SCIENTIFIC & REVIEW COMMITTEE

SCIENTIFIC CHAIRMAN
Prof. univ. dr. Sorin Mihai CIMPEANU

MEMBERS*

- Stefano CASADEI – University of Perugia, Italy
- Carmen CIMPEANU – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Sorin Mihai CIMPEANU – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Andrea DOMINIJANNI – Politecnico di Torino, Italy
- Claudiu DRAGOMIR - University of Agronomic Sciences and Veterinary Medicine of Bucharest/ National Institute for Research and Development - URBAN-INCERC, Bucharest, Romania
- Eric DUCLOS-GENDREU – Spot Image GEO-Information Services, France
- Jean-Luc HORNICK – Université de Liège, Belgium
- Hossein KAZEMI – GUASNR, Gorgan, Iran
- Bela KOVACS – University of Debrecen, Hungary
- Raluca MANEA – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Tamara van OMMEREN-MYSLYVA – Ministry of Spatial Planning and Environment of Suriname
- Jovan Br. PAPIC – Ss. Cyril and Methodius University, Skopje, R. N. Macedonia
- Nelson PÉREZ-GUERRA – University of Vigo, Spain
- Nicolae PETRESCU – Valahia University Targoviste, Romania
- Dorin Dumitru PRUNARIU – Romanian Space Agency, Romania
- Andrei Victor SANDU – „Gheorghe Asachi" Technical University of Iași, Romania
- Mirela Alina SANDU – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Umut Gunes SEFERCIK – Gebze Technical University, Turkey
- Ando SHIN – Tokyo University of Science, Japan
- Marisanna SPERONI – Centro di Ricerca Zootecnia e Acquacoltura, Consiglio per la Ricerca in Agricoltura e L'analisi Dell'economia Agraria (CREA), Italy
- Razvan Ionut TEODORESCU – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Péter UDVARDY – Óbuda University, Hungary
- Neven VOĆA – University of Zagreb, Croatia

CONTENTS

ENVIRONMENTAL SCIENCE AND ENGINEERING

1 EVALUATION OF CHEMICAL COMPOSITION OF ESSENTIAL OIL AND TOXIC METAL ACCUMULATION OF TARRAGON (*ARTEMISIA DRACUNCULUS* L.) CULTIVATED ON METAL-CONTAMINATED SOILS - **Violina ANGELOVA** ……. 17

2 EVALUATION OF WASTE BIOMASS FROM AROMATIC PLANTS FOR ENERGY PURPOSES - **Violina ANGELOVA** 24

3 DETECTION AND MONITORING OF HYDROCARBON POLLUTION SOURCES IN THE PETROMIDIA REFINERY AREA - **Sorin ANGHEL** 30

4 INVESTIGATING CURRENTS, FLOW VELOCITIES, AND RIVERBED MORPHOLOGY - AN ADCP-CENTRIC APPROACH TO UNDERSTANDING HYDRODYNAMICS AND EROSION PATTERNS - **Maxim ARSENI, Adrian ROȘU, Nina-Nicoleta LAZĂR, Mădălina CĂLMUC, Mihail VESTE, Cătălina ITICESCU** 37

5 STRUCTURAL ANALYSIS OF SLUDGE FROM THE ARAD WASTEWATER TREATMENT PLANT: REDUCING QUANTITY AND ENHANCING ITS POTENTIAL AS FERTILIZER - **Denisa BACALU-RUS, Lucian COPOLOVICI, Dana COPOLOVICI, Ioan BOTH, Maria MIHĂILESCU** 44

6 DEVELOPMENT AND VALIDATION OF A GC-MS/MS METHOD FOR THE DETECTION OF ORGANOCHLORINE AND ORGANOPHOSPHATE PESTICIDES IN COMPOST AND SOIL - **Silviu-Laurențiu BADEA, Carmen CONSTANTIN, Liliana BĂDULESCU** 52

7 PRELIMINARY RESULTS VALIDATION ON THE THEORETICAL AND EXPERIMENTAL APPROACH FOR USING SPENT GARNET RESIDUES OF ROMANIAN LOCAL INDUSTRIES IN CONSTRUCTION MATERIALS - **Cornelia BAERĂ, Aurelian GRUIN, Ana-Cristina VASILE, Bogdan BOLBOREA, Alexandru ION, Luiza VARGA, Alexandra Marina BARBU** …… 59

8 STRUCTURAL INTEGRITY IN EARTHEN ARCHITECTURE WITH NDT METHODS - **Bogdan BOLBOREA, Cornelia BAERĂ, Aurelian GRUIN, Sorin DAN, Ana-Cristina VASILE** ……... 73

9 EVALUATING AGGREGATE CONTENT AND ITS EFFECT ON CLAY MORTAR PERFORMANCE - **Aurelia BRADU, Alexandrina-Elena ANDON, Alexandra-Marina BARBU, Claudiu-Sorin DRAGOMIR** 81

10 INTEGRATION OF UAV-BASED LIDAR, PHOTOGRAMMETRY, AND SLAM TECHNOLOGIES FOR THE COMPLETE ABOVE AND BELOW GROUND MAPPING OF MOUNTAINOUS HYDRO-TECHNICAL INFRASTRUCTURE - **Simion BRUMA, Catalin-Stefanel SABOU, Ioana POP, Florica MATEI, Paul SESTRAS, Mircea NAP, Elemer-Emanuel SUBA, Tudor SALAGEAN** 87

11 CLAY APPLICATION IN THE REMEDIATION OF NICKEL RICH SOIL – **Teuta BUSHI, Aida BANI, Selma MYSILHAKA, Franz OTTNER, Ilaria COLZI, Isabella BETTARINI, Seit SHALLARI** 99

12 A PIONEERING STUDY ON THE INVESTIGATION OF MICROPLASTIC POLLUTION IN THE WATER OF THE SOMOVA-PARCHEȘ LACUSTRINE COMPLEX, ROMANIA - **Mădălina CĂLMUC, Valentina Andreea CĂLMUC, Nina Nicoleta LAZĂR, Marius IVANOV, Puiu-Lucian GEORGESCU, Cătălina ITICESCU** 105

13 INVESTIGATION OF THE PHARMACEUTICALS PRESENCE IN THE SOMOVA-PARCHEȘ AQUATIC COMPLEX - **Valentina Andreea CĂLMUC, Mădălina CĂLMUC, Carmen CHITESCU, Silvia DRĂGAN, Cătălina ITICESCU, Puiu-Lucian GEORGESCU** 112

14 VALIDATION OF A UHPLC-HRMS METHOD FOR THE ASSESSMENT OF PER AND POLY-FLUOROALKYL SUBSTANCES (PFAS) IN BIOTA - **Andreea-Miruna CODREANU, Ștefania-Adelina MILEA, Valentina Andreea CĂLMUC, Justinian-Andrei TOMESCU, Alin Constantin DÎRȚU, Cătălina ITICESCU, Puiu-Lucian GEORGESCU** 119
15 INDICATORS OF THE STRUCTURAL AND COMPOSITIONAL DIVERSITY OF STANDS ON DEGRADED LANDS IN THE VRANCEA AREA - **Cristinel CONSTANDACHE, Ciprian TUDOR, Laurențiu POPOVICI** 125
16 GROUND MOTION DATA QUALITY ASSURANCE: FUNDAMENTAL REQUIREMENTS AND THEIR PRACTICAL IMPLEMENTATION WITHIN THE NATIONAL NETWORK FOR THE SEISMIC MONITORING AND PROTECTION OF BUILDING STOCK, NIRD URBAN-INCERC, ROMANIA **- Iolanda-Gabriela CRAIFALEANU, Claudiu-Sorin DRAGOMIR, Daniela DOBRE, Emil-Sever GEORGESCU, Alexandra-Marina BARBU** 133
17 COMPREHENSIVE ANALYSIS OF PARTICULATE MATTER VARIABILITY IN AN URBAN ENVIRONMENT USING Rapid-E MONITORING - **Mădălin CRISTEA, Adrian ROȘU, Bogdan ROȘU, Daniel-Eduard CONSTANTIN, Simona CONDURACHE-BOTA, Mirela VOICULESCU, Cătălina ITICESCU, Puiu- Lucian GEORGESCU, Silvia DRĂGAN** 143
18 THE IMPACT OF LAND USE CHANGES ON NATURAL PROTECTED AREAS IN THE OLTEȚ PIEDMONT (ROMANIA) - **Raluca Lucia DINCULOIU, Daniel SIMULESCU, Carmen Otilia RUSĂNESCU, Mihaela BEGEA, Gigel PARASCHIV, Sorin Ștefan BIRIȘ, Maria CIOBANU** 152
19 A CRITICAL REVIEW OF SUSTAINABLE APPROACHES FOR REDUCING THE ENVIRONMENTAL IMPACT OF PLASTIC PRODUCTION - **Andreea DOROFTE, Ira-Adeline SIMIONOV, Ștefan-Mihai PETREA, Cătălin PLATON, Puiu-Lucian GEORGESCU, Cătălina ITICESCU** 159
20 MONITORING THE INACTIVE LANDFILL STABILITY IN GORJ COUNTY - **Silvia Alexandra DREGHICI, Levente DIMEN, Mircea RÎȘTEIU, Tudor BORȘAN, Florin FAUR** 169
21 SOIL FLUX AND SOIL GAS MONITORING OF A NATURAL LABORATORY FOR THE STUDY OF CO_2 LEAKAGE - **Alexandra-Constanța DUDU, Corina AVRAM, Gabriel IORDACHE, Constantin-Ștefan SAVA, Lia STELEA, Andrei-Gabriel DRAGOȘ** 180
22 POSSIBILITIES FOR THE RECOVERY OF AGRICULTURAL VEGETABLE WASTE - **Timea GABOR, Andreea HEGYI, Stelian COSTE, Alina Iuliana CADAR, Cristian PETCU, Carmen FLOREAN, Ioana Monica SUR** 186
23 GROUND AIR MICROFLORA STUDY USING A CASCADE IMPACTOR - **Bilyana GRIGOROVA-PESHEVA, Asen PESHEV** 196
24 POSSIBILITIES OF SURFACE TREATMENT OF PLASTERS BASED ON CLAY **- Andreea HEGYI, Cristian PETCU, Claudiu Sorin DRAGOMIR, Gabriela CĂLĂTAN, Alexandra CSAPAI** 202
25 EVALUATION OF THE POSSIBILITIES OF USING CLAY SOILS FOR THE REALIZATION OF VERNACULAR CONSTRUCTIONS - **Andreea HEGYI, Gabriela CĂLĂTAN, Cristian PETCU, Stefan BAKOS, Alexandra CSAPAI** 218
26 HIERARCHY OF ALTERNATIVES FOR THE REHABILITATION OF ASBESTOS WATER SUPPLY NETWORKS BASED ON ENVIRONMENTAL CRITERIA - **Iulian IANCU, Sorin PERJU, Ioan BICA, Alexandru-Nicolae DIMACHE** 231
27 AFFORESTATION OF SANDY SOILS OF OLTENIA - A REVIEW - **Paula IANCU, Marin SOARE, Mariana NICULESCU** 239
28 CURRENT TRENDS AND INSTITUTIONAL FRAMEWORKS IN CLIMATE CHANGE RESEARCH: A EUROPEAN AND NATIONAL PERSPECTIVE - **Ionela-Alexandra ION, Carmen Otilia RUSĂNESCU, Sabrina-Maria BĂLĂNESCU** 246
29 BEHAVIOR OF ASPHALT MIXTURES MANUFACTURED WITH RECYCLED MATERIALS AND THEIR *IN SITU* PERFORMANCE LEVEL - **Nicoleta-Adaciza IONESCU, Daniela DOBRE**... 252
30 SOLUTIONS FOR THE RESTORATION IN THE NATURAL CIRCUIT OF CONTAMINATED SITES FROM THE PETROLEUM INDUSTRY - **Cristian Mugurel IORGA, Lucian-Gabriel ZAMFIR**, **Alina Ceoromila CANTARAGIU** 260

31 ASSESSMENT OF IRON, COPPER, AND ZINC IN THE MUSCLE OF PONTIC SHAD: INFLUENCE OF YEAR, WEIGHT, AND LENGTH - **Nina-Nicoleta LAZĂR, Mădălina CĂLMUC, Ira-Adeline SIMIONOV, Maxim ARSENI, Mihaela TIMOFTI, Puiu-Lucian GEORGESCU, Cătălina ITICESCU, Violeta DOMNITEANU** 268
32 SUSTAINABLE GEOPOLYMER BINDERS: MECHANICAL AND DURABILITY INSIGHTS INTO FLY ASH-BASED COMPOSITES - **Adrian-Victor LAZARESCU, Brăduț-Alexandru IONESCU, Mihail CHIRA, Tudor-Panfil TOADER, Alexandra CSAPAI, Andreea HEGYI, Carmen-Teodora FLOREAN** 274
33 THERMAL CONDUCTIVITY OF SILTY SOILS IN THE SOUTH-EAST REGION OF ROMANIA - **Daniel-Marcel MANOLI, Cristian-Ştefan BARBU, Mihaela-Elena STAN, Manole-Stelian ŞERBULEA, Alina TATOMIR, Oana-Cristina CARAŞCA, Ruxandra-Irina ERBASU, Andrei-Dan SABAU** 284
34 DISTRIBUTION OF HEAVY METALS IN THE DANUBE RIVER ECOSYSTEM AND THE IMPACT ON THE ENVIRONMENT. A REVIEW - **Maria Daniela (IONICA) MIHAILA, Valentina Andreea CĂLMUC, Cătălin PLATON, Puiu-Lucian GEORGESCU, Cătălina ITICESCU** 292
35 EXPLORING THE QuEChERS - GAS CHROMATOGRAPHY APPROACH FOR SEDIMENT PESTICIDE ANALYSIS - **Stefania-Adelina MILEA, Maria Daniela (IONICA) MIHAILA, Valentina Andreea CĂLMUC, Cătălina ITICESCU, Puiu-Lucian GEORGESCU, Alin-Constantin DIRTU, Cătălin Eugen PLATON** 305
36 MATHEMATICAL MODEL FOR PREDICTION OF NO_2 CONCENTRATION IN THE SOUTHEASTERN REGION OF ROMANIA, USING RECURSIVE LEAST SQUARES FILTER METHODS - **Gabriel MURARIU, Sorin FRASINA, Adrian ROȘU, Corneliu DOROFTEI, Iulian RACOVIȚĂ, Bogdan ROȘU, Cătălin FETECĂU, Mirela VOICULESCU, Cătălin NEGOIȚĂ** 312
37 PLANT RESPONSE TO SOIL WATERLOGGING: PHYSIOLOGICAL, MORPHOLOGICAL AND BIOCHEMICAL ADAPTATIONS - A REVIEW - **Senad MURTIĆ, Adnan HADŽIĆ** 318
38 HEAVY METAL ACCUMULATION IN FOOD CROPS CULTIVATED IN CONTAMINATED SOILS IN ALBANIA - **Selma MYSLIHAKA, Aida BANI, Teuta BUSHI, Dorina XHULAJ, Eugen SKURA, Irena DUKA** 330
39 BIOMOLECULE PRODUCTION BY MICROORGANISMS ISOLATED FROM SALINE ENVIRONMENTS - **Simona NEAGU, Mihaela Marilena STANCU** 337
40 ENERGY-ENVIRONMENT INTERACTIONS FOR AN IMPROVED SUSTAINABILITY OF DÂMBOVIȚA COUNTY - THE ROLE OF INNOVATION AND TECHNOLOGY TRANSFER FROM UNIVERSITIES - **Otilia NEDELCU, Ioan Corneliu SALISTEANU, Iulian UDROIU, Aurora DIACONEASA, Claudia GILIA, Daniel DUNEA** 346
41 THE SWELLING PRESSURE OF ACTIVE CLAYS ACCORDING TO VARIOUS TECHNICAL NORMS AND PROCEDURES - **Ernest Daniel OLINIC** 356
42 THE SHEAR STRENGTH PARAMETERS OF SOIL-ROOT SYSTEMS - **Tatiana OLINIC** 362
43 BIOACCUMULATION OF CADMIUM, LEAD, ZINC AND COPPER IN RED FESCUE (*FESTUCA RUBRA* L.) GROWN IN POLLUTED MEADOWS IN COPȘA MICĂ - **Bogdan Ștefan OPREA, Dumitru-Marian MOTELICĂ, Nicoleta Olimpia VRÎNCEANU, Vera CARABULEA, Georgiana Iuliana PLOPEANU, Mihaela COSTEA** 368
44 CHEMICAL STATE AND ECOLOGICAL ASSESSMENT OF ATMOSPHERIC AIR QUALITY - **Georgi PATRONOV, Diana KIRIN, Petya ZAHARIEVA, Radoslava ZAHARIEVA, Dimitrinka KUZMANOVA** 377
45 ECOMONITORING STUDIES OF GROUNDWATER AND SOIL FOR POLLUTION WITH OIL AND PETROLEUM PRODUCTS - **Georgi PATRONOV, Diana KIRIN, Radoslava ZAHARIEVA, Petya ZAHARIEVA, Marian VARBANOV** 384
46 ANALYSIS OF GROUNDWATER RESOURCES IN STARA ZAGORA DISTRICT, BULGARIA: QUALITY AND ENVIRONMENTAL RISKS - **Alexander PETROV, Svetla STOYKOVA, Diyana DERMENDZHIEVA, Gergana KOSTADINOVA, Milen STOYANOV, Georgi PETKOV, Stefka BOYANOVA, Georgi BEEV** 391

47 ASSESSMENT OF SOIL CONTAMINATION BY POLYCYCLIC AROMATIC HYDROCARBONS (PAH_S) IN BUCHAREST: SOURCES AND DISTRIBUTION - **Mihaela PREDA, Veronica TĂNASE, Nicoleta Olimpia VRÎNCEANU, Florența JAFRI, Mihaela COSTEA, Bogdan-Ștefan OPREA** 402
48 THE EFFECTS OF AIR POLLUTION WITH PARTICULATE MATTER ON HUMAN HEALTH - **Elena-Denisa PREDESCU, Carmen Otilia RUSĂNESCU, Irina Aura ISTRATE, Roxana-Elena FRÎNCU, Sabrina Maria BĂLĂNESCU** 412
49 ASSESSMENT OF SUSPENDED SEDIMENT CONCENTRATION AND GRANULOMETRY USING AQUASCAT 1000S ON THE SULINA BRANCH OF THE DANUBE RIVER - **Adrian ROȘU, Mădălin CRISTEA, Bogdan ROȘU, Maxim ARSENI, Mihai Ștefan PETREA, Cătălina ITICESCU, Puiu-Lucian GEORGESCU, Silvia DRĂGAN** 418
50 ADVANCING URBAN AIR POLLUTION MONITORING WITH REMOTE SENSING AND LOW-COST SENSOR TECHNOLOGIES - **Adrian ROȘU, Daniel-Eduard CONSTANTIN, Maxim ARSENI, Mirela VOICULESCU, Cătălina ITICESCU, Puiu-Lucian GEORGESCU, Ionuț Cornel BEJAN, Sorin FRĂSINĂ, Silvia DRĂGAN, Mădălin CRISTEA** 429
51 HYDROTHERMAL ASSESSMENT OF MAIN AGRICULTURAL AREAS IN SOUTHERN ROMANIA AND NORTHERN BULGARIA - **Nadezhda SHOPOVA, Desislava SLAVCHEVA-SIRAKOVA** 439
52 FIRE SAFETY OF ETICS BASED ON EPS TYPE POLYSTYRENE - **Adrian SIMION, Claudiu-Sorin DRAGOMIR** 447
53 DEVELOPMENT AND APPLICATION OF AN OPTIMIZED TD-GC/MS METHOD FOR MONITORING VOLATILE ORGANIC COMPOUNDS (VOCs) IN AMBIENT AIR - **Alexandru-Florin SIMION, Angela-Nicoleta GĂMAN, Sorin SIMION, Marius KOVACS** 453
54 NUMERICAL STUDY OF THE CYLINDRICAL SHAFT'S BEHAVIOUR USING 3D FINITE ELEMENT METHOD - **Elena-Mihaela STAN, Horațiu POPA, Daniel MANOLI** 465
55 AMBIENT AIR POLLUTION: A GLOBAL HEALTH CRISIS - **Svetla STOYKOVA, Diyana DERMENDZHIEVA, Gergana KOSTADINOVA, Miroslava IVANOVA, Milen STOYANOV, Georgi PETKOV, Lilko DOSPATLIEV, Georgi BEEV** 472
56 STUDY ON THE DYNAMICS OF CEREALS CULTIVATED IN TULCEA COUNTY IN THE CONTEXT OF CLIMATE CHANGE - **Traian Ciprian STROE, Oana MIHAI-FLOREA, Liliana MIRON** 486
57 STUDIES AND MEASUREMENTS FOR THE IDENTIFICATION OF NOISE AND VIBRATION LEVELS IN A SITE IN BUCHAREST - CASE STUDY - **Marta Cristina ZAHARIA, Daniela DOBRE, Claudiu-Sorin DRAGOMIR** 496

DISASTER RESILIENCE AND SUSTAINABLE DEVELOPMENT

1 INCREASING THE SAFETY LEVEL CONSIDERING SOIL-STRUCTURE INTERACTION IN HIGH SEISMIC HAZARD-PRONE AREAS - **Stefan Florin BALAN, Bogdan Felix APOSTOL** 506
2 DURABILITY AND SUSTAINABILITY OF MOUNTAIN FARMS IN ROMANIA WITH A FOCUS ON AGRICULTURAL DIVERSIFICATION - **Daniela-Mihaiela BOCA, Tudor Panfil TOADER, Andreea HEGYI, Marius VLADU** 518
3 INTEGRATING VEGETABLE WASTE IN CLAY COMPOSITIONS: A SUSTAINABLE PATH FOR ECO CONSTRUCTION - **Aurelia BRADU, Alexandrina-Elena ANDON, Alexandra-Marina BARBU, Claudiu-Sorin DRAGOMIR** 528
4 THE IMPACT OF EXTREME WEATHER PHENOMENA ON THE MANAGEMENT OF CONIFEROUS STANDS - **Ghiță Cristian CRAINIC** 534
5 UPGRADING THE TRADITIONAL DATABASE THROUGH BIM-BASED SHM VISION - **Daniela DOBRE, Claudiu-Sorin DRAGOMIR, Iolanda-Gabriela CRAIFALEANU, Cornelia-Florentina DOBRESCU, Emil-Sever GEORGESCU** 548

