate change mitigation even if further research is needed to validate these.

Abstract

This study presents a predictive data acquisition system that integrates the Arduino Leonardo development platform with the Python programming language for automated environmental monitoring. The system employs a suite of sensors - DHT22 for temperature and humidity, BMP180 for atmospheric pressure, and MQ-7 for gas concentration - to collect real-time data. These measurements are transmitted to a Python-based processing environment, where time-series forecasting algorithms, including ARIMA, are applied to analyze trends and predict environmental variations. The system offers a cost-effective and adaptable solution for air quality assessment, meteorological research, and environmental data analysis, facilitating timely interventions and enhanced resource management.

Key words*: Arduino Leonardo, BMP180, DHT22, MQ3, Python, environmental prediction.*

INTRODUCTION

The automated acquisition of data from sensors deployed in remote or challenging environments is essential for ensuring accuracy and efficiency in environmental monitoring. Automation reduces human error, improves data reliability, and streamlines the information-gathering process - especially in conditions where manual data collection is impractical.

Data acquisition systems (DAQ) play a crucial role in scientific research and engineering, providing solutions for testing, automation, and advanced analysis. These systems utilize various sensors and transducers to convert physical phenomena into measurable signals. Core functions of a DAQ system include signal conditioning, analog-to-digital conversion, and data processing, all of which contribute to a comprehensive understanding of environmental variables and support evidence-based decision-making (Maurizio, 2013).

Two critical components in the data acquisition process are data analysis and prediction. Data analysis enables the identification of patterns, correlations, and statistical relationships within collected datasets, forming the basis for reliable interpretation and trend recognition. Techniques such as descriptive statistics, correlation analysis, and probability distributions are applied to extract actionable insights.

Prediction, in contrast, focuses on estimating future values based on historical data. This is achieved through statistical and machine learning methods, which are used to construct models capable of anticipating environmental changes. These predictive techniques are instrumental in transforming raw data into practical forecasting tools.

Machine learning algorithms form a critical component of this predictive framework. They can be broadly categorized as follows:

- Regression – for forecasting continuous variables such as temperature or pressure.
- Classification – for categorizing environmental conditions (clear, cloudy, rainy).
- Unsupervised Learning – utilized to identify patterns and relationships in data without predefined labels.
- Semi-Supervised Learning – combining labeled and unlabeled data for improved prediction accuracy.

Recent advances in machine learning have significantly enhanced environmental monitoring by enabling automated analysis of complex datasets. In addition to machine learning, statistical methods are essential for predictive modeling, offering a solid theoretical basis for analyzing data relationships. Key statistical approaches include:

- Regression Analysis – used to estimate the relationships between variables, enabling the

prediction of one variable based on the behavior of others.

- Time Series Analysis – focuses on detecting patterns within temporally ordered data, making it especially effective for identifying trends and forecasting future values.
- Bayesian Methods – utilize probabilistic reasoning and prior knowledge to update predictions as new data becomes available, allowing for dynamic and adaptive forecasting (Siahaan et al., 2023).

Given the wide range of signals and parameters that can be sampled and stored, DAQ involves numerous techniques and skills. A DAQ system consists of various components, including sensors, communication links, signal processors, computers, databases, and data acquisition software. These components must function cohesively to ensure the system's reliability and effectiveness (Potter et al., 2012; Singh et al., 2009; Fisher et al., 2012; Sarma et al., 2018).

This study presents the design and evaluation of a predictive DAQ system built on the Arduino Leonardo platform and integrated with Python. The system incorporates key environmental sensors and leverages statistical forecasting methods to facilitate real-time environmental monitoring and predictive analytics. Applications include air quality assessment, meteorological research, and smart environmental management systems.

MATERIALS AND METHODS

Hardware component

Arduino is a popular open-source platform for rapid prototyping and data acquisition. This study uses the Arduino Leonardo, featuring the ATmega32u4 microcontroller with built-in USB communication for efficient data transfer (Arduino Leonardo, 2025; Monk, 2022).

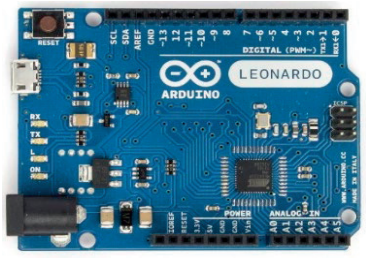

Figure 1. Arduino Leonardo development platform (Arduino Leonardo, 2025)

The Arduino Leonardo board includes 19 digital and 12 analog input/output ports, facilitating compatibility with a wide array of sensors and external modules. This versatility makes it particularly well-suited for customizable applications, such as predictive environmental monitoring.

The board operates at a nominal voltage of 5V, with each I/O pin capable of sourcing or sinking up to 40 mA of current. It features an internal pull-up resistor (disabled by default), which provides enhanced control during circuit design. Additionally, it includes 32KB of flash memory, 2.5KB of SRAM, and runs at a clock speed of 16 MHz.

In the developed system, the ATmega32u4 microcontroller functions as the central unit, responsible for sensor data acquisition and transmission. Its ability to handle multiple I/O operations and communicate via USB makes it an ideal solution for integration with the Python-based processing environment.

Sensor specifications

The proposed system integrates three types of sensors to monitor key environmental parameters – temperature and humidity, atmospheric pressure, and gas concentration.

The **DHT22** sensor (Figure 2, Table 1) provides accurate digital measurements of temperature and relative humidity. It employs proprietary signal acquisition and humidity sensing technology, ensuring both high precision and long-term operational stability. The sensor outputs data into a calibrated digital format, simplifying its integration with microcontroller-based systems.

Figure 2. DHT22 sensor module used for temperature and humidity measurement (DHT22, 2025)

The **BMP180** sensor (Figure 3, Table 1) adds atmospheric pressure monitoring capability to the data acquisition system. It combines a high-resolution barometric pressure sensor with a

temperature sensor, making it suitable for weather-related applications.
As the successor to BMP085, the BMP180 is optimized for accuracy and energy efficiency, and is commonly used in consumer-grade environmental monitoring devices.

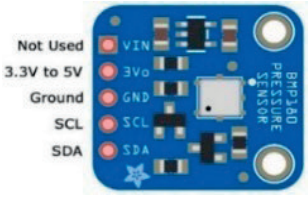

Figure 3. BMP180 sensor module used for atmospheric pressure measurement (BMP180, 2025)

The **MQ-7** sensor (Figure 4, Table 1) is employed for detecting gas concentrations, particularly carbon monoxide (CO) and hydrogen (H_2). It plays a critical role in evaluating air quality, contributing valuable data to the system's predictive analytics. However, it is sensitive to environmental noise and requires a preheating phase to stabilize reading.

Figure 4. MQ-7 sensor module used for gas concentration monitoring (MQ7, 2025)

Table 1. Technical characteristics of sensors

Sensor	DHT22	BMP180	MQ7
Measured parameters	Temperature, humidity	Atmospheric pressure	Gas concentration (CO, H_2)
Accuracy	±0.50°C ±2% RH	±0.12 hPa	Varies by gas
Communication interface	Digital (single wire)	I2C	Analog via ADC
Operating voltage	3.3-6V	1.62-3.6V	5V
Additional notes	Calibrated output, 2s reading interval	Include EEPROM for calibration; temperature compensation	Requires preheating; sensitive to environmenttal noise

Software tools and programming

The Arduino Leonardo microcontroller is programmed using the Arduino language via the Arduino Integrated Development Environment (IDE). This platform allows for the development of custom scripts to control sensor operations, manage collected data, and transmit information to a Python-based environment for further analysis.
Python serves as the core platform for data processing in this study, selected for its readability, versatility, and robust ecosystem of libraries. Its object-oriented structure and extensive community support make it well-suited for implementing complex data analysis and predictive modeling tasks (Fuentes, 2018).

Data processing and prediction pipeline

Figure 5 illustrates the end-to-end data processing workflow of the developed system.
Environmental data from DHT22, BMP180, and MQ-7 sensors is first displayed on the Arduino IDE Serial Monitor. Using Python's serial communication libraries, the data is captured and organized into a Pandas DataFrame for efficient handling. The processed data is then exported to Excel for storage and traceability.

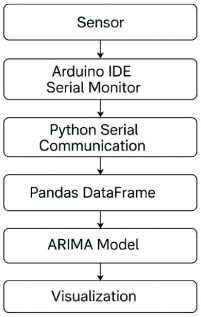

Figure 5. Data processing flow for DAQ system

For predictive analysis, the system applies an ARIMA (AutoRegressive Integrated Moving Average) model to the time-series data, enabling the forecasting of future environmental conditions. Results are visualized through Python-based plotting libraries, providing insights into data trends and supporting real-time, informed decision-making.

RESULTS AND DISCUSSIONS

System implementations

The proposed system utilizes the Arduino Leonardo platform (Figure 6) to acquire data

from three environmental sensors: the BMP180 (atmospheric pressure), the DHT22 (temperature and humidity), and the MQ-2 (gas concentration). Sensor readings are initially displayed on the Arduino IDE Serial Monitor, enabling real-time data visualization.

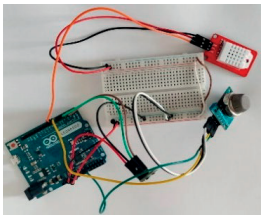

Figure 6. System implementation using Arduino and environmental sensors

Data Collection and Visualization

Sensor data is retrieved via Python using serial communication, structured into data frames, and stored in Excel files for traceability and further analysis. Figures 7 to 10 present graphical outputs generated using the Arduino Plotter, providing a visual overview of temperature, humidity, gas levels, and atmospheric pressure as measured in real time.

This data forms the basis for analyzing environmental conditions and identifying trends over time - supporting applications in air quality monitoring, precision agriculture, and meteorological research.

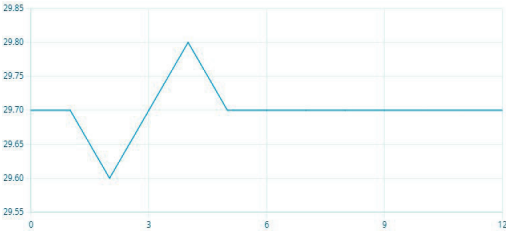

Figure 7. Temperature readings from DHT22 in Arduino Plotter

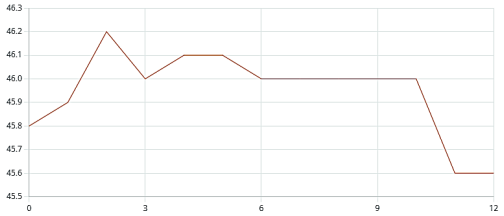

Figure 8. Humidity readings from DHT22 in Arduino Plotter

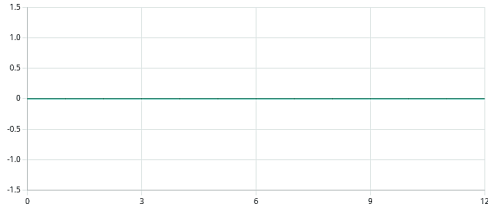

Figure 9. Gas concentration readings from MQ-7 in Arduino Plotter

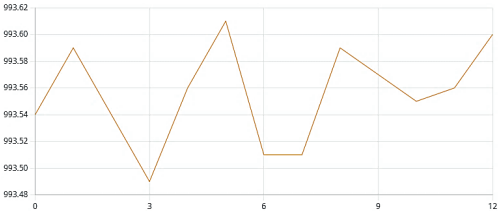

Figure 10. Atmospheric pressure readings from BMP180 in Arduino Plotter

Python's extensive ecosystem enhances the system's data processing and modeling capabilities. Key libraries include:

- Pandas – efficient for managing tabular data, offering tools for filtering, aggregation, and transformation.
- Matplotlib and Seaborn – visualization libraries that support the creation of insightful and interpretable charts.
- Scikit-learn – a machine learning toolkit providing access to models such as linear regression, decision trees, and more.

These tools collectively empower the system to bridge environmental sensing and predictive analytics. To support this, two Python programs were developed - one for data acquisition and formatting, and another for predictive modeling - each playing a vital role in the end-to-end analysis pipeline.

Predictive Modeling with ARIMA

To enable predictive analysis, two Python programs were developed - each with a distinct role in the data acquisition and forecasting pipeline.

In the first program, Python libraries such as serial and pandas were employed to manage communication between the Arduino and the host computer. The serial library facilitated data extraction from the Arduino sensors, while pandas enabled efficient organization, manipulation, and export of the data to Excel format.

This framework ensured clean, structured datasets for further processing.

The second program focused on time-series forecasting using the ARIMA (AutoRegressive Integrated Moving Average) model.

Libraries used included pandas for data handling, statsmodels.tsa.ARIMA.model for implementing the ARIMA algorithm, matplotlib.pyplot for visualization, and NumPy for numerical operations.

ARIMA, a well-established statistical technique, leverages past observations to model and predict future values in a time series - an approach particularly useful in environmental monitoring. An ARIMA model is defined by three parameters:

- p: the autoregressive order (number of lagged observations),
- d: the degree of difference (used to make the data stationary),
- q: the moving average order (size of the error window used for smoothing).

Fine-tuning these parameters allows for the creation of an optimized forecasting model tailored to the nature of the dataset (Wicaksana et al., 2022; Herrera-Gonzalez et al., 2024; Ganghetty et al., 2021; Spyrou et al., 2022; Kulkarni, et al., 2023).

ARIMA models can be adapted into simpler forms - such as AR (AutoRegressive), MA (Moving Average), or ARMA - by setting one or more parameters to zero. While ARIMA assumes that past values influence future trends, it is important to recognize its limitations, particularly in cases where external, non-recurring factors influence environmental conditions (Tibshirani, 2023). To assess the model's predictive accuracy, we evaluated three commonly used performance metrics:

- RMSE (Root Mean Square Error)
- MAE (Mean Absolute Error)
- MAPE (Mean Absolute Percentage Error)

For example, in forecasting humidity using the ARIMA(5,1,0) configuration, the results showed a marked improvement when data was sampled more frequently:

- Case 1 (one reading/day): RMSE = 1.34, MAE = 1.09, MAPE = 2.06%
- Case 2 (three readings/day): RMSE = 0.92, MAE = 0.71, MAPE = 1.28%

These results demonstrate that increasing the sampling frequency significantly enhances forecasting accuracy. The findings underscore the importance of data resolution in predictive modeling, particularly in dynamic environmental contexts.

Table 2. Values for the once-per-day reading frequency

Day	DHT22H (%)	DHT22T (°C)	MQ-7 (ppm)	BMP180 (hPa)
1	59.5	9.4	21	987.41
2	49.6	7.9	0	989.76
3	48.5	9.8	0	988.34
4	52.3	10.1	0	987.98
5	54.3	10.4	3	988.85
6	50.4	10.6	0	987.43
7	52.8	11.2	0	989.32
8	51.5	11.3	0	988.32
9	49.7	11.8	2	988.54
10	53.7	11.9	0	989.53
11	52.4	11.4	0	987.98
12	51.8	12.1	0	988.93
13	50.4	12.3	0	987.78
14	53.2	12.4	0	985.32

Comparative Analysis - Case 1

Table 2 presents the sensor data collected with a sampling frequency of one reading per day.

Notably, the MQ-7 sensor - designed to detect flammable gases such as carbon monoxide (CO) and hydrogen (H_2) - is also sensitive to other environmental variables. This high sensitivity may result in considerable fluctuations in the recorded values, as observed in the dataset.

These unexpected variations in reading highlight the need for careful analysis and interpretation to accurately assess the system's performance and

the environmental conditions affecting the MQ-7 sensor. The corresponding analysis results are illustrated in Figures 11 to 14.

Eight ARIMA model configurations were tested by varying the parameters p and d, as shown in Table 3. Among these, the model with parameters ARIMA (scaled_data, order = (5,1,0)) yielded the best results, producing predicted values that closely matched the actual sensor readings presented in Table 2.

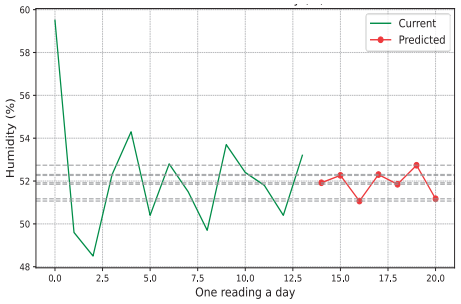

Figure 11. The graph and humidity prediction using DHT22

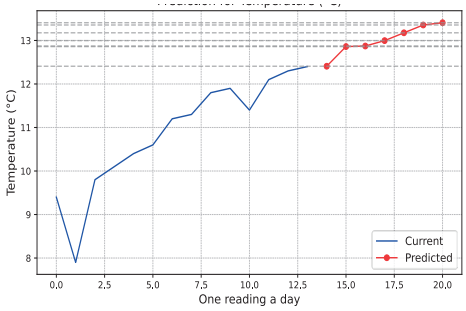

Figure 12. The graph and temperature prediction using DHT22

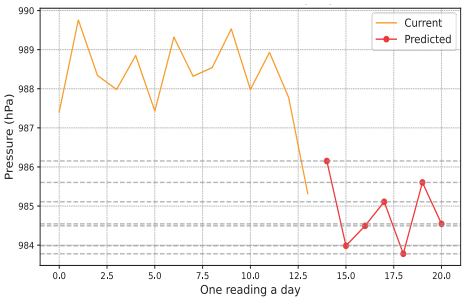

Figure 13. The graph and atmospheric pressure prediction using BMP180

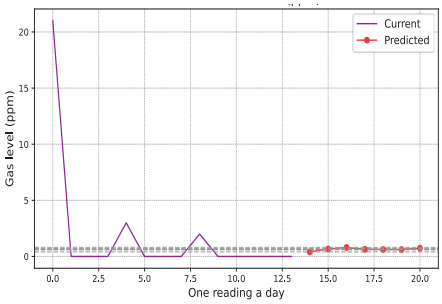

Figure 14. The graph and gas level prediction in the atmosphere using MQ-7

The comparative analysis indicates that the MQ-7 sensor is highly sensitive to environmental changes. This is reflected in its output, which often fluctuates from baseline values (typically zero) to peaks between 2 and 21 ppm in the measured data (Table 2), and from 0.13 to 6.96 ppm in the predicted data (Table 3). Such sensitivity underscores the need for precise calibration and controlled measurement conditions to ensure reliable predictions.

Table 3. Testing the ARIMA model for data acquisition once a day for 7 days

Cases	Sensor	Day						
		1	2	3	4	5	6	7

	54.7	13.2	0	989.24
	56.3	13.3	0	988.45

Predicted trends for humidity, temperature, gas concentration, and pressure are shown in Figures 15 to 18, demonstrating improved accuracy with increased sampling.

The most accurate results were obtained using the ARIMA model with the configuration ARIMA(scaled_data, order = (4,2,0)), based on multiple test iterations.

The outcomes of these tests are summarized in Table 5.

The results shown in Figures 11–14 and Tables 2-3 correspond to Case 1 (one reading per day), while Figures 15-18 and Tables 4-5 represent Case 2 (three readings per day).

	5	51.44	13.08	983.90	0.30
	6	52.03	13.28	985.75	0.30
	7	52.30	13.40	984.89	0.26

To illustrate why Case 2 yields better performance, we compare measured and predicted values for each sensor.

For the DHT22H sensor (humidity):

- Case 1: Measured values ranged from 48.5% to 59.5% (Table 2), with predicted values between 51.06% and 52.73% (Figure 11, Table 3).
- Case 2: Measured values ranged from 48.9% to 65.5% (Table 4), while predictions ranged from 56.06% to 57.54% (Figure 15, Table 5).

In both cases, predictions tend to cluster around the mean, underestimating peak values. However, Case 2 shows better alignment with the actual trend, thanks to the increased sampling frequency.

Table 6 summarizes the average measured and predicted humidity values for both cases.

For the DHT22T sensor (air temperature):

- In Case 1, measured values ranged from 7.9°C to 12.4°C (Table 2), while predicted values ranged from 12.4°C to 13.4°C (Figure 12, Table 3).
- In Case 2, measured temperatures varied from 6.2°C to 13.3°C (Table 4), with predictions between 13.4°C and 14.0°C (Figure 16, Table 5).

In both cases, the predicted values exceed the actual measurements, indicating a consistent overestimation. This effect is more pronounced in Case 1, where predictions are centered around a higher average. While Case 2 shows improved responsiveness due to more frequent sampling, the predicted values still reflect a bias toward higher temperatures. The maximum measured temperature in Case 2 was 13.3°C, compared to a predicted peak of 14.0°C.

Table 7 provides a comparison of average measured and predicted temperature values for both cases.

For the MQ-7 sensor (gas concentration):

- In Case 1, measured values ranged from 0 to 21 ppm (Table 2), while predicted values remained between 0.4 and 0.8 ppm (Figure 13, Table 3).
- In Case 2, measured values ranged from 0 to 18 ppm (Table 4), whereas predicted values remained fixed at 0 ppm (Figure 17, Table 5).

In Case 1, although the predicted values generally follow the average trend, they fail to capture peak variations, indicating a degree of underfitting. In Case 2, despite the increased sampling frequency, the model consistently predicts 0 ppm, failing to reflect actual fluctuations. This persistent underestimation may result from sensor calibration issues or excessive environmental noise sensitivity.

Table 8 compares the average measured and predicted gas concentrations for both cases.

Table 6. Comparison of results for DHT22H sensor (air humidity)

Cases	Measured value			Predicted value		
	Min	max	average	min	max	average
1	48.5	59.5	52.15	51	52.7	51.89
2	48.9	65.5	54.69	56	57.5	56.62

Table 7. Comparison of results For DHT22T sensor (air temperature)

Cases	Measured value			Predicted value		
	Min	max	average	min	max	average
Case 1	7.9	12.4	10.9	12.4	13.4	13
Case 2	6.2	13.3	11.05	13.4	14	13.7

Table 8. Comparison of results for MQ-7 sensor (gas level in the atmosphere)

Cases	Measured value			Predicted value		
	Min	max	average	min	max	average
Case 1	0	21	1.87	0.4	0.8	0.63
Case 2	0	18	0.83	0	0	0

For the BMP180 sensor (atmospheric pressure):

- In Case 1, measured values ranged from 985.32 to 989.76 hPa (Table 2), while predicted values ranged from 983.77 to 986.15 hPa (Figure 14, Table 3).
- In Case 2, measured values ranged from 987.42 to 989.95 hPa (Table 4), with predicted values between 988.22 and 988.62 hPa (Figure 18, Table 5).

In Case 1, predicted values were relatively close to actual measurements but tended to underestimate the pressure, clustering around a lower average. In Case 2, with more frequent sampling, the predicted values showed improved alignment, though the model still slightly underpredicted the peak pressure (988.62 hPa vs. the actual 989.95 hPa).

A comparison of prediction performance between the two sampling intervals reveals notable improvements:

- Humidity (DHT22): RMSE reduced by ~23%
- Pressure (BMP180): RMSE reduced by ~19%

These reductions highlight the benefits of increased measurement frequency for enhancing prediction accuracy.

Table 9 summarizes the average measured and predicted pressure values for both cases.

Table 9. Comparison of results for BMP180 sensor (atmospheric pressure)

Cases	Measured value			Predicted value		
	Min	max	average	min	max	average
1	985.32	989.76	988.24	983.77	986.15	984.80
2	987.42	989.96	988.71	988.22	988.62	988.38

CONCLUSIONS

The proposed system successfully achieved its primary objective: developing an integrated, low-cost solution for environmental data acquisition and predictive analysis with a satisfactory level of accuracy. Among the ARIMA configurations tested, the ARIMA(5,1,0) model yielded the most reliable results, particularly in forecasting humidity and temperature trends.

Regarding sensor performance, the DHT22 sensor demonstrated high reliability for both temperature and humidity measurements, while the BMP180 sensor provided consistent and accurate atmospheric pressure readings. Conversely, the MQ-7 gas sensor exhibited considerable variability, which negatively impacted the accuracy of gas concentration predictions. In both sampling scenarios, predicted gas values were either consistently zero or significantly underestimated, suggesting potential issues related to sensor calibration or sensitivity to environmental noise.

Despite this limitation, the system establishes a solid foundation for real-time environmental monitoring and predictive analytics. Future improvements should focus on refining gas sensor calibration and enhancing the robustness of predictive models for volatile environmental parameters.

Abstract

Recycling construction soil and debris is a key strategy for reducing pollution and enhancing economic efficiency. The process of sand production from construction debris, while beneficial, results in the accumulation of dense sludge containing harmful elements in sand-washing machines like EvoWash. This study investigates the potential reuse of mineral-rich sludge from the EvoWash machine for cultivating non-fruit-bearing plants, addressing environmental concerns at the Aabali landfill in Tehran. Eight plant species were selected: Nerium, Spruce, Rose, Eucalyptus, Bitter Olive, Myrtle, Ornamental Pistachio, and Cactus, chosen for their compatibility with the heavy metal content in the sludge and their native presence in Tehran, facilitating reuse without extensive transportation. Comprehensive laboratory analyses identified essential mineral elements in the sludge, indicating its potential for plant growth. Bi-weekly monitoring of plant growth over four months showed that a mixture of sludge and garden soil significantly improved plant development compared to pure sludge or garden soil alone. While certain plants struggled in 100% sludge, the mixed medium yielded superior growth outcomes. The study provides insights into the feasibility of using EvoWash sludge for sustainable plant cultivation, presenting a promising solution for reusing construction debris sludge and aligning with eco-friendly waste management practices. The findings highlight the potential of EvoWash sludge in enhancing soil fertility and supporting plant growth, contributing to sustainable agricultural practices and environmental conservation.

Key words*: Sand-Washing Sludge, Sustainable Growth Medium, Non-Fruit Bearing, Environmental Conservation, EvoWash.*

INTRODUCTION

Recycling of construction soil and debris has long been considered as an effective method to reduce pollution and negative environmental impacts, while also enhancing economic efficiency and job creation. Among the recycling methods, producing sand from construction debris is noteworthy. Although this process reduces many environmental risks and contributes to generating income and returning a significant portion of debris to the cycle, it is not without environmental challenges. The most significant drawback of this process is the accumulation of dense sludge and clay-like sediment at the bottom of the recycled sand-washing machine such as EvoWash. Due to the nature of the recycled raw materials, this sediment contains environmentally harmful elements.

The management of sludge resulting from the EvoWash process after washing recycled sand from construction debris is a critical issue in modern sludge treatment. Tests indicate that this sludge, similar to sewage sludge, is rich in nutrients, especially organic matter, and can be successfully used to improve soil fertility (Roig et al., 2006; Urbaniak et al., 2016) and enhance agricultural productivity (Salehi, 2022; 2023; Sugurbekova et al., 2023; Zhakypbek et al., 2024). However, there are general concerns that the presence of potential pathogenic microorganisms (Bibby & Peccia, 2013; Ye et al., 2011), toxic organic compounds (Clarke & Smith, 2011; Peng et al., 2015; Santos et al., 2009), and heavy metals (Bloemendal et al.,

2008; She et al., 2022; Tiruneh Ababu et al., 2014) may be generated in the sludge, similar to the challenges associated with the use of sludge from the EvoWash process.

Therefore, addressing this sludge appropriately with economically viable and environmentally acceptable methods has become a topic of significant importance (Salehi, 2022; 2023; Xu et al., 2023). The use of sludge in agriculture has been implemented globally, with numerous studies showing positive effects on soil and crop production, including increased nutrient and organic matter content (Mohan et al., 2014; Suhadolc et al., 2010; Wang et al., 2008), improved soil structure and porosity, enhanced cation exchange capacity (Angin & Yaghanoglu, 2011), and enzymatic activity (Siebielec et al., 2018).

However, the quality of sludge from the EvoWash process is generally dependent on the treatment technology and the composition of recycled construction waste in the overall amount of treated water (Eid et al., 2017). Therefore, methods for its use should be developed separately for each sand production facility to prevent environmental damage and pollutant accumulation with sustainable development (Cieślik et al., 2015; Kacprzak et al., 2017; Mohan et al., 2014).

The production of sludge from washing sand by the EvoWash machine in Iran is limited to the disposal and reclamation center for soil and construction debris in Tehran, located in the Aabali landfill. The Aabali landfill, situated at approximately 12°44'35" N latitude and 39°39'51" E longitude, about 25 kilometers east of Tehran, at an altitude of 1700 meters in the Hazar Dareh mountains, has a total area of about 545 hectares (Figure 1). The disposal areas within this complex have different applications based on the types of incoming waste. Over the years, to prevent the loss of construction materials and reduce the amount of buried and released debris, equipment for reclaiming sand from debris has been installed with a nominal capacity of 120,000 tons per year.