6 RISK OF WINDTHROWS STANDS WITH VARIOUS STRUCTURES USING VERTICAL DIFFERENTIATION INDEX - **Lucian Sorin DOROG** 555
7 InSAR TECHNOLOGY FOR RISK MANAGEMENT AND NATURAL DISASTER IMPACT ASSESSMENT IN BUCHAREST - **Ana-Maria GLOD-LENDVAI, Iuliana ARMAȘ, Razvan TEODORESCU, Aurora DIACONEASA, Virgil MOISE, Daniel DUNEA** 562
8 FLOOD IMPACT ASSESSMENT ON RAILWAY INFRASTRUCTURE USING NUMERICAL MODELLING: CASE STUDY OF NĂDAB, ROMANIA - **Dorian HAUSLER COZMA, Teodor Eugen MAN, Robert Florin BEILICCI, Erika BEILICCI** 569
9 NATURE-BASED SOLUTIONS FOR THE SUSTAINABLE DEVELOPMENT OF GREEN AND BLUE INFRASTRUCTURE IN ROMANIA - **Andreea Catalina POPA, Teodora UNGUREANU, Claudiu-Sorin DRAGOMIR, Antonio-Valentin TACHE** 578
10 COMPATIBILITY BETWEEN NATURAL AGRO-INDUSTRIAL BY-PRODUCTS AND SYNTHETIC MATERIALS, A BASIC ELEMENT IN OBTAINING BIOCOMPOSITE MATERIALS WITH POTENTIAL FOR USE IN CONSTRUCTION - **Irina POPA, Vasilica VASILE, Alexandrina MUREȘANU** 586
11 THE INTEGRATION OF CERAMIC WASTE AS A PARTIAL SUBSTITUTE OF NATURAL AGGREGATES IN EXPERIMENTAL CONCRETE RECIPES - **Mircea SĂLCUDEAN, Maria POPA** 594

WATER RESOURCES MANAGEMENT

1 IMPACT OF FLOOD DISCHARGE ON WATER QUALITY IN DANUBE RIVER BIFURCATIONS AND SELECTED LAKES (GORGOVA-UZLINA HYDROGRAPHIC UNIT) - **Irina CATIANIS, Dumitru GROSU, Laura DUTU, Albert SCRIECIU, Andrei TOMA, Ana Bianca PAVEL, Ovidiu BORZAN, Gabriel IORDACHE** 601
SPATIAL DISTRIBUTION OF TOTAL ORGANIC MATTER IN RECENT SEDIMENTS OF DANUBE DELTA LAKES (GORGOVA-UZLINA HYDROGRAPHIC UNIT) **- Irina CATIANIS, Ion STANESCU, Dumitru GROSU, Ana Bianca PAVEL, Albert SCRIECIU, Ovidiu BORZAN, Andrei TOMA, Florin DUTU, Gabriel IORDACHE** 613
3 ADAPTING ROMANIA'S IRRIGATION INFRASTRUCTURE TO CLIMATE CHANGE: OPPORTUNITIES AND CHALLENGES - **Mihai Teopent CORCHEȘ** 623
4 DRIP IRRIGATION'S INFLUENCE ON CHERNOZEM SOIL: ELECTROPHYSICAL AND SALINITY DYNAMICS - **Yurii DEHTIAROV, Zinaida DEHTIAROVA** 630
5 WATER RESOURCE MANAGEMENT IN FRUIT AND VEGETABLE PRODUCTION USING ALTERNATIVE MULCHES - **Gary L. HAWKINS** 644
6 ASSESSMENT OF GROUNDWATER QUALITY AND POLLUTION RISKS NEAR A HYDROCARBON POWER PLANT **- Ramona-Carmen HĂRȚĂU, Simona GAVRILAȘ, Claudiu-Ștefan URSACHI, Simona PERȚA-CRIȘAN, Florentina-Daniela MUNTEANU** 650
7 METAL CONTAMINATION IN THE SYSTEM WATER - SEDIMENTS – *PERCA FLUVIATILIS* LINNAEUS, 1758 AND *EUSTRONGYLIDES EXCISUS* JÄGERSKIÖLD*,* 1909 LARVAE - **Nikolina ILIEVA, Diana KIRIN** 663
8 CONTAMINATION OF POLLUTANTS IN *ABRAMIS BRAMA* (LINNAEUS, 1758), BIOINDICATION AND ECOLOGICAL RISK ASSESSMENT OF THE WETLAND MANDRA-PODA, BULGARIA - **Nikolina ILIEVA, Diana KIRIN** 670
9 SEDIMENT TRANSPORT MODELING WITH ADVANCE HYDRAULICS SOFTWARE - **Dorina Gabriela IONESCU, Robert Florin BEILICCI, Erika Beata Maria BEILICCI, Mihai NEGURA, Mirela Laura IEREMCIUC** 676
10 ECOLOGICAL MONITORING OF THE PARVENETSKA RIVER, PART OF THE MARITSA RIVER WATERSHED - **Diana KIRIN, Radoslava ZAHARIEVA, Petya ZAHARIEVA, Marian VARBANOV, Georgi PATRONOV, Gergana METODIEVA** 684

11 ECOLOGICAL ASSESSMENT OF THE BOROVITSA RIVER, EAST AEGEAN SEA BASIN - **Diana KIRIN, Petya ZAHARIEVA, Radoslava ZAHARIEVA, Georgi PATRONOV, Marian VARBANOV, Gergana METODIEVA, Dimitrinka KUZMANOVA** 690
12 ADVANCED HYDRAULIC MODELINGOF IRRIGATION CHANNEL - **Mihai NEGURA, Robert Florin BEILICCI, Erika Beata Maria BEILICCI, Mirela Laura IEREMCIUC, Dorina Gabriela IONESCU** 696
13 WATER USE EFFICIENCY IN IRRIGATED AGRICULTURE IN ROMANIA: OPTIMIZATION STRATEGIES IN THE CONTEXT OF CLIMATE CHANGE - **Oana Alina NIȚU, Ionuț Ovidiu JERCA, Mihaela BĂLAN, Elena Ştefania IVAN** 705
14 ASSESSMENT OF SURFACE WATER QUALITY IN THE SFÂNTU GHEORGHE BRANCH OF THE DANUBE DELTA - **Ana Bianca PAVEL, Laura DUTU, Florin DUTU, Irina CATIANIS, Gabriel IORDACHE, Catalina GAVRILA** 711
15 PHYSICO-CHEMICAL CHARACTERISTICS OF SURFACE WATER SAMPLES FROM THE GORGOVA-UZLINA DEPRESSION AND THE IZMAIL AND SF. GHEORGHE CONFLUENCES (SEPTEMBER–OCTOBER 2024) - **Ana Bianca PAVEL, Irina CATIANIS, Laura DUTU, Gabriel IORDACHE, Catalina GAVRILA** 729
16 ASSESSMENT OF SURFACE WATER QUALITY ACROSS SELECTED DANUBE RIVER SECTORS BASED ON PHYSICO-CHEMICAL PARAMETERS AND HYDROCARBON LEVELS - **Ana Bianca PAVEL, Andrei TOMA, Albert SCRIECIU, Catalina GAVRILA, Irina CATIANIS** 749
17 EVALUATION OF THE DEGREE OF MICROBIOLOGICAL CONTAMINATION OF GROUNDWATER IN GORJ COUNTY - **Emil Cătălin ȘCHIOPU, Roxana Gabriela POPA, Irina Ramona PECINGINĂ, Ramona Violeta CAZALBAȘU, Marinela Florica BODOG** 766
18 ECOLOGICAL STATUS ASSESSMENT OF MECHKA RIVER WATER (MARITSA RIVER BASIN) - **Petya ZAHARIEVA, Radoslava ZAHARIEVA, Diana KIRIN** 776
19 ECOLOGICAL ASSESSMENT OF THE KAYALIIKA RIVER WITHIN THE MARITSA RIVER WATERSHED USING MACROZOOBENTHOS AS A BIOINDICATOR - **Radoslava ZAHARIEVA, Petya ZAHARIEVA, Diana KIRIN** 782

REMOTE SENSING AND GEOINFORMATICS

1 THE EFFECTS OF APPLYING THE LAW IN CADASTRE ACTIVITY – A COMPARATIVE STUDY OF THE RESOLUTIONS THAT CAN BE ADOPTED FOR THE REGISTRATION OF REAL ESTATE PROPERTIES IN THE LAND REGISTRY - **Andreea BEGOV-UNGUR, Ioana Aurica BERINDEIE, Levente DIMEN** 788
2 THE APPLICABILITY OF GIS TECHNOLOGY IN THE STUDY OF RIVERBED DYNAMICS AND MORPHOLOGY - **Gabriela BIALI, Maria Catalina PASTIA, Paula COJOCARU, Carmen Elena MAFTEI** 794
3 CASE STUDY ON THE USE OF SCANNING EQUIPMENT UAV IN ORDER TO DRAW UP A MULTIFUNCTIONAL DATABASE, IN CÂRȚIȘOARA LOCALITY, SIBIU COUNTY - **Jenica CĂLINA, Aurel CĂLINA, Marius MILUȚ** 802
4 STUDY ON THE IMPACT OF THE APPLICATION OF INFORMATION SYSTEMS ON THE EFFICIENCY AND PRECISION OF TOPO-CADASTRAL WORKS IN THE PREPARATION OF DOCUMENTATION FOR A ROAD IN DOLJ COUNTY - **Jenica CĂLINA, Aurel CĂLINA, Alin CROITORU** 816
5 TECHNICAL METHODOLOGIES FOR CADASTRAL PLAN DEVELOPMENT USING GNSS AND UAV TECHNOLOGIES: A CASE STUDY IN PIETROASA, ROMANIA - **Flavia Mălina CIOFLAN, Flavius IRIMIE, Nicu Cornel SABĂU** 827
6 ASSESSMENT OF LAND USE CHANGES IN NON-COLLECTIVIZED AREAS USING GEOMATIC APPLICATIONS: A CASE STUDY IN VÎRFURILE, ROMANIA - **Flavia Mălina CIOFLAN** 839

7 ACCURACY IN VERTICAL ASSESSMENT OF TELECOMMUNICATIONS TOWERS THROUGH 3D SCANNING - **Andreea Diana CLEPE, Sorin HERBAN, Clara-Beatrice VÎLCEANU, George CRISTIAN** 851
8 FLOOD SUSCEPTIBILITY ASSESSMENT IN THE NERA RIVER BASIN USING GIS: IMPACTS ON LAND USE AND LAND COVER **- Loredana COPĂCEAN, Luminița COJOCARIU** 858
9 ADVANCING CADASTRAL UPDATES AND GIS SPATIAL ANALYSIS FOR FORESTED AREAS - **Iulia COROIAN, Silvia CHIOREAN, Rodica SOBOLU, Diana FICIOR, Paul SESTRAS, Luca-Pavel RUS, Catalin-Stefanel SABOU, Luisa ANDRONIE** 868
10 INTEGRATING UAS, LiDAR, AND GROUND-BASED SURVEYING FOR PRECISE DEMOLITION VOLUME ASSESSMENT: A CASE STUDY OF THE DOLJ CHIM INDUSTRIAL COMPLEX - **George CRISTIAN, Sorin HERBAN, Carmen GRECEA, Clara-Beatrice VÎLCEANU, Andreea Diana CLEPE** 878
11 THE USE OF THE GIS TECHNIQUE IN HIGHLIGHTING THE HUMAN PRESSURE ON THE ENVIRONMENT IN OLTEȚ PIEDMONT (SOUTHERN ROMANIA) - **Raluca Lucia DINCULOIU, Daniel SIMULESCU, Carmen Otilia RUSĂNESCU, Irina Aura ISTRATE, Gabriel Alexandru CONSTANTIN, Mihaela BEGEA, Edmond MAICAN, Gheorghe VOICU, Maria CIOBANU** 886
12 ASPECTS RELATING TO THE POSITIONING BY THE SEMI-KINEMATIC METHOD (STOP AND GO) OF DETAIL CHARACTERISTIC POINTS, NECESSARY FOR THE DESIGN OF COMMUNICATION WAYS - **Călin Ioan IOVAN, Tudor Andrei FLORIȘ, Georgiana Denisa BOJINCĂ** 894
13 SPATIAL POSITIONING OF TOPOGRAPHIC DETAILS WITH INTEGRATED MODERN TECHNOLOGIES, IN AREAS WITH FOREST VEGETATION - **Călin Ioan IOVAN, Tudor Andrei FLORIȘ, Georgiana Denisa BOJINCĂ, Călin Gheorghe PĂȘCUȚ** 904
14 SPATIAL POSITIONING WITH COMBINED METHODS OF TOPOGRAPHIC POINTS NECESSARY FOR ACCESSIBILITY OF FORESTS IN MOUNTAIN AREA - **Flavius IRIMIE** 914
15 APPLICATION OF HIGH-RESOLUTION SATELLITE IMAGERY FOR EVAPOTRANSPIRATION ESTIMATION - A SCIENTIFIC REVIEW - **Vanya IVANOVA, Zhulieta ARNAUDOVA, Rossitza MERANZOVA** 925
16 ANALYZING THE INFLUENCE OF TEMPERATURE ON NDVI FOR A POTATO CROP IN BRAȘOV AREA - **Mihai IVANOVICI, Maria ȘTEFAN, Angel CAȚARON, Adrian GHINEA, Gheorghe OLTEANU** 933
17 ENGINEERING AN INTERACTIVE MAP OF STATUES AND MONUMENTS FROM CLUJ-NAPOCA - **Florica MATEI, Tudor SĂLĂGEAN, Ioana POP, Elemer-Emanuel ŞUBA, Mircea-Emil NAP, Silvia CHIOREAN, Paul SESTRAŞ, Simion BRUMĂ, Ştefan BORCAN-CONȚEVICI, Cristian MĂLINAŞ, Lucia-Adina TRUȚĂ** 940
18 HYBRID MODELLING APPROACHES FOR LAND USE/LAND COVER CHANGE PREDICTION AND CARBON DYNAMICS IN MAROWIJNE, SURINAME - **Tamara MYSLYVA, Christiaan Max HUISDEN, Marek MROZ, Nataliia TSUMAN, Yurii BILYAVSKYI** 951
19 DETERMINATION OF LAND VALUATION FACTORS FOR THE PROCESS OF LAND CONSOLIDATION - A CASE STUDY IN SASCHIZ ADMINISTRATIVE UNIT IN ROMANIA - **Vlad PAUNESCU, Divyani KOHLI, Raluca MANEA, Mariana (CALIN) CIOLACU, Alexandru Iulian ILIESCU** 964
20 INVESTIGATION BETWEEN VEGETATION INDICES, METEOROLOGICAL DATA AND PHENOLOGY OF WINE GRAPE VARIETIES - **Anelia POPOVA, Zhulieta ARNAUDOVA** 976
21 RIVER CORRIDOR CHANGE DETECTION USING SATELLITE IMAGERY AND LIDAR DATA: A CASE STUDY OF THE SIRET RIVER NEAR CORBU VECHI VILLAGE - **Catalin-Stefanel SABOU, Simion BRUMA, Ioana POP, Florica MATEI, Paul SESTRAS, Jutka DEAK, Silvia CHIOREAN, Tudor SALAGEAN** 985

22 A GIS-BASED MULTICRITERIA APPROACH FOR IDENTIFYING OPTIMAL REFUGE LOCATIONS FOR SEVERE STORMS: A CASE STUDY IN CLUJ COUNTY, ROMANIA - **Paul SESTRAS, Ioana POP, Florica MATEI, Catalin-Stefanel SABOU, Simion BRUMA, Silvia CHIOREAN, Elemer Emanuel SUBA, Mircea NAP, Iulia COROIAN, Jutka DEAK, Tudor SALAGEAN** 994

Corresponding author email: vileriz@yahoo.com

Abstract

This study evaluates the quality of tarragon essential oil, toxic metals content, and the growth potential of tarragon on heavy metal-contaminated soils. Tarragon demonstrated tolerance to toxic metals and can be cultivated on highly polluted soils. The levels of toxic metals in tarragon essential oil were below the Maximum Permissible Concentrations. Based on translocation and bioconcentration coefficients, tarragon is a Cd, Pb, Zn and Hg excluder and suitable for phytostabilization. Tarragon essential oil exhibits a mixed sabinene/elemicin/isoelemicin/methyleugenol chemotype and could be used in the pharmaceutical, cosmetic, and related industries.

Key words*: essential oil, phytoremediation, polluted soils, tarragon, toxic metals.*

INTRODUCTION

Artemisia dracunculus L., commonly known as tarragon, is a perennial plant belonging to the Asteraceae family. Tarragon is widespread across North America, Europe, Southeastern Russia, Central Asia, Turkey, and Mongolia (Aglarova et al., 2008; Fildan et al., 2019; Sharopov et al., 2020). It is cultivated in Europe, Russia, Asia, Africa, and North America and is widely used in food flavoring, medicine, and perfumery (Obolskiy et al., 2011; Fildan et al., 2019; Sharopov et al., 2020).

Tarragon is a small perennial shrub that grows 120-150 cm tall. Its alternate leaves measure 2-6 cm in length and 1-8 mm in width, often covered with fine hairs and featuring smooth or slightly toothed edges. The plant produces small yellow flowers with whitish petals, arranged in globose, inclined baskets that form broom-shaped racemes. The entire herb is green and mossy, with a pleasant aroma and taste, and flowers in the second half of summer. Tarragon thrives in various environments but produces the highest yields in moist, sandy loam soils with an alkaline reaction. Depending on the variety, it can be propagated by seed (Russian tarragon) or rhizome cuttings (French and German tarragon). In Europe, plantings are established in April, with cuttings placed 60 cm apart and covered with a thin layer of soil. The first harvest occurs in the same year, and in subsequent years, up to three harvests per season are possible. The harvested material is dried using natural air circulation or heated to 35°C before the leaves are separated from the stems (Aglarova et al., 2008; Obolskiy et al., 2011).

Tarragon essential oil, a pale yellow to amber liquid with a spicy scent, is extracted from the plant's aerial parts during flowering (Fildan et al., 2019). Traditionally, it has been valued for a wide range of therapeutic properties, including antioxidant, antimicrobial, antidiabetic, and anti-inflammatory effects (Obolskiy et al., 2011; Fildan et al., 2019; Sharopov et al., 2020).

Certain medicinal plants, such as mint, St. John's wort, and sage, are known to accumulate significant amounts of toxic heavy metals in their tissues. These plants can be used for phytoremediation, serving as an alternative to food crops grown in contaminated conditions. The concentrations of plant by-products depend on growing conditions, influencing metabolic pathways responsible for the synthesis of natural compounds (Akula & Ravishankar, 2011). Heavy metals can significantly alter the chemical composition of secondary metabolites in aerial plant parts, affecting the quality, safety, and efficacy of plant-derived products.

Although the composition of tarragon essential oil is well studied, limited information is available on toxic metal accumulation in tarragon's aboveground biomass and essential oil when grown on contaminated soils.

This study aims to conduct a comparative analysis to determine heavy metal accumulation, macro- and trace element deposition in the vegetative organs of tarragon, and the quality of its essential oil. Additionally, this study explores the feasibility of cultivating tarragon on heavy metal-contaminated soils.

MATERIALS AND METHODS

This experiment was conducted on an agricultural field contaminated with Zn, Pb, and Cd, located 0.5 km from the Non-Ferrous Metals Plant (NFMW) near Plovdiv, Bulgaria.

Tarragon seedlings were purchased and planted in the spring at sites 0.5 km from the pollution source. In the second and third years after planting, plants were collected and analyzed. Tarragon was hand-harvested at the flowering stage in late August. After transport to the laboratory, plants were separated into individual organs (roots, stems, leaves, and flowering tops) using scissors. Samples were air-dried at room temperature until reaching a stable dry mass, followed by further drying at 35ºC. The concentrations of metals in different plant parts - roots, aboveground mass (stems and leaves), and flowering tops - were determined.

Tarragon essential oil was extracted under laboratory conditions via steam distillation for 2 hours using a Clevenger-type apparatus.

The pseudo-total metal content of soils was determined following ISO 11466. The microwave mineralization method was used to measure metal concentrations in tarragon and its essential oil. Quantitative measurements were performed using ICP (Jobin Yvon Emission - JY 38 S, France). Hg content was analyzed without sample pretreatment using a mercury analyzer. The accuracy and performance of the ICP and mercury analyzer were validated using standard reference material from apple leaves (SRM 1515, National Institute of Standards and Technology, NIST).

The chemical composition of the essential oil (diluted in hexane, 1:1000) was analyzed using an Agilent 7890A gas chromatography (GC) system equipped with an FID detector and an Agilent 5975C mass spectrometer. Compounds were identified by comparing retention times and Kovats retention indices (RI) with standard substances and mass spectral data from the NIST'08 library (National Institute of Standards and Technology, USA).

RESULTS AND DISCUSSIONS

Soil Characteristics

The soils in the study area have a neutral to slightly alkaline reaction (pH = 7.5), with moderate organic matter content (2.1%) and average nutrient levels (P, K). The total Zn, Pb, and Cd concentrations are significantly elevated, measuring 2423.9 mg/kg Zn, 2509.1 mg/kg Pb, and 63.7 mg/kg Cd, far exceeding the maximum permissible concentrations (MPC) of 400 mg/kg Zn, 100 mg/kg Pb, and 3.0 mg/kg Cd (Table 1).

Table 1. The total content of Pb, Zn, Cd (mg/kg) and Hg (µg/kg) in soils

Element	Pb	Zn	Cd	Hg
Total, x±sd	2509.1±6.5	2423.9±4.5	63.7±1.8	488.0±13
MPC	100	400	3.0	1.5

x = mean value (mg/kg) from five repetitions; sd = standard deviation

Metal content in tarragon

Table 2 presents the results obtained for the toxic metals and nutrient contents in the organs of the essential oil crop studied. The Pb content in tarragon roots reached 141.8 mg/kg, while Zn, Cd, Hg, Cu, Fe, and Mn levels were 50.9 mg/kg, 3.9 mg/kg, 48.3 µg/kg, 7.1 mg/kg, 157.8 mg/kg, and 5.6 mg/kg, respectively. These results can be attributed to tarragon's anatomical and biological characteristics. The plant's rhizomatous root system consists of thick, lignified, serpentine rhizomes with a dense network of thin, branched roots extending 30-45 cm deep. This structure enhances nutrient and water absorption, allowing tarragon to thrive in various soil conditions.

The movement and accumulation of toxic metals in tarragon's vegetative organs varied significantly. Notably, Pb was highly accumulated in the aerial parts, reaching 1144.1 mg/kg in leaves. Typically, plants

absorb only a small fraction of Pb from soil, with most Pb retained in the roots. However, findings suggest that tarragon efficiently translocates Pb to aboveground tissues, likely due to its anatomical and morphological features. Leaf hairs may contribute to Pb fixation from airborne pollutants.

Cadmium, known for its high mobility in plants, was present at 39.0 mg/kg in tarragon leaves, exceeding the toxic threshold of 5.0 mg/kg (Kabata-Pendias, 2001). Similarly, Hg accumulation in tarragon was attributed primarily to aerosol deposition, as leaves are the primary uptake site, with soil absorption being secondary. Hg concentrations were higher in the aerial parts and flowering tops than in the roots.

The Zn content in tarragon leaves reached 556.1 mg/kg, below the phytotoxic threshold of 500-1500 mg/kg (Kabata-Pendias, 2001). The Cu concentration in leaves was 74.3 mg/kg, exceeding the toxic range for most plants (25-40 mg/kg). Fe accumulated mainly in leaves (396.3 mg/kg), surpassing normal plant values (50-250 mg/kg), while Mn levels (56.5 mg/kg) remained well below phytotoxic thresholds (400-2000 mg/kg).

Most macroelements accumulated in tarragon's aerial parts. In leaves, P, K, Mg, and Ca levels reached 1590.1 mg/kg, 9843.0 mg/kg, 540.4 mg/kg, and 2387.0 mg/kg, respectively. In flowering tops, these concentrations were significantly higher: 5062.1 mg/kg P, 24,233.6 mg/kg K, 2536.6 mg/kg Mg, and 16,915.4 mg/kg Ca.

Despite accumulating heavy metals at levels exceeding critical toxicity thresholds, tarragon exhibited no visible symptoms of heavy metal toxicity, indicating a high level of tolerance. Heavy metal and nutrient accumulation was significantly higher in flowering tops than in leaves, except for Pb and Zn. In flowering tops, Pb reached 932.8 mg/kg, Zn 304.8 mg/kg, Cd 35.1 mg/kg, and Hg 78.2 µg/kg.

Overall, metal distribution in tarragon was selective, primarily depending on the plant organ and its surface characteristics. Heavy metals and micro- and macroelements were predominantly accumulated in leaves and flowering tops (Figure 1).

Table 2. Content of toxic metals and nutrients (mg/kg) in tarragon

	Roots	Stems	Leaves	Flowering tops
Pb	148.8±1.2	45.3±0.3	1084.7±2.6	932.8±2.0
Cd	3.9±0.1	15.5±0.2	39.0±0,,5	35.1±0.5
Zn	50.9±1.3	68.5±1.5	556.1±8.7	304.6±4.6
Cu	7.1±0.8	13.3±1.0	74.3±3.5	79.5±3.8
Fe	57.8±0.8	166.9±3.4	396.3±4.6	4790.1±8.9
Mn	5.6±'0.5	16.0±1.0	56.5±1.8	232.2±2.6
P	493.0±5.5	675.8±5.9	1590.1±9.8	5062.1±12.7
Ca	1420.4±8.8	2387.0±10.8	16915.3±25.0	19226.8±26.0
Mg	216.7±1.9	540.4±2.8	2536.6±10.6	4616.8±12.7
K	5751.5±8.7	9843.0±9.8	24233.6±23.0	36562.5±26.9
Hg*	48.3±3.8	45.0±4.5	284.7±10.0	78.2±7.1

x - average value (mg/kg) from 5 repetitions; sd - mean standard deviation; *- µg/kg.

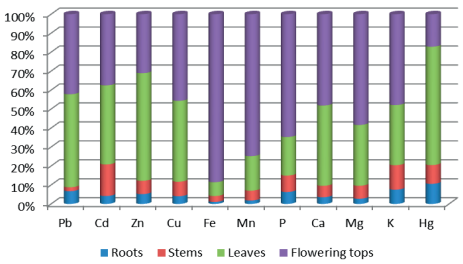

Figure 1. Distribution of toxic metals and nutrients in tarragon

Toxic Metal Content in Tarragon Essential Oil

The toxic metal content of tarragon essential oil was also analyzed. The results indicate that most metals present in flowering tops do not transfer into the oil during distillation. Consequently, their concentrations in the oil are significantly lower. The Pb content in tarragon essential oil reached 0.27 mg/kg, and Zn 1.09 mg/kg, while Cd and Hg levels were below the detection limits of the analytical method.

These findings strongly suggest that a substantial portion of metals present in tarragon flowering tops does not pass into the essential oil. Furthermore, the levels in the oil remain below the accepted maximum limits for an environmentally safe product (5 mg/kg Pb, 1 mg/kg Cd, 0.1 mg/kg Hg) as per the Council of Europe (2021).

These results confirm previous findings by Angelova et al. (2015), which demonstrated that the heavy metal content in essential oils remains minimal, regardless of soil contamination levels. This is primarily due to the high molecular weight and non-volatile nature of heavy metals, preventing their concentration during the distillation process.

Phytoremediation potential of tarragon

The phytoremediation efficiency of tarragon was evaluated using the Bioaccumulation Factor (BCF) and Translocation Factor (TF). These indices are commonly used to assess plant-based remediation potential and depend on factors such as soil conditions, plant species, and heavy metal bioavailability.

The coefficients were calculated using the following equations:

- Translocation Factor (TF):

$$TF = \frac{Cshoots}{\text{Croots}}$$

where:

- *Cshoots* represents the heavy metal content (mg/kg) in the aerial parts (stems, leaves, flowering tops);
- *Croots* represents the concentration in the roots (mg/kg).

- Bioaccumulation Factor (BCF):

$$BCF = \frac{Cplant\ parts}{\text{Csoil}}$$

where:

- *Cplant parts* represents the heavy metal content (mg/kg) in various plant organs (roots, stems, leaves, flowering tops);
- *Csoil* represents the heavy metal concentration in the corresponding soil (mg/kg).

A plant species is considered suitable for phytoextraction when its translocation factor (TF) > 1. If TF < 1, the plant is more suitable for phytostabilization.

The results indicate that tarragon exhibits high translocation potential for heavy metals: Pb: TF = 8.15; Cd: TF = 9.96; Zn: TF = 10.93; Hg: TF = 5.89.

The bioaccumulation factor for roots (BCFroots) was calculated as follows: Pb: BCFroots = 0.059; Cd: BCFroots = 0.061; Zn: BCFroots = 0.021; Hg: BCFroots = 0.099 and is presentet in Tabel 3.

Table 3. Bioaccumulation (BCF) and translocation (TF) factors for tarragon

	TF	BCFroots	BCFleaves	BCF tops
Pb	8.15	0.059	0.43	0.37
Cd	9.96	0.061	0.61	0.55
Zn	10.93	0.021	0.22	0.13
Hg	5.89	0.0995	0.58	0.16

For flowering tops, the BCF values were all below 1, indicating limited metal accumulation in this plant part (Table 4).

RI - Kovacs relative indices

BCF for leaves reflects the plant's ability to absorb and transfer metals to the leaves, which can be harvested for remediation purposes. The classification of plants based on BCF values is as follows: BCF < 1: Excluder; BCF = 1: Indicator; 1 < BCF < 10: Accumulator; BCF > 10: Hyperaccumulator. The BCF values for tarragon leaves were: Pb: 0.43; Cd: 0.61; Zn: 0.23; Hg:0.58. These results suggest that tarragon functions as an excluder of Cd, Pb, Zn, and Hg when grown in contaminated soils.

Previous studies support the findings of Kocaman (2022) classified tarragon as an accumulator of Pb and Cd (1<Cd-Pb<10) and an excluder of Hg (Hg<1). Ghasemidehkordi et al. (2018) reported Pb bioaccumulation in Artemisia dracunculus L. in Iran. Ozyigit et al. (2018) found that tarragon accumulates low levels of Cd and has not been identified as a heavy metal accumulator.

Essential oil quality

The quantity and composition of tarragon essential oil are influenced by genetic factors, phenological stage, and environmental conditions (e.g., soil composition and light intensity).

The essential oil yield varied between 0.15% and 3.1%, with the highest concentrations occurring at the beginning of flowering (Fildan et al., 2019). The results from this study align with previous reports.

In total, 36 components were identified in tarragon essential oil, primarily belonging to the terpene group (monoterpenes and sesquiterpenes) and phenylpropanoids, which together accounted for 99.059% of total oil composition (Table 4). The dominant compounds (>10%) were: Sabinene (21.414%), Elemicin (17.429%) Isoelemicin (15.259%), Methyleugenol (13.107%).

Based on functional group classification, tarragon oil was composed of:

- Phenylpropanoids: 48.975%
- Monoterpene hydrocarbons: 35.052%
- Sesquiterpene hydrocarbons: 7.253%
- Oxygenated monoterpenes: 5.574%
- Oxygenated sesquiterpenes: 2.205%.

The main phenylpropanoids in essential oil are elemicin (17.429%), isoelemicin (15.259%), methyleugenol (13.107%), methyl isoeugenol (2.734%). The amount of phenylpropanoid compounds in tarragon oils varies widely (25.4% (Sharopov et al., 2020), 36.41% (Fildan et al., 2019), 51.93% (Varban et al., 2023), 52.2%, (Lopez-Lutz et al.,2008), 62.2% (Zawislak and Dzida, 2012), 73.3% (Fraternale et al., 2015).

Variation in methyleugenol composition was found (0.2% (Fraternale et al., 2015), 6.2% (Zawislak and Dzida, 2012), 9.09% (Fildan et al., 2019), 13.107% (this study) 29.19% (Varban et al., 2023). The content of methyleugenol depends on the phenophase, with the highest content identified in *A. dracunculus* in mass flowering (Khodakov et al. 2009). The content of elemicin also varies widely (7.95% (Fildan et al., 2019), 11.43% (Varban et al., 2023), 17.429% (this study), 56.0% (Zawislak and Dzida, 2012). Elemicin has antimicrobial, antioxidant, antiviral and psychoactive effects, and there is no significant difference in its content at the growth stages of tarragon (Varban et al., 2023). Significant differences were also found in the content of estragole (methyl chavicol) (phenylpropanoid compound) (0.446% (this study), 3.9% (Russia), 16.2% (Canada) (Obolskiy et al., 2011), 24.6% (Sharopov et al., 2020), 73.3% (Italy, Fraternale et al., 2015), 82% (USA, Obolskiy et al., 2011). This compound is considered a key component of French tarragon oil (>80%) (Sharopov et al., 2020). Monoterpenes belong to the second primary chemical class of oil constituents, which reach 40.626% of the total oil composition. The amount of monoterpene hydrocarbons reaches 35.052%, of which sabinene (21.414%), trans-beta-ocimene (3.529%), terpinolene (2.342%), cis-beta-ocimene (2.244%), β-myrcene (1.615%).

Sabinene is a significant component in tarragon essential oils from different geographical origins (Sharopov et al., 2020). It was found in high concentrations in the essential oil of *A. dracunculus* growing in Tibet (China| (19.2%, Liu et al., 2018), Lithuania (14-25%, Sharopov et al., 2020), Romania (9.44-42.4%, Fildan et al., 2019; Varban et al., 2023), Kazakhstan (20.2%, Suleimenov et al., 2010), Poland (20.9%, Zawislak and Dzida, 2012), Tajikistan (29.1%, Sharopov et al., 2020), while in India – trace amount (Verma et al., 2010).

The number of oxygenated monoterpenes reaches 5.574 % of the total composition of the oil. The main oxygenated monoterpenes are citronellyl acetate (2.565%) and geranyl acetate (1.411%).

The sesquiterpenes reach 9.458%. The amount of sesquiterpene hydrocarbons reaches 7.253%. Germacrene D (3.923%) and bicyclogermacrene (2.597%) are the main components that predominate in this group.

The amount of oxygenated sesquiterpenes reaches 2.205% of the total oil composition.

The oil contains (> 1.0 %) caryophyllene oxide (1.076%).

The results show significant differences in the composition of oils obtained from different geographical locations. Studies have shown significant differences in the composition of tarragon essential oil. These differences in the chemical composition of the essential oil extracted from the aerial parts of *A. dracunculus* may be due to environmental conditions (Fildan et al., 2019), habitat, soil pH, plant part used, extraction method applied, and other factors such as genotypes and ontogeny (Obolskiy et al., 2011; Fraternale et al., 2015; Fildan et al., 2019). According to Ekiert et al. (2021), the main components in the essential oil of *A. dracunculus* are estragole (40-85%), sabinene (up to 35%), methyleugenol (up to 25%) and elemicin (up to 57%). The essential oil of tarragon from Tajikistan is characterised mainly by sabinene (29.1%), and estragole (24.6%), the oil from Turkey contains Z anethole (81.0%) (Kordali et al., 2005), the oil from Cuba - elemicin (53.0%) and methyleugenol (17.6%) (Pino et al., 1996), the oil from Iran - anethole (21.2%), E-(β)-ocimene (22.6%) and limonene (12.4%) (Sayyah et al., 2004). The Russian tarragon oil is rich in sabinene (39.4%), elemicin (16.0%), methyl eugenol (14.7%) and iso-elemicin (7.7%), while the French tarragon oil has the main component methyl chavicol (68.6%) (Arabhosseini et al., 2006).

Based on 30 components of 105 essential oils of different geographical origins, Sharopov et al. (2020) established 7 main chemotypes of tarragon essential oil. The results show that the essential oil of *A. dracunculus* belongs to the mixed chemotype variation without a dominant component. Tarragon essential oil is characterised by a mixed sabinene/elemicin/isoelemicin/methyleugenol chemotype.

CONCLUSIONS

Based on the results obtained, the following key conclusions can be drawn:

1. Toxic metal tolerance and phytoremediation: Tarragon is tolerant to toxic metals and can be cultivated on highly contaminated soils (2423.9 mg/kg Zn, 2509.1 mg/kg Pb, and 63.7 mg/kg Cd). It is effective for phytoremediation of soils contaminated with heavy metals.
2. Heavy metal excluder: Tarragon functions as a Cd, Pb, Zn and Hg excluder when grown in contaminated environments.
3. Metal and nutrient uptake: There is a distinct pattern in the absorption and distribution of heavy metals, microelements, and macroelements between the vegetative and reproductive organs of tarragon
4. Essential oil safety: The levels of Pb, Cd, Zn, and Hg in tarragon essential oil, cultivated 0.5 km from NFMW-Plovdiv, were below the Maximum Permissible Concentrations. This makes the oil suitable for use in the pharmaceutical, cosmetic, and related industries.
5. Essential oil composition: phenylpropanoids (48.975%) are the predominant components in tarragon oil, followed by monoterpene hydrocarbons (35.052%), sesquiterpene hydrocarbons (7.253%), oxygenated monoterpenes (5.574%), and oxygenated sesquiterpenes (2.205%).
6. Chemotype classification: Tarragon essential oil from the NFMW-Plovdiv region exhibits a mixed sabinene/elemicin/isoelemicin/methyleugenol chemotype.

EVALUATION OF WASTE BIOMASS FROM AROMATIC PLANTS FOR ENERGY PURPOSES

Violina ANGELOVA

Agricultural University - Plovdiv, 12 Mendeleev Blvd, 4000, Plovdiv, Bulgaria

Corresponding author email: vileriz@yahoo.com

Abstract

This study aims to evaluate the feasibility of obtaining energy from waste biomass. The potential of waste biomass from aromatic plants, left after the production of essential oils, was assessed. The calorific value, ash content, volatile compounds, and moisture content were determined. Elemental analysis of the waste biomass was conducted to measure the C, H, N, and S contents. The results indicate that residual waste has significant potential as a quality feedstock for solid biofuel production. Compared to coal, the calculated emission factors demonstrate a reduction in CO and CO2 emissions by up to 30%, NOx by up to 80%, SO2 by up to 99%, and dust by up to 67%, depending on the waste used. When selecting suitable waste for energy production, it's essential to balance calorific value and emission factors. If energy efficiency is the priority, lavender, tansy, and thyme waste may be preferred. However, for sustainability and lower environmental impact, common sage waste could be the better choice. It's important to consider the specific context, including regulations and energy needs, when making a final decision.

Key words*: biofuel, elemental analysis, emission factors, waste.*

INTRODUCTION

In recent years, alternative energy sources characterized by low emissions, including greenhouse gases and dust particles, have been increasingly sought after (Kimming et al., 2015; Obernberger et al., 2017). Waste plays a crucial role in the European Commission's strategy for energy security and greenhouse gas (GHG) emission reduction. As a renewable energy source, the use of waste biomass has been expanding worldwide, primarily for household heating as an alternative to fossil fuels (Lasek et al., 2018; Pastorello et al., 2011). The demand for plants with high productivity, low nutrient requirements, and valuable biological composition for various bioeconomic applications is of utmost importance. Perennial plants, in particular, offer advantages by reducing production costs and energy inputs compared to annual field preparation and planting. Additionally, such a biomass production system can enhance ecosystem services and support soil conservation, aligning with the concept of "low energy consumption and high output" regarding energy investments and additional costs. Essential oil crops are primarily cultivated for their essential oils (Duce et al., 2017; Giacometti et al., 2018; Kant & Kumar, 2022). The area dedicated to essential oil production in the European Union is steadily increasing, reaching approximately 80,000 hectares (Maj et al., 2020). In recent years, global trade in medicinal and aromatic plants has grown by 10-12% annually (Chandra & Sharma, 2019). Consequently, waste generation in this industry has also increased, reaching up to 30 million tons annually (Wei et al., 2022).

A substantial amount of waste biomass is generated during harvesting, pre-processing, drying, collection of harvested crops, and plant feedstock processing. After essential oil extraction, solid residue remains, which can be utilized for fuel energy production through pyrolysis, gasification, or hydrothermal carbonization processes (Mastellone, 2015). Despite containing valuable substances, these residues are often discarded through stockpiling, landfilling, or open field burning, leading to resource waste and significant environmental pollution (Wei et al., 2022; Marcelino et al., 2023).

Despite the strong economic potential of utilizing plant biomass waste, limited research has focused on the calorific value of these residues (Maj et al., 2020; Chakyrova & Doseva, 2021; Pulidori et al., 2023).

This study aims to evaluate the energy potential of residues obtained after the steam distillation of essential oils from lavender, tansy, thyme, yarrow, and common sage. Additionally, it examines the emission factors of toxic exhaust components and explores the feasibility of using these residues for energy production.

MATERIALS AND METHODS

Aromatic plants, including lavender, tansy, thyme, yarrow, and common sage, were collected from southern Bulgaria at the flowering stage. After essential oil extraction via steam distillation, the plant residues were dried in an oven at 105°C and ground using a laboratory grinder. The physico-chemical characterization of the plant residues was conducted based on calorific value, ultimate analysis, and proximate analysis.

The heating value was determined following the ISO standard (BDS EN ISO 18125:2017) using an IKA C6000 oxygen bomb calorimeter (IKA Werke GmbH, Germany).

The samples were analyzed according to standard methods: moisture content (BDS EN ISO 18134-3:2015), ash content (BDS EN ISO 18122:2015), volatile matter (BDS EN ISO 18123:2015).

Total carbon, hydrogen, nitrogen, and sulfur contents were determined by dry combustion using a Vario Macro CHNS analyzer (Elementar GmbH, Germany) (BDS EN ISO 16948:2015).

Using the results from the ultimate analysis, emission factors for CO, CO_2, NO_x, SO_2, and dust emissions were estimated through equations (1)-(7) (Borycka, 2008):

CO emission factor

$$\mathrm{CO} = \frac{28}{12} x\ \mathrm{Ec}\ x\ (C_CO/C) \quad (1)$$

Emission factor of chemically pure coal

$$Ec = c.uc \quad (2)$$

CO_2 emission factor

$$CO_2 = \frac{44}{12} x\ (Ec - \frac{12}{28}\ x\ CO - \frac{12}{16}\ x\mathrm{ECH_4} - \frac{26.4}{31.4} x\ ENMVOC) \quad (3)$$

Methane emission factor:

$$ECH4 = \frac{16}{12} xEc \times \left(\frac{C_{CH4}}{C}\right) \quad (4)$$

NOx emission factor

$$NOx = \frac{46}{14} \times Ec \times \frac{N}{C} \times \left(\frac{N_{NOx}}{N}\right) \quad (5)$$

Emission factor of SO_2

$$\mathrm{SO_2} = \frac{2S}{100} \quad (6)$$

Dust emissions:

$$Edust = 1.5 \times A \times \frac{100 - \eta 0}{100 - k} \quad (7)$$

RESULTS AND DISCUSSIONS

Proximate and ultimate analysis

The proximate and ultimate analysis results for essential oil plant waste are presented in Tables 1 and 2. According to CEN/TS 14961, biomass for solid biofuels is categorized into three main groups: woody biomass, herbaceous biomass, and fruit biomass. Essential oil plant waste falls under the herbaceous biomass group - specifically, agricultural and garden herbs.