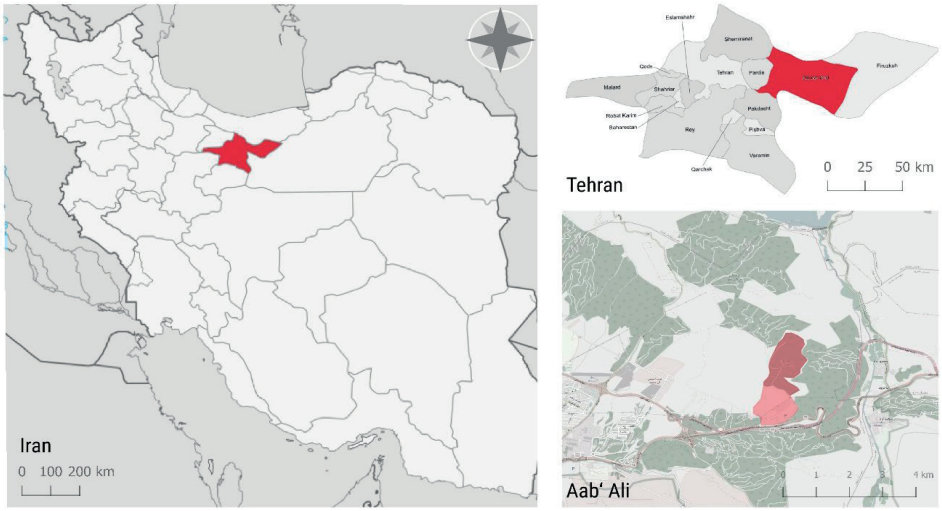

Figure 1. Geographic location of the Aabali disposal and processing center in Tehran

Tehran's Aabali landfill receives a massive influx of approximately 4,000 tons of soil and debris every day. Despite this, the center demonstrates a significant commitment to recycling, processing about 500,000 tons of sand in 2023. This effort resulted in the daily reclamation of roughly 1,370 tons of soil. Investigations indicate that this amount has increased by around 10% compared to 2020, and with the planned expansion of extraction plants in the area, it is predicted to increase by 15% until 2026 (Tehran Municipality, 2023).

A significant problem in sludge management at the Aabali landfill in Tehran is the

accumulation and disposal of sludge within the landfill area. In 2023, after the settling basins for sludge (2 ponds, each with 4,800 m^3 capacity) were filled and sludge overflowed from these basins, approximately 15,000 tons of sludge (as dry solid materials) were left in the area. Currently, there is no strategy for using this buried sludge, and the need for sludge management in the hierarchy of waste, including reducing sewage sludge production (using effective settling and dewatering processes) and finding solutions for use in construction or agriculture, has been emphasized (Salehi, 2022; 2023).

The exploration of sludge for cultivating non-fruit bearing plants has garnered attention, driven by its potential benefits. Concurrently, research has delved into cultivating aquatic plants in metal-laden sludge, envisioning them as potential fertilizers within safe metal concentration limits (Amulya et al., 2023). Furthermore, the adoption of light-emitting diodes (LEDs) in protected horticulture, particularly in Northern Europe, has demonstrated enhanced plant growth by ensuring consistent radiative fluxes across seasons (Paucek et al., 2020).

Despite these promising avenues, the use of sludge for irrigation requires careful consideration of potential risks. In arid regions facing water scarcity, sludge serves as a crucial resource for irrigating vegetable and forage crops (Othman et al., 2021). But sludges, which root in construction debris, contain significantly considerable elements. Hydroponic systems utilizing different sludge types as fertilizer and irrigation water for green plant cultivation have shown promise (Magwaza et al., 2020a; Magwaza et al., 2020b). However, untreated sludge irrigation has been associated with heavy metal accumulation in plants, with iron being a predominant metal in fruits (Ahmed et al., 2022).

The practice of utilizing sludge for irrigation, while economically advantageous, poses substantial health and environmental risks. Sludge, laden with minerals but traces of heavy metals, is notably generated in significant quantities (Ngobeni et al., 2021). Additionally, concerns arise about the fate of endocrine-disrupting compounds (EDCs) in sludge treatment and their potential impact on aquatic wildlife groups (Siegrist et al., 2005).

This pilot study explores the mineral-rich characteristics of sludge from the EvoWash machine for cultivating non-fruit bearing plants, focusing on eight distinct species including Nerium, Spruce, Rose, Eucalyptus, Bitter Olive, Myrtle, Ornamental Pistachio, and Cactus. The sludge derived from the EvoWash sand-washing process is abundant in essential elements like iron, calcium, magnesium, phosphorus, and potassium, making it a valuable resource for plant growth. The choice of these plant species is due to the presence of heavy metals such as lead, mercury, and cadmium in the sludge and the potential human and animal hazards if fruit-bearing plants were planted. Moreover, these selected plant species are native to the study area, allowing for the potential reuse of the sludges without the need for extensive transportation. Transporting these sludges via containers would result in spillage and environmental pollution due to their nature, leading to high costs.

MATERIALS AND METHODS

Identification of sludge from the EvoWash machine Characteristics

The research initiated by identifying the physical and chemical characteristics of sludge from the EvoWash sand-washing machine. This involved analyzing the levels of essential mineral elements such as calcium, magnesium, lead, cadmium, potassium, and more. The data was obtained through comprehensive laboratory tests, including Flame Photometry Method (F.P.M), Standard Methods (St. M.), and pH measurements using St. M. 4500-H+B and St. M. 4500-P-D methods.

Assessment of Soil Fauna Viability

The research focused on soil fauna, particularly earthworms, as biological indicators for soil health. Earthworms were exposed to sludge and a sludge-garden soil mixture, and their movement and survival were observed, providing insights into the ecological compatibility of EvoWash sludge, a crucial consideration for sustainable land use.

Simultaneously, eight selected plant species, including roses, bitter olive, and ornamental pistachio, were cultivated using EvoWash

sludge as the growth medium. Plant growth and health were monitored bi-weekly, with a parallel study involving the same species in pots with 100% garden soil for comparative assessment of EvoWash sludge's efficacy in supporting plant growth.

The selected plants were grown in 15 kg pots with bi-weekly irrigation after surface soil drying, and growth was documented twice a week. After two months, Rose, Bitter Olive, and Ornamental Pistachio exhibited more favorable growth than counterparts in garden soil. Eucalyptus showed limited growth in 100% EvoWash soil, prompting further investigation into a sludge and garden soil mixture. Over four months, all plants in EvoWash-based cultivation displayed superior growth compared to those in garden soil. Although certain plants struggled in 100% EvoWash soil, the introduction of mixed EvoWash and garden soil significantly improved their growth. Overall, after four months, all plants exhibited better growth in the mixed EvoWash and garden soil, indicating its potential as a viable growth medium. This comprehensive approach allowed for a holistic evaluation of EvoWash sludge in both ecological and horticultural contexts Data

Laboratory Studies and Sample Collection

In the field study stage, a total of 30 samples were collected from both old and new sedimentation basins, in packages of 1 and 3 kilograms. Additionally, for the examination of the soil characteristics outside the basins, and the investigation of avalanche soil, excavation, and reservoir water, samples were separately collected from the soil abandoned in the area through channels. Avalanche soil, excavation soil delivered by a container, and water from each reservoir were sampled from various parts and packaged as composite samples. These samples were sent to accredited environmental organization laboratories with Grade 1. The map below shows the location of the sample collection (Figure 2).

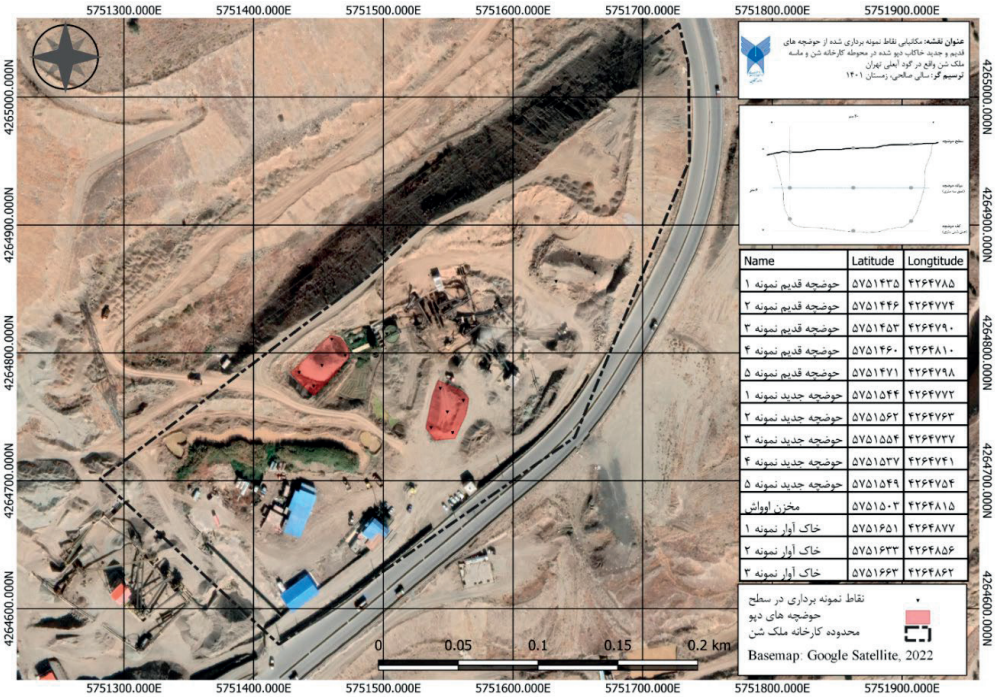

Figure 2. The location of the samples collection

Sampling Method and Volume

After exposure to sunlight, the sedimentation basin undergoes a decrease in volume by losing water and becomes compacted with the new sedimentation basin. The deeper the sedimentation basin is, the less likely it is to increase in volume and change its physicochemical properties after rainfall or snowfall in the region. Therefore, samples for examination must be taken from different depths (basin surface, three-meter depth, and six-meter depth), various points in the basins (old and new), and also from the entrance area soil released by a container and the sedimentation basin itself. Although it should be considered that due to the entry of sedimentation basins from 22 different areas of Tehran municipality with different construction materials and lifetimes, the sedimentation basin from each container has different characteristics. However, with a sufficient number of samples, general information about the sedimentation basin in the area can be obtained.

The sampling method was two-stage systematic (zigzag sampling from corner points of basins) and purposive (aiming to collect samples from different points to achieve general physicochemical characteristics of the sedimentation basin). Considering the size of the study population, nature, and research goal based on the Cochran formula (for a population with an unknown volume and variance) with a 5% error rate, a minimum of 23 samples were required for laboratory studies.

Since the sampling method in this research was two-stage, the surrounding soil soaked with the sludge and the entrance soil by containers were also sampled in the first stage. Although this soil was needed to assess the possibility of reusing the sludge, as transferring the sludge to another center for recycling is costly and may cause environmental pollution due to dust dispersion and the possibility of spillage from transport containers, the feasibility of using the sludge from the EvoWash machine in the Aabali landfill area was examined. Therefore, the available soil for mixing with the sludge must be sourced either from the surrounding area or the input soils to the area. For this reason, these soils were also examined and analyzed in the laboratory and for practical applications.

The samples' volume, according to the laboratory standards, was one kilogram. Due to the possibility of spillage, incorrect sampling, and minimizing errors, three-kilogram samples were prepared in the research area and then divided into smaller packages in the laboratory.

RESULTS AND DISCUSSIONS

In the context of managing and organizing sludge, the first step is to identify the physical and chemical characteristics of the sludge to enable its utilization in various industries and sectors. As this sludge has been used in cultivation plants, the garden chalky soil from the surrounding green spaces has been analyzed accordingly to understand the impacts of changing the level of elements of the soil comparing to the sludge. According to the findings, the results showed an increase in the levels of lead, sodium, ammonia, copper, iron, zinc, arsenic, nickel, and chromium. Additionally, the levels of electrical conductivity, total nitrogen, chloride, nitrite, and nitrate in the sludge have increased, while the levels of calcium, magnesium, potassium, soil acidity, and total phosphorus have decreased (Table 1).

Table 1. Analysis of elemental composition in garden chalky soil versus EvoWash machine sludge at the surface level (0-60 cm depth) in the new basin

	Element	Symbol	Unit	Garden chalky soil	Sludge	Changes	Test
1	Calcium	Ca	mg/kg	1532	356	decrease	F.P.M
2	Magnesium	Mg	mg/kg	252	25	decrease	F.P.M

Comparison between the garden soil and the sludge in the new basin indicates that most elements in the process of sand extraction and sludge production have changed negatively, considering the aim of the research.

By comparing the sludge at the surface of the new basin with the sludge at the bottom of the old basin, it can be concluded that some elements have increased over time, while others have decreased. This indicates that natural purification of the sludge does not occur over time, and measures should be taken to manage the sludge properly. The table below shows the changes in sludge compared to soil standards after accumulation and settling (Table 2).

Table 2. Evaluation of the lowest observed values for key parameters and elements against relevant standards for construction soil, sludge, and green space soil, as defined by Saed & Tila (2021)

	Element	Symbol	Unit	Sludge at the bottom of the old basin	Differences in accumulation	Standards for wastewater for agricultural irrigation	Standards for green space soil
1	Calcium	Ca	mg/kg	280	decrease	200	400
2	Magnesium	Mg	mg/kg	29	increase	100	40
3	Lead	Pb	mg/kg	24	decrease	50	300
4	Cadmium	Cd	mg/kg	2.5>	-	1	40
5	Potassium	K	mg/kg	5.78	decrease	6	350
6	Soil Acidity	pH	-	7.46	increase	6.5 - 8	More than 7

7	Electrical Conductivity	EC	Ds/m	2648.29	decrease	500-700	3000
8	Total Nitrogen	NT	%	197	increase	More than 2	75
10	Sodium	Na	mg/kg	205.89	decrease	8	200
11	Total Phosphorus	PT	mg/kg	0.2>	-	6	300
15	Chloride	CL	mg/kg	203	decrease	600	250

32	Chromium	Cr	mg/kg	24.55	decrease	100	110
33	Mercury	Pb	mg/kg	1.08	increase	10	50

The comprehensive analysis of parameters and elements against established standards confirms adherence to permissible limits. To optimize plant growth, a recommended mixture of soil amendments should consist of soft soil, gravel, poultry litter ash, biomass ash, and compost. (Kominko et al., 2019).

To further assess the efficacy of sludge from the EvoWash machine in comparison to other growth mediums, a comparative cultivation study was conducted using different substrates; including hundred percent sludge from the EvoWash machine, a mixture of sludge from the EvoWash machine and garden chalky soil (1:1) to reduce sludge density and permeate the structure of the planting substrate, a mixture of sludge from the EvoWash machine, garden chalky soil and compost plus powdered sulfur (to control the pH) (1:1:1) and hundred percent garden chalky soil. The data includes plant height (Figure 3), leaf count (Figure 4) and the presence of branches or buds (Figure 5) at four different time points: four weeks after planting, two months after planting, six months after planting, and one year after planting (Table 3).

Table 3. Evaluation of the growth of investigated plants in different planting substrates

	Medium	First day	After four weeks	After two months	After six months	After one year

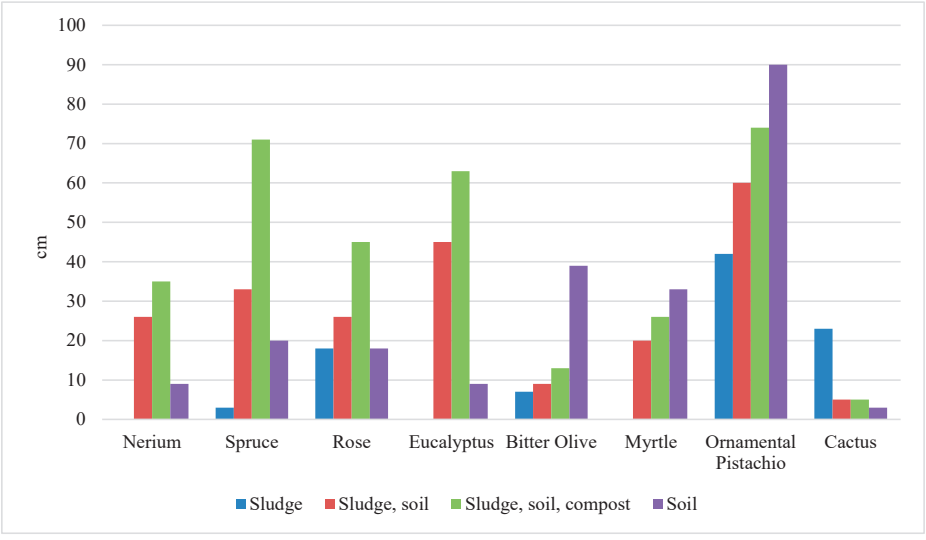

Figure 3. Changes in the growth of selected plant stems throughout the year in different planting substrates

The results of the studies indicate that, in general, all examined plants, except for bitter olive, ornamental pistachio, and cactus, have shown better growth in a mixed sludge (with soil or with soil and compost). Overall, the sludge mixed with soil and compost has proven more conducive to the growth of the examined plants than sludge mixed only with soil. Nerium, eucalyptus, and myrtle plants did not thrive and deteriorated in the pure sludge substrate. Bitter olive, ornamental pistachio, and cactus plants have exhibited better growth in garden soil compared to other substrates. Additionally, cactus plants have shown significantly better and faster growth in the sludge substrate relative to other substrates.

The observed differences in plant growth across different substrates can be attributed to various factors related to the physical, chemical, and biological properties of each substrate. Sludge, particularly when mixed with compost, may provide a richer nutrient profile for plants. This enhanced nutrient availability can contribute to better growth. Moreover, compost, when added to the sludge, increases the organic matter content. Organic matter improves soil structure, water retention, and nutrient availability, fostering favorable conditions for plant growth. It can also enhance aeration and drainage in the substrate. In addition, the addition of soil and compost help balance and buffer pH levels, creating a more suitable environment for plant growth.

On the other side, the presence of beneficial microorganisms in compost positively influences soil health and nutrient cycling, promoting better plant growth. Moreover, the addition of soil can provide a more balanced texture, ensuring proper water movement and root penetration. Cacti, known for thriving in arid conditions, also benefit from the water-retaining properties of sludge while still receiving essential nutrients. However, the physical structure of sludge may impede root development in certain plants, leading to reduced growth and vitality.

On the other hand, the number of leaves in all types of examined plants, except for ornamental pistachio and myrtle has been better and higher in the sludge mixed with soil and compost environment compared to other planting substrates. Regarding ornamental pistachio, the number of leaves in the garden soil substrate has been slightly higher than in other substrates. In the case of cactus plants, both lateral and vertical growth has been greater in the sludge substrate than in other substrates, and the number of new leaves has also been higher (Figure 4).

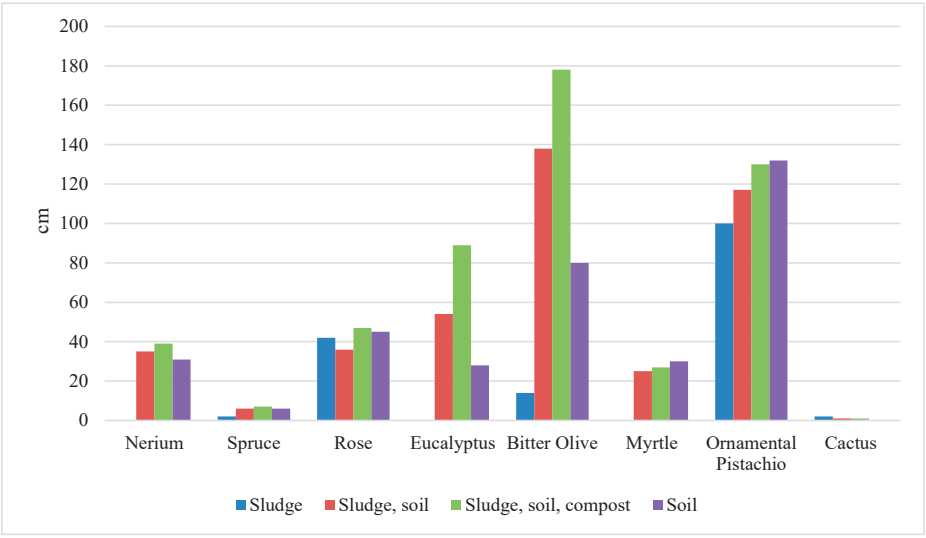

Figure 4. Changes in the leaf count throughout the year in different planting substrates

The highest level of sprouting and new shoots has been observed in the ornamental pistachio plant, which was equal across all three substrates: garden soil, sludge mixed with soil, and sludge mixed with soil and compost. In the next stage, the bitter olive plant exhibited the highest number of sprouts, particularly in the substrate of sludge mixed with soil and compost. Following in order are the narium, eucalyptus, rose, and myrtle plants (Figure 5).

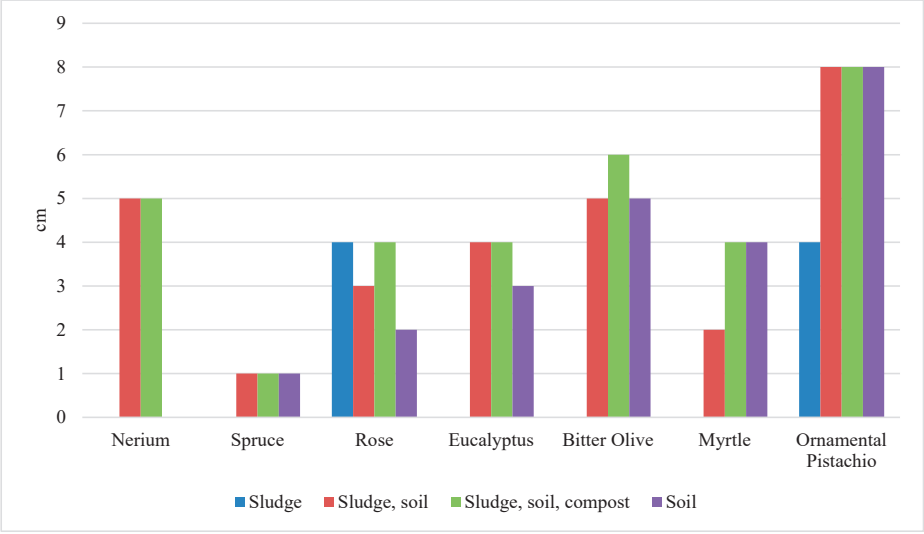

Figure 5. Changes in the branch count throughout the year in different planting substrates

The differences in the growth of various plants in the study can be attributed to several factors related to the composition of the soil and specific requirements of each plant species. The reasons may include nutrient composition, the soil structure, pH level, salinity and soluble salts, moisture content, plant species suitability, time and growth stages, and mineral elements; For instance, Calcium, Magnesium, and Potassium play essential roles in plant growth, including cell structure, enzyme activation, and photosynthesis. The high levels of iron can be detrimental to some plants, and the study mentions variations in iron content in the different soil mixtures. Moreover, essential for root development and flowering, differences in phosphorus levels could impact plant growth. In the following each plant have been analyzed based on the mineral level of its soil nature.

CONCLUSIONS

This pilot study demonstrates the potential of sludge from the EvoWash machine as a viable growth medium for non-fruit-bearing plants. Rich in essential minerals such as iron, calcium, magnesium, phosphorus, and potassium, the sludge showed promise in supporting plant growth, despite concerns regarding heavy metal content. The eight plant species tested - Nerium, Spruce, Rose, Eucalyptus, Bitter Olive, Myrtle, Ornamental Pistachio, and Cactus - exhibited varying degrees of adaptability to the sludge, with most species showing improved growth when the sludge was mixed with garden soil.

The study's findings underscore the importance of optimizing the composition of the sludge and soil mixture to enhance plant growth while mitigating potential risks associated with heavy metal accumulation. Specifically, the incorporation of compost and powdered sulfur significantly improved plant health and growth, suggesting that tailored amendments can address the inherent limitations of using EvoWash sludge as a sole growth medium. Moreover, the successful cultivation of these plants in sludge mixtures not only offers a sustainable solution for managing sludge waste from sand-washing processes but also

contributes to the reclamation of degraded land and the reduction of environmental pollution. By providing a practical method for repurposing construction debris sludge, this research aligns with broader sustainable and eco-friendly practices in waste management and urban agriculture.

Future research should focus on long-term assessments of soil health and plant productivity, exploring a wider range of plant species, and refining sludge treatment processes to further reduce heavy metal content. Additionally, economic analyses of large-scale implementation and the environmental impact of using EvoWash sludge in various agricultural and horticultural contexts would provide valuable insights for policymakers and industry stakeholders. Conducting a more comprehensive elemental analysis of the sludge will provide a deeper understanding of the specific interactions between minerals and their effects on plant growth, focusing on individual plant species to uncover species-specific mineral requirements. Extending the duration of plant monitoring will help assess the long-term effects of sludge application on plant health and productivity, providing insights into the sustainability and durability of the observed growth trends.

Investigating the microbial community dynamics in the soil treated with sludge will reveal how these microorganisms interact with minerals, impacting nutrient availability and uptake by plants. Understanding these interactions can enhance the overall effectiveness of sludge-based fertilization. A thorough toxicity assessment is essential to evaluate potential harmful effects of certain elements, such as lead and cadmium, on both plant health and soil ecosystems, ensuring safe and sustainable agricultural practices.

Considering the broader environmental benefits of sludge utilization in plant cultivation, advanced sludge treatment technologies should be investigated to further refine and enrich the sludge produced by EvoWash machines, enhancing its suitability for plant cultivation while minimizing environmental impacts. Tailoring plant cultivation practices based on the mineral composition of sludge, exploring suitable non-fruit-bearing crops that thrive in specific mineral conditions, and implementing crop rotation strategies will prevent nutrient imbalances and enhance soil fertility.

Integrating sludge utilization into a broader water resource management strategy and exploring the potential of combining treated sludge with water management practices will optimize nutrient availability for plants while reducing the environmental footprint. Engaging local communities in sustainable agricultural practices involving sludge utilization and providing educational programs to raise awareness about the benefits of responsible sludge management, will have a positive impact on both agriculture and the environment. Advocacy for supportive policies that encourage the use of treated sludge in agriculture and collaboration with policymakers to establish guidelines for safe and effective utilization will promote a circular economy approach for sludge resources.

By addressing these aspects in future research and optimizing sludge utilization practices, we can contribute to sustainable agriculture, resource conservation, and environmental stewardship. This study offers a promising pathway for the reuse of mineral-rich sludge in plant cultivation, paving the way for innovative and sustainable practices in urban waste management and green space development.

Abstract

This study investigates the integration of virtual laboratories into an undergraduate environmental engineering course through a blended learning approach. Using HybridPraxisLab, a browser-based simulation platform, second-year students engaged in optional virtual modules designed to reinforce theoretical knowledge and procedural skills. Quantitative data collected via a 14-item questionnaire revealed high student satisfaction across accessibility, engagement, and confidence dimensions. Additionally, a significant difference in final laboratory grades was observed between students with high and low virtual engagement, suggesting a positive impact on academic performance. These results support the use of virtual labs as effective and inclusive tools for enhancing learning outcomes in engineering education, especially for part-time or remote learners. The findings highlight the potential of such platforms to supplement traditional instruction and improve readiness for hands-on laboratory tasks.

Key words*: active learning, blended learning, engineering education, student perceptions, virtual laboratories.*

INTRODUCTION

Laboratory-based learning represents a foundational element of engineering education, offering students the opportunity to apply theoretical concepts to real-world scenarios while developing procedural skills and critical thinking (Feisel & Rosa, 2005; Li & Liang, 2024). However, the accessibility of physical laboratories is frequently constrained by logistical, financial, and institutional barriers, such as limited equipment, safety regulations, or scheduling conflicts (Asiksoy, 2023; Balamuralithara & Woods, 2009; Faour & Ayoubi, 2018). These challenges are particularly pronounced in high-enrollment programs or in part-time and distance learning formats (Faour & Ayoubi, 2018; Perales et al., 2019).

To address such limitations, virtual laboratories (VLs) have emerged as flexible, scalable tools that simulate laboratory procedures and allow students to engage with experimental content remotely and safely (Reeves & Crippen, 2021). VLs provide several pedagogical and logistical benefits: they reduce infrastructure costs, increase accessibility, support repeated practice, and minimize environmental and safety risks (Raman et al., 2022). These advantages are especially valuable in applied science and engineering domains where hands-on activities may involve hazardous substances or require specialized equipment that is often unavailable in traditional educational settings (Kapilan et al., 2021; Perales et al., 2019).

When integrated into blended learning models, VLs can enhance student engagement and learning outcomes. Blended approaches combine digital tools with face-to-face instruction, promoting personalized pacing, inclusivity, and active participation (Anjos et al., 2024; Cao, 2023). Within this pedagogical framework, flipped classrooms - where students engage with materials such as simulations or video lectures prior to class - have proven especially effective (Garrison & Vaughan, 2008; Lage et al., 2000). Such formats promote equity in access to learning, regardless of students' geographic location or time constraints (Abdelmoneim et al., 2022; Bonfield et al., 2020; Cao, 2023).

A growing body of evidence supports the effectiveness of VLs in improving conceptual understanding, procedural accuracy, and learner confidence (Abdelmoneim et al., 2022; Asiksoy, 2023; Li & Liang, 2024). VLs have also been linked to reduced student anxiety and improved readiness for physical laboratories, offering a safe environment for experimentation and repetition (Gungor et al., 2022;

Schnieder et al., 2022). During the COVID-19 pandemic, their role was amplified as institutions sought to maintain educational continuity (Kapilan et al., 2021; Schnieder et al., 2022). Beyond emergency use, VLs support inclusive education, particularly for non-traditional, part-time, or remote learners (Abdelmoneim et al., 2022; Bonfield et al., 2020).

Despite the expanding research, most studies on virtual laboratories have focused on domains such as physics, chemistry, or computer science (Faour & Ayoubi, 2018; Reeves & Crippen, 2021). By contrast, their application in environmental engineering - a field that demands interdisciplinary knowledge and specialized equipment - remains relatively underexplored (Wahyudi et al., 2024). Furthermore, few investigations have analyzed how engagement with virtual labs influences academic performance in blended formats that include both full-time and part-time learners (Schnieder et al., 2022).

In this context, the present study explores the use of HybridPraxisLab, a browser-based simulation platform, in an undergraduate Environmental Engineering in Agriculture course at the University of Agronomic Sciences and Veterinary Medicine of Bucharest. The objectives are threefold: (1) to assess students' perceptions of the platform in terms of accessibility, engagement, and confidence; (2) to examine the relationship between virtual lab engagement and academic performance; and (3) to evaluate the potential of virtual labs to enhance traditional laboratory instruction in a sustainable and inclusive manner.

MATERIALS AND METHODS

Study context and participants

This study was conducted at the Faculty of Land Reclamation and Environmental Engineering, within the *Environmental Engineering in Agriculture* undergraduate program at the University of Agronomic Sciences and Veterinary Medicine of Bucharest. The research involved second-year students enrolled in both full-time and part-time (distance learning) formats, who participated voluntarily in a virtual laboratory project aimed at exploring digital tools to enhance engineering education.

A total of 39 students participated: 22 from the full-time program and 17 from the part-time program. All students engaged with the same set of virtual laboratory modules and completed an online questionnaire evaluating their experience. The activity was conducted independently of the standard course curriculum and introduced solely for research purposes. Participation was voluntary and anonymous, and all students provided informed consent prior to inclusion in the study.

Description of the Virtual Lab Platform

Virtual laboratory activities were delivered using HybridPraxisLab, a browser-based educational platform designed to enhance practical skills in environmental engineering through interactive simulation. The platform provides guided access to digital experiments that replicate procedures commonly performed in environmental laboratories. These simulations are consistent with the growing adoption of scenario-based instructional design in online engineering education (Kapilan et al., 2021; Raman et al., 2022).

Each scenario-based module follows a consistent instructional sequence, consisting of: *Theoretical Background*, *Step-by-Step Method*, *Simulation*, *Self-Assessment Quiz*, and *Bibliographic Resources*. This structure supports three key aspects of effective laboratory learning: conceptual understanding, procedural training, and self-reflection (Feisel & Rosa, 2005).

At the time of this study, the platform hosted the following modules:

- Laboratory safety;
- Protocol for sampling and transport of water samples;
- Pipetting: selecting and using micropipettes;
- Acids and bases;
- Determination of pH for different water samples;
- Preparation of solution: from salt to solution;
- Determination of turbidity for different water samples;
- Determination of Chlorides in different water samples;
- Determination of Dissolved Oxygen in water;

- Mass spectrometry: exploring the instrument.

Although these modules were not part of the formal course curriculum, they were made available as optional preparatory tools to help students reinforce theoretical concepts and gain procedural familiarity before participating in physical laboratory sessions. Students received free access to the platform and could explore the simulations at their own pace, outside scheduled class time, using a standard internet connection and personal login credentials. The integration of such open-access and flexible tools has been recognized as a best practice in inclusive engineering education (Abdelmoneim et al., 2022; Bonfield et al., 2020; Schnieder et al., 2022).

Survey design and data collection

To evaluate students' perceptions of the virtual laboratory experience, a structured questionnaire was developed and distributed online after completion of the HybridPraxisLab activities.

The survey was designed to capture feedback across three key dimensions that are commonly highlighted in literature as critical to the perceived value of virtual labs: platform accessibility/ease of use, student engagement, and confidence building (preparation for real labs) (Abdelmoneim et al., 2022; Schnieder et al., 2022). These particular aspects were selected based on prior research indicating their relevance in assessing virtual lab experiences in higher education-namely improving ease of access, enhancing engagement, and boosting students' confidence before hands-on labs (Cao, 2023).

The questionnaire consisted of 14 items, grouped into thematic sections:

- Platform accessibility and usability;
- Student engagement and interest during the virtual lab experience;
- Perceived contribution to understanding and confidence before attending physical labs.

Each item was rated using a 7-point Likert scale, which allows for fine-grained analysis of perception-based data in educational research (Revilla et al., 2014). The full scale used in the questionnaire was as follows:

1 - Strongly disagree;
2 - Disagree;
3 - Slightly disagree;
4 - Neutral;
5 - Slightly agree;
6 - Agree;
7 - Strongly agree.

An additional open-ended question was included to collect qualitative feedback and suggestions for improvement. The combination of closed and open-ended responses reflects best practices in mixed-methods research for exploring learner satisfaction and experience (Reeves & Crippen, 2021).

The survey was distributed anonymously via an online form to all 39 students who participated in the virtual laboratory activities. Participation was voluntary, with no incentives offered. Data collection occurred over a one-week period following the completion of the virtual sessions.

Academic performance evaluation

To complement the perception-based data, this study also examined students' academic performance in the associated laboratory course. The aim was to explore whether engagement with the virtual lab activities was associated with learning outcomes, even though the virtual component was not part of the formal assessment. Similar analytical approaches have been used in engineering education research to evaluate the impact of supplementary digital tools on final course performance (Schnieder et al., 2022).

Final grades from the physical laboratory evaluation were used as the primary indicator of academic performance. These grades reflected students' ability to perform technical procedures, interpret results, and demonstrate understanding of laboratory concepts, as assessed through practical work and written reports.

Although participation in the virtual labs was voluntary and not formally linked to course requirements, students' final laboratory grades were analyzed in relation to their level of engagement with the HybridPraxisLab platform (i.e., number of completed modules). Due to the limited sample size and the exploratory nature of the study, this analysis was descriptive and intended to identify general trends rather than establish causal relationships.

Data analysis

Descriptive statistical methods were used to analyze survey responses and academic performance data. For each Likert-scale item, the mean and standard deviation were calculated, in line with established practices for summarizing perception-based data (Revilla et al., 2014). Survey items were also grouped by dimension to calculate aggregate mean scores for accessibility, engagement, and confidence building, allowing for cross-category comparisons.

In parallel, students' final laboratory grades were analyzed in relation to the number of completed virtual lab modules. As the study was exploratory and based on a relatively small sample (n = 39), the analysis was limited to descriptive comparisons and a Welch's t-test. Inferential analysis was conducted with caution, acknowledging that this does not establish causation but can highlight trends worthy of further investigation (Balamuralithara & Woods, 2009).

All data were processed using Microsoft Excel. No personal identifiers were collected, and all analyses were conducted anonymously to ensure confidentiality. These procedures adhered to standard ethical principles in educational research practice.

RESULTS AND DISCUSSIONS

Survey response rate and overview

Out of the 39 students who participated in the virtual laboratory activities, 36 completed the post-activity survey, resulting in a response rate of 92.3%. The sample included both full-time and part-time students, with no significant difference observed in response behavior between the two groups.

The majority of respondents reported a generally positive experience with the HybridPraxisLab platform. Across all items, responses were well-distributed across the 7-point Likert scale, with only minimal clustering at the extremes. Preliminary review indicated consistently favorable ratings in the areas of ease of use, perceived relevance, and preparation for physical lab work.

The descriptive results of the survey are detailed in the following section, organized by the three evaluated dimensions: accessibility, engagement, and confidence building.

As shown in Figure 1, students rated Confidence Building highest (M = 6.19), followed by Accessibility (M = 6.14) and Engagement (M = 5.98), indicating consistently favorable perceptions across all dimensions.

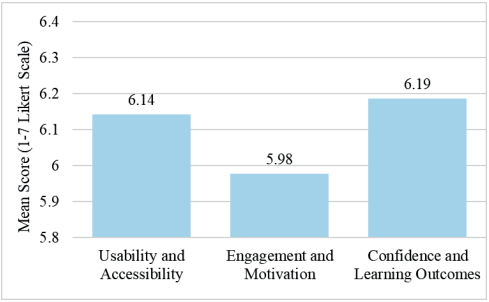

Figure 1. Average scores by survey dimension

Distribution of responses per item

A more detailed analysis of each survey item reveals that students rated the platform consistently high, particularly on items related to clarity of simulation steps, perceived usefulness for understanding lab procedures, and motivational aspects. As shown in Figure 2, the item-wise mean scores ranged between 5.6 and 6.4, reflecting positive reception across all 14 items.

Notably, the highest-rated survey item was *"I would recommend these modules to future students"* (M = 6.36), indicating a strong endorsement of the virtual lab experience. In contrast, the lowest-rated item - *"The design of the simulations encouraged participation"* (M = 5.64) - while still above the neutral midpoint, suggests a potential area for enhancement in terms of simulation interactivity and user engagement features.

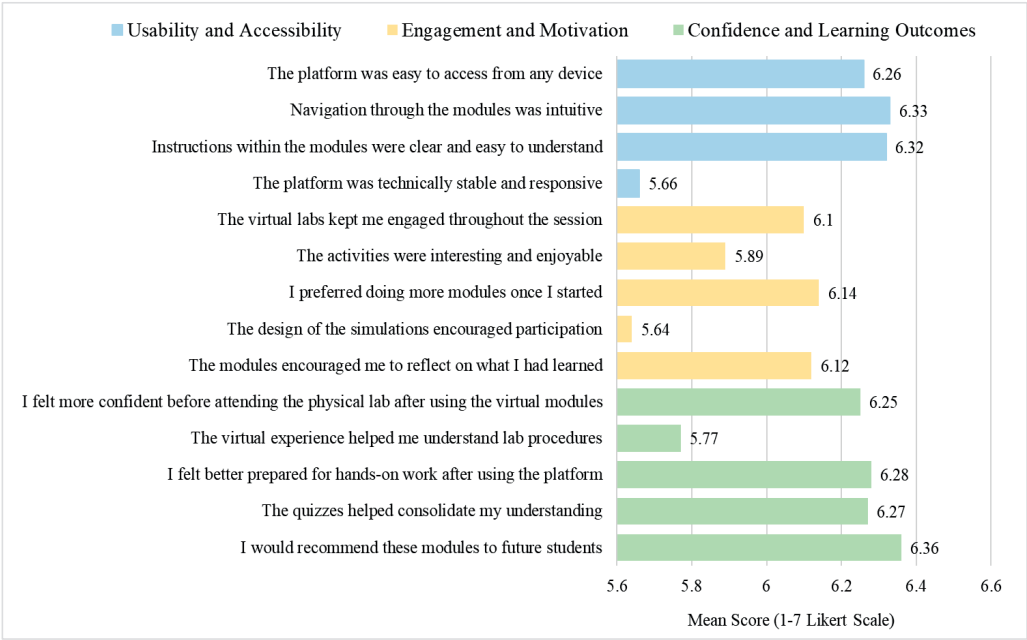

Figure 2. Mean scores on Virtual Lab questionnaire

Qualitative feedback and open-ended responses

Beyond the quantitative data, students were invited to provide open-ended feedback regarding their experience with the virtual lab modules. Out of the 36 respondents, 28 (77.8%) offered qualitative comments. Thematic analysis revealed several recurring patterns:

- **Confidence and preparation**: many students mentioned feeling more confident and better prepared before entering the physical lab session. They appreciated the clarity of procedures and the opportunity to rehearse steps in a safe, self-paced environment (Abdelmoneim et al., 2022; Asiksoy, 2023).
- **Accessibility and flexibility**: respondents frequently highlighted the ease of accessing the simulations from various devices and at their own pace, with part-time students especially valuing this flexibility (Schnieder et al., 2022).
- **Suggestions for improvement**: some students expressed interest in having more modules available, particularly covering additional topics related to sampling and analytical techniques. Others suggested improvements in visual interactivity and feedback mechanisms after quizzes, consistent with observations from prior research (Kapilan et al., 2021).

Selected comments include:

- *"Very well-structured. The simulations made me feel more confident for the real lab."*
- *"I wish more modules were available. I'd be interested in simulations for water analysis."*
- *"Clear and interactive. Helped me understand the pipetting steps in advance."*

Relationship between platform usage and academic performance

To explore whether engagement with the HybridPraxisLab modules had an academic impact, we compared final lab grades between students who completed most of the simulations (≥6 modules) and those who did not.

- **Group A** (n = 19): completed ≥6 virtual modules
  – *Mean final lab grade*: 9.06 (SD = 0.38)
- **Group B** (n = 17): completed <6 modules
  – *Mean final lab grade*: 8.39 (SD = 0.48)

A Welch's t-test indicated that this difference was statistically significant ($t(32.6) = 4.64$, $p < 0.001$), suggesting that greater engagement

with the virtual lab platform was associated with better academic performance. As shown in Figure 3, students with higher virtual lab engagement scored significantly better in the final laboratory assessment. These findings mirror those of Schnieder et al., (2022), who reported improved performance among engineering students using virtual simulations, and with Murillo-Zamorano et al., (2021), who observed similar benefits in gamified digital learning environments.

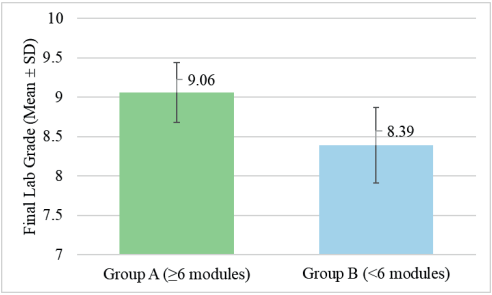

Figure 3. Final laboratory grades by virtual laboratory usage

Summary of findings

Overall, students rated the HybridPraxisLab modules positively across all dimensions. High mean scores (5.64-6.36) indicated strong perceived value, supported by qualitative comments that highlighted increased clarity and preparedness. The flexibility of the platform benefited especially remote and part-time learners, as also shown by Abdelmoneim et al. (2022) and Cao (2023). The statistically significant relationship between platform engagement and academic outcomes reinforces conclusions from broader research in STEM education (Murillo-Zamorano et al., 2021; Schnieder et al., 2022).

Limitations and future research

This study has several limitations that should be acknowledged. First, the sample size was relatively small (N = 36), and all participants were enrolled in a single engineering program at one institution. As such, the findings may not be generalizable across disciplines, academic levels, or institutional contexts.

Second, the virtual lab modules were designed primarily to support preparation for physical lab sessions. While this format proved effective, the study did not evaluate whether simulations could fully replace hands-on labs in a stand-alone virtual setting. Further comparative studies are needed to assess learning outcomes in fully remote versus blended formats.

Third, the evaluation relied primarily on self-reported perceptions and one summative performance metric (final lab grade). Although significant correlations were observed, additionnal data such as practical skill assessments, long-term retention measures, or behavioral analytics (e.g., time spent per module) could provide more nuanced insights into learning effectiveness.

Finally, technical design elements such as the level of interactivity, feedback in quizzes, and simulation realism were not systematically evaluated. Future iterations of the platform would benefit from user-centered design research, incorporating iterative testing and interface improvements based on both student and instructor feedback.

Future research should focus on expanding the range of available modules to cover a broader set of engineering topics and to test the scalability of the platform across larger, more diverse student populations. Additionally, integrating adaptive learning elements or real-time feedback systems could further enhance the effectiveness of virtual laboratory instruction.

CONCLUSIONS

This study investigated the impact of HybridPraxisLab - a virtual laboratory platform - on students' perceptions, engagement, and academic performance within an environmental engineering course. The findings demonstrate consistently positive feedback across all evaluated dimensions: usability and accessibility, engagement and motivation, and confidence and learning outcomes. Students rated all 14 items highly, with mean scores ranging from 5.64 to 6.36 on a 7-point Likert scale, indicating strong acceptance of the virtual modules as effective educational tools.

Qualitative responses further supported these findings. Students emphasized increased confidence before entering the physical lab, greater clarity of procedures, and the value of

self-paced exploration. The virtual format was particularly appreciated by part-time and remote learners, who benefited from its flexibility and accessibility.

Moreover, a statistically significant difference in final lab grades was observed between students who completed most of the modules and those who engaged with the platform less frequently. This suggests a strong association between virtual lab engagement and improved academic outcomes, especially in terms of procedural readiness and conceptual understanding.

The results suggest that virtual labs can:

- Enhance student engagement and motivation through inquiry-based and interactive learning.
- Support procedural readiness and safety awareness before entering the physical lab.
- Reduce access barriers for part-time and remote learners.
- Serve as an effective supplement - not a replacement - for hands-on laboratory experiences.

Given these outcomes, several recommendations emerge for educators and institutions:

1. **Curriculum design**: integrate virtual laboratories as preparatory modules to maximize the effectiveness of in-person sessions.
2. **Assessment strategies**: combine self-assessment tools in virtual modules with in-person evaluations to assess procedural, conceptual, and reflective skills.
3. **Teacher training**: provide instructors with pedagogical and technical support for implementing blended learning approaches.
4. **Equity and accessibility**: expand the availability of virtual labs to support inclusive and flexible learning environments.
5. **Ongoing evaluation**: use learning analytics and regular student feedback to refine content and ensure alignment with course objectives.

While HybridPraxisLab proved to be an asset in this course, further research across other subjects and educational contexts is necessary to fully understand its broader impact. Future work should explore long-term retention, cost-effectiveness, and students' ability to transfer virtual learning experiences to real-world engineering tasks.

In summary, virtual laboratories represent a powerful and scalable tool for fostering active, inclusive, and effective learning in environmental engineering - and beyond. The observed correlation between simulation engagement and lab performance suggests that structured virtual components could be embedded into standard laboratory curricula, particularly as preparatory modules.

To guide future development and institutional decisions, a SWOT analysis of HybridPraxisLab's implementation is presented in Tabel 1.

Tabel 1. SWOT analysis of the HybridPraxisLab's implementation

Strengths	**Weaknesses**
High student satisfaction and engagement	Limited to one course and institution
Improved academic performance and confidence	Not yet validated across disciplines
Flexible access for diverse student profiles	Some modules lack advanced or complex lab procedures
Supports procedural readiness and safety awareness	Not designed as a full replacement for hands-on experimentation
Opportunities	**Threats**
Expansion to other engineering or science domains	Institutional resistance to pedagogical change
Integration with adaptive learning and analytics	Uneven access to infrastructure across student populations
Alignment with blended and inclusive learning policies	Risk of over-reliance in contexts without proper physical labs
Potential for scalable deployment across programs/universities	Platform maintenance and technological dependencies

ACKNOWLEDGEMENTS

This research work was carried out with the support of University of Agronomic Sciences and Veterinary Medicine of Bucharest – Romania, Research Project 1059/15.06.2022, acronym HybridPraxisLab in the competition IPC 2022.

Abstract

This paper presents the development and evaluation of an Internet of Things (IoT)-based control system for small-scale greenhouse environments. The core of the system is the Arduino Nano 33 IoT (SAMD21 Cortex-M0, 32-bit), which integrates multiple environmental sensors to monitor temperature, air humidity, soil moisture, and light intensity. Based on user-defined parameters, the system automates plant care actions: activating an LED lighting matrix, powering a ventilation fan, and triggering a water pump for irrigation. System monitoring and control can be performed locally through an LCD interface or remotely via a cloud-based dashboard. Beyond automation, the study investigates the influence of various types of music - such as classical, techno, and meditation - on the germination and growth of lettuce and radish plants. Experimental results indicate that classical and meditation music enhanced plant development, while techno music had a negative effect, despite otherwise optimal environmental conditions. The findings demonstrate the dual potential of IoT systems for smart agriculture: enabling precision environmental control and exploring novel stimuli, such as sound, to support plant growth.

Key words*: IoT, smart greenhouse, Arduino Nano 33 IoT, plant growth, music influence, environmental control, automation.*

INTRODUCTION

Food insecurity in climate-vulnerable regions, such as Kenya, has intensified the need for automated greenhouse systems capable of maintaining stable internal conditions irrespective of external weather fluctuations. This challenge arises from increasingly erratic climatic conditions that inhibit optimal plant development. While conventional greenhouses partially address this by enclosing crops within controlled environments, they often rely heavily on manual oversight to maintain ideal growth parameters. Prior studies have emphasized the significant impact of environmental factors such as light, temperature, and humidity on plant development under greenhouse conditions (Mitova et al., 2021).

Each greenhouse operates within a specific set of environmental parameters, which vary depending on the species being cultivated (Figure 1).

To support healthy plant growth, conditions such as air temperature, humidity, light intensity, and soil moisture must be maintained within tightly controlled thresholds. Addressing both food insecurity and environmental degradation requires integrated, innovative solutions.

Figure 1. Example of a modern large-scale greenhouse

Recent research has therefore focused on low-cost, microcontroller-based systems that automate environmental monitoring and regulation. Gitonga (2020) developed a prototype utilizing sensors, SMS technology, and Bluetooth connectivity to remotely control greenhouse conditions. However, as Natonis (2023) points out, the increasing deployment of IoT devices introduces new challenges in system configuration, network behavior, and device interoperability, requiring robust architecture and management strategies.

The Internet of Things (IoT) paradigm facilitates the development of smart greenhouses that not

only automate internal processes but also allow for remote access and control. While the "Things" aspect focuses on physical devices and user interaction, cloud infrastructure plays a crucial role in processing data and supporting remote communication.

Efficient system design must go beyond enhanced processing power to include scalable architectures that minimize bandwidth consumption and latency. RESTful web services, which operate over the HTTP protocol, can serve as flexible interfaces for these user interactions (Wang, 2017), as illustrated in Figure 2.

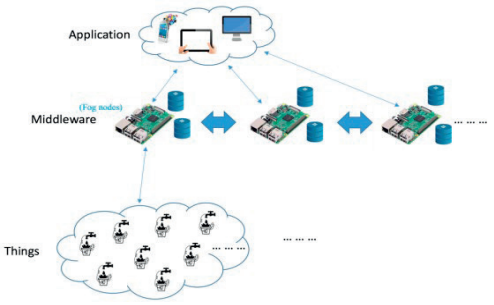

Figure 2. The proposed architecture of the system (Wang, 2017)

Despite these technological advancements, high costs and design complexity have limited the widespread adoption of smart greenhouses. This study proposes the development and testing of an affordable IoT-enabled greenhouse prototype equipped for remote monitoring and environmental automation. In addition to automation, the study explores the use of music as a non-invasive stimulus to enhance plant growth - an emerging area of interest in sustainable agricultural research.

Lai and Wu (2020) found that lettuce seedlings exposed to Gregorian chant, new-age, and waltz music exhibited significant improvements in radicle and hypocotyl elongation, suggesting that certain acoustic frequencies may enhance early plant development. In their experiment involving nine distinct music genres, alfalfa seeds exposed to rock music germinated less effectively, while classical, nature sounds, and waltz promoted germination. Lettuce seedlings responded positively to Gregorian chant, jazz, nature sounds, and new-age music.

This research introduces a user-friendly interface that integrates mobile applications and cloud-based platforms for monitoring and managing greenhouse conditions. By transforming a conventional greenhouse into a smart, responsive system, the study contributes to understanding how IoT automation and acoustic stimuli can jointly promote sustainable, resource-efficient plant growth in controlled environments.

MATERIALS AND METHODS

This section describes the hardware and software components employed in constructing the smart greenhouse prototype. It outlines the configuration of microcontrollers, sensors, actuators, and user interfaces. Additionally, it details the experimental protocol designed to evaluate plant growth under controlled environmental conditions and various musical exposures.

Hardware Components

The smart greenhouse system is built around two primary processing units: the **Arduino Nano 33 IoT** and the **Raspberry Pi 4 Model B**. The Arduino Nano 33 IoT (Figure 3) was chosen for its integrated wireless capabilities and compatibility with the Arduino Cloud platform. During the initial design phase, the Arduino Cloud "Starter Plan" was used to collect sensor data and create a basic dashboard for environmental monitoring. To improve flexibility and system performance, the configuration was later expanded to incorporate a Raspberry Pi.

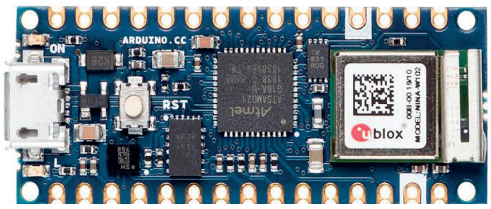

Figure 3. Arduino Nano 33 IoT (Arduino, 2025)

The Raspberry Pi 4 Model B, equipped with 4 GB of RAM, a 16 GB microSD card, built-in Wi-Fi, and a touchscreen display (Figure 4), serves as the local server. This unit manages the graphical interface, local database, and actuator control logic. Its inclusion ensures enhanced system scalability, data security, and offline functionality.

Figure 4. Raspberry Pi 4 Model B (Raspberry Pi, 2025)

The Raspberry Pi 4 Model B, equipped with 4 GB of RAM, a 16 GB microSD card, built-in Wi-Fi, and a touchscreen display (Figure 4), serves as the local server. This unit manages the graphical interface, local database, and actuator control logic. Its inclusion ensures enhanced system scalability, data security, and offline functionality (Table 1).

Sensor Specifications

The smart greenhouse prototype integrates three primary sensors to monitor key environmental parameters essential to plant development:

- *DHT11 (Air Temperature and Humidity Sensor).* This sensor measures ambient temperature and relative humidity. It operates within a temperature range of 0-50°C with ±2°C accuracy, and a humidity range of 20-90% with ±5% accuracy. The DHT11 requires an input voltage of 3.0-5.5 V, communicates through a single digital pin, and consumes between 0.5-2.5 mA during active operation (100-150 µA in standby mode).
- *BMP180 (Barometric Pressure Sensor).* The BMP180 monitors atmospheric pressure and temperature. It operates between 3.3 V and 5 V and communicates via the I²C protocol through the SDA (A4) and SCL (A5) pins. It measures pressure within the 300-1100 hPa range with an accuracy of ±0.12 hPa and has a minimal current consumption of approximately 3 µA. Its compact form factor (14 mm × 12 mm) enables easy integration into embedded systems.
- *Soil Moisture Sensor*. This sensor uses two conductive probes to assess soil moisture by measuring resistance. It operates at 3.3-5 V and provides an analog output signal ranging from 0 (dry) to 1023 (wet), as interpreted by the Arduino's 10-bit ADC.

The environmental parameters were monitored using a set of three sensors: DHT11 for air temperature and humidity, BMP180 for atmospheric pressure, and a soil moisture sensor. A summary of these sensors and their technical specifications is presented in Table 2.

Table 1. Central Computing Units Used in the Smart Greenhouse System

Component	Arduino Nano 33 IoT	Raspberry Pi 4 Model B
Function	Sensor interfacing and real-time control	Local server for control and visualization
Specifications	Wireless, ARM Cortex-M0+ core, integrated Wi-Fi	4 GB RAM, Wi-Fi, touchscreen display
Rationale	Easy wireless setup, Arduino Cloud compatible	Custom UI, local database, higher flexibility

Table 2. Environmental Sensors and Their Technical Specifications

Sensor	**DHT11**		**BMP180**	**Soil**
Parameter	Temperature	Humidity	Pressure	Moisture
Measurement Range	0–50°C	20-90%	300-1100 hPa	0-1023 (ADC)
Accuracy	±2°C	±5%	±0.12 hPa	N/A
Voltage	3-5.5 V	3-5.5 V	3.3-5.5 V	3.3-5.5 V

System Configuration and Components

The physical structure of the system is divided into three functional compartments: the experimental chamber, the control panel, and the water reservoir, as shown in Figure 5.

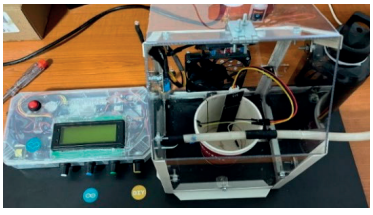

Figure 5. The system setup

- Control panel includes breadboard with all interfacing components:
  - *DS3231 real-time clock (RTC) module* for accurate timestamping of sensor data;
  - *Transistors* to switch actuators (fan, pump, lights);
  - *Potentiometers* to define custom threshold values;
  - *Resistors, jumpers, and wiring* for circuit completion;
- Water tank houses - a submersible pump positioned at its base;
- Ventilation fan - mounted in the main chamber, ensures airflow via small circular vents;

- LED lighting system - 8 UV, 4 red, and 4 sky-blue LEDs simulate daylight spectra to promote photosynthesis.