Table 1. Proximate analysis and heating values of plant waste

Plant waste	M, %	Ash, %	FC, %	VM, %	LHV, MJ/kg	HHV, MJ/kg
Lavender	8.42	7.28	11.5	80.08	17.41	19.23
Tansy	7.31	8.35	12.69	80.0	18.16	19.78
Thyme	7.08	8.24	14.42	78.5	17.85	19.17
Yarrow	6.22	8.79	16.48	77.3	16.7	17.96
Commom sage	8.95	6.22	13.46	77.59	16.24	18.06
ISO 17225-6	≤12 - 15	≤ 6-10	-	-	≥14.5	-
CEN/TS 14961-1Harvest (July - Oct.)	-	6.5 (2.5-10)	-	-	16.6	-

M - moisture, FC- fixed carbon, VM - volatile matter, LHV - lower heating value, HHV - higher heating value

The key parameters of biomass waste were compared against the requirements of the ISO 17225-6 standard for herbaceous biomass and data from other studies.

Heating Value and Energy Potential: The LHV (Lower Heating Value) is a crucial parameter for evaluating biomass as a biofuel. According to ISO 17225-6, the standard LHV for solid fuel is ≥14.5 MJ/kg. The LHV of the tested plant waste ranged from 16.24 MJ/kg (common sage) to 18.16 MJ/kg (tansy). The tested biomass meets or exceeds ISO 17225-6 standards for LHV (≥14.5 MJ/kg), indicating good energy potential.

The HHV (Higher Heating Value), which represents the total energy content, ranged from 17.96 MJ/kg (yarrow) to 19.78 MJ/kg (tansy). Tansy waste shows the highest energy efficiency (19.78 MJ/kg HHV), making it an excellent candidate for biofuel. Conversely, the lower HHV of common sage implies reduced energy potential. These values align with previous studies, such as Pulidori et al. (2023) for lavender waste (19.2 MJ/kg) and thyme waste (17.8 MJ/kg), Maj et al. (2020) for mint waste (15.90-16.64 MJ/kg), and Zając et al. (2019) for miscanthus (17.99 MJ/kg), wood (18.35 MJ/kg), and rapeseed straw (15.97 MJ/kg).

Moisture Content and Ash Content: Moisture content significantly affects combustion efficiency, as lower moisture levels lead to better energy performance. The tested biomass had moisture content ranging from 6.22% (yarrow waste) to 8.95% (common sage waste), which complies with ISO 17225-6 (≤12-15%).

Ash content is a critical parameter in biomass fuel quality, as higher ash levels can reduce combustion efficiency and cause operational challenges. The tested samples contained 6.22% (common sage) to 8.79% (yarrow) ash, which is within the acceptable ISO 17225-6 range (≤6-10%). Moisture and ash contents are within acceptable ranges, ensuring good combustion properties. These values are comparable to previous findings for lavender waste (6.7-7.8%) (Chakyrova & Doseva, 2021) andmint waste (7.23-10.29%) (Maj et al., 2020).

Fixed Carbon and Volatile Matter: Fixed carbon content is a positive attribute of biomass, as it determines combustion stability and burning duration. While ISO 17225-6 does not specify a standard for fixed carbon, the values in this study ranged from 11.5% (lavender) to 16.48% (yarrow), with yarrow showing the highest combustion stability. Similar values were reported for mint waste: 9.40-15.77% (Maj et al., 2020) andlavender waste: 15.3% (Chakyrova & Doseva, 2021).

Volatile matter plays a key role in biomass combustion, with higher volatile content leading to easier ignition and more intense burning. Fixed carbon and volatile matter values indicate stable burning characteristics. Biomass typically contains 60-80% volatile matter, and the tested biomass samples ranged from 77.3% (yarrow) to 80.08% (lavender). These values align with mint waste (64.99-70.36%) (Maj et al., 2020), miscanthus (72.5%) and rapeseed straw (73.5%) (Zając et al., 2019).

Table 2 presents the results of the ultimate analysis of the tested wastes. These values are compared with the requirements of ISO 17225-6 and with findings from other studies. The main components of solid biofuels are carbon (C), hydrogen (H), and oxygen (O). During combustion, C and H undergo oxidation in exothermic reactions, forming CO_2 and H_2O, which impact the gross calorific value of the fuel (Clarke & Preto, 2011). Higher C content indicates a greater energy potential for biomass, making it more viable as a renewable energy source. The total C content in the tested samples ranged from 46.9% to 49.3%, with lavender waste exhibiting the highest values. Similar C content has been reported for mint waste (44.82-47.05%) (Maj et al., 2020), lavender (45.4-48.1%) (Chakyrova & Doseva, 2021), willow biomass (50.84%) (Szczukowski et al., 2015), and wood (49.80%) (Kajda-Szczesniak, 2013). Hydrogen content ranged from 3.8% (tansy waste) to 5.53% (common sage waste). Comparable H content has been observed in mint waste (5.54-5.76%) (Maj et al., 2020), lavender waste (5.8-6.77%) (Chakyrova and Doseva, 2021), willow biomass (5.86%) (Szczukowski et al., 2015), and wood (6.30%) (Kajda-Szczesniak, 2013). These values are also close to those of wheat, barley, flax, and timothy straw (6.1-6.4%). Oxygen content negatively affects the energy value. The O content of the tested biomass ranged from 37.81% to 41.00%, with no significant differences among the samples. These values are similar to those of wheat, barley, flax, and timothy straw (44.4-52.1%) but lower than those reported for mint waste (29.14-36.09%) (Maj et al., 2020) and lavender waste (37.8%) (Chakyrova & Doseva, 2021). According to Vassilev et al. (2010), the elemental composition of biomass is a key factor in estimating heating values, combustion air requirements, and the composition of flue gases. Knowledge of elemental composition also helps assess gaseous emissions from fuel combustion. From an environmental

perspective, N and S contribute to greenhouse gas emissions and are considered undesirable in biomass fuels. During combustion, N leads to NOx emissions, while S contributes to SOx emissions, which can cause particulate pollution, acid rain, and corrosion (Clarke & Preto, 2011). The N content in the tested biomass ranged from 0.178% (lavender waste) to 0.36% (tansy waste), remaining well below the 1.5-2% limit set by ISO 17225-6. Lower nitrogen levels improve the suitability of biomass for combustion. Comparable N values have been reported for mint waste (0.23-0.70%) (Maj et al., 2020) and lavender (1.3%) (Chakyrova & Doseva, 2021).

Sulfur content in biomass is generally low but still plays a role in emissions. The sulfur levels in the tested samples ranged from 0.0334% (lavender waste) to 0.0784% (yarrow waste), remaining well below the 0.2-0.3% standard limit. Comparable S content has been reported for lavender waste (0.1%) (Chakyrova & Doseva, 2021) and mint waste (0.0-0.19%) (Maj et al., 2020). Low S content minimizes the risk of releasing SO_2 during combustion, reducing environmental impact.

Table 2. Ultimate analysis of tested wastes

Waste	N, %	S, %	Cl, %	C, %	H, %	O, %
Lavender	0.178	0.0334	0.0220	49.3	5.40	37.81
Tansy	0.360	0.0738	0.0895	49.2	3.80	38.22
Thyme	0.240	0.0593	0.0358	48.5	3.80	39.16
Yarrow	0.250	0.0784	0.2121	46.9	4.60	39.38
Common sage	0.198	0.0500	0.0148	47.0	5.53	41.00
ISO 17225-6	1.5-2	0.2- 0.3	0.1-0.3	-	-	-
CEN/TS 14961-1 Harvest (July-Oct.)	1.3	0.1 (0.1-0.2)	0.5 (0.2-0.6)	46	5.7	40

Chlorine levels ranged from 0.0148% (common sage) to 0.2121% (yarrow), staying within the allowable limits for solid fuels. Lower chlorine content is beneficial as it reduces the potential for corrosion and harmful emissions.

Emission factors

Determining emission factors is essential for estimating the levels of pollutants emitted during fuel combustion. To determine these factors, it's crucial to understand the physicochemical characteristics of the waste being used. The emission factors for CO, CO_2, NOx, SO_2, and dust emissions from the plant waste studied are presented in Table 3, along with data for coal emissions for comparison.

Table 3. Emission factors (kg/mg) for analysed waste and coal

Waste	CO	CO_2	NOx	$S0_2$	Edust
Lavender	60.74	1487.07	0.63	0.067	9.20
Tansy	60.61	1484.05	1.27	0.148	10.55
Thyme	59.75	1462.94	0.85	0.119	10.41
Yarrow	57.78	1414.66	0.88	0.157	11.10
Common sage	57.90	1417.68	0.70	0.100	7.86
Hard coal	82.01	1969	4,09	5,2	23,57

No significant differences were observed in the carbon monoxide (CO) emission levels of the investigated plant wastes. The highest CO emission rate was observed for lavender (60.74 kg/mg), while the lowest was for yarrow (57.78 kg/mg), with a difference of up to 3%.

The Nox emissions ranged from 0.6289 kg/mg for lavender waste to 1.27 kg/mg for tansy waste.

The CO_2 emission factor was highest for tansy waste (1484.05 kg/mg) and lowest for yarrow waste (1414.66 kg/mg).

SO_2 emissions ranged from 0.067 kg/mg for lavender waste to 0.118 kg/mg for thyme waste. Dust emissions were highest for yarrow waste (11.10 kg/mg) and lowest for common sage (7.86 kg/mg).

The emission factors show that the tested wastes exhibit similar emission levels to those of mint waste (Maj et al., 2020), Eucalyptus globulus tree (Mateos et al., 2019), and larch needles (Maj, 2018). Overall, emissions are comparable to other waste types, and the SO_2 content in the wastes is minimal. CO and CO_2 emission factors are similar to those for mint (Maj et al., 2020), larch needles (Maj, 2018), and hazelnut husk and leaves (Maj, 2018; Borkowska et al., 2024).

Plant wastes have significantly lower NOx emissions compared to straw pellets, sunflower stalks, corn stalks, and wood pellets (Krugly et al., 2014), as well as Eucalyptus globulus (Mateos et al., 2019).

Wastes from lavender, thyme, and yarrow showed higher particulate emissions similar to those from mint waste (9.14-13.0%) (Maj et al., 2022), tree leaves (10.80%) (Maj, 2018), and hazelnut waste (10.95%) (Borkowska et al., 2024). The high dust emissions are associated with the high ash content of the tested wastes, so technological solutions to reduce these

emissions (e.g., using additional filters to capture emitted dust) should be considered.

The emission method for determining gas and dust emissions allows for an assessment of the environmental impact of plant waste when used for energy purposes, without requiring specialized analytical equipment. This method enables quick estimation of biofuel emissivity, which is often overlooked when assessing biomass suitability for energy.

Differences in emissions among the tested wastes may influence selection decisions, especially when considering environmental aspects and incineration efficiency. Based on the emission factors, common sage waste is characterized by low emissions. Higher emission factors for CO and CO_2 were found for lavender and tansy waste. Using common sage waste as a source of energy can contribute to reduction in GHG emissions.

Using waste from essential oil crops results in emission reductions compared to coal (Borycka et al., 2008). Emission levels decreased by 26-30% for CO, 24-28% for CO_2, 68-84% for NOx, 97-99% for SO_2, and 53-67% for dust, depending on the type of waste used. Therefore, utilizing these wastes as fuel provides real environmental benefits.

CONCLUSIONS

Significant differences were found between the plant wastes in terms of calorific value. Lavender waste (17.40 MJ/kg; 19.23 MJ/kg), tansy waste (18.16 MJ/kg; 19.78 MJ/kg), and thymewate (17.85 MJ/kg; 19.17 MJ/kg) showed higher lower and higher heating values, making them an excellent candidate for biofuel compared to yarrow waste (16.7 MJ/kg; 17.96 MJ/kg) and common sage (16.24 MJ/kg; 18.06 MJ/ kg).

The chemical composition of plant wastes affects their energy value and emission factors. The common sage waste is characterised by a higher moisture content (8.95%), which negatively affects the energy value of the waste.

The type of waste mainly influences the amount of emissions from waste incineration. Higher emissions of CO (60.61 and 60.76 kg/mg) and CO_2 (1484.05-1487.07 kg/mg) were found for tansy and lavender waste, NOx - for tansy waste (1.26 kg/mg), while for yarrow there are higher dust emissions (11.10 kg/mg).

When selecting suitable waste for energy production, it's essential to balance calorific value and emission factors. If energy efficiency is the priority, lavender, tansy, and thyme waste may be preferred. However, for sustainability and lower environmental impact, common sage waste could be the better choice. It's important to consider the specific context, including regulations and energy needs, when making a final decision.

DETECTION AND MONITORING OF HYDROCARBON POLLUTION SOURCES IN THE PETROMIDIA REFINERY AREA

Sorin ANGHEL

National Institute for Research and Development on Marine Geology and Geoecology -GeoEcoMar, 23-25 Dimitrie Onciul, District 2, Bucharest, Romania

Corresponding author email: soanghel@geoecomar.ro

Abstract

The detection and spatiotemporal monitoring of hydrocarbon contamination in the geological environment (soil, geological formations, and groundwater) represent the main objective of the study, conducted during the period of 2023-2024. The study focused on areas adjacent to the Petromidia refinery with industrial activity exceeding five decades, located in the vicinity of the city of Navodari. Both `classic` geophysical techniques (VES - Vertical Electrical Sounding, IP - Induced Polarization) and recently introduced techniques on a global scale (GPR - Ground Penetrating Radar) were employed. Electrical and electromagnetic measurements were complemented by magnetic investigations, drilling works, and geological and hydrogeological observations. The most effective geophysical measurements, both for detecting and monitoring underground hydrocarbon contamination, were the geoelectrical resistivity ones, due to the significant contrast in electrical resistivity between the highly resistive pollutant substances and the affected geological environment, consisting of rocks and fluids with much higher electrical conductivity. The geological and hydrogeological data from shallow boreholes were used for the correct interpretation of geophysical anomalies, while the results of magnetic measurements indicated the routes of buried pipelines, and potential sources of pollution.

Key words*: electrometry, hydrocarbon, pollution, soil.*

INTRODUCTION

Contamination with hydrocarbons of the land and groundwater in the vicinity of refineries, fuel depots, oil wells, and even transportation pipelines, constitutes one of the significant environmental protection issues (Onutu & Tita, 2018). The localization and determination of the spatial-temporal distribution of contamination currently rely exclusively on the use of direct methods of biochemical analysis of soil and water samples taken from the surface or from boreholes.

The information obtained in this way is point-based and therefore cannot provide an overall picture of land and groundwater contamination. Analyses are costly and require an extended period for observations to be made.

The integration of point-based information into a three-dimensional spatial-temporal image of areas contaminated with hydrocarbons and residual waters becomes possible through the appropriate use of geophysical methods, supported by hydrogeological information.

The main objective of the geophysical investigation was to develop a geophysical monitoring of hydrocarbon contamination resulting from refining, storage, and transportation activities of petroleum products in the vicinity of refinery located in the area of the city of Navodari.

MATERIALS AND METHODS

1. Physical-geographical characterization

The objective under analysis is located on the coastal strip separating the Black Sea from the Gargalac (Corbu) and Tașaul lakes, an integral part of the Central Dobrogea Platform.

The relief generally exhibits the characteristics of a high hilly plain, with wide valleys and terraces, reaching heights of up to 100 meters.

The average relief energy is 50 meters. Genetically, the area represents a paneplain (nearly flat land surface resulting from long - continental erosion and denudation) of the Caledonian mountains (Green Shale Formation), covered in the Quaternary by a loess cover.

Beneath this cover of aeolian deposits, patches of eroded Jurassic limestone emerge, featuring karstic landforms such as caves and gorges.

Towards the coastal zone, the relief is lower, featuring lagoons, fluvio-marine estuaries, and sandy coastal barriers.
The climate is typically continental, with the sea exerting its influence over a coastal strip 10-15 kilometres wide. The basin of Lake Taşaul is situated on the contact zone between Jurassic limestone and the Proterozoic substrate of the Green Shale Formation. Along this stratigraphic contact, the course of the Casimcea River has insinuated itself, more active during cold, glacial periods of the Quaternary (Chitea, 2011). From a geomorphological perspective, the studied objective is situated on the "complex barrier beach" (barrier beach) of Taşaul - Corbu, which extends southward to the Mamaia complex barrier beach.

2. Aspects of historical hydrocarbon contamination in the Petromidia refinery area

The pollution phenomenon with petroleum products from industrial areas related to the extraction, transportation, and processing of oil in Romania, noted in the last 40 years, especially through its harmful effects on the quality of some drinking and surface water sources, as well as on the productivity of soil in some agricultural lands, has been the subject of special research initiated in the 1960s.
These studies were prioritized through hydrogeological and geophysical investigations conducted in the vicinity of refineries and fuel transportation pipelines by ISPIF Bucharest and the University of Bucharest starting from 1975.
The contamination with hydrocarbons of land, groundwater, and surface water near major pollution sources (refineries, fuel depots, oil and fuel transportation pipelines, oil extraction rigs, petroleum residue ponds, etc.) represents one of the largest and most challenging environmental protection issues in Romania (Paraschiv, 1979).

The placement near Navodari city of the country's most important sources of petroleum pollution (the Petromidia refinery, petroleum and fuel depots, and petroleum product transportation pipelines) makes this area the subject of numerous research endeavours and the primary motivation for selecting this perimeter for implementing hydro-geophysical research (Figure 1).

Figure 1. Petromidia refinery

The pollution sources in the Petromidia refinery area are classified as follows:
- systematic losses of petroleum products in the technological processes of extraction, transportation, and storage;
- accidental losses of petroleum products in the transportation and refining processes (explosions, fires, pipeline corrosion, earthquakes, technical accidents, pipeline breakages for fuel theft);
- slow leaks of products through cracks in pipelines, tanks, ponds, basins, sewers;
- losses of petroleum products during long-distance transportation of pollutants through watercourses, rainwater, and wind.

The migration of hydrocarbons, immiscible with water, occurs in two ways:
a) In unsaturated conditions, under the influence of gravity and meteoric waters (within refinery);
b) In saturated conditions, at the surface of groundwater in the form of a laminar contamination plume, laterally advancing in the direction of groundwater flow (outside refinery, in the direction of groundwater flow).
An example of contamination in saturated conditions at the level of the groundwater table is represented by the area southeast of the Petrobrazi refinery, where the boundary of the spread of groundwater contamination with petroleum products covered an area of approximately 11 km^2 in January 1981, separated into two distinct sectors according to the degree of pollution:
A central sector, affected by intense pollution, with significant concentrations of pollutants in the form of a lens-shaped layer above the groundwater, ranging from 1 cm to 5 m in thickness, predominantly spreading within the refinery premises and extending south-eastward

to approximately 2.5 km away; A sector with reduced pollution, with thin films, iridescence, or a specific petroleum smell in the groundwater, with the boundary located approximately 3.5 km from the refinery. In the Petromidia refinery case, the depths of the petroleum layer were frequently recorded at values of 2-6 m and are variable over time, depending on the vertical oscillation of local groundwater levels. The general propagation direction of the petroleum pollution front is similar to that of the predominant groundwater flow (NW - SE), but the advancement speed differs from that of water, being slower in the case of petroleum pollutants due to the different physical-mechanical characteristics (higher viscosity and adhesion of petroleum products) and the specific horizontal and vertical migration mechanism of petroleum products (depending on the action of capillary forces in the porous medium).

3. Geoelectric detection of hydrocarbon contamination

The use of various geoelectrical techniques for detecting underground hydrocarbon pollution is an efficient and non-invasive method for soil investigation in search of contamination. Among these techniques are VES (Vertical Electrical Sounding), IP (Induced Polarization), ERT (Electrical Resistivity Tomography), and GPR (Ground Penetrating Radar). Measurements of VES (Vertical Electrical Sounding) conducted with instruments such as AGI MINISTING (Figure 2) is extremely useful in identifying zones of hydrocarbon contamination.

VES involves measuring the electrical resistance of the soil in a vertical manner, allowing for the determination of the vertical distribution of the electrical properties of the subsurface. These techniques are particularly effective when placed on profiles that traverse areas of interest, such as refineries or other potential sources of hydrocarbon pollution.

By combining data obtained from various geoelectrical techniques, a more comprehensive picture of the distribution and characteristics of subsurface contamination can be obtained, which can better guide strategies for remediation and environmental monitoring (Greenhouse, 1993).

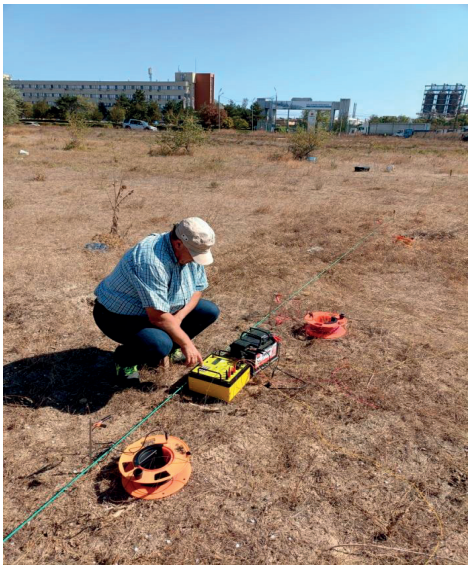

Figure 2. Geoelectric data acquisition using Ministing system from AGI

The observation data has been processed and interpreted using specialized software such as Res_2DInv, EarthImager, as well as programs developed by the research team members. Analysing the curves of the vertical electrical soundings conducted in the area of the four refineries, it was observed that from a geoelectric standpoint, two main modes of electrical resistivity distribution in depth can be distinguished in the investigated region (Figure 3):

- VES curves representative of type H (for example-yellow colour) in the northeastern area, where the Petromidia refinery is located;
- VES curves representative of type K (for example-blue colour) in the southwestern area, where the Petromidia refinery is located.