Experimental Protocol

To investigate the effects of musical stimulation on early-stage plant development, five experimental groups were established. Each group consisted of four Lactuca sativa seedlings (cultivar 'May King'), cultivated under identical environmental conditions inside the smart greenhouse. Musical exposure was administered using a speaker placed at a fixed distance from the seedlings, delivering audio at an average intensity of approximately 65 dB for 3 hours daily over a 9-day period. The auditory conditions applied were:

1. Control group (no music);
2. Techno (aggressive);
3. Classical music;
4. Meditation 432 Hz.

Throughout the experiment, the system continuously logged temperature, humidity, soil moisture, and light intensity. In addition, daily measurements of radicle and hypocotyl length were recorded to assess plant growth dynamics and correlate physiological responses with the respective auditory treatments.

RESULTS AND DISCUSSIONS

Between 2024 and 2025, five experiments were conducted to evaluate the influence of musical stimuli on plant growth within a smart greenhouse prototype.

The tested species included *Lactuca sativa* (cultivars 'May King' and 'Helmut') and *Raphanus sativus* ('Helga'), cultivated under controlled conditions of temperature, humidity, light, and soil moisture.

Each experiment lasted between 7 and 9 days, during which environmental parameters were continuously monitored through an integrated data acquisition system.

The experimental conditions are summarized in Table 3.

Table 3. Experimental setup and conditions

Experiment	**1**	**2**	**3**	**4**	**5**
Species	*L. sativa*	*R. sativus*	*L. sativa*	*L. sativa, R. sativus*	*L. sativa, R. sativus*
Music type	No music	No music	Techno (aggressive)	Classical music	Meditation 432 Hz
Duration	9 days	9 days	9 days	9 days	9 days
Temperature (^{0}C)	Not recorded	20-23	21-24	20-24	23-26
Air humidity (%)	Not recorded	81-84	80-82	82-85	79-84
Soil moisture index	Not recorded	4-5	4-6	4-6	5-6
LED exposure (h/day)	Not recorded	3	3	3	3
Volume (dB)	-	-	~70	~65	~60
Playback	-	-	3 h/day, speaker	3 h/day, speaker	3 h/day, speaker

Plant height – summary by species and experiment

At the conclusion of each experiment, the average plant height was measured to evaluate the effects of musical exposure. Results showed notable differences based on the music type and plant species. The outcomes are presented in Table 4.

Table 4. Average plant height at the end of experiments

Species	**Exp.2 - No music**	**Exp.3 - Techno**	**Exp.4 - Classical**	**Exp.5 - Meditation**
L. sativa	-	2.1 cm	5.7 cm	6.8 cm
R. sativus	6.3 cm	-	6.2 cm	6.5 cm

In the absence of music (Experiment 2), *R. sativus* achieved an average height of 6.3 cm, while lettuce was not included. When exposed to techno music (Experiment 3), *L. sativa* demonstrated significantly stunted growth, averaging only 2.1 cm. In contrast, classical (Experiment 4) and 432 Hz meditation music (Experiment 5) enhanced vertical development in lettuce, with the highest average height recorded under meditation music. *R. sativus* showed more stable growth across treatments, with slight improvements under meditation sound.

Leaf number - summary by species and experiment

Leaf count served as a secondary growth indicator. The average number of leaves per plant is summarized in Table 5.

Table 5. Average number of leaves per plant at the end of experiments

Species	Exp.2 - No music	Exp.3 - Techno	Exp.4 - Classical	Exp.5 - Meditation
L.sativa	-	1-2 leaves	3-4 leaves	4-5 leaves
R. sativus	2-3 leaves	-	3-4 leaves	3-4 leaves

Results indicate a correlation between musical exposure and foliar development. *L. sativa* exposed to techno music developed fewer leaves, while those exposed to classical and meditation music exhibited significant improvements in leaf formation.
R. sativus also showed slightly increased leaf counts under musical conditions compared to the control, with minimal variation between the classical and meditation groups.
These outcomes suggest that harmonic and soothing music may positively influence physiological processes such as photosynthetic efficiency and hormone regulation, contributing to improved plant morphology.

Environmental parameters comparison across experiments

To confirm that observed differences in plant growth were attributable to music rather than environmental variability, average environmental conditions were compared across Experiments 2 through 5. These values are presented in Table 6.

Table 6. Environmental conditions across experiments (average values)

Experiment	Exp.2 - No music	Exp.3 - Techno	Exp.4 - Classical	Exp.5 - Meditation
Temperature (^{0}C)	21.8	22.3	21.9	22.7
Air humidity (%)	82.0	81.5	82.2	81.7
Soil moisture index (0-6)	4.3	4.5	4.4	4.6
Light index (0-10)	1.4	1.6	1.5	1.7

The environmental data confirm that all parameters remained within optimal ranges throughout the trials, with only slight variations. Temperatures were consistently maintained between 21.8°C and 22.7°C, air humidity levels stayed above 80%, and soil moisture remained within the ideal index range of 4 to 5.
Light intensity, though low due to indoor conditions, was supplemented uniformly by a calibrated LED matrix.
These results support the conclusion that differences in plant development are attributable to auditory stimuli rather than uncontrolled environmental factors.

Graphical interpretation of monitored variables

To evaluate the consistency of environmental control and its potential interaction with music exposure, the daily evolution of four key parameters - temperature, air humidity, soil moisture, and light intensity - was graphically analyzed across Experiments 2 to 5. These results are presented in Figures 6 to 9.
Figure 6 shows the daily temperature profiles for the four experiments. Despite minor fluctuations, all temperature values remained within the optimal growth range of 20-26°C. The highest average temperatures were recorded in Experiment 5 (meditation music). However, no thermal stress was observed, indicating that the system maintained an effective microclimate, even with modest variation.

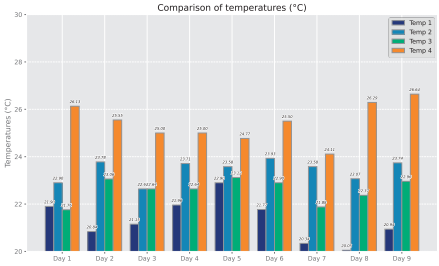

Figure 6. Temperature comparison across experiments

As shown in Figure 7, relative humidity levels remained above 70% throughout all experiments. The most stable and elevated values were recorded during Experiment 4 (classical music), suggesting that the enclosed environment efficiently retained moisture. This stable humidity may have supported the enhanced growth observed under classical music exposure.

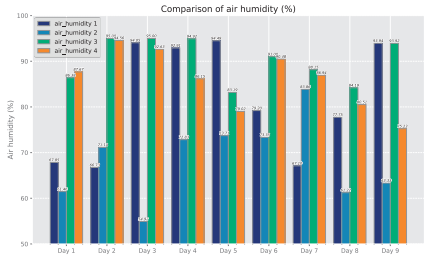

Figure 7. Air humidity comparison

Figure 8 presents soil moisture index trends, with values ranging from 0 (dry) to 6 (high moisture).

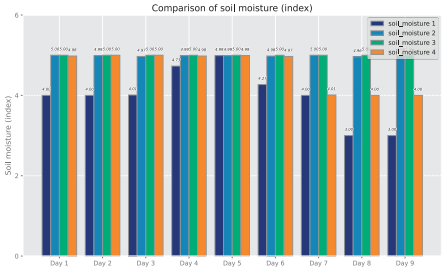

Figure 8. Soil moisture index

Most experiments maintained a consistent range between 3 and 5. Slightly more variability was observed in Experiment 3 (techno music), which may have contributed to the reduced plant growth and germination observed in that group.

Figure 9 depicts natural light levels across experiments, measured on a scale from 0 (complete darkness) to 10 (full daylight). Due to the shaded placement of the setup, natural light intensity remained low (~1.5). However, consistent supplemental lighting from the LED matrix ensured adequate photosynthetic conditions across all trials.

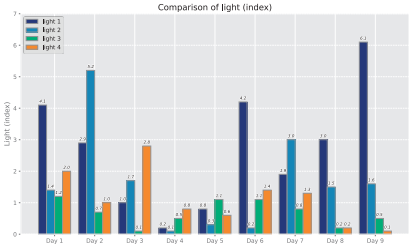

Figure 9. Light index comparison

Final comparative interpretation of prototype versions and music effects

To consolidate the findings, a final comparative analysis was conducted across all prototype versions, including earlier trials without musical treatment (Experiments 1.1 and 1.2) and later ones incorporating music (Experiments 3-6). Environmental variables were compared and visualized in Figures 10 to 14, with corresponding color codes provided in Table 7.

Table 7. Analysis - the legend of colours

Analysis - the legend of colours	
Analysis 1.1	Dark blue
Analysis 1.2	Steel blue
Analysis 3	Mediumseagreen
Analysis 4	Dark orange
Analysis 5	Salmon
Analysis 6	Orchid

All temperature values across experiments remained within the optimal range. Slightly elevated mean temperatures were recorded in Experiments 5 and 6 (meditation and classical music), yet these did not adversely affect plant growth, demonstrating effective thermal regulation by the system (Figure 10).

Experiment 4 (classical music) and Experiment 5 (meditation music) exhibited the most stable and elevated air humidity values (Figure 11).

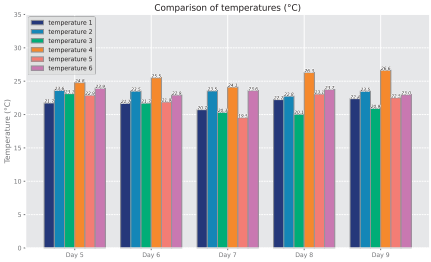

Figure 10. Comparative temperature trends

These findings support the hypothesis that stable humidity levels may contribute to improved germination and plant vigor. Greater variability was observed in Experiments 1.1 and 3 (no music and techno music), potentially correlating with less robust growth.

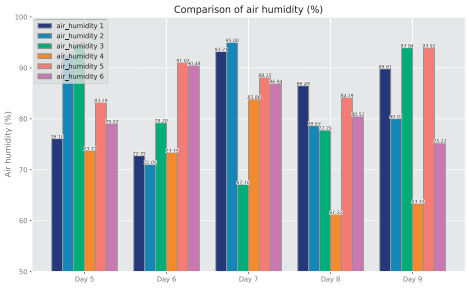

Figure 11. Comparative air humidity trends

Soil moisture remained within optimal levels in most experiments. However, Experiment 3 (techno music) exhibited lower and more fluctuating values, which may have hindered seedling development (Figure 12). This reinforces previous observations of suboptimal plant performance under techno exposure.

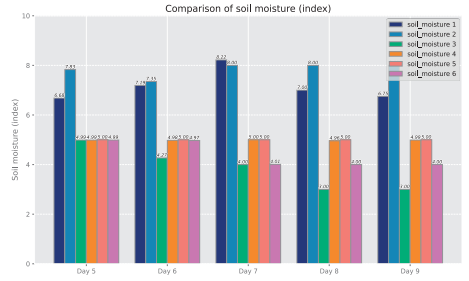

Figure 12. Comparative soil moisture trends

Light levels were consistently low throughout all experiments due to limited natural lighting. The LED matrix effectively compensated for this limitation. Slightly higher light index values were recorded in Experiment 4, possibly due to better placement and reflectivity within the setup (Figure 13).

Atmospheric pressure readings remained relatively stable across all trials (Figure 14). Slight increases were noted in Experiment 5, but no direct influence on plant development was observed. While atmospheric pressure is not typically a manipulated variable in greenhouse conditions, its consistency supports the overall environmental stability of the experimental setup.

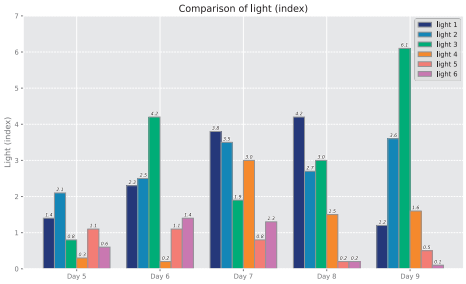

Figure 13. Comparative light intensity

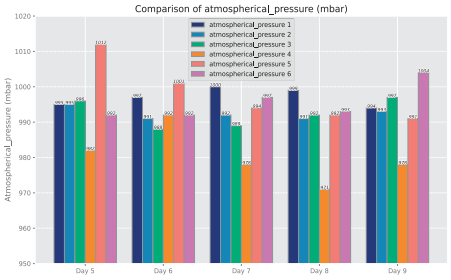

Figure 14. Comparative atmospheric pressure

CONCLUSIONS

The developed smart greenhouse prototype demonstrated effective control over key environmental parameters, outperforming traditional non-automated systems in maintaining stable conditions conducive to plant growth. The integration of sensor-based automation, cloud connectivity, and remote monitoring significantly enhances the system's potential for scalability and full automation in future applications.

Experimental results confirmed that music, particularly classical and meditation genres, served as a notable non-invasive stimulus influencing the physiological development of plants. Lettuce (*Lactuca sativa*) and radish (*Raphanus sativus*) responded positively to harmonic sound treatments, exhibiting increased plant height and greater leaf production under stable environmental conditions.

A detailed analysis of Figures 10-12 revealed a strong interdependency between temperature, air humidity, and soil moisture. Elevated temperatures correlated with increased humidity

- likely due to condensation effects within the enclosure - which in turn helped sustain optimal moisture levels. These dynamics were especially evident in Experiments 4 and 5 (classical and meditation music), where environmental consistency aligned with enhanced plant growth outcomes.

By contrast, Experiments 1.1 and 1.2 (no music) recorded slightly lower values for temperature and humidity, along with less vigorous plant development. This contrast suggests that musical stimulation may play a supportive role in enhancing plant physiological responses, possibly through mechanisms involving hormone regulation or photosynthetic efficiency.

Light intensity, shown in Figure 13, exhibited minimal variation across trials due to the continuous use of an LED lighting matrix. Although natural light contributions were low, consistent artificial lighting maintained photosynthetically active radiation levels sufficient for healthy growth. Observed phototropic behavior, where plants oriented toward the light source, further confirmed its effectiveness.

Atmospheric pressure, illustrated in Figure 14, remained stable across experiments. While no direct relationship was established between pressure fluctuations and plant morphology, its consistency reinforced the environmental control achieved by the prototype. Manipulating this variable for research purposes would require substantial structural modifications and was deemed impractical for small-scale implementations.

Collectively, these findings underscore the complex interplay between environmental variables and plant development. They highlight the value of precision agriculture tools, especially IoT-enabled systems, in advancing sustainable cultivation practices.

Despite its promising results, the study presents several limitations. The small sample size, short experiment duration, and limited variety of music genres constrain the generalizability of the findings. Future research should explore larger-scale prototypes, a broader range of plant species, and more diverse auditory stimuli to deepen our understanding of how environmental and acoustic factors synergistically influence plant development.

Abstract

Carbon capture and storage (CCS) is a promising solution for reducing carbon emissions, but the risk of CO_2 leakage requires monitoring. As part of project PN 23300404, we aim to develop an environmental monitoring methodology for onshore geological storage sites, evaluating vegetation surveys as a monitoring tool. In 2024, we conducted combined vegetation and geochemical surveys at two sites: Bodoc, an analogue for safe storage, and Băile Lăzărești, an analogue for CO_2 leakage. Using a grid-based sampling approach, we measured soil-flux and concentrations alongside floristic observations. At Bodoc, no significant relationship was observed between CO_2 levels and vegetation state. In contrast, at Băile Lăzărești, areas with high CO_2 concentrations had sparse vegetation and exposed soil, though these features were also present in some low-CO_2 areas due to landscaping. Follow-up surveys are planned for next year to determine the natural variability of the vegetation. Currently, we conclude that vegetation surveys have the potential to be used for leakage identification.

Key words: *CO_2 geological storage, monitoring, vegetation surveys, soil flux, natural analogues.*

INTRODUCTION

The sixth IPCC report (IPCC, 2023) states that the rise in average global temperature measured since preindustrial times is most likely caused by the anthropogenic greenhouse gas (GHG) emissions. Carbon capture and storage is a solution to reduce GHG emissions, recommended by the IPCC as needed, in order to achieve the climate targets (IPCC, 2022). One of the main challenges related to the deployment of this technology is mitigation of potential leakage risk and also assessing its potential impact on ecosystems (West et al., 2005).

The impact of a potential CO_2 seepage from an anthropogenic reservoir on vegetation is relevant considering that this information can be used as an early indicator of leakage (Noble et al., 2012).

Several studies have been made worldwide, based on natural analogues, highlighting the relationship between increased CO_2 concentration in soils, vegetation health and/or substitution of species. The effect of CO_2 can be direct or indirect through pH changes and the remobilisation of nutrients or toxic compounds (Noble et al., 2012). There have been two research directions: the first using controlled leakage sites and the second using natural analogues. The first research direction uses experimental field sites where CO_2 has been injected into soil and documents the effects on the ecosystems. The most important experimental sites are the ZERT site (Keith et al., 2009; Male et al., 2010) and ASGARD site (West et al., 2009). The second research direction is related to natural sites where CO_2 releases are present, such as Germany – Laacher See (Krüger et al., 2009, 2011), Greece – Florina basin (Ziogou et al., 2013), Italy - Latera (Beaubien et al., 2008; Oppermann et al., 2010) Slovenia – Stavešinci (Macek et al., 2005, Pfanz et al., 2007) and the United States – Mammoth Mountain (Bergfeld et al., 2006; Biondi & Fessenden, 1999; McFarland, Waldrop & Haw, 2013).

From previous research it was observed that botanical changes are site and species specific (Noble et al., 2012). Vegetation changes also

depend on factors like soil moisture and pH (Krüger et al., 2011). In general, plants are resistant to an increase in CO_2, with no obvious response at moderate concentrations (Bouma et al., 1997). Plants can show a decrease in height, root respiration and rooting depth (Nobel & Palta, 1989; Vodnik et al., 2006). They can also present yellowing or browning of leaves and other signs of stress following a rapid flux of CO_2 (Pfanz et al, 2011; West et al., 2009). Grasses generally dominate the high CO_2 sites (Beaubien et al., 2008; West et al., 2009). Depending on site, there can be potential bioindicator species like *Polygonum arenastrum* (Krüger et al., 2011), *Polygonum aviculare* (West et al., 2015) and *Minuartia glomerata* (Ziogou et al., 2013). Dead vegetation (e.g. Bergfeld et al., 2006) or the lack of plant cover (Beaubien et al., 2008) can also be indicators.

Romania offers a great potential for this type of studies, since there are many sites that could be used as natural laboratories. Considering this, two natural analogues have been selected as test areas in the framework of a nationally funded research project started in 2023 and aiming to develop an environmental monitoring methodology. The two selected sites are Bodoc (Covasna County), a natural analogue for safe storage and Lăzărești (Harghita County), a natural analogue for leakage of CO_2 in the near environment. On these two sites gas measurements and vegetation surveys have been conducted in September 2024.

MATERIALS AND METHODS

Study areas

Bodoc site corresponds with a carbonated mineral water reservoir. The location used for measurements is on a pasture for cattle on the outskirts of the Bodoc commune along the Borviz brook.

Geologically, the Bodoc area is located at the western limit of the Cretaceous flysch, intensely folded and faulted. The Cretaceous flysch deposits (Sânmartin-Bodoc strata) are composed of an alternation of sandstones, marls, shales and conglomerates. In the deposits of the basement rock there are medium depth aquifers and in the upper side there are post tectonic deposits of the sedimentary cover, with shallow aquifers.

The conglomerate facies, located in a synclinal structure, are strongly affected by tectonic movements (a series of transverse faults), responsible for the migration of mineral waters to the surface (Mutihac, 1990).

Bodoc is known for its mineral waters. On the left bank of Borviz brook there is the well F1 SNAM Talomir (presently in conservation) in Upper Pliocene-Quaternary deposits and on the right bank there is the well F2 SNAM, with oligomineral mineral water (SNAM, 2025).

Băile Lăzărești is situated next to Lăzărești village, within Cozmeni commune, approximately 16 km North-East from Băile Tușnad. It is renowned by highly concentrated carbon dioxide emissions which can exceed 85% in volume (Dudu et al., 2024). From a geological point of view, Băile Lăzărești area is situated on a succession of geological deposits, from the Cretaceous flysch (Sânmartin-Bodoc, Barremian-Albian strata) at the base, to the terrace deposits. The deep geological structure of the area is dominated by a fault system that includes geological complexes, facilitating the migration and distribution of post-volcanic emissions, such as mofettas or mineral water springs (Mutihac, 1990).

Flux and concentration measurements of soil gases

Soil flux and concentration measurements were done using the West Systems portable fluxmeter equipped with CO_2, CH_4 and H_2S sensors. The measurements were done at Bodoc site on two perimeters, one along the brook valley (P4) and one on a pasture for cattle (P3), with a variable sampling distance of 2 or 5 m. In total, 244 points were measured.

At Lăzărești site, gas measurements were done also on two perimeters, one in the area with the most important touristic features (basin, mineral spring and wet mofettas) (P1) and one on a hill recently landscaped on three terraces (P2). The sampling point were 5 m apart. 52 sampling points were measured in total.

Concentration and flux data was processed using FluxRevision software, provided by West Systems.

Vegetation surveys

The quantitative vegetation survey was done in the same place or in the immediate vicinity of the measurement point for gas flux and concentration, in order to correlate the dominance of a given type of vegetation and the concentrations of gases at the soil level at the same place. We used a rectangular quadrant with the sides of 50 cm placed in the points where gas measurements were done.

The interior of every quadrant was digitally photographed with the camera of a Xiaomi Poco M3 mobile phone in order to have a visual record and to analyse the abundance of different categories of vegetation and soil coverage. Digitally, by using the software GIMP 2.6, a grid of 25 points situated at equal distance was created inside the quadrant and the category where each element belongs for each point was selected.

For the quantitative survey there were used 107 points for Bodoc (Figure 1) and 52 points for Băile Lăzărești (Figure 2). Although in Bodoc area there were gas measurements done in 213 points, we chose just some of them for the vegetation survey, for logistic reasons. Also, four points with blurry photographs were eliminated.

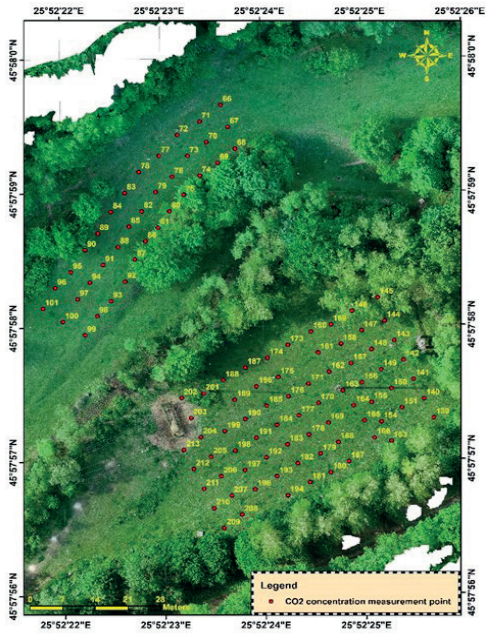

Figure 1. The network of points used at Bodoc for gas measurements and vegetation survey

Figure 2. The network of points used at Băile Lăzărești for gas measurements and vegetation survey

For this survey we intended to do a quantitative evaluation through the presence and dominance of some wide categories of herbaceous or small-sized plants, also considering their apparent state of health. Where possible, the main taxa of herbaceous plants were identified in order to offer us further clues about the character of the plant community.

The most common genera and species were readily identified, while the less common ones were identified using the mobile application iNaturalist (iNaturalist, 2024) through its dedicated function, with its observations georeferenced and made public through the GBIF (GBIF, 2024) network.

The following soil coverage categories were used:

1. dicotyledonous angiosperms (dicots) not known as indicators - healthy organs;
2. monocotyledonous angiosperms (monocots) - healthy organs;
3. herbaceous angiosperms - withered, yellowed, brown or dried organs;
4. mosses;
5. pteridophytes;

6. external (tree leaves, branches, litter etc.) or unidentified (shaded) elements;
7. bare ground;
8. known indicator plants from other studies: *Polygonum sp*., *Minuartia glomerata.*

The criteria according to which the categories 1 and 2 were selected are primarily from literature, where it was concluded that the monocotyledonous angiosperms are generally more frequent than dicotyledonous in areas with high CO_2 (Krüger et al., 2009; Krüger et al., 2011; Noble et al., 2012; West et al., 2009). Category 3 was selected because very high CO_2 emissions can make the plant organs appear yellow or brown (West et al., 2009), or can lead to their death (Bergfeld et al., 2006). Categories 4 and 5 can be dominant in certain locations although literature does not specify whether their presence is related to given CO_2 concentrations. Category 6 is neutral. At the highest level, long-term CO_2 emissions categories 7 or 8 can appear, bare ground or indicator plants. Concerning the latter, the genus *Polygonum* must be mentioned with the species mentioned as indicators in the literature *Polygonum arenastrum* (Krüger et al., 2009) and *Polygonum aviculare* (West et al., 2015), possible other members of the genus, as well as *Minuartia glomerata* (Ziogou et al., 2013), which was not found in the study area. However, the presence of *Polygonum* sp. isn't an unequivocal indication for the presence of high CO_2, being a very common genus present in anthropically disturbed areas.

Using the program Microsoft Excel and the photographs, as well as mapping techniques, we tried to highlight relationships between the percentual composition of soil coverage categories and the flux and concentration of the gases CH_4, CO_2 and H_2S. This was tested for both Bodoc and Băile Lăzărești.

RESULTS AND DISCUSSIONS

Flux and concentration measurements of soil CO_2

Four perimeters for the soil CO_2 concentrations were used: P1 and P2 at Băile Lăzărești, P3 and P4 at Bodoc, all considered separately.

P3 at Bodoc is the pasture for cattle, where the minimum concentration recorded is 413.8 ppm, the average 427 and the maximum is 483.5 ppm. P4 at Bodoc is close to the Borviz brook, with the minimum concentration recorded as 420.4 ppm, the average 438 ppm and maximum as 474 ppm (Figure 3).

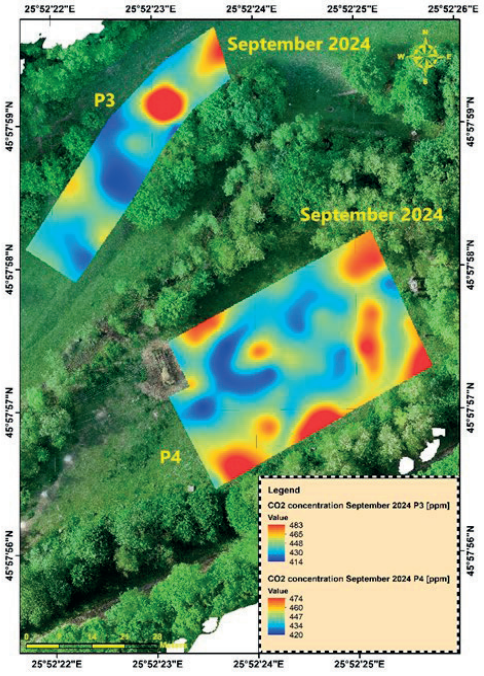

Figure 3. CO_2 concentrations at Bodoc

All these values are close to the background level and do not exceed 500 ppm. On the other hand, Băile Lăzărești have a minimum value of 516.6 ppm in P1 and a maximum measured value of 25863.2 ppm (Figure 4) and an average of 3240 ppm. However, the maximum measured value is not the maximum value for the area, which is probably found in the mofetta set up for tourists close to point 44 (Figure 2).

The perimeter P2 on the hillside has generally above background levels of CO_2, with a minimum of 428.9 ppm, an average of 743.7 ppm and a maximum of 1764.2 ppm (Figure 4).

Vegetation survey at Bodoc

The herbaceous vegetation consists of a cattle pasture in the vicinity of oak forest (Figure 1), with a slight slope in the upper area and flat in the brook area, separated by a slope with ungrazed vegetation. The upper area is shaped like a wide stripe, with the orientation NE-SW.

In the pasture area, the plants are generally no more than 5 cm high from the ground up, due to grazing, except some taxa like *Cirsium arvense*, *Urtica* sp. and *Plantago* sp. Grazing made the species hard to identify. The plants were generally affected by the drought, being withered, yellowed or dried as a result of unusually hot a hot and dry summer and autumn. More vigorous are the plants found close to Borviz brook or in the shade of the surrounding trees and shrubs. The human influence is visible because the upper part bears the traces of a construction's foundation and the lower part, next to the brook, contains several boreholes.

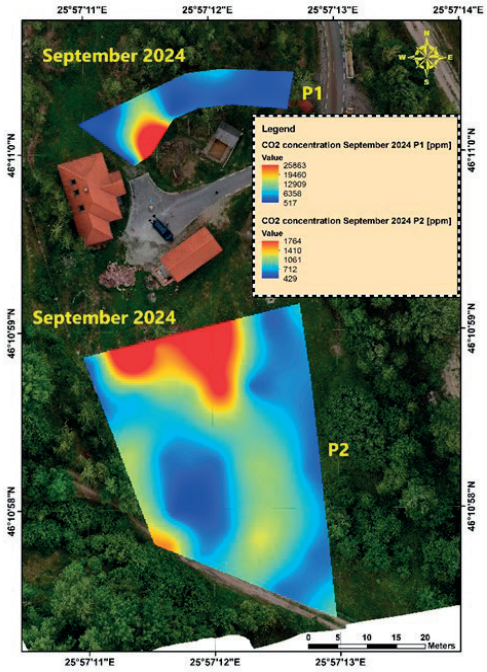

Figure 4. CO_2 concentrations at Băile Lăzărești

Vegetation survey at Băile Lăzărești

The study area has a strong anthropic footprint, being enclosed with a fence and has built structures for balneotherapy and some terracing works. The area has a marked, but not steep slope, with Northern exposure. The herbaceous vegetation doesn't have signs of intervention through grazing or mowing, but can be prevented to grow through treading, mulching or by the presence of balneotherapy constructions (Figure 2). Where present and their growth is not impaired, the herbaceous plants are generally vigorous. Some plants are yellowed in appearance. The trees and shrubs at the site are birches (*Betula pendula*), some small-sized willows (*Salix capraea*) and juniper (*Juniperus communis*).

Mosses are present, without being identified by genus or species. The pteridophytes found are *Lycopodium clavatum*, *Equisetum* sp., *Athyrium filix-femina* and *Pteridium aquilinum*. The dicotyledonous angiosperms are dominated by the families Asteraceae and Fabaceae, especially by the genus *Trifolium*.

Among the monocotyledonous angiosperms dominates the order Poales, with the family Poaceae with the genera *Poa* and *Phleum* and the species *Agrostis capillaris* and *Dactylis glomerata*. We can also find the families Cyperaceae and Juncaceae from the same order.

Comparative analysis

Comparing the two surveys, Bodoc has much more dry or yellowed vegetation compared with Băile Lăzărești, from exposure to the sun and drought probably (Figure 5). The shaded areas have greener plants, especially dicots. From a taxonomical viewpoint, in Băile Lăzărești dominate the monocots, approximately twice as abundant compared to dicots. In Bodoc area healthy monocots and dicots have approximately equal proportions, although the stressed angiosperms tend to be monocots, especially in the sunny areas (Figure 6). Dry or withered angiosperms were generally not identified by class, because they were harder to distinguish. In Băile Lăzărești, the stressed angiosperms (almost completely monocots) are found mostly in balneotherapy and terraced areas (Figure 7). We consider than the effect is probably caused by human activity.

An important mention is the absence of the indicator plants from all photographed quadrants. Although *Polygonum aviculare* was present in both areas, it wasn't found where gas measurements took place, but in the surrounding areas, disturbed by treading.

As neutral elements there are mosses, more frequent in Bodoc, and pteridophytes, more frequent in Băile Lăzărești. Due to the anthropically removed vegetation in Băile Lăzărești, there is a higher percentage of bare ground. In Bodoc, bare ground is present on patches of at most a few centimetres in length.

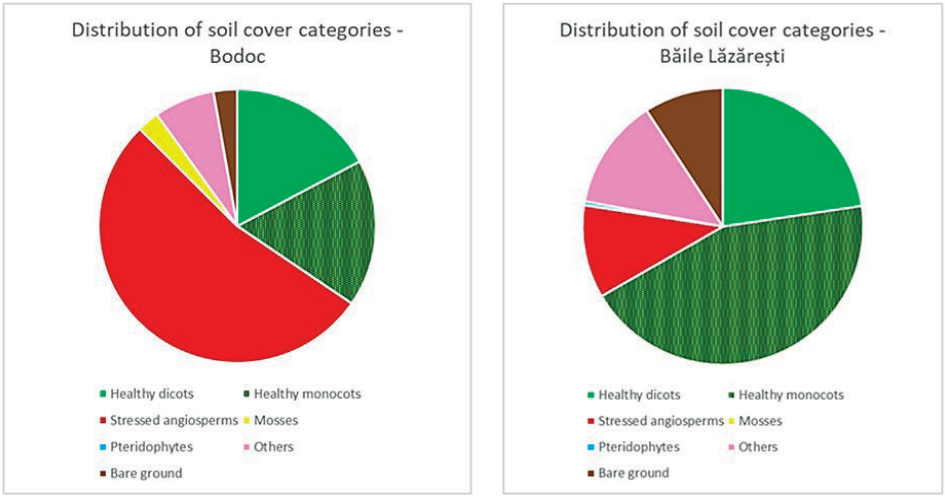

Figure 5. Distribution of soil cover categories at Bodoc and Băile Lăzărești

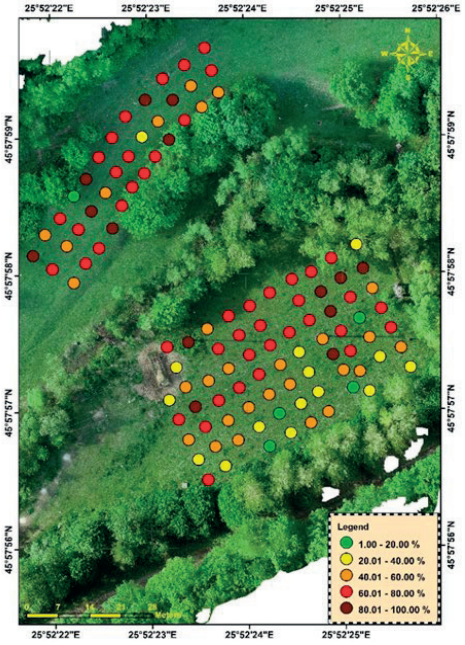

Figure 6. Stressed angiosperms at Bodoc (percentage of total soil coverage)

At Bodoc, most plants found are either stressed or dried. Healthy dicots predominate in the south-western part, which is an area shaded by trees. Healthy monocots seem to be distributed randomly. Increasingly towards the north-west, grows the relative dominance of the monocots over dicots, as well as that of the stressed plants of both classes. The most stressed plants and the most patches of bare ground are found in the upper, North-Western part (Figure 6).

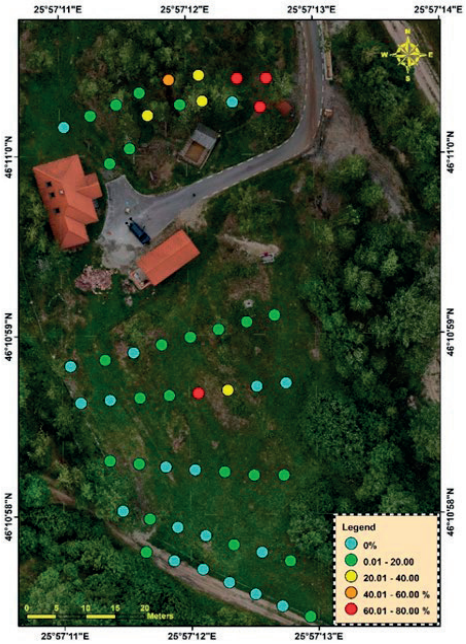

Figure 7. Stressed angiosperms at Băile Lăzărești (percentage of total soil coverage)

For Băile Lăzărești, most plants appear healthy, with a dominance of monocots. The dicots are mostly found in the upper Eastern part, while

the monocots are mostly found to the South-West. The most stressed plants are found in the lower, northernmost area, close to the spa facilities and in the areas where terracing works were done (Figure 7).

The relationship between the vegetation survey and the gas measurements in Bodoc and Băile Lăzărești

For Bodoc, we couldn't highlight the relationships between the composition of soil coverage categories and the higher fluxes or concentrations of CH_4, CO_2 and H_2S. The areas where slightly higher concentrations are present aren't significantly different floristically from the neighbouring areas which have smaller fluxes or concentrations.

For Băile Lăzărești, the points with the highest fluxes and concentrations of CO_2 and other gases are associated with the scanty vegetation, with some dried plants and exposed soil. Plants that are present are predominantly monocots (Poaceae), with some dicots (*Trifolium* sp.). The same soil coverage pattern is present on the stretches of soil where have not been recorded higher concentrations of CO_2 or other gases following the measurements. It is not excluded that those points may indicate intermittent gas sources, but which haven't been captured by measurements.

CONCLUSIONS

The survey represents a preliminary assessment of the herbaceous vegetation from the two studied areas, considering its usage as a bioindicator for carbon dioxide emissions. The selection of the coverage categories was made considering those present in the literature.

The floristic composition of the two areas is too different, thus they cannot be compared among themselves. The Bodoc study area is a cattle pasture, and in the case of Băile Lăzărești, there is an ecosystem without mammalian herbivores, but affected anthropically. Băile Lăzărești has plants of colder climate and higher humidity.

The vegetation succession in Bodoc is not related to the variations in CO_2. In Băile Lăzărești area, on stretches with higher CO_2 flux and concentration, the vegetation is partially absent and the soil is exposed, which could be due to gases, anthropic intervention or a mix of both.

As this is a preliminary study, there is a need for more detailed studies to make a better characterization of the vegetation of the area, using a denser sampling grid and, if possible, identifying all species present.

ACKNOWLEDGEMENTS

The research leading to these results was made within the project PN 23 30 04 04 "Development of an environmental monitoring methodology for potential CO_2 storage sites in Romania (Dezvoltarea unei metodologii de monitorizare de mediu pentru potențialele situri de stocare de CO_2 din România)", financed by the Ministry of Research, Innovation and Digitalization of Romania through the Core Program.

The authors would like to acknowledge and to thank for the support of town halls of Cozmeni and Bodoc, who facilitated the access to the site and the smooth running of the campaigns.

We also thank the anonymous reviewers for all suggestions provided for improving the manuscript.

Abstract

The Bahnele Bancului peatlands, located in Suceava County, were selected for restoration due to multiple threats, such as habitat degradation, overgrazing, and drainage. The peatland currently faces an unfavourable conservation status, with Picea abies trees, over 80 years old, being the dominant vegetation. By integrating national moss species surveys with ongoing peatland restoration efforts, local research has been significantly supported. Field assessments conducted between 2022 and 2023 revealed valuable species and habitat data. Buxbaumia viridis (Moug. ex Lam. & DC.) Brid. ex Moug. & Nestl., a key moss species that serves as an indicator of well-preserved spruce forests and is protected by the EU Habitats Directive, was identified on the site in June 2022. In addition, priority habitats, such as 91D0 Bog Woodland were observed, with notable species including Sphagnum spp., the rare orchid Epipactis helleborine, and the Carpathian newt (Lissotriton montandoni). These findings have contributed to the completion of the Natura 2000 site designation forms, which include detailed habitat and species data along with a map, highlighting the site's importance for conservation.*

Key words*: bryophytes, threatened species, bog woodland.*

INTRODUCTION

The European network of natural areas, Natura 2000, serves as an umbrella for the long-term conservation of valuable natural habitats in accordance with the Habitats Directive 92/43/EEC, as well as for the protection of threatened flora and fauna species. Peatland habitats play a critical role in environmental preservation and climate change mitigation. Reducing carbon loss in peatlands, which store significantly more carbon than the world's tropical rainforests, means an important reduction in global greenhouse gas emissions (Page & Baird, 2016).

Given their importance and the imperative need to protect these peatland habitats vital for certain species of conservation concern, proposing the inclusion of Bahnele Bancului North (BBN) peatland within the Natura 2000 network represents the most appropriate solution. This will help protect the included Bog Woodland habitat (91D0*) as well as conserve *Buxbaumia viridis* (Moug. ex Lam. & DC.) Brid. ex Moug. & Nestl. (Ștefănuț et al., 2023) and *Lissotriton montandoni* (Carpathian newt) protected species.

According to Steinacker et al. (2019), Bog Woodlands (91D0*) represent the most threatened forest habitats due to their heightened vulnerability to climate change. They advocate for expanding the Natura 2000 network to reduce non-climatic stressors on this habitat, and to support climate change mitigation efforts.

Consistent with the current study, the research conducted by Ștefănuț et al. (2023) provides fundamental support for the proposal to designate new Natura 2000 sites, including BBN peatland. Given that habitat 91D0* is a priority habitat under the EU Habitats Directive (Annex I), also found in the BBN site and hosting moss species such as *B. viridis* and *Sphagnum* spp., and considering Law 49/2011, which ratifies GEO 57/2007 and emphasizes the necessity of designating special conservation areas to ensure their long-term preservation, we prioritized the

BBN peatland proposal under the Natura 2000 framework. Moreover, the solution also supports the EU Biodiversity Strategy for 2030, which calls for strict protection of 10% of the terrestrial area and the preservation of 30% of it by that year (European Commission, 2020) and to reach the Kunming-Montreal Global Biodiversity Framework Target 2 (CBD Secretariat, 2022).

The aim of this study was to assess the BBN site's degradation degree, pinpoint the limiting factors that have impacted the condition of this delicate habitat, outline the methodology employed to efficiently restore the site, and emphasize the importance of implementing legal measures to protect the site by legislation. By adding the BBN peatland to the Natura 2000 network as a Special Area of Conservation (SAC), the main goal is to guarantee its long-term conservation in optimal conditions.

MATERIALS AND METHODS

Site location and description

The BBN peatland is located in the northern region of the Eastern Carpathians and the western part of the Dornelor Depression, southwest of Suceava County. At 898 m a.s.l. elevation, the site's eastern boundary follows the Bancu (Coșnița) stream and the DC 85B communal road (Figures 1 and 2); here, the soil is classified as eutrophic peat. The terrain becomes forested at higher elevations, initially with peaty soil, then developing into a spruce forest with shallow soil, reaching an elevation of up to 970 m a.s.l.

The BBN site's geographical coordinates, covering an area of 18.85 ha, are 47°23'40.743"N 25°11'38.713"E. The BBN site belongs to the North-East administrative region, NUTS level 2 code RO 21, and is entirely located within the Alpine biogeographical region.

This peatland is owned by the Dorna Candrenilor Commune town hall and is not included in the protected natural areas managed by the National Agency for Protected Areas (ANANP).

Evaluation and monitoring activities

In the last years, many efforts have been made by several European countries to adopt national peatland restoration and conservation strategies and ensure their sustainable use. The Institute of Biology of the Romanian Academy Bucharest has also made such efforts between 2022 and 2024. Along with six other sites from the Suceava and Maramureș counties, the BBN peatland was included in the restoration process through the project "*Degraded mires and peatlands restoration of North-East 2 region of Romania (PeatRO3)*" (https://www.ibiol.ro/peatro3/index.htm) funded through EEA Grants mechanisms.

Considering the sensitivity of peatland habitats to biotic and abiotic factors, the evaluation and monitoring activities were designed accordingly. In the first stage, an initial assessment of the peatland conservation status was made, evaluating pressures and threats, vegetation changes, and the indicator species (several taxonomic groups have been inventoried), but also measuring the groundwater level and some environmental variables (water physicochemical parameters, air physical parameters). Subsequently, the monitoring was carried out over the period from 2022 to 2024.

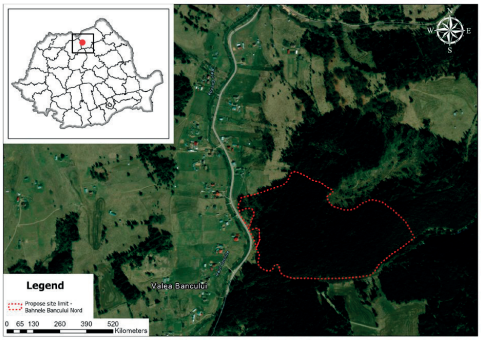

Figure 1. Geographical limits of the BBN proposed site as a SAC, under Natura 2000 network

Figure 2. The site layout next to the DC 85B communal road (drone image) (photo by Bîrsan C.)

The site pressures and threats caused by anthropic and environmental factors were detected throughout the monitoring and restoration period, the codes being assigned according to the European Environment Agency's updated list (2024).
Experts used drones (DJI Mini 2) and cameras to evaluate the vegetation changes and identification keys to assess the indicator species. Field surveys were conducted alongside these methods, allowing experts to identify plant species *in situ*, determine their proportions within the floristic composition, and study the site's conservation value. The nomenclature of plant species follows Sârbu et al. (2013), while habitat types are classified according to the *Interpretation Manual of Natura 2000 Romanian Habitats* (Gafta & Mountford, 2008; Doniță et al., 2005).
The site's water level was measured using five piezometers: four installed in the northern, eastern, southern, and western parts, and the fifth in the site's center. The water level in the five piezometers was recorded at different times during the monitoring process (June 2023, October 2023, April 2024).
The water physicochemical parameters (pH, oxidation-reduction potential− ORP, dissolved oxygen− DO, conductivity, total dissolved solids− TDS, turbidity, and temperature) were measured using the HI9829 multiparameter instrument (Hanna Instruments).
Furthermore, air physical parameters (temperature, relative humidity, and dew point) were measured every 30 minutes using EasyLog EL-USB 2 Data Loggers (DL) placed in two different locations (DL 1: 47°23.754'N 25°11.430'E; DL 2: 47°23.734' N 25°11.455' E).

Reconstruction activities
The restoration activities were determined based on the initial pressure and threats identified.

Barrage construction
In October 2023, a dam with 47°23'45.1"N 25°11'25.2"E coordinates was built to maintain the peatland's optimal hydrological level. The barrage, which measured 40 cm x 300 cm in dimensions, was constructed using natural materials: wooden spikes made from fallen trees on the site, untreated wooden planks, and soil, which were covered with local vegetation (Figure 3).

Figure 3. The barrage built to limit the water flow from the BBN peatland (arrow - the flow direction of the drainage ditch towards DC 85B and the Bancu River)

Water pond construction
To attract some characteristic invertebrates, a 20 sqm water pond (47°23'45.35" N 25°11'25.47" E) with a depth of 50 cm was constructed in September 2022 (Figure 4).

Figure 4. The water pond constructed in BBN peatland

Waste collection
Waste found in different areas of the BBN peatland was collected manually in garbage bags and then transported by the local authorities to specially designed places.

RESULTS AND DISCUSSIONS

Pressures and threats
After the initial evaluation, we found that the BBN peatland has an unfavorable conservation status. This was evidenced by the substantial garbage deposits (Figure 5), low water table caused by drainage through an artificial ditch, which is the main threat in the marshes throughout Europe (Figure 6), overgrazing, and significant vegetation changes with transition to

spruce afforestation (Figure 7), and other pressures and threats (Table 1).

Figure 5. Significant garbage deposits inside BBN

PJ01	Temperature changes and extremes due to climate change
PJ03	Changes in precipitation regimes due to climate change

Site's importance: habitats and flora

While the lowest part of the site appears as an eutrophic swamp, as elevation increases, the landscape transitions into a wooded area, first with peaty soil and then into a spruce forest on shallow soil, extending up to an altitude of 970 m.

The marshy area covers approximately 2.28 ha and is characterized by a eutrophic wetland with a shallow peat layer that has not yet been entirely isolated from infiltrating groundwater. Over time, this area may develop into a peat bog if the peat layer becomes sufficiently thick to detach from the influence of mineral-rich infiltration water (Pop, 1960). The plant species recorded in this area include: *Alnus incana* (L.) Moench, *Betula pendula* Roth, *Rhamnus frangula* L., *Salix caprea* L., *Sorbus aucuparia* L., *Caltha palustris* L., *Cirsium palustre* (L.) Scop., *Epilobium palustre* Willd., *Equisetum sylvaticum* L., *Filipendula ulmaria* (L.) Maxim., *Galium palustre* L., *Juncus effusus* L., *Lychnis flos-cuculi* L., *Lycopus europaeus L., Myosotis scorpioides* L., *Potentilla erecta* (L.) Raeusch., *Scirpus sylvaticus* L., *Urtica dioica* L.

The forested area covers 97.72 ha, consisting primarily of coniferous forests. The site is of significant conservation value due to the presence of two habitats of Community

importance: priority habitat **91D0*** Bog woodland that provides habitat for notable moss species such as *B. viridis* and *Sphagnum* spp., and also habitat **9410** Acidophilous Picea forests of the montane to alpine levels (Vaccinio-Piceetea) that hosts several important plant species, including *Sphagnum* spp., *Epipactis helleborine* (L.) Crantz, *Lycopodium annotinum* L., and *Lycopodium clavatum* L.

The **91D0*** Bog woodland habitat covers 1.54 ha of the site and consists primarily of coniferous forests. The tree layer is dominated by spruce (*Picea abies* (L.) H. Karst.), with scattered occurrences of *Pinus sylvestris* L., *Betula pendula*, *Rhamnus frangula*, and *Salix caprea*. In the most oligotrophic areas of the forest, the ground layer is dominated by a thick carpet of Sphagnum moss, often forming dense accumulations at the base of spruce trees. The characteristic moss *Sphagnum squarrosum* Crome exhibited healthy growth and adequate hydration (Figure 8). The understory vegetation is sparse, with only a few recorded species, including *Athyrium filix-femina* (L.) Roth, *Maianthemum bifolium* (L.) F.W.Schmidt, *Vaccinium myrtillus* L., and *Vaccinium vitis-idaea* L. Of particular conservation interest is the presence of *B. viridis*, a species of Community interest, which was observed growing on decomposing fallen logs in various stages of decay.

Figure 8. *Sphagnum squarrosum* in the BBN peatland (photo by Ștefănuț M.M.)

The majority of the investigated area is occupied by the **9410** Acidophilous Picea forests of the montane to alpine levels (Vaccinio-Piceetea) habitat, covering 16.88 ha. The tree layer consists almost exclusively of spruce (*Picea abies*), with occasional occurrences of *Fagus sylvatica* L., and *Sorbus aucuparia.* The shrub layer is poorly developed, with scattered individuals of *Sorbus aucuparia*, *Salix caprea,* and *Sambucus racemosa* L. The herbaceous layer is unevenly distributed, forming patches depending on the amount of light reaching the forest floor. Recorded species include *Oxalis acetosella* L., *Cardamine glanduligera* O.Schwarz, *Campanula abietina* Griseb., *Dryopteris filix-mas* (L.) Schott, *Vaccinium myrtillus, Athyrium filix-femina*, *Maianthemum bifolium, Epipactis helleborine*, *Lycopodium annotinum*, and *Lycopodium clavatum*.

Among the recorded species, *Lycopodium annotinum* and *Lycopodium clavatum* are species of Community interest (Figure 9). They are included in Annex V of the Habitats Directive due to their slow growth and sensitivity to habitat disturbances. These clubmosses are important in forest ecosystems, forming dense mats contributing to soil stabilization and moisture retention. *Epipactis helleborine* is an orchid species listed on the National Red List (Oltean et al., 1994) and included in CITES Appendix II, highlighting its conservation concern.

Figure 9. *Lycopodium clavatum* (left) and *Lycopodium annotinum* (right) (photo by Nicoară G.-R.)

In Romania, according to the European Environmental Agency (EUNIS), 91D0* habitat is already protected in 27 Natura 2000 sites (*Bog Woodland. EUNIS*), while 9410 habitat is protected in 66 Natura 2000 sites (*Acidophilous Picea forests of the montane to alpine levels, Vaccinio-Piceetea, EUNIS*).

Following the inventory of some animal and plant groups, two species protected under the EU Habitats Directive were identified: *B. viridis* and *Lissotriton montandoni* (Carpathian newt).

The Carpathian newt (*Lissotriton montandoni*, Figure 10) was found in April 2024 at the edge of the BBN site (coordinates: 47.396137° N,

25.190248° E), and we only observed one male. Although locally abundant in its distribution range, the species is endemic to the Carpathian Mountains, where it is distributed primarily in the Eastern Carpathians and partially in the Southern Carpathians from 200 to 1900 meters a.s.l. Its terrestrial habitats are represented mainly by moist deciduous, coniferous, or mixed forests, and meadows. Sometimes individuals can be found above the tree line in alpine habitats. The species is mainly affected by the destruction and modification of aquatic breeding habitats. Listed as Least Concern (LC) by the IUCN Red List, the Carpathian newt nevertheless has a descending population trend, although it is protected by the Bern Convention and the Habitats Directive, as well as Laws 13/1993 and 49/2011 in Romania.

Figure 10. *Lissotriton montandoni* in the BBN peatland (Carpathian newt) (photo by Maria G., April 2024)

Figure 11. Mature sporophyte of *Buxbaumia viridis* in the BBN peatland (photo by Ștefănuț S., June 2022)

B. viridis, an important moss species that indicates well-preserved spruce woods, was discovered in the BBN site 91D0* on June 23, 2022 (Ștefănuț et al., 2023). Six individuals were located on a decayed coniferous log at an altitude of 900 m a.s.l., facing west, (47°23'43.8" N 25°11'27.2" E, 895 m a.s.l.) (Ștefănuț et al., 2023) (Figure 11). On April 12, 2024 two individuals were found in the same spot (Figure 12).

Figure 12. Sporophytes of *Buxbaumia viridis* in the BBN peatland (photo by Ștefănuț S., April 2024)

B. viridis is a circumpolar species that is found in Europe, North America, and East Asia. It is also found in Romania in the Alpine bioregion. Sapro-lignical, characteristic of natural and mature spruce forests, *B. viridis* primarily grows on dead wood; however, it can also be rarely found on wood remnants on the ground (Deme et al., 2020; Kropik et al., 2020). It prefers wood in an advanced stage of decay, and it could be found on large fallen trunks and stumps, especially conifers, particularly those close to the streams, because it needs high humidity (Ștefănuț et al., 2023; Puntillo & Puntillo, 2024). However, it has also been found on beech, birch, mountain ash, maple and alder. These special requirements, along with its small size, dioecy, short life span, and low competitiveness with other larger bryophytes, cause its scarcity (Wiklund, 2002). Kropik et al. (2020) state that the climate has the most significant influence on the occurrence of *B. viridis*, with the dead wood quality coming secondarily.

B. viridis has a small size (10-18 cm), with a reduced gametophyte and a well-developed sporophyte, with brown setae that measure 5-10

mm, and a large, green capsule that measures 5-7 mm (Mihăilescu et al., 2015). The upper side of the capsule is slightly flattened, and the cuticle of the capsule exfoliates at maturity. Being an annual, acrocarpous, and dioecious species, *B. viridis* depends on the distance between the male and female bryospores to germinate as well as the existence of a water film that facilitates the antherozoid's progression towards the female (Ștefănuț et al., 2023).

While the gemmae are produced all year round, the juvenile sporophyte individuals start to develop in the fall, and around half of them die before they reach maturity in the summer (Deme & Csiky, 2021); both freezing followed by drought can hinder the development of sporophyte (Dierssen, 2001; Wiklund, 2002). According to Guillet et al. (2021), one of the most important factors influencing the presence of sporophytes− which are regarded as poor competitors (Hola et al., 2014)− may be the humidity. Due to its high-water level and forestation, the BBN peatland offers this protected species an ideal habitat.

Legally protected in Europe by Annex I of the Bern Convention, Annex II of the Habitat-Fauna-Flora Directive *(Directive 92/43/CEE),* and first included in the European List of Bryophytes as a Critically Endangered category - CR (Schumacker and Martiny, 1995)− *B. viridis* was also recently added to the new European Red List's Least Concern group species (Hodgetts et al., 2019). Plášek (2004) suggests that the species needs to be conserved in protected areas designated under the Natura 2000 network.

In a previous study, Ștefănuț et al. (2023) recommended reclassifying the conservation status in Romania of *B. viridis* from Endangered - EN A3c; C1 (Hodgetts and Lockhart, 2020; Ștefănuț & Goia, 2012) to Vulnerable - VU A3c. According to the European Environment Agency EUNIS, *B. viridis* is already protected in about 532 Natura 2000 sites across 18 countries (*Buxbaumia viridis*, *EUNIS*). In Romania, the species is protected in 11 Natura 2000 sites (*Buxbaumia viridis*, *EUNIS*). In the meantime, new reports of this species have been made for both Natura 2000 sites and areas not currently protected, supporting the update of management plans as well as declaring new sites.

The uniqueness and significant conservation value of the site are primarily defined by the presence of two habitats of Community importance (habitat 91D0* Bog Woodland and habitat 9410 Acidophilous Picea forests of the montane to alpine levels) and the occurrence of protected species, specifically *B. viridis* and the endemic *L. montandoni*. The distribution of *B. viridis* is well-documented in the Southern Carpathians, including protected sites, whereas in the Eastern Carpathians, it remains less studied. Consequently, distribution data in this region is scarce, highlighting the need to establish new protected areas in alignment with the EU's Biodiversity Strategy for 2030 (European Commission, 2020).