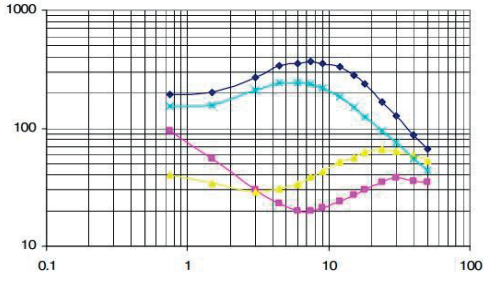

Figure 3. Representative VES curves

The main difference between the two separately identified sectors, with distinct variations in electrical resistivity, lies in the presence of a clay layer electrically conductive at the upper part of the geological structure in the northeastern part of investigated area (type H VES curves), a layer absent in the south-western part of investigated area (type K VES curves). The mentioned clay layer, intercepted in shallow boreholes, largely protects the northeastern area, with hydrocarbon contamination significantly lower compared to the southwestern area. The rapid increase in electrical resistivity in the electrical soundings conducted in the investigated area is due to the presence at shallow depths (1.5-4 m) of the resistive layer containing the pollutant film and geological formations impregnated with petroleum products. The processing and quantitative interpretation of VES data have resulted in obtaining resistivity sections down to a depth of 4 meters along the profiles in the investigated areas. The outlined anomalies of maximum resistivity (Figure 4 - red colour) illustrate the presence of hydrocarbon contamination plumes at depth.

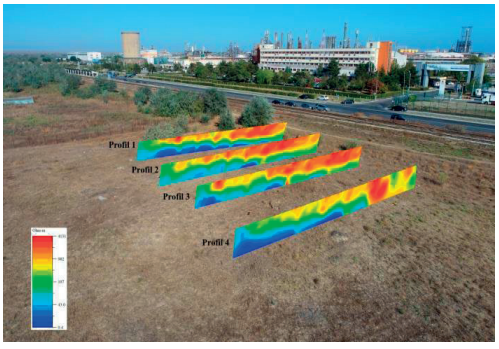

Figure 4. Apparent resistivity sections - Perimeter I

Figure 4 shows the distribution of electrical resistivity along profiles I, II, III and IV (Perimeter I), which traverses the north-south direction of the pollution zone associated with the Petromidia refinery. The elongated anomaly of maximum resistivity located at depths of 1.5-3 meters is interpreted as being due to the presence of the hydrocarbon contamination plume located at the aquifer's surface. Interruptions or variations in the thickness of the resistive layer are interpreted as being caused by variations in the compaction of the contaminated gravel (Berkowitz, 2008).

The thickness of the resistive layer (Figure 4– red colour), greater than the contaminant film at the aquifer's surface, also includes that of the gravel impregnated with hydrocarbons during seasonal variations in the hydrostatic level (historical contamination). The interpretation of these resistivity anomalies was supported by direct information from recently executed hydrogeological boreholes and from artisanal excavations present in the immediate vicinity of the investigated perimeters (McNeill, 1980).

In order to obtain detailed information on the distribution of resistivity in depth in areas significant for understanding the relationships between the contaminant and the polluted geological environment, VES measurements were conducted on Perimeter II (Figure 5).

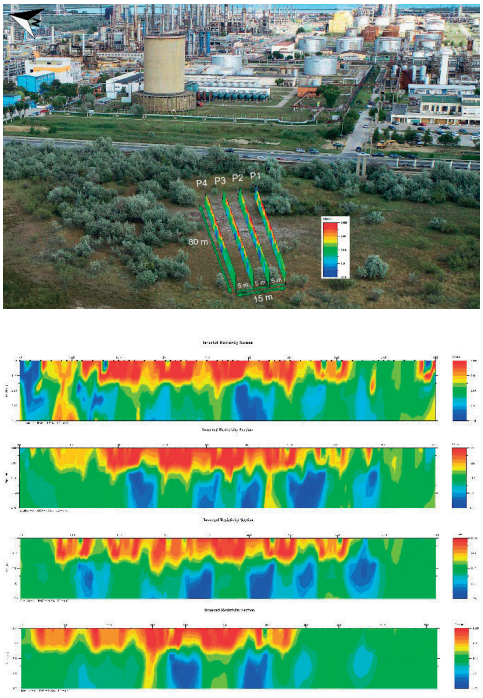

Figure 5. Apparent resistivity sections-Perimeter II

The electrical resistivity section obtained down to a depth of 4 meters illustrates details of anomalies of maximum resistivity associated with the hydrocarbon contamination plume on each profile. Variations in the intensity of resistivity anomalies can be interpreted as

variations in contaminant concentration, while interruptions in the major resistivity maximum anomaly can be attributed to the effects of local tectonic accidents.

4. Georadar detection of hydrocarbon contamination

The georadar investigation at the Petromidia refinery in the southeastern sector revealed some interesting findings. The underground limit interpreted as the water table suggests the presence of groundwater at that depth. Additionally, the zones of weak electromagnetic signal could indicate the presence of a hydrocarbon plume within the upper aquifer. This suggests the possibility of hydrocarbon contamination in the groundwater, which is a concern for environmental and remediation efforts. Further investigation and monitoring would likely be necessary to assess the extent of the contamination and develop appropriate mitigation measures (Fuente, 2021).

In the Petromidia refinery area, 10 longitudinal profiles and 6 transverse profiles were continuously recorded using a 100 MHz antenna (Figure 6).

The analysis of the recordings on the longitudinal profiles shows the existence of a well-defined geophysical boundary located at 0.75 m (Figure 7). The detected interface is practically continuous along the entire length of the measurement profiles. Correlating these observations with archive data obtained from previous boreholes, the following values for velocity and permittivity are obtained:

- a velocity of 6.5-7.6 cm/ns for the medium above the first georadar limit, considering this interface as the water level;
- the permittivity varies in the range of 15.58-21.30 (Kapicka, 1997).

Considering that the permittivity of a sandy medium saturated with water is around 25, and the reflection sign is negative, we can conclude that the interface encountered at 0.75 m (Figure 7) is due to the level of petroleum product. Electric permittivity (or dielectric constant) is a quantity, denoted by ε, which indicates the resistance to electric polarization of a dielectric material (Tezkan, 2005).

In practice, a dimensionless quantity expressed by the ratio of the permittivity of a medium to that of vacuum is used. The groundwater level is located at depths of 1.5-2 m. Below the first detected georadar limit, the value of electromagnetic wave velocity decreases due to the presence of water in the propagation medium. By decreasing the velocity, the travel time of the wave increases.

Areas where reflection coefficients have high values and do not allow the delimitation of a reference radar horizon have been interpreted as being due to hydrocarbon intrusions (yellow zones - Figure 8).

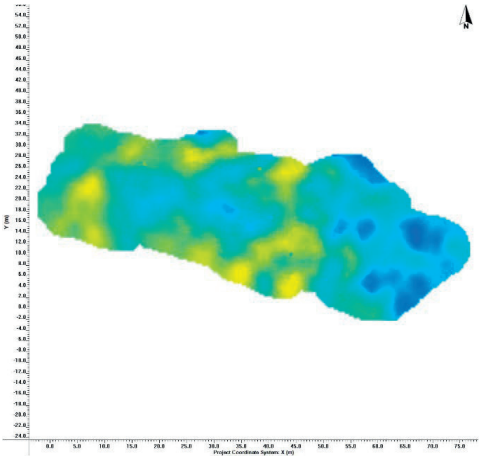

Figure 8. Georadar section

RESULTS AND DISCUSSIONS

Geophysical monitoring of the temporal and spatial evolution of hydrocarbon contamination plumes has been studied in the Petromidia refinery area. The hydrocarbon contamination plume, resulting from the temporal overlay of historical contamination with current contamination, is largely influenced by the regional dynamics of the aquifer. Geoelectrical VES measurements conducted for monitoring has investigated the central part of perimeter I and II.

The results of monitoring measurements were analysed in the form of resistivity pseudo sections to avoid disturbances caused by quantitative interpretation programs. The observed changes in resistivity during monitoring, considered for interpretation, are due to variations in moisture in surface layers (soil, paleosol, loess), fluctuations in the water table level, and some quantities of pollutants recently introduced into the geological environment in the refinery area (Figures 3, 4 and 5). The fragmentation of the major resistivity maximum anomaly is due to active processes of surface water infiltration along a fault system, which affects the geological structure and the soil layer (Figures 3, 4 and 5).

The results obtained from the georadar investigation were presented in the form of radargrams or depth sections, which can highlight geological structures at shallow depths, including the localization of tectonic features with local significance, as well as the delineation between hydrocarbon-saturated and unsaturated zones (Manescu, 1994).

CONCLUSIONS

The results of geophysical investigations dedicated to the detection and monitoring of hydrocarbon contamination plumes near the Petromidia refinery have shown that VES geoelectrical resistivity measurements are the most effective. Elongated anomalies of maximum electrical resistivity, located at depths where the first aquifer is localized, illustrate the presence of contamination plumes due to the hydrocarbon film and the geological environment impregnated with contaminants during seasonal variations in the water table level. Interruptions in the maximum resistivity anomalies are due to variations in the compaction of gravel or local tectonic accidents. The geoelectric monitoring of hydrocarbon contamination plumes was conducted using vertical electrical soundings, through the sequential analysis of resistivity pseudo sections. The geoelectric effect of hydrocarbon contamination is evident even under significantly different seasonal climatic variations, with the maximum resistivity anomaly determined by the presence of hydrocarbons being well delineated through repeated geophysical measurements.

This resilience in detection is particularly significant in delineating the maximum resistivity anomaly associated with subsurface hydrocarbon contamination (Allred, 2010). Repeated geophysical measurements serve as a reliable tool in accurately mapping out these anomalies, aiding in the assessment and management of hydrocarbon contamination in diverse environmental conditions. It's interesting to hear that geophysical investigations near the Petromidia refinery have identified VES (Vertical Electrical Sounding) geoelectrical resistivity measurements as the most effective method for detecting and monitoring hydrocarbon contamination plumes. Geophysical methods play a crucial role in environmental studies, especially when dealing with issues such as pollution and contamination. VES involves measuring the electrical resistivity of subsurface materials at different depths using a vertical electrode array. In the context of hydrocarbon contamination, variations in resistivity can be indicative of changes in the subsurface caused by the presence of hydrocarbons (Vafidis et al., 2014). Here are some reasons why VES geoelectrical resistivity measurements might be effective in this scenario:

Contrast in Resistivity - hydrocarbons generally have a lower electrical resistivity than the surrounding soil or rock. This contrast allows for the detection of hydrocarbon plumes in the subsurface.

Depth Profiling - VES provides information at different depths, allowing for a vertical profile of subsurface resistivity. This can help in understanding the depth and extent of the contamination plumes.

Spatial Resolution - VES can offer good spatial resolution, helping to map the lateral extent of contamination. This information is crucial for effective remediation strategies.
Cost-Effectiveness - compared to some other geophysical methods, VES can be relatively cost-effective, making it a practical choice for large-scale monitoring projects.
Non-Invasive Nature - geoelectrical methods are non-invasive, meaning they don't require drilling or excavation. This minimizes disturbance to the site and provides a more environmentally friendly approach.
Real-Time Monitoring - VES measurements can be conducted periodically, allowing for real-time monitoring of changes in subsurface resistivity. This is important for tracking the dynamic nature of contamination plumes.
It's essential to note that the effectiveness of geophysical methods can vary based on site-specific conditions. Additionally, integrating multiple geophysical techniques can provide a more comprehensive understanding of subsurface conditions.
If VES has proven to be the most effective in this case, it demonstrates the importance of selecting the right geophysical tools for the specific challenges posed by hydrocarbon contamination near the Petromidia refinery. The GPR data was obtained using a NOGGIN system with 100, 250, and 500 MHz antennas. The 100 and 250 MHz antennas provided the best results in terms of spatial resolution and depth, while the shallow groundwater level provided excellent conditions for GPR.

Abstract

The sediment movement on a river plays a crucial role in safe navigation and economic activities on navigable channels. Environmental changes in time are given by the morphological characteristics of the riverbed during seasonal water variation on the Danube River. This study presents a comprehensive assessment of the Danube River`s velocity and current characteristics based on Acoustic Doppler Current Profiler measurements. The correlation between flow velocities and depths helps to understand the factors that influence sediment patterns and provides insights into the sustainable management of the river system. The study was conducted along a 71-kilometer length of the Sulina Branch from the Danube River, where ADCP measurements were collected at multiple locations and over periods. The data collected included water depth, flow velocity, and current direction. By clustering the column depth cell velocities it revealed significant spatial and temporal variations in the velocity and current patterns, influenced by factors such as river morphology, discharge, and seasonal changes.

Key words*: ADCP survey, currents direction, Danube discharge, hydro-morphology, water flow velocities.*

INTRODUCTION

The Danube River divides into 2 branches at Patlageanca Village. Chilia - the first branch, flows in the North-East direction. The second one flows to the East, and after at, the Tulcea city is divided into two other branches, Sulina respectively Sfantu Gheorghe (Figure 1).

The Sulina branch is the main waterway of Romania, for the ships with a maximum 7.01 m ± 10-15 cm draught, from the Black Sea up to Braila city (Cociasu et al., 1996; Giosan et al., 2006; Kuhl, 1891).

The rectification of the Sulina arm was carried out during the 1868-1902 period, shortened this branch by about 25% (83.8 km before the cut-offs and only 69 km today) (Cociasu et al., 1996; Giosan et al., 2006; Kuhl, 1891; Panin & Jipa, 1998).

This cut-off program induced a redistribution of water and sediment discharge among the delta distributaries.

The Sulina discharge increased from 7-9% up to 16-17% in 1921 and to about 18-20% of the total Danube discharge at present (Panin & Jipa, 1998).

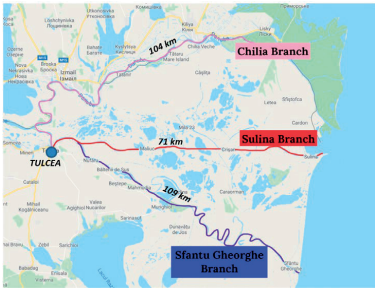

Figure 1. The main branches of the Danube River

The Sulina Channel, one of the branches of the Danube River, has specific dimensions: a length of 71 kilometers, a maximum width of 50 meters, a maximum depth of 18 meters, and a minimum depth of 7.32 meters (Banescu et al., 2020a). This arm of the Danube has been regulated and channelized, allowing for maritime navigation of seagoing vessels with a draft of up to 7 meters. The maintenance and

management of this waterway fall under the responsibility of the Lower Danube River Administration (AFDJ), based in Galati, the largest city along the Romanian stretch of the Danube. It is noteworthy that the Sulina Channel, also referred to as the Sulina arm, is the shortest and most direct branch of the Danube, flowing directly into the Black Sea near the town of Sulina. Sulina is the easternmost settlement within the European Community.

The Sulina branch carries a significant amount of sediment, particularly during flood events, which can lead to the deposition and accumulation of sediments Danube Delta. Sediment transport and deposition in the Sulina Channel can affect water depths and navigation channels, necessitating periodic dredging operations to maintain the required depths for maritime traffic. The management of sediment transport and dredging activities in the Sulina Channel is crucial for maintaining navigation and preventing potential blockages or shallow areas that could hinder vessel movement. Monitoring and modeling of sediment transport patterns, as well as implementing appropriate sediment management strategies, are essential for the sustainable management of the Sulina Channel and the Danube Delta region.

At the same time, the sediment deposition influences the stock of heavy metals on the Danube River (Popa et al., 2018; Teodorof et al., 2021). According to Lazăr (2024), the heavy metals from sediments and water in the Danube River are ingested directly by biota, especially in the *Alosa immaculata* fish. According to the study conducted by Burada (2015), hydro-morphological parameters are important for identifying the areas where the speed of flow currents decreases because sedimentation increases in these areas, and with it the accumulation of pollutants (heavy metals) also occurs. This suggests that the morphology of the riverbed and the hydrodynamics of the river are key factors in identifying areas vulnerable to contamination, and can be achieved by accurate ADCP measurements.

The present study aims to investigate the relationship between hydro-morphological parameters surveyed on the Sulina branch from the Danube River. The physical characteristics and dynamic parameters help to understand the patterns of erosion, underwater forms, and turbulence in the study area.

STUDY AREA

The study area is focused on the Sulina branch of the Danube River. There are 6 points of observation. Each of them is located downstream of Partizani, Maliuc, Gorgova, Crisan, and Sulina villages (Figure 2), and one at an intermediate point between Crisan and Sulina.

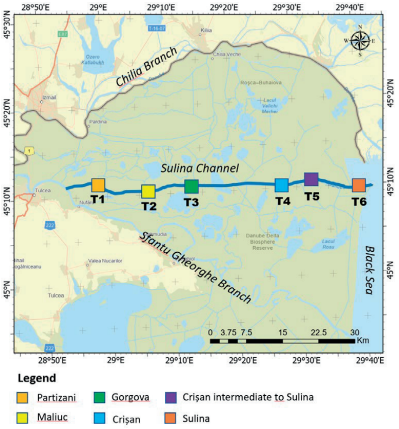

Figure 2. Study area map located on the Sulina navigable channel from the Danube Delta area

The points labeled T1 through T6 mark specific cross-sections where Acoustic Doppler Current Profiler (ADCP) data are collected. These six cross-sections are conveniently located along one of the main tributaries of the Danube River, the Sulina arm.

The corresponding ADCP cross-sections measured in July 2023 and August 2023 from this transects are crucial to understanding how riverine discharge, velocity profiles, and sediment deposition are influenced across the river continuum, particularly in the tidal junction near the mouth of the river (Banescu et al., 2020b; Pomázi & Baranya, 2025).

MATERIALS AND METHODS

To better understand the flow dynamics of the Sulina channel, which is an arm supposed to hydrotechnical development works, it is important to measure the hydro-morphological

parameters in different hydrological periods of the channel.

Thus, we can assess whether sediments are transported from one section to another. Along with the transport of sediments, the minor channel bed is also modified, but also their deposition by favouring the increase in the surface area of the Danube Delta.

To obtain a detailed picture of the hydro-morphological parameters on the Sulina branch, several measurement campaigns were carried out. These aimed to evaluate the spatial and temporal variability of current speeds and flows, essential information for determining the sediment transport regime. Within these campaigns, ADCP (Acoustic Doppler Current Profiler) technology was used, a modern instrument for measuring water current speeds in three dimensions, at different depths (Figure 3). The device used was the RiverSurveyor M9 model produced by SonTek, a high-performance equipment designed specifically for river measurements.

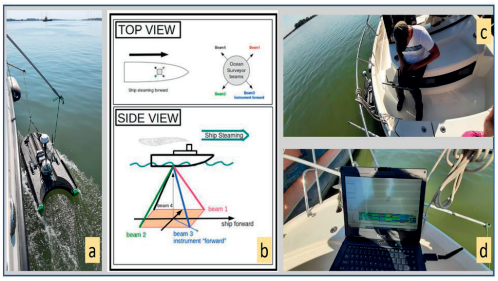

Figure 3. The Sontek M9 ADCP work principle: a - mounting on a moving boat; b - beam spread principle (Deogade et al., 2023); c, d - main setting applying and real-time display data

The ADCP works based on the Doppler effect: it emits sound waves in the water, which, when reflected from suspended particles, change their frequency according to the relative motion of these particles. By analyzing this frequency change, the instrument can calculate the speed of the current in different layers of the water column, according to equation 1 (Liu et al., 2024).

$$v = (\Delta f \times c) / (2 \times f_0 \times cos(\theta)) \quad (1)$$

where:

- v represents particle (water current) velocity in the direction of the sound beam [m/s];
- Δf represents Doppler frequency difference (f_r - f_0), i.e. the difference between speed of sound in water (approximately 1500 m/s);
- c represents frequency of the signal emitted by the ADCP [Hz];
- θ - angle between the acoustic beam and the vertical direction.

In addition to the basic hydromorphological parameters measured, it is important to determine the energy in each flow section. The calculation of the current energy (or kinetic energy of flowing water) in a section measured with an ADCP is based on the application of fluid mechanics principles, in particular the formula for the kinetic energy of a volume of water moving at a given speed. Equation 2 represents the calculation of the energy flow on a river cross-section measured with ADCP equipment (Guseva et al., 2021).

$$E = \frac{1}{2} \cdot \rho \cdot Q \cdot v^2 \quad (2)$$

where:

- E represents current energy (mechanical power) [W – watts, i.e. J/s];
- ρ represents water density [kg/m³] (usually ≈ 1000 kg/m³ for fresh water);
- Q represents water volume flow or disgharge [m³/s], obtained directly from ADCP data;
- v represents average current velocity [m/s], measured by ADCP.

RESULTS AND DISCUSSIONS

The monitoring of sediment transport comprises suspended sediments, a well as bedload. To understand, to assess, and to give potential solutions for sediment-related problems in the Danube River, especially on the Sulina Branch, the amount of transported sediments, varying both in time and space, has to be known. For this purpose, ADCP cross-sections are measured during two different campaigns, in July and August 2023. The results of ADCP cross-sections at T1 to T6 monitoring points are represented in Figure 4.

The ADCP measurement from both survey campaigns shows a well-distributed water velocity in the middle of the cross-section. The water velocity decreases near the left and right banks in all cases.

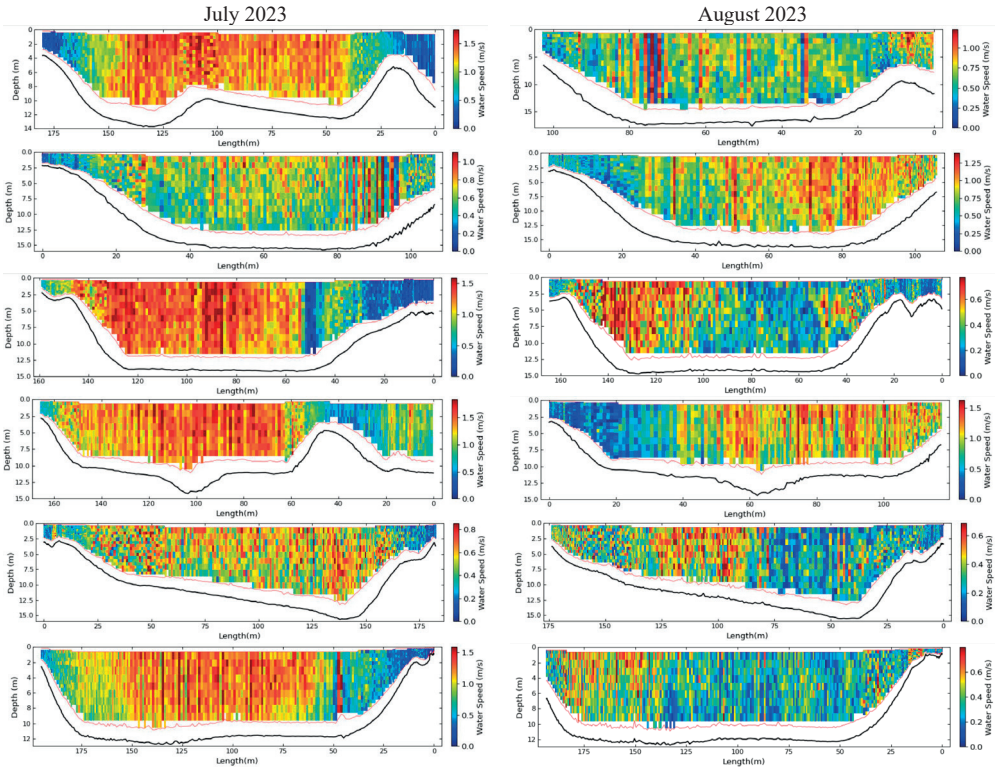

Figure 4. The ADCP velocity representation on the T1 to T6 cross-section

The maximum of 1.13 m/s water velocity was recorded at T1 section in July 2023, and 0.988 m/s at T2 section in the August campaign.

Figures 5 and 6 highlight a vector representation of the flow currents in the cross-sections T1-T6. The orientation or angle of inclination of the black vectors indicates the flow currents' direction, and the length of the vectors shows the intensity of the flow currents.

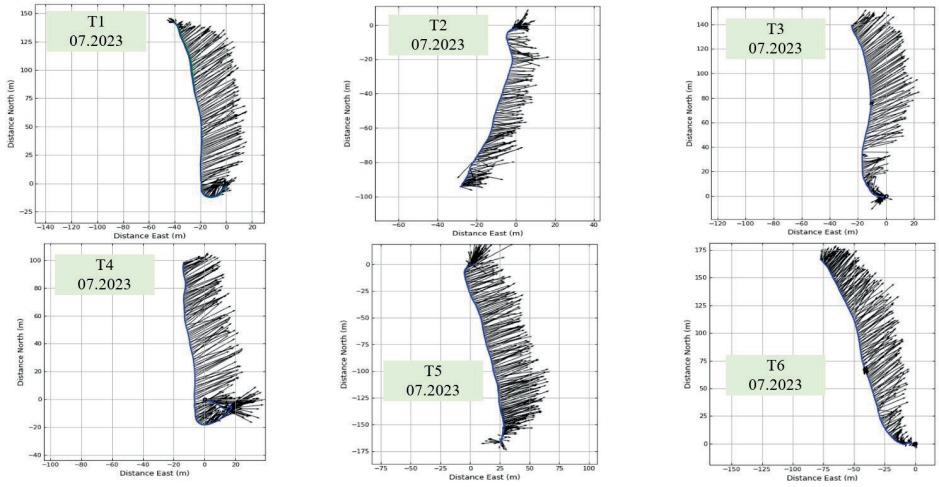

Figure 5. Comparison of flow patterns, directions, and intensities of currents for the July survey across T1-T6 transects

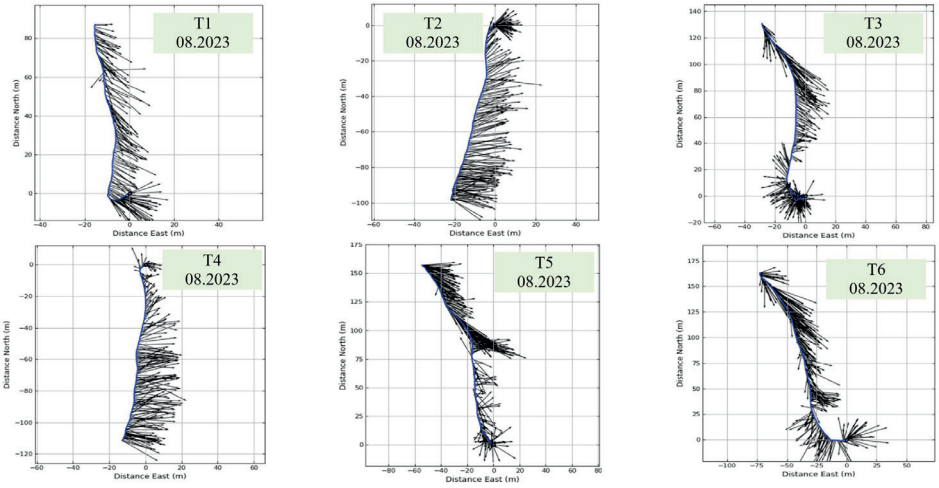

Figure 6. Comparison of flow patterns, directions, and intensities of currents for the August survey across T1-T6 transects

If we analyse the data in the context of the riverbed morphology of the Sulina channel, we can mention that in the sections T3 and T4, we have a series of eddy currents that favor the engagement of sediments in the water suspension and their transport from upstream to downstream.

Figure 7 shows a decrease in water velocity downstream of the Sulina channel. Compared to discharges, it can be mentioned that these parameters are influenced directly by water velocity.

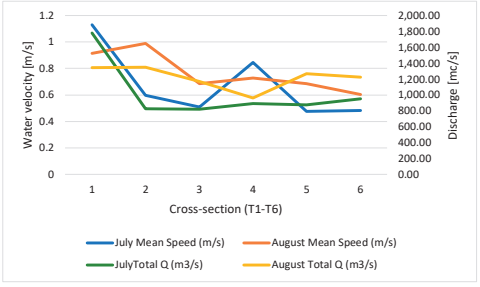

Figure 7. The water velocity average values in each cross-section are compared to the total discharge at two different survey times

The calculated energy values increase from upstream to downstream of the river, and it is higher for the August survey campaign when the discharges are also higher (Figure 8).

In the assumption that the sediment suspended concentration is calculated by Equation 3, the total suspended sediment concentration (SSC) on each vertical profile from each cross-section was calculated (Boldt, 2015).

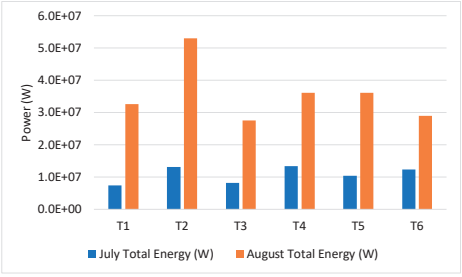

Figure 8. The total energy power of T1 to T6 cross-section

$$log_{10}(SSC) = log_{10}(a \cdot 10^{b \cdot DB}) \quad (3)$$

The a=0.005, and b=0.01 are the coefficients averaged from different scientific sources, related to Danube River SSC values. According to Baranya and Józsa (2013), in the Danube River, a 125 mg/l average SSC was measured. The SSC estimated from the SWAT method in the Danube River Basin by Vigiak (2017) was about 80 mg/l.

Between the T1 and T6 transects in July 2023, significant variations in the SSC values are given across transect length (Figure 9).

In the T1, T2, and T5 sections, where the currents are stronger, the average SSC is: 53.5 mg/l, 69.7 mg/l, and 50.8 mg/l,

respectively. This suggests a higher transport of sediment from one section to another.

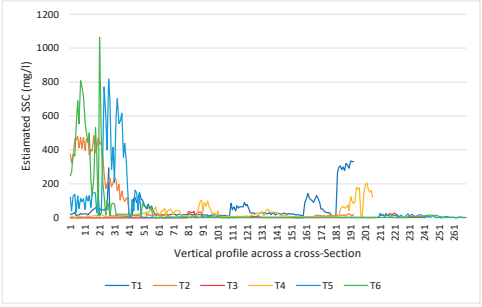

Figure 9. Suspended sediment concentration estimation based on backscatter signal (dB) on the July 2023 survey

In section T6, with the maximum value of SSC concentrations of 1064.59 mg/l, it is demonstrated that all sediments are transported downstream to the mouth of the Black Sea, more precisely, the "Bara Sulina" area.
Analyzing Figure 10, we observe an increase in the SSC value for transects T5 and T6.

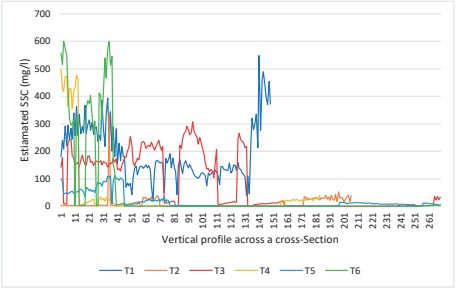

Figure 10. Suspended sediment concentration estimation based on backscatter signal (dB) on the August 2023 survey

These only confirm the fact that the sediments are transported in large quantities downstream in the area of Sulina, where the intensity of the current gradually decreases and their storage takes place. In section T1, the highest mean value of the EFS of 193.2 mg/l and a high standard deviation (100.1 mg/l) were estimated. This denotes the fact that the hydrodynamic conditions in this area are varied and with strong suspended sediment entrainment. In the T6 section, the maximum of 941.5 mg/l suggests the presence of intense sedimentary accumulation events.

CONCLUSIONS

The research study carried out for the monitoring of flow currents by the ADCP method helps to determine the phenomenon of sediment transport in fluvial environments.
The high values of the SSC concentration in July 2023 (1064.5 mg/l) and August 2023 (941.4 mg/l) in section T6 show the presence of sediment transport processes towards the confluence with the Black Sea, and their deposition in the "Bara Sulina" area.
The hydrodynamic parameter E (energy), increased in value especially in August 2023, in the upstream sections T1 (3.3×10^7 W) and T2 (5.3×10^7 W), and decreased in value in the T6 section in both months, indicates the erosion trend from upstream to downstream.
Applying the method of estimating the SSC from the backscattering of the ADCP signal, we concluded that the largest amounts of sediments are in the downstream area of the Sulina channel.
The effect of sediment transport from upstream to downstream only increases the clogging of the Sulina channel at the confluence with the Black Sea. Thus, continuous monitoring and investigation of currents and flow velocities by the ADCP method is mandatory. The ADCP and SSC estimation method offers an integrated approach to measuring hydro-morphological parameters and correlating with sediment transport processes, helping to plan hydrotechnical maintenance works and emergency interventions on the maritime-river navigation infrastructure in the respective area.

ACKNOWLEDGEMENTS

The studies based on which this work was carried out were carried out within the project 101094070 - DALIA - Danube Region Water Lighthouse Action, HORIZON-MISS-2021-OCEAN-02-02, implemented in the REXDAN Research Infrastructure.

Abstract

Sludge from sewage treatment plants is a byproduct of wastewater treatment processes, consisting of solid particles, microorganisms, and organic and inorganic substances. It is generated during sedimentation and digestion processes to remove contaminants such as organic matter, heavy metals, and chemicals from water. Before storage or disposal, sludge is typically treated to reduce its volume and eliminate pathogens. Standard treatment methods include dehydration, biological stabilization, and incineration. Depending on its composition, treated sludge can be repurposed for agricultural use as fertilizer, provided it meets strict regulatory standards to prevent soil and groundwater contamination. In Romania, sewage sludge is generally classified as waste under European and national legislation. According to the European Union Waste Directive 2008/98/EC, sludge is considered waste if it cannot be safely treated, recovered, or reused. Studies have explored its potential environmental risks, including soil contamination and its suitability as a fertilizer. This article presents a structural sludge analysis, focusing on its physicochemical properties and moisture content. Experiments were conducted to evaluate the behavior of sludge samples under varying temperatures, exposure durations, and drying conditions. Results showed that evaporation rates increased with temperature, with significant differences observed between ventilated and non-ventilated drying environments. At temperatures ranging from 50°C to 100°C, sludge mass consistently decreased, with the lowest masses recorded in ventilated drying processes at 100°C. In non-ventilated conditions, the percentage of evaporation increased progressively with prolonged heat treatment. Additionally, heavy metal concentrations in the sludge were experimentally determined and found to be below the limits imposed by national legislation. These results confirm that the analyzed sludge samples are suitable for agricultural use, aligning with regulatory requirements.

Key words*: chemical composition, heavy metals, sludge, unventilated currying, ventilated heat currying.*

INTRODUCTION

During the pre-accession period to the European Union (EU), various strategies for sludge management were formulated, though their execution differed among countries. A primary strategy involved aligning national legislation with EU directives, specifically the Urban Wastewater Treatment Directive (91/271/EEC) and the Sewage Sludge Directive (86/278/EEC), which set forth regulations for sludge treatment, monitoring, and land application (Council of the European Communities, 1991; Council of the European Communities, 1986). Simultaneously, investments were directed towards enhancing wastewater treatment infrastructure to upgrade facilities and optimize sludge handling processes. Various disposal and valorisation strategies have been investigated in light of the rising sludge production. Land application in agriculture is advocated as a sustainable practice, contingent upon the sludge adhering to strict criteria concerning heavy metal levels

and pathogen reduction (Fytili & Zabaniotou, 2008). Due to constrained treatment capacities, numerous countries have opted for landfilling or temporary storage, contrary to the EU's long-term goal of minimizing sludge disposal in landfills. Composting and co-composting are promoted as methods for transforming sludge into a beneficial soil amendment for agricultural, landscaping, and land reclamation purposes (Smith, 2009). The exploration of anaerobic digestion as a method for reducing sludge volume and generating biogas for renewable energy production was initiated. However, the adoption of this technology was limited at that time (Yaser et al., 2022). In addition to these technical strategies, public awareness campaigns and institutional capacity-building initiatives were launched to inform stakeholders, such as municipalities, farmers, and industries, about the safe and effective management of sludge (Benedetti et al., 2008; Vinayagam et al., 2024). The initial strategies established a foundation for developing more sophisticated sludge management policies after EU accession. Thus, only 0.2% of the sludge was used on agricultural land (Ministerul Mediului și Pădurilor, Direcția Generală AM POS Mediu, 2011).

Accumulated sewage sludge is essentially wet matter, which can currently be stored on special platforms equipped with drainage systems or directly on the ground (Qasim & Shareefdeen, 2022), subsequently finding a solution to remove it, to make room for another amount of sludge, or it can be used in some branches of agriculture, to improve the quality of soils, through the content of phosphorus and nitrogen (Shi et al., 2021).

Sludge recovery is not the main objective of the urban wastewater treatment process. Still, it should be considered as a means of removing sludge from the treatment plant area without having a negative impact on the environment. Therefore, it is crucial to balance the amount of sludge generated and recovered through effective sludge management (Andreoli et al., 2015).

Unfortunately, significant amounts of dewatered sewage sludge are stored in improper conditions, causing the sludge to become a source of pollution (Iacob & Deac, 2021).

The peculiarities of the circular economy (CE) in the management of municipal wastewater and sewage sludge in the specific context of local conditions, such as those in Poland, were analyzed by Kacprzak (Kacprzak & Kupich, 2021) and Lipińska (Lipińska, 2018), with a focus on clean and ecological technologies. From the perspective of the circular economy, in addition to the recovery, collection, and use of biogas as an energy source, the recovery of materials resulting from the purification process, such as gravel, or the extraction of phosphorus from sludge or ash (piles) can also be considered (Domini et al., 2022).

Russian Federation researchers conducted a preliminary assessment of the possible uses of biogas from sewage sludge in the Water - Wastewater - Sludge and Circular Economy sector. They used a computational model for biogas and biomethane, MCBioCH$_4$, comparing the results with laboratory tests on sewage sludge fermentation (Kiselev et al., 2019).

Bratina et al. (2016) carried out a study in which it presented a method of drying the sludge in a vacuum at low temperatures, as well as treating the sludge by reducing heavy metals with nanoparticles covered with chitosan.

MATERIALS AND METHODS

To analyze the influence of temperature on the drying of dewatered sludge under different ventilation conditions, 14 sludge samples were collected from the sewage treatment plant in the Municipality of Arad. They were dried in an oven and weighed at regular intervals. The purpose of the determinations was to evaluate the efficiency of the drying process according to its duration. As part of the experiment, tests were carried out using sludge samples with known moisture, exposed to drying for different periods. The drying time was divided into three intervals: 30 minutes, 60 minutes, and 100 minutes.

To study the evaporation phenomenon in more detail, the impact of temperature on the drying process of dewatered sludge was also investigated, using two distinct temperatures: 50°C and 100°C. Before and after drying, the samples were weighed using Petri dishes and a

high-precision analytical balance Kern Adb 100-4. After measuring the initial mass of the dewatered sludge samples (m_1) and the final mass (m_2) after drying, the degree of evaporation (GE) was calculated, which represents the evaporated mass concentration, expressed as a percentage (Olsson & Newell, 2015), which was later used to evaluate the degree of evaporation of the sludge samples analyzed in this research using the calculation formula:

$$GE = ((m_1 - m_2) / m_1)) \cdot 100\ [\%] \quad (1)$$

Experiments were conducted under both ventilated and unventilated conditions to assess the impact of airflow on the drying process. Additionally, heavy metal content was determined using flame and electrothermal atomic absorption spectrometry (FAAS/ETAAS) to evaluate the potential environmental risks associated with sludge re-use (ISO 11047:1998).

The collected sludge was subjected to a physicochemical analysis to check if the samples meet the necessary parameters for use in other fields, according to the requirements established in the experimental research.

RESULTS AND DISCUSSIONS

The dehydrated sludge at 50°C under unventilated conditions

To carry out the experiments in non-ventilated conditions of the drying space, three of the 14 samples taken and prepared by weighing will be used. Sampling was performed in duplicate, and the estimated value is the average of the two measurements. Dewatered sludge with a solids (SS) content of 22% was the source from which the samples were selected for the experiments. The three samples will be introduced simultaneously into the drying space at a temperature of 50°C. Samples will be drawn at 30, 60, and 100 minute intervals. After each draw, the samples will be weighed immediately to determine the percentage of water evaporated.

It is assumed that all parameters are identical, namely the size of the drying space, the temperature, and the absence of ventilation. Table 1 shows the values obtained by calculation, according to formula (1), for the three samples subjected to drying in a non-ventilated space at 50°C for 30, 60, and 100 minutes.

Table 1. Results for 50°C - unventilated

Time [min]	Initial mass m_1 [g]	Final mass m_2 [g]	Petri dish [g]	Evaporation rate [%]
30	15.32	14.16	36.2	7.57
60	16.12	14.33	36.2	11.10
100	17.23	13.51	36.2	21.59

It can be seen from Table 1 that after 30 minutes, the percentage of humidity decrease is 7.57%. After 60 minutes, the humidity decreases by 11.10%, increasing to 21.59% at a holding time of 100 minutes.

In order to determine the optimal temperature at which sludge drying is effective, another 3 (three) samples from the remaining 11 samples were used.

The dehydrated sludge at 100°C under unventilated conditions

The research was carried out under the same conditions (unventilated closed space), increasing the working temperature from 50°C to 100°C. For this set of experiments, the conditions of the previous experiment were maintained in terms of periods.

The parameter change is only the temperature, which has increased from 50°C to 100°C. In conditions where the workspace is not ventilated, the parameter that influences the degree of evaporation is the temperature, which increases from 50°C to 100°C.

This experiment was done to show how water evaporation is influenced by increasing temperature. The first experiment showed how water evaporation is influenced by holding time to dry. Also, through the graphic representation in the temperature-time coordinates, it is possible to see how the holding time for drying influences the evaporation of water under conditions where the working temperature doubles. The results align with findings from other researchers, who reported that proper air circulation prevents water vapor from recondensing on sludge, enhancing drying efficiency (Santos et al., 2020).

Table 2 shows the values resulting from the calculations according to the calculation formula (1), results obtained for the three samples subjected to drying in a non-ventilated space, at a temperature of 100°C, for time intervals of 30, 60 and 100 minutes.

Table 2. Results for 100°C - unventilated

Time [min]	Initial mass m_1 [g]	Final mass m_2 [g]	Petri dish [g]	Evaporation rate [%]
30	16.32	12.06	36.2	26.10
60	16.58	10.15	36.2	38.78
100	17.05	5.21	36.2	69.44

Table 2 shows that, in the case of the sample subjected to the thermal treatment of 100°C, after 30 minutes, the percentage of moisture decrease is 26.10%. After 60 minutes, the humidity decreases by 38.78%; after 100 minutes, the decrease reaches 69.44%.
The graphical representation in Figure 1 illustrates the evolution of evaporation as the temperature increases from 50°C to 100°C. Thus, water evaporation rises from 7.57% after 30 minutes at 50°C, reaching 21.59% after 100 minutes.