Restoration efforts - preliminary results

The PeatRO3 project's reconstruction efforts in the BBN peatland were designed to rebalance the ecosystem. One of the main targets was restoring the optimal hydric regime by reducing water loss through the drainage ditches. This goal was achieved by building a barrage across the drainage channel. This measure will encourage the growth of native plant species and limit the emergence of invasive vascular plant species. As a result, the ecosystem can function independently, self-regulate, and develop into an active peat bog that sequesters carbon dioxide through peat production.

The water pond construction aimed to attract invertebrate species such as the protected species *Leucorrhinia pectoralis* (Charpentier, 1825) (Natura 2000). Like other odonates, this species' life cycle depends on a water body, as they lay eggs on the water surface or aquatic vegetation. Dragonfly species can colonize a new water pond in three years after restoration (Elo et al., 2015). In the case of the BBN peatland, if the hydric level increases and remains at an optimum level, the newly formed water ponds can be colonized by *Leucorrhinia pectoralis* (Charpentier, 1825), as a high number of individuals have been reported in the nearby located Pilugani peatland (Manci & Iorgu, 2021).

After waste collection and disposal in September 2022 and October 2023 (25 garbage bags), an informative panel mentioning the restricted activities was placed at the site entrance (Figure 13) to minimize further

garbage accumulation. Besides interdicting garbage disposal, the panel also contains warning messages aimed at restricting other harmful anthropic activities such as grazing and tree cutting. Also, by scanning the QR codes (in Romanian and English) installed on the panel, visitors and local community members can access details about the restoration project, the eco-touristic potential of the site, and additional information on responsible behaviour, thus contributing to the long-term success of habitat preservation.

In their study, Strzelecka et al. (2022) emphasize the importance of a strong link between the residents' relationship with nature and the conservation policies, thus resulting in the need to engage them in various forms of nature stewardship. A better understanding of the residents' bond with nature, an "engagement in" approach through a collaboration that reduces pressures on the habitat (in our case grazing, waste disposal, etc.), will strengthen the connection between nature and the local community, which is directly involved in protecting the site (Restall et al., 2021).

Figure 13. The billboard from the entrance to the site

Monitoring Results - preliminary effects

At the BBN peatland, piezometer data readings indicated optimal hydration, albeit with uneven water distribution across the ecosystem. These variations were influenced by the site topography, the presence of water sources, and the peat`s capacity to retain moisture. Measurements of water level variations from the piezometers undertaken within the site between October 2023 and April 2024 revealed a general increase in hydration with 8, -1, 6.5, -4, and 6 cm, respectively, indicating an improvement in the peatland`s water retention capacity.

Two EasyLog EL-USB 2 Data Loggers (DLs) recorded the meteorological parameters: temperature, humidity, and dew point (Figures 14 and 15). Unlike temperature and dew point, which exhibited constant trends across the two monitoring points (corresponding with normal monthly and seasonal variations), some variations in humidity level were observed. Namely, slight differences were recorded between the humidity of the two site zones, especially in the warmer months. Local environmental factors such as vegetation, water availability, and sun exposure can contribute to these disparities. However, the monthly average humidity levels, which ranged from 74.23% to 98.84% relative humidity, showed that the atmospheric conditions were favourable, with a tendency for higher humidity levels in the southern part of the site.

Variations between the designated points (natural water pond and artificial water pond) were found by *in situ* measurements of water quality parameters using the HI9829 multiparameter instrument (Hanna Instruments) (Table 2).

Table 2. Water parameter values

Parameter	Natural water pond	Artificial water pond
pH	6.69	8.03
ORP (mV)	177.3	-5.5
DO (%)	7.3	3
DO (mg/L)	0.74	0.26
Conductivity (µS/cm)	50	102
TDS (mg/L)	25	49
Turbidity (NTU)	11.4	22.4
Water temperature (°C)	9.39	22.4

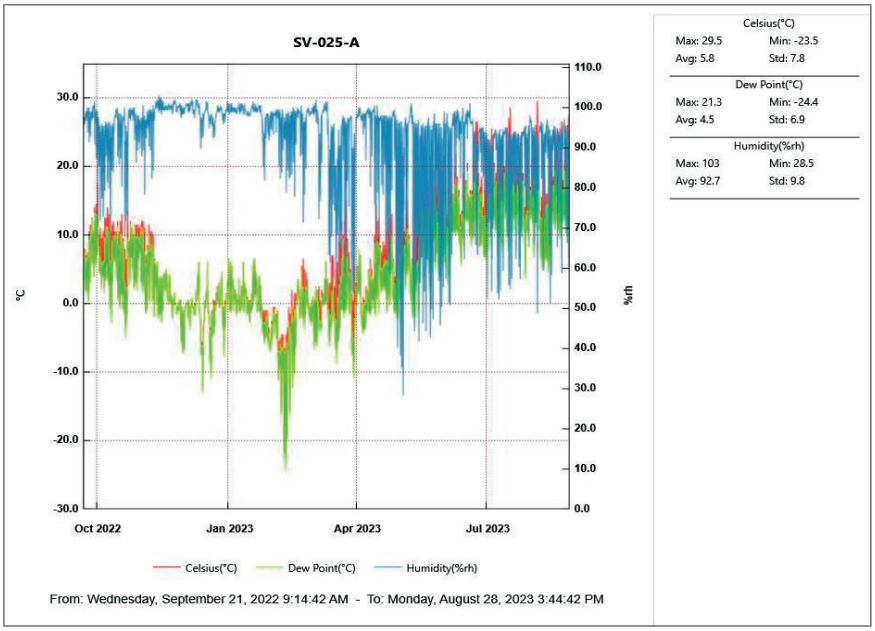

Figure 14. Variations in parameters measured with Data Loggers (September 2022 - August 2023)

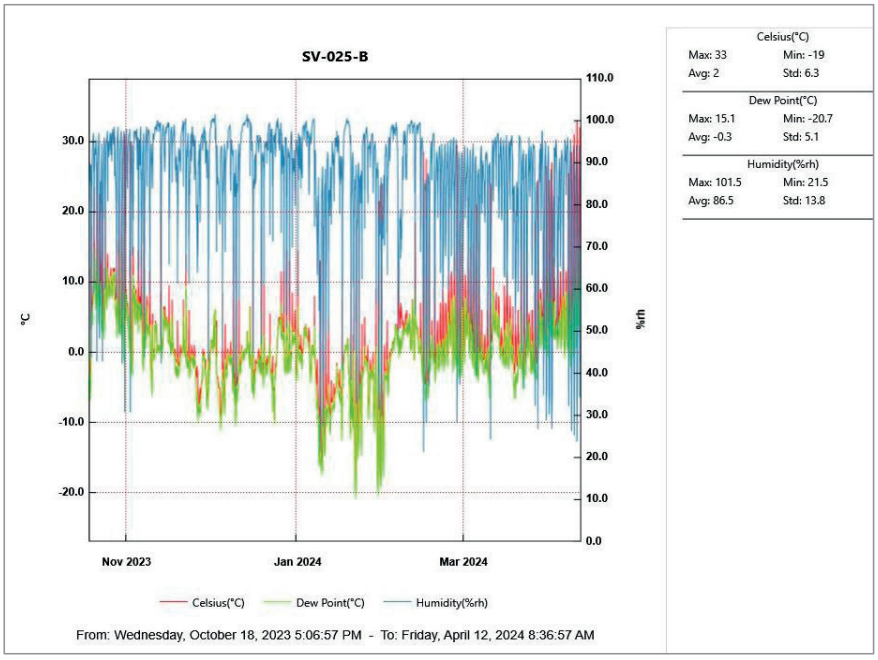

Figure 15. Variations in parameters measured with Data Loggers (October 2023 - April 2024)

The pH values were within the optimal range for both water bodies. Instead, in the natural pond, a positive ORP was recorded, indicating the oxidation of organic materials, whereas the artificial pond had a negative ORP, reflecting reducing reactions. Dissolved oxygen (DO) saturation also differed, measuring 7.30% in the natural pond and 3.00% in the artificial pond,

supporting further chemical processes as indicated by the ORP values. Peat formation occurs through the anaerobic decomposition of organic matter. Due to sediment accumulation, the artificial pond showed higher conductivity, TDS, and turbidity, which led to a reduction in water clarity. Also, water temperature influenced both biological and chemical activities, with lower temperatures slowing these processes and higher temperatures accelerating them.

A better understanding of the restoration process's quality may result from the ongoing improvement and adaptation of the monitoring protocol, guided by methodologies employed in other peatland restoration projects in other countries (Kyrkjeeide et al., 2024). Beyond the national strategies of restoration and conservation of peatlands, in a comparative study, Nordbeck & Hogl (2024) conclude that the European governments are becoming more politically committed to sustainable management of peatlands. Also, maintaining peatlands in good conservation status means a better potential for carbon-storage, an efficient solution for climate change mitigation (IPCC, 2021). Therefore, for the long-term preservation of peatland habitats in our country, a legislative framework must be established supporting these strategies.

CONCLUSIONS

The BBN peatland restoration efforts implemented during the PeatRo3 project led to an overall water table rise, despite the initial unfavourable conservation status.

Ongoing and improved monitoring, alongside the identification of key indicator species will be essential to assess the long-term stability and success of the restoration.

This improvement of the hydric level constitutes a starting point for the development of a legal framework aimed at the conservation and protection of this site.

This study scientifically supports the BBN peatland's designation as a Natura 2000 site, as proposed in April 2024. The primary objective of this designation is to ensure the long-term legal preservation of the protected species, namely *B. viridis* and *L. montandoni,* as well as the priority habitat Bog Woodland (91D0*), with a particular emphasis on their conservation. Furthermore, it advances the broader objective of achieving tangible progress towards the EU's goal of expanding terrestrial protected areas across Europe.

ACKNOWLEDGEMENTS

This research work was carried out from project no. RO1567-IBB03/2024 through the Institute of Biology Bucharest of Romanian Academy and was also financed by the EEA Grants: "Degraded mires and peatlands restoration of North-East 2 region of Romania (PeatRO3)" project.

Abstract

Peatland habitats are well-known for their function in sequestering carbon, characterized by peat-forming species such as Sphagnum mosses. The Avrig peat bog, located at the foothills of the Făgăraș Mountains in the Olt River basin, is a small site (less than 4 hectares) proposed for designation as a Natura 2000 site. A eutrophic palustrine zone encircles the peat bog`s center oligotrophic zone, dominated by Sphagnum mosses. This area is characterized by the presence of the European-protected priority habitat Active raised bogs (habitat code 7110). We employed a combination of field surveys and aerial investigations to assess the site`s biodiversity and evaluate potential threats. The collected Sphagnum samples were morphologically examined in the laboratory, revealing several species, like Sphagnum medium Limpr., Sphagnum capillifolium (Ehrh.) Hedw. and Sphagnum girgensohnii Russow. The bog also supports rare plant and amphibian species of conservation interest. Targeted management strategies are necessary to mitigate pressures including agricultural runoff, drainage, invasive species, and peat extraction.

Key words*: Sphagnum, peatland restoration, amphibians, rare plant species, Natura 2000, raised bogs.*

INTRODUCTION

Peat bogs are among the most ecologically significant habitats due to their dual role as refugia for endangered species, including glacial relicts, and as natural carbon sinks that accumulate atmospheric CO_2 over millennia. These habitats, particularly in continental regions such as the Făgăraș Mountains' Olt Basin (Sibiu County), are under increasing conservation scrutiny.

In the continental region of Romania, several peat bogs are found in the Făgăraș Mountains' Olt Basin, within the administrative area of Avrig, Sibiu County. Historically, the vascular flora of the Avrig peat bogs has been documented extensively by researchers such as Pop (1937; 1945; 1955; 1960), Șerbănescu (1961; 1964), and Drăgulescu (2003; 2010). Peat stratigraphy and formation processes have been analyzed since the 19th century (Herbich, 1884; Staub, 1884; 1891; Pax, 1908), confirming the Avrig peat bogs as some of the oldest in Romania, with an estimated age of 13,880 ± 90 years (Tanțău et al., 2006; 2009). Notably, the term "Avrig" has been attributed to a specific paleoclimatic cooling phase, dated at 12,360 ± 70 years BP.

Evidence of early anthropogenic influence, dating back 6,000-6,500 years BP, is supported by pollen analyses indicating the presence of cereal crops (Tanțău et al., 2011).

This paper presents the results of the biodiversity and conservation status assessment conducted within the framework of two major restoration projects PeatRO and PeatRO2 - focusing on peat bogs restauration and Natura 2000 site proposals in Romania.

MATERIALS AND METHODS

Among the four peat bogs in Avrig, Sibiu County, previously described by Pop (1960), one was rediscovered in 2016 as part of the PeatRO project. Although the habitat was found in a degraded state, it showed high restoration potential due to the presence of *Sphagnum* species and peatland indicator vascular plants such as *Drosera rotundifolia* L. and *Menyanthes trifoliata* L.

Within the PeatRO2 project - *Degraded Mires and Peatlands Restoration in North-East Romania* (2021-2024), funded by an EEA grant - restoration efforts were carried out, including assessments of vegetation (vascular and bryophyte), faunal composition, and conservation status. We employed a combined qualitative approach, integrating field surveys and drone-based assessments, to evaluate the site's biodiversity, existing pressures, and potential threats. Bryophyte samples were collected and morphologically identified in the laboratory using light microscopy. *Sphagnum* species were classified based on the keys by Plămadă (1998) and Laine et al. (2018), while vascular plants were identified following Ciocârlan (2009). Bryophyte nomenclature adheres to Hodgetts et al. (2020), and vascular plant taxonomy follows *Flora Europaea* with updates from the Euro+Med PlantBase. Plant associations were described in accordance with Sanda et al. (2008a; 2008b).

RESULTS AND DISCUSSIONS

The Avrig peat bog is situated in Sibiu County at 405 m a.s.l. (45.716282°N, 24.400133°E). Ecosystem evaluation during restoration confirmed the presence of species and habitats protected under Council Directive 92/43/EEC (1992). Based on field surveys and drone-based assessments, the area encompassing species and habitats of European interest was delineated. Consequently, the 3.6 h area (Figure 1) was proposed as a new Natura 2000 site, "Mlaștina Avrig" (Avrig Peat bog), aligning with the 2020 Eu State Nature Report emphasis on conservation and biodiversity assessment.

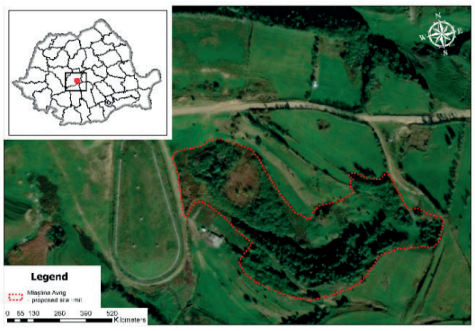

Figure 1. The area of Avrig Peat bog - new NATURA 2000 site proposal

The proposal received official endorsement from Avrig City Hall and the Sibiu Environmental Protection Agency, and has been submitted to the Ministry of Environment, Waters and Forests for final approval. The most ecologically significant area is located at the center of the site - an oligotrophic habitat characterized by acidophilic plant communities and dominated by typical *Sphagnum* species (Figure 2).

This zone corresponds to the EU priority habitat "Active Raised Bogs" (habitat code 7110), covering approximately 1 hectare. The dominant taxa within this habitat belong to the *Sphagnum magellanicum* complex (Figure 3).

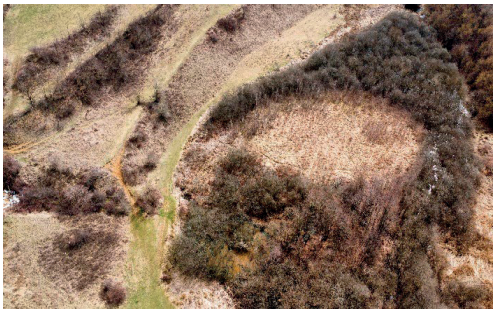

Figure 2. Avrig Peat bog - drone image.
The *Sphagnum* area is an open area surrounded by forest trees (13.03.2025)

Recent taxonomic revisions have limited the distribution of *Sphagnum magellanicum* Brid. to South America, with all previous European occurrences now attributed to either *Sphagnum medium* Limpr. or *S. divinum* Flatberg & K. Hassel (Hassel et al., 2018). Within the Avrig Peat bog, *S. medium* (Figure 4) was recently documented and formally reported as a new record for the Romanian flora (Tomović et al., 2024), highlighting the site's significance for bryological diversity and biogeographical research.

The plant association characterizing this habitat is *Sphagnetum magellanici* (Malcuit, 1929) Kästner et Flösner, 1933. Dominant bryophyte species include *Sphagnum medium* Limpr., *S. divinum* Flatberg & K. Hassel, and *S. palustre* L. (Figure 5). These are accompanied by a diverse assemblage of other *Sphagnum* species, notably *S. angustifolium* (Russow) C.E.O. Jensen (Figures 3 and 6), *S. girgensohnii* Russow, *S. capillifolium* (Ehrh.) Hedw., *S. fallax*

(H. Klinggr.) H. Klinggr. var. *fallax* (Figure 6), and *S. russowii* Warnst. Additional bryophytes recorded include *Polytrichum strictum* Menzies ex Brid. and *Aulacomnium palustre* (Hedw.) Schwägr., further enriching the site's moss flora and underscoring its ecological complexity.

Figure 3. *Sphagnum* species (*S. divinum* - red plants and *S. angustifolium* - geen and yellow plants) from Avrig Peat bog (Photo: Ștefănuț M.-M., 18.11.2022)

Figure 4. *Sphagnum medium* from Avrig Peat bog (Photo: Ștefănuț M.-M., 18.11.2022)

Figure 5. *Sphagnum palustre* from Avrig Peat bog (Photo: Ștefănuț M.-M., 18.11.2022)

Figure 6. *Sphagnum angustifolium* and *Sphagnum palustre* in the bottom right corner (Photo: Ștefănuț M.-M., 18.11.2022)

Among the characteristic vascular plants of peatland ecosystems identified at the site were *Drosera rotundifolia* (Figure 7), *Eriophorum vaginatum* L., and *E. gracile* W.D.J. Koch ex Roth. These species are indicative of acidic, oligotrophic conditions and are commonly associated with well-preserved raised bog habitats.

The site is also ecologically significant due to the presence of the priority habitat *Depressions on peat substrates of the Rhynchosporion* (habitat code 7150). This habitat includes plant assemblages characteristic of the *Sphagno cuspidati–Rhynchosporion albae* Osvald 1923 em. Koch 1926 association. Notable species within this community include *Sphagnum angustifolium*, *S. fallax* var. *fallax*, *Aulacomnium palustre*, *Epipactis palustris* (L.) Crantz, *Eriophorum angustifolium* Honck., *Menyanthes trifoliata* (Figure 8), *Comarum palustre* L. (Figure 9), and *Lysimachia thyrsiflora* L.

The peat bog is encircled by a broad, marshy, eutrophic zone dominated by woody species such as *Salix caprea* L., *Betula pendula* Roth, *Alnus glutinosa* (L.) Gaertn., and *Rhamnus frangula* L. The herbaceous and bryophyte layer comprises a diverse mix, including *Phragmites australis* (Cav.) Trin. ex Steud., *Typha angustifolia* L., *Carex acutiformis* Ehrh., *C. rostrata* Stokes, *Equisetum fluviatile* L., *Thelypteris palustris* Schott, *Alisma plantago-aquatica* L., *Menyanthes trifoliata*, *Caltha palustris* L., *Sphagnum fallax* var. *fallax*, *S. angustifolium*, *S. centrale* C.E.O. Jensen, *Aneura pinguis* (L.) Dumort., *Atrichum*

undulatum (Hedw.) P. Beauv., and *Brachythecium rutabulum* (Hedw.) Schimp.
This zone corresponds to the plant association *Salici cinereae–Sphagnetum recurvi* (Zólyomi 1931) Soó 1954. It is important to note that *Sphagnum recurvum* sensu stricto has recently been confirmed only in the Azores (Dias et al., 2009); in most European contexts, this name refers to a complex comprising *Sphagnum flexuosum* Dozy & Molk., *S. fallax*, and *S. angustifolium* (Hodgetts et al., 2020).

Figure 8. *Menyanthes trifoliata* from Avrig Peat bog (Photo: Ștefănuț S., 27.07.2016)

Figure 9. *Comarum palustre* from Avrig Peat bog

In stagnant water zones within the peatland, an additional carnivorous plant, *Utricularia* sp., was observed, alongside notable herpetofauna of conservation concern. These include the European tree frog (*Hyla arborea*, Linnaeus, 1758) and the European fire-bellied toad (*Bombina variegata*, Linnaeus, 1758), both listed under the annexes of the EU Habitats Directive (Council Directive 92/43/EEC, 1992).
Under the PeatRO2 project, restoration efforts at the Avrig Peat bog targeted the removal of invasive wood vegetation and the mitigation of hydrological degradation.
The overarching goal was to reestablish a favourable water regime, thereby promoting the proliferation of characteristic peatland species while inhibiting the spread of invasive vascular plants.
Restoration activities involved several key interventions:
a) *Hydrological Restoration:* the ecological function of the peatland was enhanced by blocking existing drainage channels to restore natural water retention. During the 2016 assessment (PeatRO project), a drainage channel was identified as a significant source of water loss. In 2023, this channel was blocked by constructing a dam, resulting in a water level increase of approximately 25 cm. This intervention successfully maintained soil moisture even during the severe drought conditions of the 2024 summer and autumn seasons (Figures 10 and 11).
b) *Vegetation Management and Peatland Reconstruction:* the ecological reconstruction of the peatland included the manual removal of invasive woody plant species from its central zone. During the 2016 PeatRO project assessment, this core area was found to be heavily colonized by species such as *Betula pendula*, *Alnus glutinosa*, and *Rhamnus frangula*, whose presence was contributing significantly to water loss through elevated evapotranspiration rates (Figure 12).
As part of the PeatRO2 project, in 2022, the central area of the peatland was cleared of woody plant species (Figure 13). The activity was carried out manually by the project team

members, through careful selection of the cut plants.

Figure 10. Blockage of the drain channel (13.03.2025)

Figure 11. Drone image with the drainage channel and the dam (13.03.2025)

Figure 12. The *Sphagnum* area, invaded by woody plants, before restoration
(Photo Bîrsan C.-C., 18.11.2022)

Several ongoing pressures have been identified at the site, including the illegal dumping of household waste and manure, elevated nitrogen input from potential runoff originating at a nearby sheepfold, recurring wildfires, and the encroachment of invasive plant species.
To address these concerns and ensure long-term ecological stability, the area has been integrated into a monitoring program under the sustainability phase of the PeatRO2 project, which extends from 2024 to 2029. Continued efforts will be essential to maintain the peatland in a favourable hydrological state, safeguarding its ecological functions and biodiversity value.

Figure 13. Drone image with the *Sphagnum* area, after restoration (Photo Ștefănuț S., 13.03.2025)

The restoration activities were promoted on the website of the Institute of Biology Bucharest (IBB) and locally, through discussions with locals, local entrepreneurs and the local administration, and by installing an information board at the entrance to the site (Figure 14). The information board provides two links to the dedicated website (RO and EN) via QR codes.

Figure 14. Information panel installed at the site entrance (Photo: Ștefănuț S., 05.07.2024)

In Romania, peat bog restoration is guided by the National Peat Bog Restoration Strategy, developed in 2017 under the PeatRO project. As part of this initiative, 218 peat bogs were assessed for their biodiversity and conservation status, and 80 were selected for restoration. Among these, the 45 most threatened peat bogs were included in the RO-MEDIU Programme - Environment, Climate Change Adaptation, and Ecosystems - funded through the European Economic Area (EEA) Financial Mechanism. These sites were restored between 16 December 2021 and 30 April 2024.

Under the PeatRO2 project, 12 additional peat bogs in Romania were restored, including the Avrig Peat Bog. The structure of this bog, particularly its central area overgrown with woody vegetation, closely resembles that of Mlaca Tătarilor, the pilot restoration site from the original PeatRO project where the feasibility of peat bog restoration in Romania was first tested. Given that Mlaca Tătarilor, restored over eight years ago, shows promising signs of ecological recovery as of March 2025 (Figure 15), it is likely that the restoration of the Avrig Peat Bog will also result in a better-preserved bog habitat. This aspect supports the conservation of the peatland vegetation, in line with a synthesis of evidence for the effects of such restoring interventions (Taylor et al., 2019) and with the monitoring frameworks and best practices outlined in the European Environment Agency`s 2025 Guidebook for Monitoring and Evaluating Ecosystem-based Adaptation Interventions.

CONCLUSIONS

Peat bogs represent a priority conservation target at the European level, and the restoration actions undertaken by the Institute of Biology Bucharest (IBB) align closely with the objectives outlined in the EU Biodiversity Strategy for 2030. These include expanding the protected area network, enforcing strict protection for high-biodiversity-value sites (covering at least 10% of EU land), and ensuring legal protection of a minimum of 30% of EU territory.

The activities implemented at the Avrig Peat bog not only contribute to achieving these strategic goals but also offer a replicable model for future peatland restoration initiatives. As such, this case study holds significant value for informing Romania's forthcoming national restoration plan, to be finalized by 1 September 2026, under the provisions of EU Regulation 2024/1991. The Avrig Peat bog exemplifies how small-scale restorations can contribute meaningfully to continental biodiversity goals.

ACKNOWLEDGEMENTS

This research work was carried out with the support of the PeatRO2 (RO-ENVIRONMENT-0004) EEA grant. The *Sphagnum* species were identified by Ștefănuț M.-M. in the frame of the Romanian Academy PhD thesis.

Abstract

In recent years, indoor plant cultivation has become an increasingly popular hobby. However, the natural environment required for optimal plant growth is not universally available, and therefore, it is necessary to replicate the missing environmental factors. Successful cultivation can be greatly enhanced by monitoring and adjusting environmental conditions. By collecting and analysing environmental data, it is possible to set appropriate parameters and optimize the operation of an environmental control system. This system requires sensors and actuators to compensate for environmental deficiencies and automate relevant processes. If the system's parameters are flexible enough, it can support the growth of a wide range of plant species. An effective approach to achieve this flexibility is through an online interface that allows remote access and enables the display of measured data as well as the adjustment of control parameters. A microcontroller-based system can be employed to manage this process. This paper outlines the hardware and software architecture, describes the communication protocols used, and provides an analysis of the system's expected performance.

Key words*: IoT, indoor planting, controlled environment.*

INTRODUCTION

Indoor plant cultivation

There are numerous reasons why individuals may choose to cultivate their own edible plants. While plant cultivation can certainly serve as a fulfilling hobby, extensive research has also demonstrated the positive effects of plants on human well-being. Moreover, various studies explore the specific impacts of different plant species on individuals (Yeo, 2021).

Another significant factor driving home cultivation is the rising cost of food, which is partly attributed to the increasing prices of imported goods. Such price fluctuations are influenced by global events beyond individual control. For instance, rising fuel costs lead to increased transportation expenses, which are ultimately passed on to consumers. In these situations, producing food locally can help reduce household expenditures, thereby mitigating some of the negative financial impacts. Consequently, the practice of growing at least locally suitable edible plants may regain popularity (Arora, 2019).

However, cultivating plants is not always a viable solution. Certain species may not be suitable for open-field cultivation in a given climate due to climate change or their inherent sensitivity to environmental conditions. Some plant varieties are highly susceptible to sudden heavy rainfall, which can damage their yield due to inefficient water distribution. Others struggle with prolonged drought periods, hindering their proper development.

A potential solution is to cultivate plants in controlled or semi-controlled environments, managing their development across various growth stages. Indoor cultivation methods have already gained traction, with industrial-scale operations successfully producing crops such as tomatoes in a cost-effective manner. However, such large-scale solutions are not feasible for the average individual, as not everyone has access to rooftop greenhouses or similar infrastructure. Instead, smaller, more portable, and user-friendly systems could provide a more practical alternative for everyday users (Pehin et al., 2020; Garcia, 2020).

In some cases, full environmental control is not required throughout the plant's entire lifecycle. Certain species only require additional support during specific growth phases, such as the early development stages when they are most

vulnerable. This period typically includes germination and early seedling growth, lasting until the first buds appear. Afterward, some plants become sufficiently resilient to local environmental conditions, allowing for outdoor cultivation until the end of their lifecycle (Leavy & Hossain, 2014).

Environmental control processes must be executed periodically or under specific conditions in response to environmental fluctuations. However, maintaining such conditions requires a level of attention that many individuals, due to their busy schedules, may be unable to provide consistently. Additionally, some people may lack the expertise to recognize when intervention is necessary for optimal plant development. A common example is improper watering - either forgetting to water houseplants entirely or overwatering seedlings to the point of damaging or killing them.

Modern technology enables the automation of processes such as irrigation through the application of appropriate knowledge and tools. Numerous successful experiments and widely implemented systems already regulate or supplement specific environmental factors. Some advanced systems can simultaneously monitor and control multiple parameters, adapting to specific plant needs. However, complexity varies, and some existing solutions are unnecessarily intricate, reducing their efficiency (Palande et al., 2018).