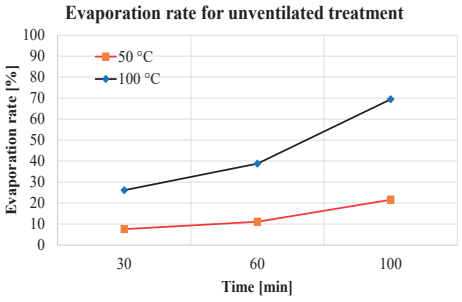

Figure 1. Evaporation rate for unventilated treatment.

The evaporation phenomenon significantly intensifies when the temperature is increased from 50°C to 100°C, reaching 26.10% after 30 minutes and 79.44% after 100 minutes.

The dehydrated sludge at 50°C under ventilation conditions

In order to highlight the influence of ventilation on the drying process, experiments were carried out under the same temperature and time conditions, replacing the non-ventilated drying space with a ventilated one.
The three samples were simultaneously introduced into the drying space at a temperature of 50°C. The first sample was left in the drying space for 30 minutes, the second was dried for 60 minutes, and the third was dried for 100 minutes. After each time interval, each sample was weighed to compare the weight of the dried sample with its weight before drying. The difference in weight was considered equal to the weight of the amount of water evaporated following drying.
Table 3 shows the values obtained by calculation, according to formula (1), for the three samples subjected to drying in a ventilated space at 50°C for 30, 60, and 100 minutes.

Table 3. Results for 50°C - ventilated

Time [min]	Initial mass m_1 [g]	Final mass m_2 [g]	Petri dish [g]	Evaporation rate [%]
30	16.77	13.26	36.2	20.93
60	17.12	10.13	36.2	40.83
100	18.02	7.11	36.2	60.54

Table 3 shows the decrease in humidity after 30 minutes, at a temperature of 50°C, in a ventilated space, by 20.93% for the first sample. After 60 minutes, under the same conditions, the degree of evaporation increases to 40.83%, and after a period of 100 minutes in the drying space, the evaporation reaches 60.54%.
These experiments highlight how the phenomenon of water evaporation from the dewatered sludge is influenced by the holding time, under the conditions of a ventilated drying space, at a temperature of 50°C.

The dehydrated sludge at 100°C under ventilation conditions

The research was conducted under the same conditions (ventilated closed space), but the working temperature increased from 50°C to 100°C. Three other samples were used for the second set of experiments (at a temperature of 100°C).
In these experiments, the conditions of the first set were kept unchanged, the only change being

the temperature increase from 50°C to 100°C. The purpose of these experiments was to highlight how temperature influences the evaporation of water during the heating process.

Table 4 shows the values obtained by calculations, according to formula (1), for the three samples subjected to drying in a ventilated space at a temperature of 100°C for 30, 60, and 100 minutes. The results presented in Table 4 indicate that, under the conditions of drying in a ventilated space, at a temperature of 100°C, the evaporation of water is 47.76% after 30 minutes. After 60 minutes, at the same temperature, the degree of evaporation reaches 62.43%, and after 100 minutes, at a temperature of 100°C, in the ventilated space, the degree of evaporation reaches 78.24%.

Table 4. Results for 100°C - ventilated

Time [min]	Initial mass m_1 [g]	Final mass m_2 [g]	Petri dish [g]	Evaporation rate [%]
30	15.62	8.16	36.2	47.76
60	16.29	6.12	36.2	62.43
100	16.13	3.51	36.2	78.24

Ventilation of the drying space significantly increases the efficiency of the drying process. Figure 2 shows that the drying differences between 50°C and 100°C (which are very large in the case of drying without ventilation) are greatly reduced when using ventilated spaces. Proper ventilation of the space can reduce the drying temperature while maintaining the efficiency of the drying process.

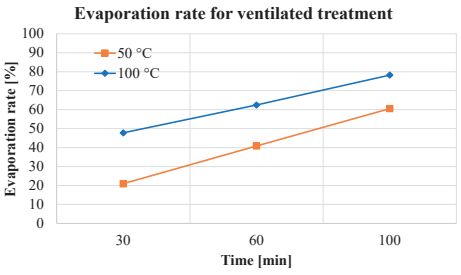

Figure 2. Evaporation rate for ventilated treatment

Interpreting the results offers multiple solutions and combinations of temperatures, drying spaces, and time that can optimize the drying process. One can analyze the degree of increase in evaporation percentage under different temperature conditions and the same time conditions to identify the most efficient settings. The results in Figures 3 and 4 highlight the optimal conditions of time, temperature, and drying space necessary to ensure efficient drying of the dehydrated sludge originating from the wastewater treatment process in the treatment plants.

Moreover, in the case of non-ventilation of the drying space, a progressive increase in the percentage of evaporation was observed, which increased as the heat treatment progressed. This phenomenon suggests that, in the absence of ventilation, the evaporation process continues progressing as the drying time increases, but with a lower efficiency than in ventilated conditions.

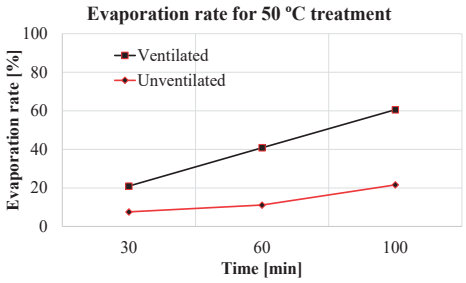

Figure 3. Evaporation rate for 50°C treatment.

The investigated dewatered sludge samples were subjected to a chemical analysis to determine the composition of the elements in the sludge, to identify the presence of heavy metals, which may constitute a risk of environmental pollution (Suciu et al., 2008).

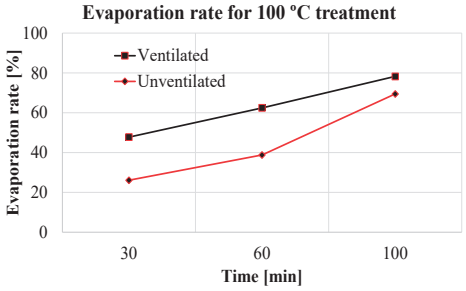

Figure 4. Evaporation rate for 100°C ventilated treatment

The dewatered sludge was chemically analyzed for heavy metals in accordance with ISO 11047:1998.

Table 5 shows the results of the analyses. Chemical: dry matter, organic matter, heavy metals (ISO 11047:1998), total nitrogen (ISO 13878:1998). The analyses were mainly conducted to determine the heavy metals in the dewatered sludge. The percentage of these elements in the dewatered sludge is essential in determining the final destination of the dewatered and dried sludge.

The nutrient content of experimentally determined sludge (ISO 11047:1998) is of remarkable importance when the sludge is utilized as an agricultural fertilizer or used to improve soil conditions. They enrich the soil with substances essential for plant growth, making dewatered sludge a useful resource in agriculture. Also, the use of sludge in agriculture is conditioned by the presence and amount of heavy metals (copper, zinc, lead, chromium, etc.), which have a high degree of toxicity and accumulate in the soil (ISO 11047:1998).

Table 5. Chemical analyses performed on the sludge sample

Determined parameters	UM	The value obtained	Analysis method	Maximum limit*
Dry substance (DS)	[%]	17	STAS12586-87	
Organic Substance	[%]	82,5	STAS12586-87	
Manganese	[mg/kg DS]	283	ISO 11047/1999	
Copper	[mg/kg DS]	337	SR EN ISO 11047/1999	*500
Zinc	[mg/kg DS	988	SR EN ISO 11047/1999	*2000
Crom	[mg/kg SU]	181	SR EN ISO 11047/1999	*500
Lead	[mg/ kg DS]	34	SRENISO 11047/1999	*300
Total nitrogen	[% DS]	5.19	ISO 13878:1998	-
Cobalt	[mg/kg DS]	110	SR EN ISO 11885:2009	*50
Calciu	[%]	2.88	EPA7000B	-
Potasiu	[%]	0.61	EPA7000B	-

Suppose urban sludge contains low amounts of heavy metals, generally below the permissible limits. In that case, sludge resulting from the combined treatment of domestic and industrial water may have higher concentrations of heavy metals, depending on the industry profile. Therefore, periodic chemical analysis of sludges is required to monitor and control their levels.

CONCLUSIONS

The comparative graphic representation of the results of drying the samples at a temperature of 50°C and 100°C (without ventilation) shows a linear increase in water evaporation from 7.57% after 30 minutes at 50°C, reaching a value of 21.59% after 100 minutes. The phenomenon of evaporation intensifies as the temperature increases from 50°C to 100°C. After 30 minutes, the percentage of evaporation is 26.10%. After 100 minutes, the value is 79.44%.

Following these experiments, it was highlighted how the evaporation of water is influenced by the temperature and the time allocated to the drying process in the conditions of a non-ventilated drying space. The increase in the degree of evaporation from 7.57% to 26.10% after 30 minutes, with the increase in temperature from 50°C to 100°C, represents a 3.4-fold increase. After 60 minutes, the increase is from 11.10% to 38.78%, representing a 3.4-fold increase. After 100 minutes, the evaporation percentage increases from 21.59% to 69.44%, a 3.2-fold increase.

The drying process is carried out in the non-ventilated drying space without evenly distributing the heat throughout the sludge mass. Lack of ventilation causes water vapor released during drying to condense and return to the dried sludge.

The ventilation of the drying space significantly increases the efficiency of the drying process. The drying differences between 50°C and 100°C, which are very large in the case of drying in non-ventilated spaces, are greatly reduced when using ventilation spaces with an increasing trajectory, but a linear trajectory.

In contrast, in the ventilated drying space, at a temperature of 50°C and a drying time of 30

minutes, the degree of dehydration is 20.93%. Raising the temperature to 100°C and keeping the drying time the same results in an evaporation rate of 47.76%, a 2.2-fold increase. After 60 minutes, the degree of dehydration increases from 40.83% to 62.43%, a 1.5-fold increase. After 100 minutes, the degree of evaporation is 60.54% at 50°C, and at 100°C it increases to 78.24%, a 1.3-fold increase. The rate of increase in evaporation remains relatively constant, and the increase is more uniform in the case of ventilation of the drying space, as opposed to drying in unventilated spaces.

Water vapor returning to the sludge negates dewatering efforts. Moreover, these vapors can be toxic and, by accumulation, become dangerous. Sludge drying should only be done in properly ventilated areas that allow evaporation to be controlled and vapors to be directed to safe areas for condensation and disposal without endangering the safety of the work area.

Experiments carried out in unventilated spaces have shown that sludge drying is possible with higher temperatures and longer times. Still, the uncontrolled presence of vapors in the working space constitutes a significant risk and prevents the process from being carried out on an industrial scale. The degree of evaporation remains relatively constant during drying. The lack of homogeneity of temperature in the drying space, caused by the absence of ventilation, leads to high evaporation rates.

The values obtained from these experiments highlighted the correlation between temperature, drying time, and the degree of evaporation.

With the increase in the drying temperature, a constant increase in the evaporation percentage was observed, which increased as the heat treatment increased. This phenomenon indicates that evaporation continues to occur in the absence of ventilation as drying time increases, but at a lower efficiency compared to ventilated drying conditions. Following the analysis of the chemical substances from the sludge samples from the Arad Wastewater Treatment Plant, especially the heavy metals, it was proven that they are far below the limits allowed by the standards in force (Directive 86/278/CEE), which means that it can be used as a fertilizer for plants and used on agricultural land, without affecting the ecological balance.

Future research will focus on finding safe areas for the use of dewatered and dried sludge so that in the near future, sludge will be viewed not as a colossal waste but as an inexhaustible resource.

Abstract

Many legacy and emerging chemicals pose significant environmental concerns due to their persistence, bioaccumulation potential, toxicity, and widespread presence in environment. Among those, are organochlorine (OCs) and organophosphate (OPs) pesticides. This study aimed to develop a GC-MS/MS method for the targeted analysis of selected OCs (1,2,3,4,5,6-hexachlorocyclohexane (HCH) isomers, aldrin, and chlordecone) and OPs (dichlorvos, chlorpyrifos, and chlorpyrifos-methyl). The linearity of the developed method was assessed for selected organochlorine and organophosphate pesticides, yielding good R^2 values (≥ 0.98) for all target compounds except chlordecone. Furthermore, a spiking procedure in sol and compost was developed for OCs and OPs. To quantify OCs and OPs in soil and compost, Soxhlet extraction with toluene was used, followed by clean-up with silica-based chromatographic columns. Good recoveries were obtained for aldrin and chlorpyrifos-methyl. Lower correlation with spiked concentrations for some compounds was likely due to matrix effects. The results showed that GC-MS/MS is an efficient method for the quantification of OCs, and OPs, in complex matrices as soil and compost, highlighting their applicability for environmental monitoring and contamination assessment.

Key words*: GC-MS/MS, compost, soil, clean-up.*

INTRODUCTION

Spiking organic chemicals into soil enables controlled and reproducible experiments to study their interactions with the soil matrix and to validate analytical methods. In the same time, spiking can be used to validate analytical methods for detecting chemicals in soil (Brinco, Guedes, Gomes da Silva, Mateus, & Ribeiro, 2023). High-volume spiking facilitates homogenous distribution of compounds in samples, enhancing reproducibility and analytical method validation (Keighley, Ramwell, Werner & Sinclair, 2021). Furthermore, it is a technique commonly used in environmental science, soil chemistry, and ecotoxicology that is introducing relatively large concentrations of specific organic compounds (van Hall & van Gestel, 2025). In the same time, high-volume spiking ensures a uniform and known concentration across samples, improving reproducibility of lab-based experiments (Brinch, Ekelund & Jacobsen, 2002; Northcott & Jones, 2000). The ageing process of organic chemicals in soil reduces their bioavailability and extractability, influencing their environmental fate and toxicity (Alexander, 2000; Hatzinger & Alexander, 1995; Wang, Schlenk & Gan, 2019). This phenomenon is particularly important for understanding the environmental fate, persistence, and toxicity of pollutants such as pesticides, polycyclic aromatic hydrocarbons (PAHs) (Preda, Mocanu & Tănase, 2024), and other hydrophobic organic compounds (Duan et al., 2015). Many organic chemicals may diffuse into micropores or become tightly associated with soil organic matter, making them harder to extract or degrade (Barriuso, Benoit & Dubus, 2008; Jespersen, Trapp & Kästner, 2024; Ukalska-Jaruga et al., 2023). Furthermore, some organic contaminants can form non-extractable residues through covalent or strong non-covalent interactions with humic substances in soil (Loeffler et al., 2020). For this reason, in order to avoid the formation of non-extractable residues it is recommended that for some organic contaminants, the tests or the analysis with the

spiked soils to be performed no longer than several weeks after the spiking procedures (Northcott & Jones, 2000).

Organochlorine pesticides (OCs), such as HCH isomers, aldrin, and chlordecone, are persistent synthetic compounds previously used in agriculture and now recognized for their environmental persistence and toxicity (Micuți et al., 2018; Pang et al., 2022). Among them, the 1,2,3,4,5,6-hexachlorocyclohexanes (HCHs). HCHs can be considered as model compounds since they are persistent, global pollutants that were banned by the Stockholm Convention (Liu et al., 2017). Other priority organochlorine pesticides are: aldrin, and the chlordecone a synthetic organochlorine pesticide, extensively used in banana plantations of the French West Indies from 1972 to 1993 and which therefore was detected in pumpkin and zucchini in the French Region Aquitaine (Chevallier et al., 2018). Comparing with the HCHs, the persistence of chlordecone in the environment is higher due to its bis-homocubane structure (Momtaz & Khan, 2024) numerous chlorine atoms. Organophosphate pesticides (OPs) are a group of synthetic chemicals used to control insects on crops, animals, and in homes. Among them, dichlorvos is an is an insecticide and acaricide, while chlorpyrifos and chlorpyrifos-methyl are acetylcholinesterase inhibitors and they were extensively used to control insect pests on various crops and in stored grain (Kunwar et al., 2021; Mazari et al., 2020). Reliable quantification of OCs and OPs in complex matrices such as soil and compost requires advanced analytical methods with high sensitivity and specificity. In the case of contaminants suitable for gas chromatography-mass spectrometry methods, the used of tandem mass spectrometry using triple quadrupole analysers (GC-QQQ-MS) is employing the development of multiple reaction monitoring (MRM) methods. MRM method development involves three critical steps: (1) selection of precursor ions, (2) optimization of collision energy, and (3) adjustment of dwell time to balance sensitivity. A higher dwell time increases the sensitivity but also decreases the number of points available for each target peak (Badea, Geana, Niculescu & Ionete, 2020). GC-QQQ-MS is considered a highly sensitive technique for targeted and trace-level analysis (pg to fg range on-column). GC-QQQ-MS allows for the selection of a specific precursor ion, its fragmentation in the collision cell, and the subsequent selection of a fragment ion for detection, significantly reducing chemical noise and enhancing the signal-to-noise ratio. In spite of its sensitivity, the linearity domain of the MRM methods is somewhat limited and depends on the sensitivity of the mass spectrometer, as well on the ionization efficiency of the compound and on matrix effects (Vijaykumar et al., 2025). Usually, the linearity domain of the MRM methods is ranged from sub-ng/mL to µg/mL, depending on the compound and method sensitivity.

This study aims to develop and validate a GC-MS/MS method for quantifying selected organochlorine and organophosphate pesticides in soil and compost. The method includes assessment of linearity, recovery rates, and matrix effects in both sample types.

MATERIALS AND METHODS

Chemicals. Most of the target chemicals (α-HCH (analytical purity: 99%, β-HCH (99 %), γ-HCH (97 %), δ-HCH (99 %), hexachlorobenzene (HCB) (99 %), dichlorvos (99 %) and chlordecone (99 %) were obtained from Sigma-Aldrich (Darmstadt, Germany), while aldrin (99%), chlorpyrifos (99%) and chlorpyrifos-methyl (99%) and triphenyl phosphate (TPP) (99%) were purchased from Dr. Ehrenstorfer (Germany).

Linearity domain test. To evaluate the linearity, two calibration mixtures - one for OCs and one for Ops - were prepared in dichloromethane (DCM).

Table 1. The concentration domains of OCs and OPs tested in the linearity test.

Compound	Tested concentration range (ng/mL)
Aldrin	54-8130
α-HCH	45-6750
β-HCH	57-8625
γ-HCH	58-8700
δ-HCH	45-6825
Chlordecone	50-8812
Dichlorvos	49-7481
Chlorpyrifos	59-8850
Chlorpyrifos-methyl	50-7620

HCB (505 ng/mL) and TPP (505 ng/mL) were used as internal standards for OCs and OPs, respectively. The range of concentration range for OCs and OPs is summarized in Table 1.

Spiking of soil and compost. Approximately 60 g of soil and 60 g of compost were spiked with 25 mL of an acetone solution containing the target OCs and OPs (excluding dichlorvos and chlordecone). Samples were homogenized manually, to accelerate acetone evaporation. The theoretical concentration for the target compound in soil were: 0.09 µg/g for aldrin, 0.08 µg/g for α-HCH 0.04 µg/g for β-HCH, 0.05 µg/g for γ-HCH, 0.05 µg/g for δ-HCH, 0.10 µg/g for chlorpyrifos and 0.09 µg/g for chlorpyrifos-methyl while the theoretical concentration for the target compounds in compost were 0.09 µg/g for aldrin, 0.08 µg/g for α-HCH 0.05 µg/g for β-HCH, 0.05 µg/g for γ-HCH, 0.06 µg/g for δ-HCH, 0.11 µg/g for chlorpyrifos and 0.09 µg/g for chlorpyrifos-methyl.

Extraction and clean-up of the soil and compost samples. Triplicate 10 g portions of each spiked matrix were extracted via Soxhlet using toluene for 24 hours. Internal standards (100 µL of 100 µg/mL HCB for OCs and 100 µL of 100 µg/mL TPP for OPs) were added prior to extraction. Upon evaporation, the clean-up of the extracts was performed both with 3 x 3 mL of n-hexane on SPE columns containing 500 mg silica (55 µm, 70 Å) and with 120 mL hexane on 8 g of silica gel deactivated with 10% water (w/w) packed on glass columns. About 1 ml of toluene was added to the eluates followed by the evaporation of n-hexane. Before GC-MS analysis, the recovery standard (RS), consisting of heptachlor was added.

GC-MS analysis. The target compounds were analysed using an Agilent 7890B gas chromatograph (GC) coupled to Agilent 7010 triple quadrupole mass spectrometer (Agilent Technology, Palo Alto, USA) operated in positive electron ionization (EI) mode (70 eV) and configured in multiple reaction monitoring (MRM). The samples (volume: 1 µL) were injected at 225°C into a PTV injector operated in split less mode, while the flow rate of carrier gas (helium) was 1 mL/min. The target compounds were separated on a Agilent HP-5MS (5% Phenyl Polysilphenylene-siloxane) capillary column (30 m × 0.25 mm × 0.25 µm), using the following oven program: initial temperature of 40°C (5 min isothermal), ramp with 5°C min^{-1} to 110°C (0 min), 20°C min^{-1} to 180°C (0 min), 5°C min^{-1} to 230°C (0 min) and 20°C min^{-1} to 310°C (3 min isothermal).

RESULTS AND DISCUSSIONS

Assessment of linearity domains. The linearity domains across two orders of magnitude concentrations were assessed. The respective domains were assessed as linear if the R-Square values (R^2) of the linear regressions were at least 0.98 or higher. For aldrin, linearity was observed in the concentration range of 54–1622 ng/mL ($R^2 \geq 0.98$). Higher concentrations (2710 ng/mL and 8130 ng/mL) fell outside the linear range (Figure 1).