The rise of IoT devices enables real-time monitoring and user adjustments. With intelligent algorithms and proper hardware, these systems can also become self-learning, making them easier to use and more efficient. Given these needs and technological advancements, designing a system that supports individuals in successfully cultivating plants at home presents a valuable and engaging research opportunity. Such a system could significantly improve accessibility and encourage more people to adopt home cultivation practices (Ragaveena et al., 2021).

MATERIALS AND METHODS

Lighting sensor

A wide range of lighting solutions is available for indoor plant cultivation, with their design significantly influenced by specific application requirements. One of the most critical characteristics of lighting fixtures is the electromagnetic wavelength spectrum in which they emit radiation.

For plants, the most suitable wavelengths for photosynthesis and photomorphogenesis - developmental processes influenced by light - are found within the visible light spectrum. Blue light (425-450 nm) and red-orange light (600-700 nm) play a crucial role in plant growth and development. Regarding ultraviolet (UV) radiation, wavelengths below 315 nm are considered harmful, as they can cause structural damage to plant cells.

Different regions of the visible light spectrum have varying effects on plant growth stages. In the early developmental phase, when stem and leaf formation are predominant, the blue wavelength range (400-500 nm) is the most effective, particularly for chlorophyll a absorption. In contrast, during the flowering stage, the red wavelength range (600-700 nm) becomes dominant, as it plays a crucial role in supporting chlorophyll b function (Paradiso & Proietti, 2022). Figure 1 shows the photosynthetic active light spectrum.

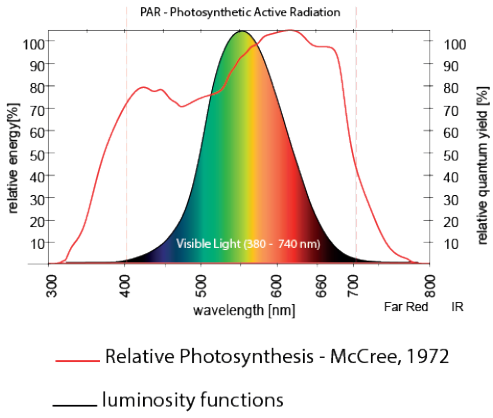

Figure 1. Photosynthetic active light
Source: https://hortione.com/2018/10/lighting-terminology-part-1-par-ppf-ppfd/

For successful indoor plant cultivation, it is essential to use light sources that emit radiation in the most suitable spectrum for each growth stage. During the vegetative phase - when the plant is growing but has not yet entered the flowering stage - the blue wavelength range (400-500 nm) promotes compact and robust

growth. This reduces stem elongation, increases leaf density, and encourages branching, ultimately leading to higher flower production and improved yield (Beszédes et al., 2022).
Various lighting technologies are available for indoor plant cultivation, with LED-based solutions gaining increasing popularity over traditional incandescent bulbs and fluorescent tubes. LEDs are particularly favoured for their high efficiency, long lifespan, and customizable spectral output. In our own cultivation setup, natural light LED strips were used. Although I considered COB (Chip-on-Board) LEDs - known for their higher light intensity and broader coverage - I ultimately opted for lower-power LED strips. These offer easier installation, provide light tailored to the size of the cultivated area and specific plant needs, and require less cooling.

Soil Moisture Sensor

To optimize irrigation, it is essential to determine the moisture content of the soil in which plants are growing. This can be achieved using a capacitive soil moisture sensor, which, when connected to the analog input of an ESP32 microcontroller, represents soil capacitance variations as voltage levels. The capacitance increases proportionally with soil moisture content.
The sensor operates within a supply voltage range of 3.3 V to 5.5 V, allowing it to be powered directly from the 3.3 V output of the microcontroller. The core principle of capacitive sensing is that soil capacitance increases as moisture levels rise. The sensor utilizes a TL555C timer oscillator, which generates periodic square wave signals to charge the sensor. Higher capacitance results in longer charge times, leading to a decrease in the analogue signal read by the microcontroller.
Another approach to soil moisture measurement involves resistive sensors, which determine soil moisture based on electrical resistance. While these sensors are initially more cost-effective and simpler to implement, their major drawback is the oxidation of electrodes in direct contact with the soil, which shortens their lifespan. In contrast, capacitive sensors do not have exposed conductive surfaces in contact with the soil, making them more durable and capable of providing more reliable measurements over time (Mittelbach, 2012).

Other sensors

To determine the intensity of natural light, light-dependent resistors (LDRs) were applied, which vary their resistance based on the amount of incident light. For the measurement setup, I connected the LDR in series with a 10 kΩ resistor, forming a voltage divider. The voltage drop across the divider is measured by the analog input of an ESP32 microcontroller. The voltage value read by the analog input is directly proportional to the intensity of incoming light, enabling continuous monitoring of ambient illumination levels.
The HC-SR04 is an ultrasonic distance sensor widely used in various electronics and robotics projects for accurate and reliable distance measurement. It can be easily integrated with microcontrollers such as Arduino or ESP32 platforms. The HC-SR04 emits ultrasonic waves and detects the reflected signal. By measuring the time taken for the sound waves to travel to an object and return, the sensor calculates the distance between itself and the detected object.
The DHT22 (also known as AM2302) is a digital temperature and humidity sensor commonly used in various electronics and IoT projects for environmental data measurement. It is easy to use, provides accurate readings, and communicates with a microcontroller via a single data line (Yue et al., 2020).

Microcontroller

The ESP32 is more of a family of microcontrollers than a single microcontroller. It offers a wide range of variants that can be selected based on the specific application requirements and essential parameters. For my selection, I had access to three types of ESP32: the ESP32 S3, the ESP32 C6, and the "standard" ESP32 (such as the ESP32-WROOM or ESP32-WROVER modules). These models differ in several important aspects, primarily related to their architecture, functionalities, and intended application areas. The original ESP32 chip is widely available and popular, making it an ideal choice for general IoT projects such as sensor data processing, control tasks, or basic Wi-Fi and Bluetooth applications. It is particularly suitable for low-budget projects due to its cost-

effectiveness while still offering a robust set of features (Maier et al.,2017).

Software

Visual Studio Code, when complemented by PlatformIO, evolves into an open-source integrated development environment (IDE) that supports a wide range of microcontroller types. This integration provides an intuitive, yet professional development environment tailored for embedded systems engineers (https://code.visualstudio.com/).

VS Code is a highly versatile code editor widely adopted in the industry for programming in well-established languages such as Python, C++, C#, and many others. One of the key factors contributing to its widespread success is its open-source nature, which has led to the development of numerous extensions that allow users to tailor the editor to their specific needs. Among these extensions, PlatformIO stands out as a powerful open-source ecosystem designed for IoT system development. It integrates multiple development frameworks, maximizing the number of supported microcontrollers to ensure broad compatibility. The development frameworks supported by PlatformIO include Arduino, ESP-IDF: ESP32, Zephyr OS, Mbed OS, FreeRTOS and LibOpenCM3.

As seen from this list, PlatformIO fully supports ESP32 microcontrollers alongside numerous other platforms. Compared to the original Arduino IDE, the combination of VS Code and PlatformIO offers several advantages. However, due to its broad compatibility and extensive feature set, this platform is inherently more complex and requires a steeper learning curve than the traditional Arduino development environment.

The Arduino Integrated Development Environment (IDE) serves as a primary tool for programming Arduino microcontrollers, providing an intuitive interface for uploading programs to various types of microcontrollers. By default, the IDE offers native support for the Arduino platform.

In addition to its built-in capabilities, the Arduino IDE allows developers to extend its functionality through downloadable extensions, enabling the programming of microcontrollers from other manufacturers. One such extension provides support for ESP32-based microcontrollers, allowing developers to program Espressif-manufactured chips within the same development environment. The selected microcontroller's corresponding compiler processes the source code, ensuring compatibility with the target hardware.

DesignSpark Mechanical is a free, easy-to-use 3D Computer-Aided Design (CAD) software developed by RS Components, built on SpaceClaim technology. It is primarily designed for rapid prototyping, mechanical component and device modeling, and 3D printing projects. The software enables engineers and designers to quickly create and modify complex geometries, making it a valuable tool for product development and iterative design processes (https://www.rs-online.com/designspark/mechanical-software).

RESULTS AND DISCUSSIONS

System development process

In the system, an ESP8266 functioned as the web server and handled data transmission, while an Arduino Mega was responsible for data acquisition from sensors, actuator control, storing operational data in non-volatile memory, and providing a local menu interface to allow data input beyond the web interface.

The primary advantage of the dual-microcontroller system was the increased number of I/O pins, which facilitated the integration of additional sensors. However, based on empirical observations, the system provided more input and output pins than necessary. The ESP32 eliminates the need for two separate microcontrollers sharing tasks and exchanging data internally, thereby simplifying system architecture and reducing communication overhead.

First, the key data points were defined that the device should transmit via the web interface:

- soil moisture content expressed as a percentage, essential for irrigation control;
- threshold soil moisture level at which the system should automatically initiate irrigation;
- the direction of the highest light intensity and the light intensity itself, presented as a percentage. This information helps determine the primary natural light source

based on the system's orientation, which is particularly useful when operating in supplemental lighting mode;
- illumination activation time intervals, displayed in a tabular format;
- the current time according to the ESP32's internal clock;
- sensor scale limits, providing reference points for easier adjustment of new threshold values;
- a graphical representation of system-measured values over a specified time interval.

Next, it is essential to determine which parameters can be modified remotely via the web interface. Based on empirical observations, the following controls provide sufficient flexibility over the system:
- input fields for modifying the lighting activation time intervals;
- action button for changing the lighting operation mode;
- adjustable scaling for sensor measurements: To display sensor readings as percentages, a scale with defined upper and lower limits is required. Users can modify these limits via the web interface for both light intensity detection and soil moisture measurement through dedicated input fields;
- action button for switching the irrigation mode;
- adjustable thresholds for automated irrigation: Users can modify the automatic irrigation threshold via the web interface, as well as specify the "depth" of the water reservoir to define when it should be considered empty. These parameters can be set through dedicated input fields.

Ideally, when the ESP32 receives an empty request to its IP address (i.e., when there is no content following '/' in the URL), it automatically serves the web page to the client. This web page is stored as a string in the ESP32's memory and includes the current data managed within the microcontroller's variables. These data are transmitted along with the entire web page to the client.

When the user fills out a form and clicks the Submit button, the client sends the entered data to the ESP32 using the POST method. The GET method was deliberately avoided, as it appends data to the URL, leading to potential security and usability issues. For instance, data stored in the browser history or saved as a bookmark could be inadvertently reused, resulting in outdated or incorrect information being sent back to the web server. Figure 2 shows the ESP 32 data connection steps.

Figure 2. ESP 32 data connection

The POST method is a more secure and practical alternative, as the transmitted data do not appear in the URL or browsing history. The ESP32 executes the appropriate program function based solely on an action identifier associated with the URL (e.g., /submit1), which handles data reception and processing. After processing is completed, the ESP32 returns either an updated or a reset web page to the client, allowing the user to enter additional data or verify that the intended system changes have been successfully applied. The ESP32 initially stores the form-submitted data in its internal variables. If a change occurs, the data are subsequently saved to external non-volatile memory for long-term storage. Once the HTML code for the web page and the corresponding ESP32 code for serving the web interface are completed, the functionality of the web server can be tested. Figure 3 shows the flowchart of the main project programme.

The ESP32 must be connected to a network. To achieve this, the SSID (wireless network name) and password of the router are provided to the ESP32, allowing it to establish a connection. To determine the IP address assigned to the ESP32 by the router, one can either check the list of connected devices in the router's interface - provided that the router recognizes the ESP32's hostname - or identify the microcontroller using its MAC address. Some routers automatically assign a device name based on the ESP32's identifier, while others do not. For instance, on the router used during development, the ESP32 was assigned the device name ESP-283150. Alternatively, the microcontroller can be identified by retrieving its MAC address through other means.

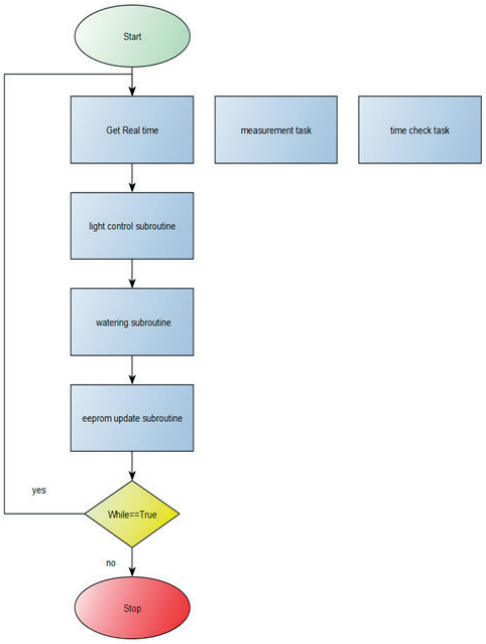

Figure 3. Flowchart of the main programme and tasks

IoT lighting system

The ESP microcontroller performs an hourly check to determine whether a predefined activation time requires the operation of the LED strips and whether a corresponding deactivation time mandates their shutdown.

If these conditions are met, the microcontroller activates the LED strips. The system allows only whole-hour time settings rather than minute-based configurations because the effect of illumination duration is negligible for time intervals smaller than an hour. However, if precise minute-level control becomes necessary, the program can be modified accordingly.

The lighting mode depends on the user-selected operating mode, in Supplementary Lighting Mode the duty cycle of the LED strips' PWM signal is adjusted based on ambient light intensity. This enables the system to optimize illumination by complementing natural light and in Illumination Mode the LED strips operate with a fully saturated PWM signal, meaning they emit continuous maximum brightness. Figure 4 shows how the light sensor reacts to the light intensity and light direction changes.

Due to their low heat emission, the LED strips do not require additional cooling. The generated heat is safely dissipated into the surrounding environment, preventing damage to both the LEDs and the supporting board during operation.

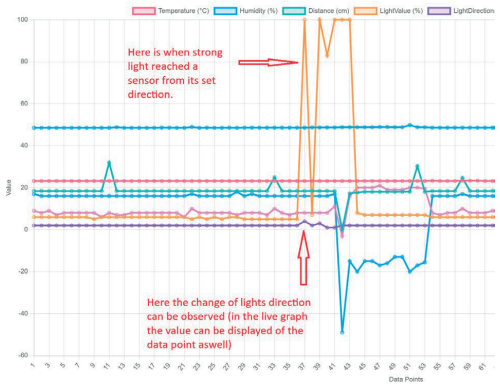

Figure 4. Changes in the light sensor readings/status

Soil moisture

The selected soil moisture sensors provide an output voltage ranging between 1.2 V and 2.8 V based on measurement results. These signals are converted into digital values by the analog input of the ESP32 microcontroller. Since the voltage range of individual sensors may vary slightly, these threshold values can be configured independently.

During the calibration process, the first step is to determine the sensor's output in dry air, which is typically around 3000. Next, by immersing the sensor's soil-contacting portion in water, the lower threshold value is obtained, usually around 1000. After calibration, variations in soil moisture percentage can be accurately tracked, and the sensors provide reliable measurements.

Periodic recalibration may be necessary, for instance, when replacing sensors. The minimum and maximum values of new sensors can be easily set via the web interface. This feature is particularly useful because some newer sensor models, such as the capacitive soil moisture sensor v2.0, operate within a different voltage range (e.g., between 900 and 4000). This flexibility ensures that threshold values can be conveniently adjusted when replacing sensors.

During this process, only automatic irrigation is possible. Before executing irrigation, the system verifies whether there is a sufficient water level in the storage container; otherwise, the pump will not be activated. During irrigation, a

predetermined volume of water is dispensed over a specific time period. The exact amount of water per cycle was determined through experimental testing. For the duration of irrigation, the lighting system is automatically turned off to indicate that irrigation is in progress and to allocate sufficient power to the pump, preventing system overload due to excessive current draw. After the irrigation cycle is completed, the lighting is reactivated if necessary.

If the size of the plant containers changes, it may become necessary to adjust the dispensed water volume or increase the number of irrigation cycles. Currently, these modifications can only be implemented by reprogramming the system. However, in the future, a more flexible and user-friendly solution could be developed if needed.

The system allows for two types of irrigation methods. As the name suggests, in top-down irrigation, water is applied to the soil surface and infiltrates downward under the influence of gravity. This method enables soil moisture sensors to respond immediately to irrigation since water reaches the sensor area more quickly. As a result, the measured moisture level rapidly reaches the predefined upper threshold. After irrigation, the soil moisture level gradually decreases, but the variation is not significant.

Figure 5 shows the flowchart of the irrigation management.

In bottom-up irrigation, water is delivered beneath the plant's soil, requiring it to be absorbed from below. This method is slower because water wicking through the soil takes time, particularly in larger volumes of substrate. Consequently, soil moisture sensors display delayed responses to irrigation. However, this can be advantageous, as it results in more stable moisture readings, avoiding abrupt fluctuations. Due to the slower response time, time-based control is necessary between irrigation cycles to prevent excessive water application. Additionally, this method requires sufficiently large overflow containers beneath the plant holders; otherwise, water may overflow. This issue can be managed by using adequately sized reservoirs. Although alternative solutions exist to prevent overflow, this method has proven to be effective in practice.

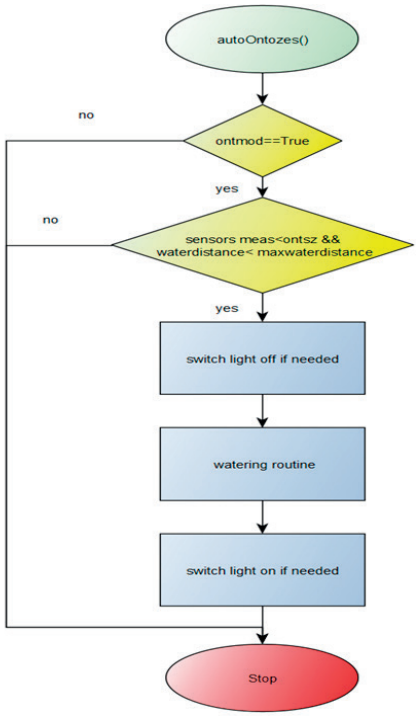

Figure 5. Flowchart of the irrigation management

Figure 6 shows the changes of soil moisture content and the threshold point.

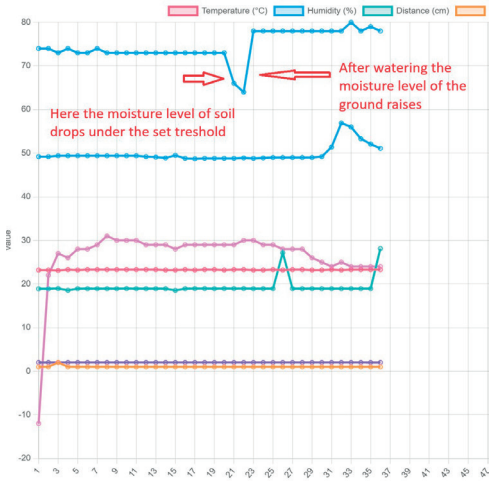

Figure 6. Changes of the moisture sensor status

CONSLUSIONS

The potential for further development of the system is somewhat limited due to the constraints of the ESP32 microcontroller. The primary limitation is its relatively low number of input and output pins. Additionally, certain pins cannot be fully utilized for all functions; for example, some internal resources required for ADC operations are also needed to support Wi-Fi functionality. As a result, ADC2 pins cannot be used as analog inputs within the system.

However, a more complex system could be designed by integrating multiple ESP32-based microcontrollers alongside a central processing unit. In such a configuration, individual units would handle specific tasks while the central unit would collect data via Bluetooth or Wi-Fi and manage the control of actuators based on the gathered information.

Since the LED strips are not fixed to the mounting surface, they can be easily replaced as needed, allowing for the use of strips with different light spectra. It is also possible to install multiple LED strips with varying spectra, and by modifying the program, users could select which strips should be active based on the current growth stage of the plants.

However, a drawback of this approach is that inactive strips do not emit any light, which may reduce the overall illumination output. On the other hand, if full illumination from all four strips is not necessary, and only half of them is sufficient, this can be advantageous. In this way, plants receive a light spectrum more closely aligned with their optimal growth requirements, ultimately improving cultivation quality.

If higher-power light sources, such as COB LEDs, are required, the system can accommodate their control. However, due to their significant heat generation, COB LEDs necessitate the use of large heat sinks to prevent overheating, which could damage the LEDs or substantially reduce their lifespan. For implementation, it is recommended to replace the current base that integrates the electronics and components with a substrate that can also function as a heat sink, as wood is not suitable for this purpose.

By controlling multiple pumps, it would be possible to irrigate the plants in individual seedling containers separately, significantly enhancing the system's flexibility and functionality. The ESP32 microcontroller has enough PWM-capable I/O pins to facilitate this implementation. Furthermore, the system could be improved by incorporating a predefined maximum soil moisture threshold during irrigation, preventing overwatering. This feature would be particularly beneficial for plants sensitive to excessive moisture, allowing the system to support the care of such species as well.

The system can be expanded with a camera module compatible with certain microcontrollers, such as the ESP32-CAM. By integrating an ESP32-CAM, it would be possible to visually monitor the plants, capture images, or even stream real-time video. The captured images could be displayed on the system's web interface, or the stream could be transmitted directly to the user's device. To implement this feature, in addition to the ESP32-CAM, a web server capable of handling video streaming would need to be developed. However, this integration would also increase the system's complexity, as the camera functions as a separate microcontroller unit.

An additional challenge may arise from the fact that transmitting the video stream to the central microcontroller and subsequently to the user client does not necessarily represent the most efficient use of resources. However, such an expansion could significantly enhance the system's functionality and user experience in the future.

Plant growth is influenced by various environmental factors, the monitoring of which can provide valuable insights for system users. For instance, soil temperature measurement can be achieved by integrating an appropriate sensor. However, expanding the current system is necessary, as all available analogue inputs are occupied. One possible solution is to integrate an additional microcontroller to manage the new sensor. Alternatively, a more extensive system redesign could be implemented, such as utilizing sensor modules that transmit data in digital format to the central unit via an interface like I2C. This approach would facilitate the connection of multiple sensors more efficiently.

The enhanced system offers a greater number of useful functionalities compared to its predecessors. Its efficiency has been improved,

and its design has been simplified in certain aspects by utilizing a single microcontroller as its core, rather than two separate units with distinct functions. However, this design choice entails some limitations regarding the system's potential for further expansion. The system facilitates plant growth by automating key developmental processes and collecting data on both the plants and their surrounding environment.

Throughout the period in which the system supports plant growth, valuable data is gathered regarding the direction of optimal lighting exposure and other environmental factors that influence plant development. During the development process, multiple opportunities for further improvement were identified. These enhancements could significantly extend the system's functionality and lifespan while making plant care more convenient and efficient for users.

Wuhan city, Hubei province, PR China

Corresponding author email: yuanbz@mail.hzau.edu.cn

Abstract

This study analyzed 5,166 research and review articles on the topic of soil pollution published up to July 20, 2024, including 72 top-cited papers. The publications, primarily written in English, originated from 129 countries or regions and appeared in 961 journals and five book series. The five most productive journals were Science of the Total Environment (298 articles, 5.77%), Environmental Science and Pollution Research (218, 4.22%), Environmental Pollution (162, 3.14%), Chemosphere (142, 2.75%), and Environmental Monitoring and Assessment (138, 2.67%). The top five contributing countries - China, Spain, the United States, Poland, and India - each published more than 275 papers. Using co-occurrence network visualization with VOSviewer, the keywords were grouped into seven distinct thematic clusters. In addition, the 25 keywords with the strongest citation bursts were identified through CiteSpace analysis. Most of the publications were aligned with three key Sustainable Development Goals: Sustainable Cities and Communities (SDG 11), Zero Hunger (SDG 2), and Climate Action (SDG 13). The findings of this study not only provide a comprehensive overview of the current state of research in soil pollution but also offer valuable guidance for shaping future research directions in this critical environmental field.

Key words: *bibliometric analysis, soil pollution, VOSviewer, CiteSpace, Web of Science.*

INTRODUCTION

Soil, as one of the most fundamental natural resources for human survival, is increasingly threatened by various types of pollutants. Among these, environmental pollution caused by agricultural mulch film residues has become a growing concern, attracting significant research attention in recent years (Wang et al., 2024). Bibliometric analysis has provided valuable insights into the research landscape, trends, and thematic domains within the field of soil micro- and nanoplastics pollution (Liu et al., 2023).

Gao et al. (2022) conducted a comprehensive literature review on the subject of "land pollution" using CiteSpace software, performing both bibliometric analysis and visual presentation. Similarly, Pan et al. (2024) analyzed global trends and the evolution of research hotspots in soil microplastic pollution. Gong et al. (2023) conducted a bibliometric study on global research activities related to micro- and nanoplastic toxicity in earthworms.

Another emerging area of concern is military-related soil pollution, where heavy metal contamination remains the primary issue, as highlighted by Stadler et al. (2022). Du et al. (2022) reviewed influencing factors, threshold derivation, and the application of heavy metal limits in soils using a combined approach of bibliometric analysis and scientific knowledge mapping. Gao et al. (2022) also applied bibliometric techniques to evaluate global research efforts in soil remediation. In a related context, Ajibade et al. (2022) found that incorporating biochar and compost into soils can reduce pollutant uptake by plants and improve soil nutrient content and productivity. As research on soil health has expanded, Liu et al. (2020) performed a bibliometric analysis of publications on soil health from 1999 to 2018. Furthermore, Sun and Yuan (2023) analyzed top-cited papers in the field of soil science, while Yuan and Sun (2023) investigated research trends related to rice and greenhouse gas emissions.

The purpose of the present study is to conduct a bibliometric analysis of global research

output on the topic of "Soil Pollution" using the Web of Science (WoS) Core Collection from Clarivate Analytics. The analysis was carried out using CiteSpace and VOSviewer software to map trends, hotspots, and knowledge structures in the field.

MATERIALS AND METHODS

1. Web of Science

The publication data were retrieved from the Web of Science Core Collection, specifically from the following indexes: the Science Citation Index Expanded (SCIE, 1900–present) and the Social Science Citation Index (SSCI, 2005–present). Additionally, records were collected from the Conference Proceedings Citation Index–Science (CPCI-S, 2015–present) and the Conference Proceedings Citation Index–Social Science & Humanities (CPCI-SSH, 2015–present).

2. Data collection

Data collection was completed on July 20, 2024. The search was conducted using the following topic (TS) keywords: "Soil Pollution", "Agricultural Soil Pollution", "Soil Pollution Assessment", "Soil Pollution Control", "Urban Soil Pollution", and "Water and Soil Pollution". Only documents categorized as articles or review articles were included.

In total, 5,166 records were obtained from the WoS Core Collection. Journal impact factors (both IF 2023 and 5-year IF) were obtained from the *Journal Citation Reports* (JCR 2023), published in June 2024, which contained the most recent available data.

3. VOSviewer and CiteSpace

For bibliometric visualization, VOSviewer version 1.6.20 (van Eck & Waltman, 2023) was used with its default parameter settings. The top 25 keywords with the strongest citation bursts were identified and analyzed using CiteSpace (Basic version 6.3.R1).

RESULTS AND DISCUSSIONS

1. Document type and language of publication

All 5,166 publications analyzed in this study were indexed in the following databases: SCIE (5,111 papers, 98.94%), SSCI (307, 9.94%), CPCI-S (190, 3.68%), and CPCI-SSH (231, 5.83%). Regarding document type, the majority were research articles (4,776 papers, 92.45%), followed by review articles (390 papers, 7.55%) and proceedings papers (190 papers, 3.68%). Most papers were published in English (5,015 papers, 97.08%). Other publication languages included Portuguese (43 papers, 0.83%), French (24 papers, 0.47%), Chinese (19 papers, 0.37%), Spanish (18 papers, 0.35%), German (12 papers, 0.23%), and Polish (11 papers, 0.21%).

2. Publication output

Figure 1 illustrates the temporal distribution of publications on soil pollution research between 1990 and 2024. The highest annual output was recorded in 2022, with 580 papers.

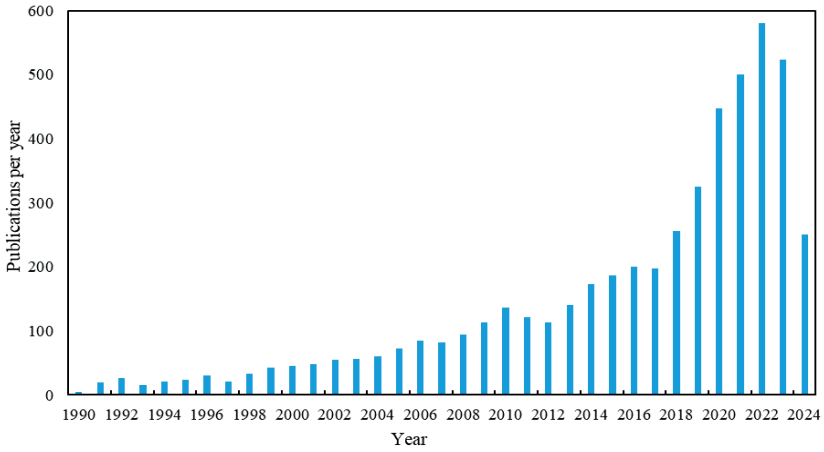

Figure 1. Trends in the quantity of published papers on soil pollution topic research from 1990 to 2024

The number of publications increased steadily over the decades, with 239 papers published between 1990 and 1999, 711 papers from 2000 to 2009, 1,851 papers during 2010 to 2019, and 2,302 papers between 2020 and 2024. An additional 62 papers were published between 1903 and 1989, although this early period is not represented in Figure 1 due to the low volume. Cumulatively, the 5,166 papers have an h-index of 144 and a total citation count of 140,047, resulting in an average of 27.11 citations per paper**.** The earliest identified publication on the topic of soil pollution is titled *"Soil Pollution and Disease in Camps"*, authored by Caldwell in 1903 and published in the *British Medical Journal.*

3. Web of Science categories and research areas

Between 1903 and 2024, publications related to soil pollution were distributed across 152 Web of Science (WoS) subject categories and 97 research areas.

Table 1 presents the top 20 categories and areas based on the number of published papers.

Table 1. Top 20 WoS categories and research areas on soil pollution topic research from 1903 to 2024

Rank	WoS categories				Research areas		
	Categories	No. papers	% total papers		Areas	No. papers	% total papers

20	Biotechnology Applied Microbiology	103	1.994		Food Science Technology	44	0.852

The top five categories included Environmental Sciences (3,033 papers, 58.711%), Soil Science (521 papers, 10.085%), Water Resources (505 papers, 9.775%), Engineering Environmental (475 papers, 9.195%), Public Environmental Occupational Health (283 papers, 5.478%). The top five research areas include Environmental Sciences Ecology (3,166 papers, 61.285%), Agriculture (781 papers, 15.118%), Engineering (648 papers, 12.544%), Water Resources (505 papers, 9.775%), Chemistry (375 papers, 7.259%).

4. Core journals

All 5,166 publications analyzed in this study were published across 961 scientific journals and five book series**.** Table 2 presents the top 20 core journals, each of which has published more than 47 papers on the topic of soil pollution. The table includes data on the number of articles per journal, 2022 impact factor (IF), five-year impact factor, quartile ranking in the highest WoS category (if the journal belongs to multiple), total citations, and average citations per article. The top five journals are *Science of the Total Environment* (298 papers, 5.768%), *Environmental Science and Pollution Research* (218 papers, 4.22%), *Environmental Pollution* (162 papers, 3.136%), *Chemosphere* (142 papers, 2.749%), *Environmental Monitoring and Assessment* (138 papers, 2.671%). Among the top 20

journals, nine were classified in Quartile 1 (Q1), indicating the highest level of scientific impact and visibility. Three journals were ranked in Q2, another three in Q3, two in Q4, while three journals did not have an available impact factor in 2023. When assessed by average citations per article, *Geoderma* ranked highest with 63.6 citations per paper, followed by *Science of the Total Environment* (62.7), *Chemosphere* (59.3), *Environmental Pollution* (56.0), and *Journal of Hazardous Materials* (51.7). Citation network analysis further revealed that 168 journals met the minimum threshold of five published articles in this domain, with 161 of them exhibiting citation interconnections. The resulting network visualization, based on Web of Science data, identified 15 distinct clusters, each represented by a unique color in Figure 2, reflecting the thematic and collaborative structure within the field of soil pollution research.

Table 2. Top 20 core Journals on soil pollution topic research indexed in the WoS

Rank	Journal	TP	Ratio	IF 2023	IF 5year	QC	Citations	Avg. citations
1	*Science of the Total Environment*	298	5.768	8.2	8.6	Q1	18688	62.7

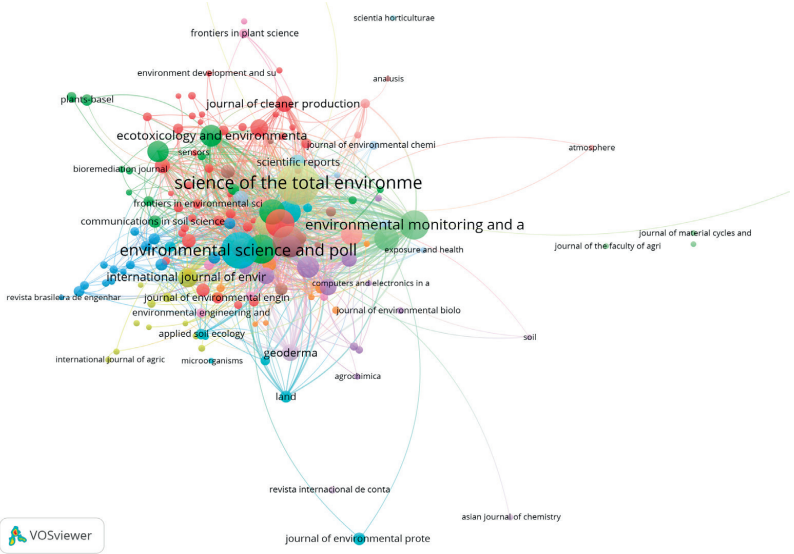

Figure 2. Network visualization maps of citation journals with minimum of 5 publications in the field of soil pollution topic research based on WoS with 161 circles and fifteen clusters

5. Countries/regions co-authorship analysis

A total of 129 countries or regions contributed to the 5,166 publications analyzed in this study.

Table 3 presents the top 20 contributors, each having published at least 90 papers on soil pollution, as indexed in the Web of Science Core Collection. Among these, the leading contributors were the People's Republic of China, Spain, the United States, Poland, and India, each of which produced more than 275 publications.

Out of the 129 participating countries or regions, 91 met the minimum threshold of five publications required for inclusion in the co-authorship network analysis. Of these, 90 demonstrated active collaborative relationships and were interconnected through co-authorship links.

The resulting international collaboration network was visualized and categorized into nine distinct clusters, as shown in Figure 3, illustrating the structural patterns of global cooperation and regional research alliances within the domain of soil pollution.

Table 3. Top 20 countries published papers in the field of soil pollution topic research based on WoS

Rank	Countries/Regions	Records	% of 5,166
1	Peoples R China	1,544	29.888
2	Spain	372	7.201

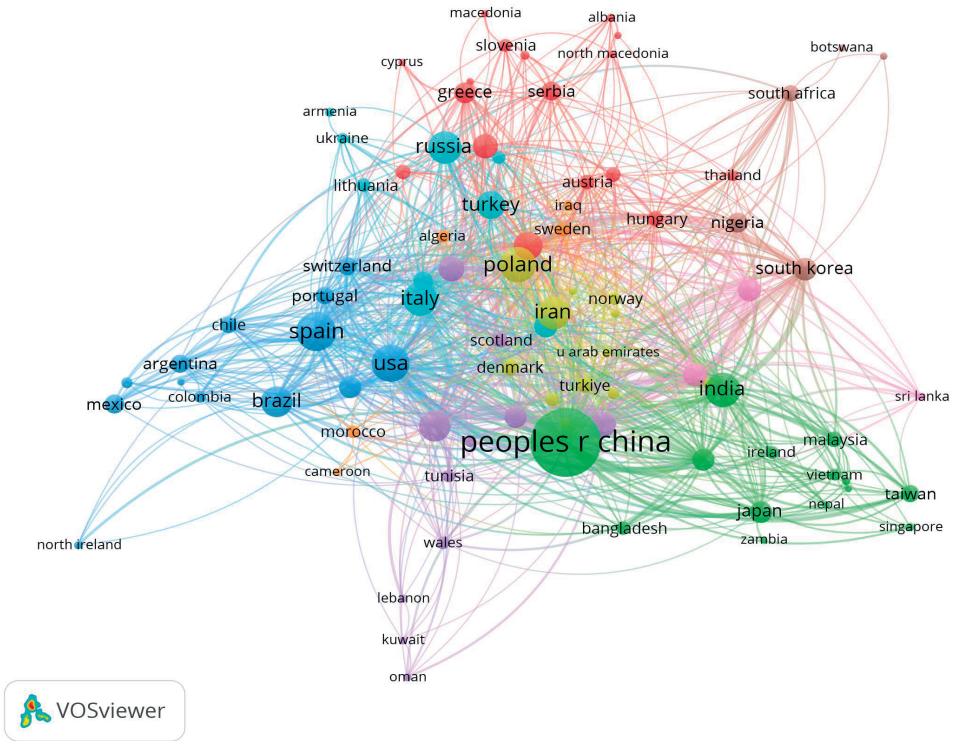

Figure 3. The country co-authorship network map of soil pollution topic research based on WoS with 90 nodes and nine clusters

The co-authorship network, based on publication volume, revealed a structured distribution across nine clusters.

The first cluster (red) comprised seventeen countries or regions, including Germany, Romania, and others. The second cluster (green) included fourteen countries or regions, most notably the People's Republic of China and India. The third cluster (blue) consisted of thirteen countries or regions, such as Spain, the United States, and Brazil.

The fourth cluster (yellow) encompassed twelve countries or regions, including Poland and Iran. The fifth cluster (violet) contained eleven countries or regions, with France, Pakistan, and England among the notable contributors. The sixth cluster (light blue) was composed of ten countries or regions, including Italy, Russia, and Turkey. The seventh cluster (orange) included five countries or regions, such as Sweden and Morocco, while the eighth cluster (pink) also comprised five countries or regions, including South Korea and Nigeria. Lastly, the ninth cluster (brown) consisted of three countries or regions: Saudi Arabia, Egypt, and Sri Lanka.

6. Organizations (Affiliations) co-authorship analysis

According to publication data from the Web of Science, a total of 4,636 organizations contributed to the 5,166 papers analyzed in this study.

Table 4 lists the top 15 organizations, each of which produced more than 49 publications, along with their respective share of the total output and country of origin.

The five most prolific institutions were the Chinese Academy of Sciences (339 publications, 6.56%), the University of Chinese Academy of Sciences (116, 2.25%), the Consejo Superior de Investigaciones Científicas (CSIC) in Spain (100, 1.94%), the Centre National de la Recherche Scientifique (CNRS) in France (98, 1.90%), and the Russian Academy of Sciences (97, 1.88%). Among the top 15 organizations, nine were based in China, two in France, two in Russia, and one in Spain, indicating a strong research presence from institutions in East Asia and Europe in the field of soil pollution.

Table 4. Top 15 organizations publishing papers in the field of soil pollution topic research based on WoS

Rank	Organizations	Records	% of 5,166	Country

7. All Keywords co-occurrence analysis

Using the full counting method for co-occurrence analysis, a total of 11,242 author keywords were identified. Among these, 584 keywords met the minimum threshold of five occurrences and were grouped into eighteen clusters in the resulting network map visualization. The twenty most frequently co-occurring author keywords - each appearing more than 70 times - were: *soil pollution*, *heavy metals*, *soil*, *heavy metal*, *phytoremediation*, *cadmium*, *soil contamination*, *pollution*, *risk assessment*, *lead*, *trace elements*, *bioremediation*, *spatial distribution*, *ecological risk*, *arsenic*, *soil remediation*, *remediation*, *potentially toxic elements*, *biochar*, and *contamination*. Each author's keywords occurred more than 70 times.

For Keywords Plus, 7,730 terms were identified, of which 931 met the threshold of five occurrences. These were grouped into twelve clusters in the network visualization.

The top twenty Keywords Plus, each occurring more than 202 times, included: *heavy-metals*, *contamination*, *pollution*, *cadmium*, *accumulation*, *lead*, *sediments*, *agricultural soils*, *trace-elements*, *toxicity*, *water*, *spatial-distribution*, *plants*, *zinc*, *copper*, *polycyclic aromatic hydrocarbons*, *growth*, *urban soils*, and *area*. Each keyword plus occurred more than 202 times.

In total, 17,223 unique keywords were identified. Based on increasing thresholds of five, six, seven, and eight occurrences, 1,470, 1,205, 1,023, and 880 keywords met the respective criteria. These were ultimately grouped into seven main clusters, each representing a distinct thematic perspective within the field of soil pollution research, as illustrated in Figure 4.

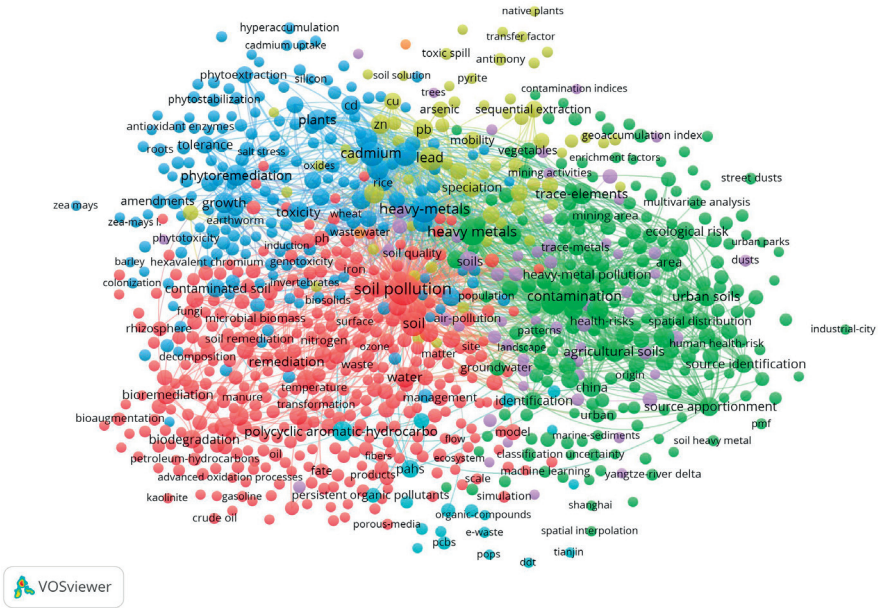

Figure 4. VOSviewer co-occurrence network visualization mapping of most frequently all keywords on soil pollution topic research with seven main clusters. Co-occurrence network of all keywords including author keywords and keywords plus

The top twenty most frequently co-occurring keywords across all sources included: *soil pollution*, *heavy-metals*, *heavy metals*, *contamination*, *pollution*, *soil*, *cadmium*, *lead*, *accumulation*, *sediments*, *agricultural soils*, *zinc*, *trace-elements*, *phytoremediation*, *toxicity*, *copper*, *water*, *remediation*, *plants*, and *spatial-distribution*. Each of these keywords appeared more than 257 times.

The same dataset visualized in Figure 4 was further analyzed by time period and presented as an overlay map in Figure 5. In this temporal visualization, blue-colored nodes represent earlier research topics, while yellow and green nodes indicate more recent areas of focus, highlighting current research fronts.

The seven thematic clusters identified in Figure 4 encompass a broad range of subfields within soil pollution research. These include: (1) soil pollution remediation, (2) soil heavy metal contamination, (3) heavy metal accumulation and phytoremediation, (4) bioavailability and extraction of heavy metals, (5) soil dust and particulate matter impacts on vegetation, (6) polycyclic aromatic hydrocarbons (PAHs), and (7) wastewater and metal toxicity.

The first cluster (red in Figure 4) consists of 347 keywords that met the threshold of eight occurrences and primarily focuses on *soil pollution remediation*. The 20 most frequently used keywords in this cluster include: *soil*

pollution, *soil*, *water*, *remediation*, *adsorption*, *bioremediation*, *removal*, *degradation*, *impact*, *organic matter*, *biodegradation*, *environment*, *quality*, *sorption*, *wastewater*, *biochar*, *diversity*, *sewage sludge*, *management*, and *extraction*, each appearing more than 87 times.

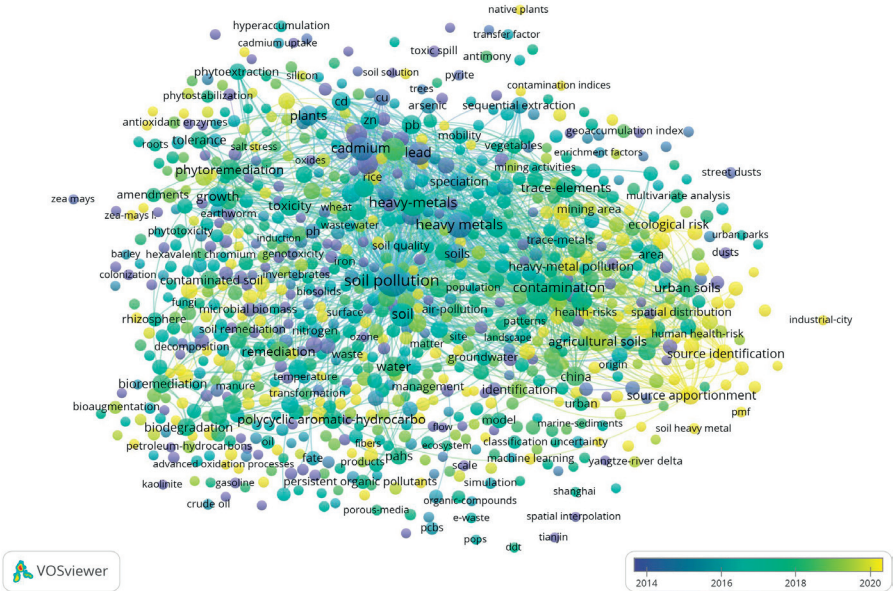

Figure 5. VOSviewer co-occurrence overlay visualization mapping of most frequently all keywords on soil pollution topic research. The years in which specific keywords frequently occur are shown by different colours

The second cluster (green) includes 206 keywords and represents research on *heavy metal contamination of soil*. This was identified as a front-line research theme. The top 22 keywords in this cluster, each with more than 123 occurrences, are: *heavy metals*, *contamination*, *pollution*, *sediments*, *agricultural soils*, *trace elements*, *spatial distribution*, *heavy metal*, *urban soils*, *China*, *area*, *source apportionment*, *heavy-metal pollution*, *ecological risk*, *elements*, *risk assessment*, *soil contamination*, *source identification*, *health risk*, *city*, *risk assessment*, and *identification*.

The third cluster (blue) comprises 183 keywords and centers on *heavy metal accumulation and phytoremediation*. The 21 most frequent terms in this group include: *heavy metals*, *cadmium*, *accumulation*, *zinc*, *phytoremediation*, *toxicity*, *copper*, *plants*, *growth*, *contaminated soils*, *Cd*, *metals, contaminated soil, contaminated soil*, *contaminated soil*, *exposure*, *tolerance*, *bioaccumulation*, *oxidative stress*, *phytoextraction*, *availability*, *plant*, and *chromium*, each occurring more than 84 times.

The fourth cluster (yellow) consists of 65 keywords and addresses *the bioavailability and extraction of various heavy metals*. The top 20 terms - each mentioned more than 35 times - include: *lead*, *Pb*, *bioavailability*, *speciation*, *Zn*, *trace elements*, *mercury*, *Cu*, *mobility*, *sequential extraction*, *fractionation*, *arsenic*, *mine*, *immobilization*, *sequential extraction procedure*, *mine tailings*, *tailings*, *toxic metals*, *manganese*, and *Spain*.

The fifth cluster (violet) comprises 57 keywords and focuses on *the effects of soil dust and particulate matter on vegetation*. The 20 most common keywords include: *soils*, *dust*, *particulate matter*, *vegetation*, *fly ash*, *heavy metal*, *magnetic susceptibility*, *vicinity*, *deposition*, *susceptibility*, *samples*, *particles*, *metal pollution*, *parameters*, *forest soils*, *atmospheric deposition*, *PAH*, *topsoil*, *Turkey*, and *India*, each with more than 20 occurrences.

The sixth cluster (light blue) includes 20 keywords and is centered on *polycyclic aromatic hydrocarbons (PAHs)*. Frequent keywords in this group, each appearing more than eight times, are: *polycyclic aromatic hydrocarbons*, *PAHs*, *persistent organic pollutants*, *polychlorinated biphenyls*, *air*, *organochlorine pesticides*, *PCBs*, *polybrominated diphenyl ethers*, *sites*, *dibenzo-p-dioxins*, *e-waste*, *DDT*, *fluxes*, *organic compounds*, *dry deposition*, *POPs*, *Tianjin*, and several variants of polychlorinated substances.

The seventh cluster (orange) is the smallest, consisting of only two keywords: *wastewater* and *metal toxicity*, each of which appeared more than eight times.

8. Burst of keywords

A keyword burst analysis was conducted using CiteSpace (Basic version 6.2.R6) to identify emerging trends and research hotspots in the field of soil pollution. The analysis focused on the top 25 keywords exhibiting the strongest citation bursts between 1994 and 2024, as shown in Figure 6.

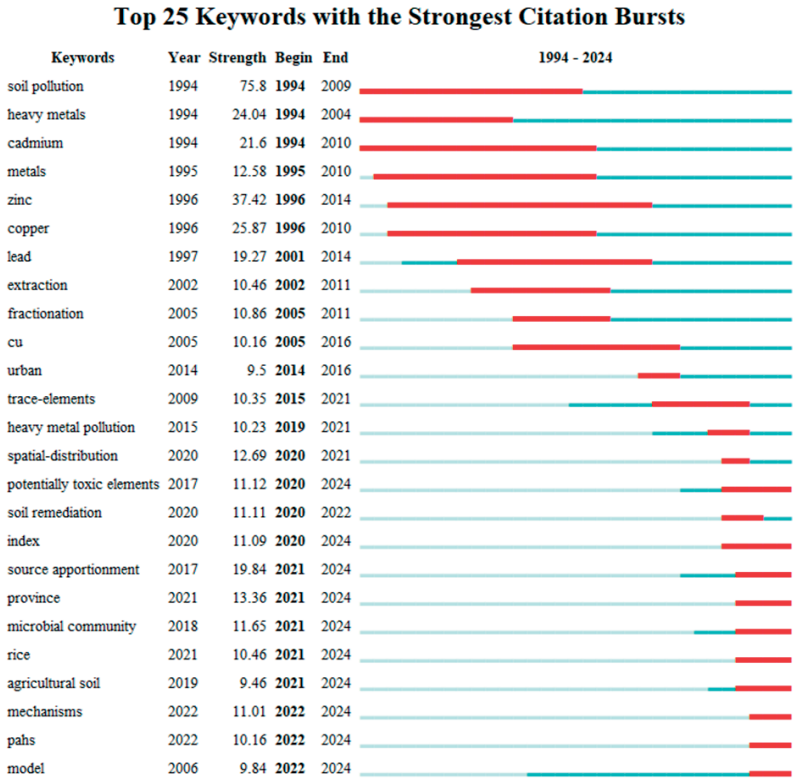

Figure 6. Information about top 25 keywords of soil pollution topic research with the strongest citation bursts from 1994 to 2024 by CiteSpace (6.2.R6). Begin, year when the burst begins; End, year when the burst ends. Red grids indicate the years when a particular term started to be frequently used. A longer the red bar, the keywords have been cited for a longer duration

These keywords - indicative of sudden increases in scholarly attention - include: *soil pollution*, *heavy metals*, *cadmium*, *metals*, *zinc*, *copper*, *lead*, *extraction*, *fractionation*, *Cu*, *urban*, *trace elements*, *heavy metal pollution*, *spatial distribution*, *potentially toxic elements*, *soil remediation*, *index*, *source apportionment*, *province*, *microbial community*, *rice*, *agricultural soil*, *mechanisms*, *PAHs*, and *model*. These terms reflect the evolving focus and interdisciplinary nature of soil pollution research over the past three decades.

9. Top papers based on Essential Science Indicators (ESI)

The analysis of top-cited literature was conducted using the Essential Science Indicators (ESI) database, which was last updated on July 11, 2024, and covers a 10-year and 4-month period from January 1, 2014, to April 30, 2024**.** According to ESI data, a total of 72 top papers were identified, including 72 highly cited papers and one hot paper**.**

These publications span a range of years, with distribution as follows: 2014 (5 papers), 2015 (4), 2016 (2), 2017 (2), 2018 (8), 2019 (6), 2020 (10), 2021 (11), 2022 (10), 2023 (12), and 2024 (2). The journals that published multiple top papers include: *Science of the Total Environment* (14 papers), *Environmental Research* (7), *Journal of Hazardous Materials* (6), *Environmental Pollution* (3), *Journal of Environmental Management* (3), *Chemosphere* (2), *Environment International* (2), *Environmental Science & Technology* (2), *Journal of Water Process Engineering* (2), and *Water, Air, and Soil Pollution* (2).

These findings underscore the prominence of multidisciplinary environmental science journals in disseminating high-impact research on soil pollution.

10. The most frequently cited articles

The annual citations of the eight papers showed an increasing trend after a year of publication (Figure 7). The eight papers were written by Li et al (2014), Duruibe et al (2007), Facchinelli et al (2001), Chen et al (2015), Bläsing and Amelung (2018), Michalak (2006), Goovaerts (1999), Manta et al (2002). From the publication year to July 20, 2024, the total citations for each paper of the most citation eight papers were 2082, 1296, 1117, 1030, 880, 867, 837 and 810 times, and the average citation per year each paper were 189.3, 72.0, 46.5, 103.0, 125.7, 45.6, 32.2 and 35.2 times.

Among the eight articles, the highest average citation paper per year were 189.3 (Li et al, 2014), also includes two papers both Chen et al (2015) and Bläsing and Amelung (2018), which were the top papers (highly cited paper) based on ESI.

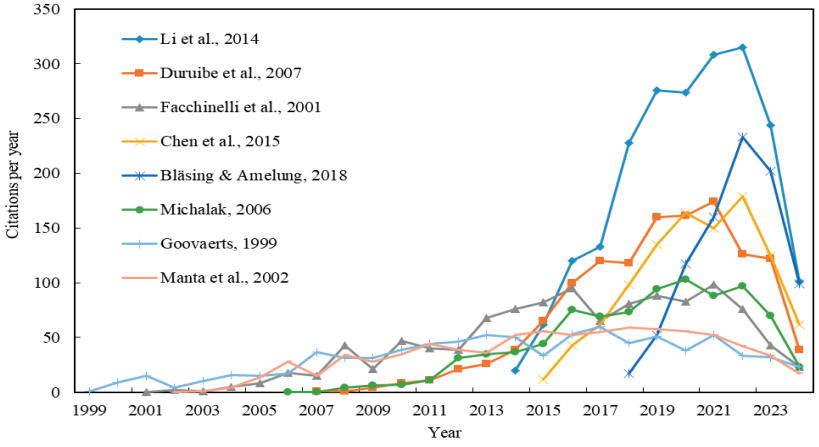

Figure 7. Comparison of the citations per year of the eight papers related to soil pollution topic research from their initial publications to July 20, 2024

11. Sustainable development goals

Table 5 presents the distribution of soil pollution research papers in relation to all Sustainable Development Goals (SDGs).

The analyzed papers addressed thirteen of the Sustainable Development Goals (SDGs), with the highest concentration of research focused on five key goals: SDG 11 – Sustainable Cities and Communities, SDG 2 – Zero Hunger, SDG 13 – Climate Action, SDG 3 – Good Health and Well-Being, and SDG 15 – Life on Land.

Table 5. All Sustainable Development Goals for soil pollution topic research papers

Rank	Sustainable Development Goals	Record Count	% of 5,166
1	11 Sustainable Cities and Communities	2144	41.502
2	02 Zero Hunger	638	12.35
3	13 Climate Action	556	10.763
4	03 Good Health and Well Being	509	9.853
5	15 Life on Land	477	9.233
6	06 Clean Water and Sanitation	443	8.575
7	12 Responsible Consumption and Production	120	2.323
8	14 Life Below Water	120	2.323
9	07 Affordable and Clean Energy	20	0.387
10	01 No Poverty	8	0.155
11	09 Industry Innovation and Infrastructure	8	0.155
12	04 Quality Education	6	0.116
13	16 Peace and Justice Strong Institutions	4	0.077

CONCLUSIONS

This study conducted a comprehensive bibliometric analysis of 5,166 publications related to soil pollution research. The leading journals contributing to this field include *Science of the Total Environment*, *Environmental Science and Pollution Research*, *Environmental Pollution*, *Chemosphere*, and *Environmental Monitoring and Assessment*. In terms of national contributions, the top five publishing countries were the People's Republic of China, Spain, the United States, Poland, and India.

Through co-occurrence network visualization using VOSviewer, author keywords were categorized into seven thematic clusters, highlighting the multidimensional nature of soil pollution research. Additionally, most papers aligned with three key Sustainable Development Goals (SDGs): SDG 11 – Sustainable Cities and Communities, SDG 2 – Zero Hunger, and SDG 13 – Climate Action.

The findings of this analysis not only reflect the current landscape and emerging trends in soil pollution research but also offer valuable insights to guide future investigations and interdisciplinary collaborations in this critical environmental domain.