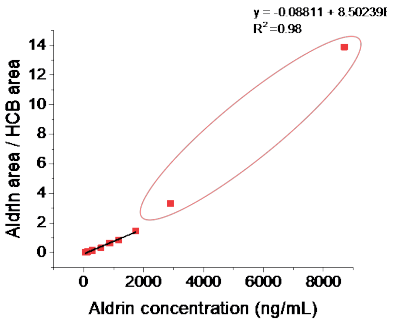

Figure 1. Linearity domain of the aldrin for developed GC-MS-MS method

Assessment of linearity domains for hexachlocylohexanes (HCHs) is presented in Figure 2. The linearity domain for α-HCH was calculated in the range 45-1347 ng/mL, while the concentrations of 2250 ng/mL and 6750 ng/mL were considered as outside of linear domain (Figure 2A). The linearity domain for β-HCH was defined in the range 57-1721 ng/mL, while the concentrations of 2875 ng/mL and 8625 ng/mL were outside of the linear domain (Figure 2B). The linearity domain for lindane (γ-HCH) was measured in the range 58-1736 ng/mL, while the concentrations of 2900 ng/mL and 8700 ng/mL were considered as outside of linear domain (Figure 2C). Also, the linearity domain for δ-HCH was defined in the range 45-1362 ng/mL, while the concentrations of 2275 ng/mL and 6825 ng/mL were outside of the

linearity domain (Figure 2D). Overall, similar linear ranges were observed for all HCH isomers, likely due to their comparable molecular structures and physicochemical properties. The assessment of linear domain for chlordecone in the range 58-2937 ng/mL gave a week R-square value (R^2 = 0.786) comparing with the other OCs, even upon exclusion of its higher concentration of 8812 ng/mL (data not shown). This indicates that hexachlorobenzene is not a good internal standard for chlordecone in GC-MS-MS determinations and Hexabromobenzene (HBB) or TPP may be preferred. The assessment of linearity domains for OPs is presented in Figure 3. Dichlorvos gave a good linearity domain in the range 49-2493 ng/mL (R^2 = 0.99) showing the highest linearity domain from all the target compounds (Figure 3A). This may be attributable to its lower molecular weight (M.W = 220.97) comparing with the rest of the target compounds. The linearity domain for chlorpyrifos was calculated in the range 59-1177 ng/mL, while the last three concentrations of 1766 ng/mL, 2950 ng/mL, 2540 ng/mL and 8850 ng/mL were considered as outside of linear domain (Figure 3B). The linearity domain for chlorpyrifos-methyl was defined in the narrow range 254-1520 ng/mL, while both the last two lowest concentrations (50 ng/mL and 101 ng/mL) and last highest concentration (7620 ng/mL) being calculated as outside linear domain (Figure 3C). Overall, the results of the linearity test shown extensively linearity domain for all the target compounds and this shown that the developed GC-MS-MS method was validated from linearity point of view.

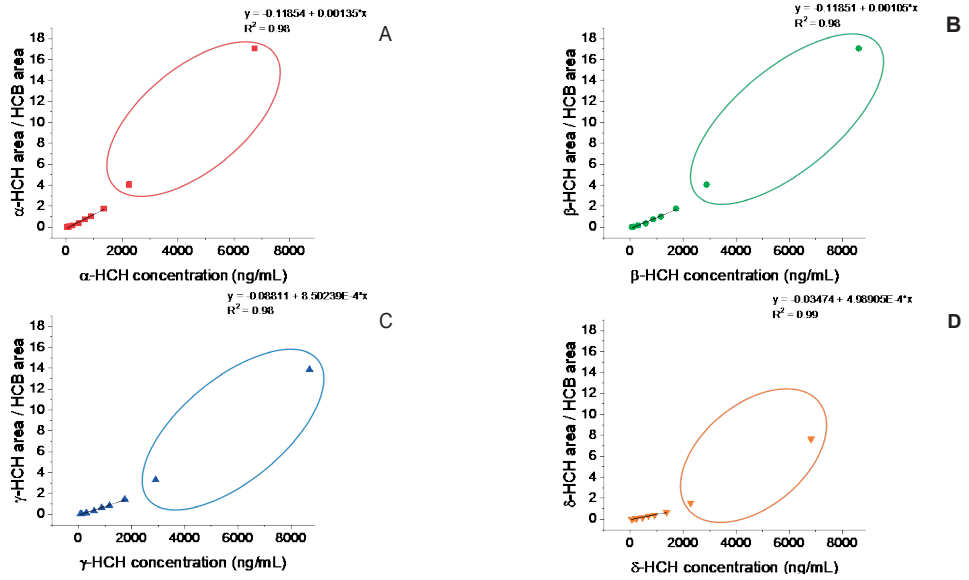

Figure 2. Linearity domain for α-HCH (■))(A), β-HCH (●) (B), γ-HCH (▲) (C) and δ-HCH (▼) (D) for the developed GC-MS-MS method

Assessment of concentrations in soil and compost. The concentrations of OCs and OPs in soil samples are presented in Table 2 and those values are comparing with those of the theoretical spiked concentrations.

Aldrin (117.20%) and chlorpyrifos-methyl (116.08%) recoveries in soil were consistent with their theoretical concentrations, indicating effective extraction and minimal matrix interference for these compounds.

For the rest of the OCs and OPs the concordance with the spiked concentration is weak (Table 2). The high recoveries may indicate a strong matrix enhancement for some compounds (e.g. γ-HCH).

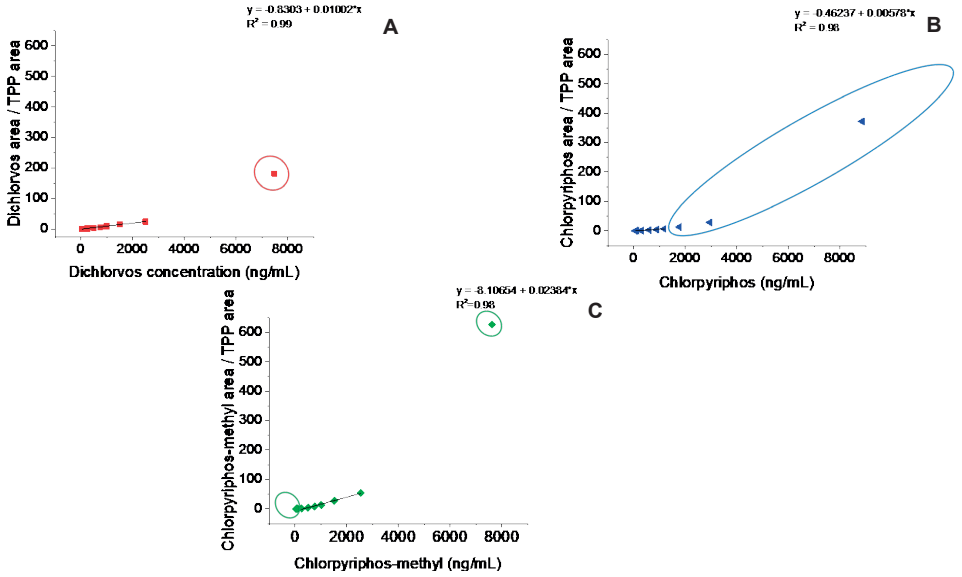

Figure. 3. Linearity domain for diclorvos (■) (A), chlorpyrifos (◀) (B), and chlorpyrifos-methyl (♦) (C) for the developed GC-MS-MS method

Table 2. Concentration of OCs and OPs pesticides determined in soil

Compound	Theoretical concentration (µg/g)	Measured concentration in sol (µg/g)	Recovery (%)
Aldrin	0.09	0.11 ± 0.002	117.20
α-HCH	0.08	0.05 ± 0.004	60.50
β-HCH	0.04	0.06 ± 0.01	134.86
γ-HCH	0.05	0.16 ± 0.01	314.24
δ-HCH	0.05	0.07 ± 0.01	127.66
Chlorpyrifos	0.10	0.15 ± 0.11	150.03
Chlorpyrifos-methyl	0.09	0.10 ± 0.05	116.08

Table 3. Concentration of OCs and OPs pesticides determined in compost

Compound	Theoretical concentration (µg/g)	Measured concentration in compost (µg/g)	Recovery (%)
Aldrin	0.10	0.08 ± 0.01	84.07
α-HCH	0.08	0.05 ± 0.002	66.50
β-HCH	0.05	0.07 ± 0.002	141.36
γ-HCH	0.05	0.08 ± 0.01	136.49
δ-HCH	0.06	0.07 ± 0.01	124.20
Chlorpyrifos	0.11	0.39 ± 0.01	363.68
Chlorpyrifos-methyl	0.09	0.11 ± 0.004	119.51

The discrepancies between measured and spiked concentrations, particularly in compost, are likely attributable to matrix effects such as co-extracted interferences causing ion suppression or enhancement in the mass spectrometer. (Wu & Ding, 2023). These effects can suppress or enhance the ionization of target OCs and OPs in the mass spectrometer detector, leading to inaccurate results. The concentrations of OCs and OPs in compost samples are presented in Table 3 and those values are comparing too with those of the theoretical spiked concentrations. Here too, the concentration of aldrin (0.08 ± 0.01 µg/g, recovery of 84.07%) and chlorpyrifos-methyl (0.11 ± 0.004 µg/g, recovery of 119.51%) are in good concordance with spiked concentrations. For the rest of the OCs and OPs, the concordance of measured concentrations with spiked concentrations is weak too, probably due to matrix effects. Non-isotopically labelled internal standards may be insufficient to fully correct for matrix effects and losses during sample preparation. Isotopically labelled analogues are recommended for improved quantification accuracy, as supported by prior studies (Badea, Lundstedt, Liljelind & Tysklind, 2013) (Peña, Sosa, Hilber, Escobar & Bucheli, 2024).

CONCLUSIONS

A GC-MS/MS method was successfully developed and applied for the quantification of selected organochlorine and organophosphate

pesticides in soil and compost. The evaluation of linearity domains gave good R^2 values for all the target compounds excepting for chlordecone. Dichlorvos exhibited the broadest linear range, likely due to its lower molecular weight and favourable ionization characteristics. Overall, the results of the linearity test shown extensively linearity domain for all the target compounds. With respect of solid matrices analyses, aldrin and chlorpyrifos-methyl showed recoveries consistent with their theoretical spiked levels in both matrices, indicating reliable quantification under the proposed method. Deviations in recovery for other analytes were attributed to matrix effects, highlighting the need for more robust internal standardization. In order to overcome those matrix effects, the use of isotopic labelled internal standards (contains atoms of ^{2}H, ^{13}C) is expecting to lead to higher accurate concentration values for a variety of OCs and OPs. Overall, the study demonstrates the feasibility of applying a GC-MS/MS method for multi-residue pesticide analysis in complex environmental matrices.

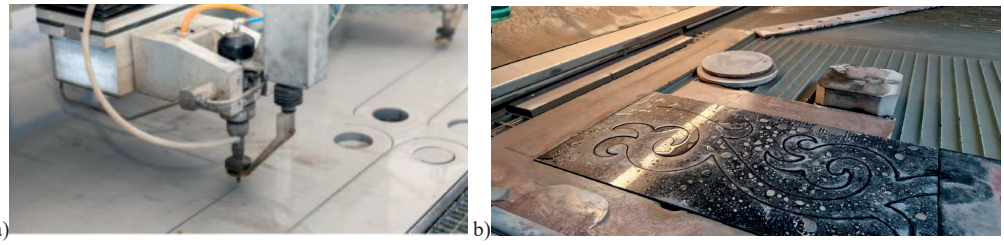
Abstract

Waterjet cutting is an industrial method that uses high-pressure water jets to cut a variety of materials such as metals, concrete, wood, ceramic, stone, rubber, foams, plastic, etc. For improving the procedure performance, in terms of speed and cutting accuracy, abrasive agents like red garnet sand is mixed with the water, generating the Abrasive Water Jet (AWJ) methodology. This is known to present environmental drawbacks, including the production of wastewater, garnet sludge and corresponding dried wastes, and microscopic particles from the cut materials, still disposed in household landfills, which generate severe environmental issues. Using Garnet Sand (SG) wastes in cementitious materials (mortars and concrete) as partial aggregate substitution is an innovative approach to enhance sustainability in construction, offering several benefits like increased strength, durability performance, etc., reduced production costs due to the re-using material approach and ecological protection as well. Preliminary studies in this direction were conducted in the last years within NIRD URBAN – INCERC, Timişoara branch, showing encouraging results in the proposed aggregate substitution proposal in the regular mortar mixes, in accordance with initial international studies in the field. The current paper aims to confirm the initial results by specific extension of the research area, reaching some critical parameters, like SG material source variation, as a mandatory validation procedure of preliminary conclusion and foundation of further specific studies regarding the viability of the SGs recycling opportunities in construction products and their effective use.

Keywords*: aggregate substitution, Circular Economy (CE), green building design, recycling, Spent Garnet (SG).*



INTRODUCTION

Abrasive waterjet (AWJ) cutting is an advanced, non-thermal machining technique that utilizes a high-pressure jet of water mixed with abrasive particles - primarily Garnets - to cut a wide range of materials with precision. The AWJ cutting technique is widely used in various industries due to its ability to accurately process a diverse range of materials (metals, ceramics and glass, composites, stone and marble, metals and other hard materials, etc.) without inducing thermal damage or structural distortion (Figure 1). Garnets, the most versatile abrasive material for the AWJ process, represents a group of silicate minerals known for their crystalline structure and diverse chemical compositions; the general chemical formula is $X_3Y_2(SiO_4)_3$, where X and Y are various metal cations, such as calcium, magnesium, aluminium, iron, and manganese (Chassé et al., 2018). The chemical composition flexibility of Garnets determines their wide range of varieties, each with distinct

physical and optical properties. The most common colour of Garnets is red (reddish-pink range of colours), but they can also be green, orange, yellow, or even black, depending on their specific type (Figure 2). Garnet varieties include (Bucher et al., 2019; Usman et al., 2021; Skanavi & Dovydenko, 2018; Vasile et al., 2024):

- Almandine (iron - aluminum, $Fe_3Al_2(SiO_4)_3$, of red to reddish-brown colour, represents the most widespread of Garnets, with a wide range of use in abrasive applications;
- Pyrope (magnesium - aluminum, $Mg_3Al_2(SiO_4)_3$), of deep red colour;
- Spessartine (manganese - aluminum): Orange to reddish-brown;
- Grossular (calcium - aluminum): Green, yellow, or colorless;
- Andradite (calcium - iron): Green, yellow, or black, etc.

Garnets are preferred for AWJ cutting procedures due to their hardness (6.5-7.5 on the Mohs scale), angular particle shape, and chemical stability, which facilitate efficient cutting while minimizing equipment wear (Baeră et al., 2023; Cornelia B. et al., 2023; Vasile et al., 2024). Garnet production varies globally, with several countries, like India, Australia, United States, China, South Africa, etc., leading the extraction and processing and also dominating the global Garnet market, as raw materials suppliers for industries such as waterjet cutting and sandblasting (https://pubs.usgs.gov/periodicals/mcs2024/mcs2024-garnet.pdf). According to Precision Business Insights (https://www.precisionbusinessinsights.com/market-reports/garnet-market) "the global Garnet market size was valued at approximately $892.8 million in 2024 and is projected to grow at a compound annual growth rate (CAGR) of 7.2% from 2025 to 2031", which predicts a corresponding growth of the industries connected to AWJ processes.

Figure 1. Abrasive waterjet cutting device for material processing: a) specific AWJ equipment (Vasile et al., 2024); b) metal piece processed by AWJ operations (TimCut SRL, Timisoara, Romania)

a) b)

Figure 2. Garnet sands: a) Garnet sand deposits, Long Island Sound in Madison, Connecticut, USA; b) Garnet sand grains (aspect and colour variation) (https://fredmhaynes.com/2021/03/11/a-sea-of-garnet-sand/)

In abrasive waterjet (AWJ) cutting operations utilizing Garnets (Figure 1), the process produces Garnet slurries as the initial waste, consisting of a liquid suspension of water mixed with smaller, altered Garnet particles of varying size distribution (Cornelia B. et al.,

2023; Vasile et al., 2024). Typically gathered in a container positioned beneath the cutting equipment, the Garnet slurries are periodically removed at irregular intervals and, through natural drying, form waste piles (Figure 3). Discarding spent Garnet sands (SGs) in landfills generates environmental pollution and increases waste management costs. Integrating sustainable materials and innovative techniques in civil engineering contributes to environmental protection while enhancing resource efficiency and structural reliability, which requires sustainable solutions (Longobardi et al., 2024; Olinic et al., 2024). Research performed in the last decade shows the potential of SG materials as a fine aggregate replacement in construction materials, mortar and concrete. This can be seen as an eco-friendly alternative to natural sand, which represents an exhaustible, natural resource. In this context, garnet waste, a byproduct of abrasive waterjet cutting in the material processing industry, can be effectively repurposed in the construction sector. It holds significant potential for use in cement-based (Budiea et al., 2021; Ab Kadir et al., 2019; Kanta & Ponnada, 2021; Lim et al., 2020; Kunchariyakun & Sukmak, 2020; Jamaludin et al., 2021) or alkali-activated concrete (Huseien et al., 2019; Muttashar et al., 2018a; 2018b) and mortars, plaster, fibre-reinforced composites, and other building materials (Cornelia B. et al., 2023; Vasile et al., 2024). The use of SG waste as a replacement for fine aggregates in cement-based materials, such as mortar and concrete, has been explored to enhance sustainability in construction. Experimental studies performed worldwide indicated that incorporating spent Garnets (SGs) in the concrete or mortar mixture can improve their physical and mechanical properties, such as densities and workability, flexural and compressive strength, while also contributing to environmental sustainability.

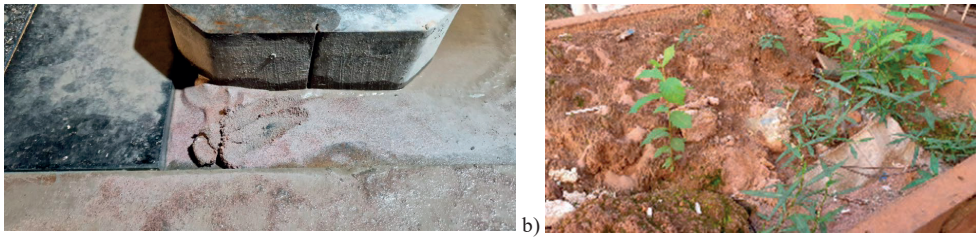

Figure 3 . AWJ processes waste generation: a) Waterjet sludge collected in recipients (TimCut SRL, Timisoara); b) Garnet waste dry slurry collected in outside recipients for medium-term storage (National Research & Development Institute for Welding and Material Testing - ISIM Timisoara, Romania) (Vasile et al., 2024)

Overview of ongoing research

Over the past decade, the rapid growth of the AWJ industry and the associated waste generation have driven an increasing need for research on SG waste management, particularly its integration into construction materials. This demand has led to a proportional rise in studies focused on repurposing SG in the building materials industry, in accordance with the Circular Economy approach: innovative transformation of potential waste into new products with distinct life cycles. In this context, SGs generated from abrasive waterjet material processing can be repurposed as a valuable by-product through improved industrial process control. The SG wastes can therefore be effectively integrated into various building materials, mortar and concrete as well (Baeră et al., 2023). Early studies conducted by Malaysian researchers explored the potential of garnet waste in alkali-activated mortars and concrete (Muttashar et al., 2018a; 2018b), while parallel research efforts investigated its application in cementitious composites as part of spent Garnet valorisation (Budiea et al., 2021; Ab Kadir et al., 2019; Kanta & Ponnada., 2021; Lim et al, 2020; Kunchariyakun & Sukmak, 2020; Jamaludin et al., 2021; Huseien et al., 2019). A common methodology in these studies involves developing a reference mortar or concrete mix, followed by testing variations with incremental sand replacement levels of

25%, 50%, 75%, and 100%. The findings consistently highlight the viability of sand substitution by SG material for cement-based mixes.

The present study was developed within the research project PN 23 35 04 01 of Nucleu Programme of the National Research Development and Innovation Plan 2022-2027, "ECODIGICONS", supported by the Ministry of Research, Innovation and Digitalization, with focus on waste management implementation, environmental protection and natural resources saving (Baeră et al., 2023; Cornelia B. et al., 2023; Vasile et al., 2024) and is consistent to the previously mentioned experimental methodology: a standard cementitious mortar was first developed as the reference mix (R). Subsequently, the conventional sand was partially replaced with SG waste material, sourced from two local companies. The first stages of the study (Baeră et al., 2023; Cornelia B. et al., 2023; Vasile et al., 2024) evaluated as favourable the compatibility of Garnet waste material with cement-based materials, by the means of comparative analysis of fresh and hardened state properties (fresh state appearance, cohesivity of the mixture, material consistency and fresh state density, etc., together with hardening age and typical mechanical performance, 7-day and 28-day flexural and compressive strength, etc.) in substitution mortars relative to the reference. The focus of this phase is the validation of the previous conclusion and evaluation of its consistency, with respect to the viability of the proposed substitution procedure. The current natural aggregate substitution was conducted by weight, following guidelines from previous studies on the subject, with replacement levels of 10%, 30% and 50% of the sand (S) content in the reference mix.

MATERIALS AND METHODS

The current experimental procedures are performed to validate the previous conclusions of the initial stages of the study. Consequently, the SG material used in this study, derived from two local providers: SG 1 and SG 3 were provided from the National Research & Development Institute for Welding and Material Testing (ISIM) (Ionescu et al., 2014; Perianu et al., 2017), but they were collected at different times - SG 1 in April 2022 and SG 3 in August 2023, over a year apart (Vasile et al., 2024). This time gap is considered significant for assessing the consistency of preliminary findings, as it allows for an evaluation of waste dynamics in terms of both material properties and compositional performance when integrating SG 1 and SG 3. Additionally, another SG source is considered, namely the local company SC Tim Cut SRL Timisoara, Romania, specializing in AWJ material processing technology (https://www.timcut.ro/); the material they provided is denoted SG 5.

The comparative evaluation is performed in terms of mechanical behaviour, of the modified mortars with respect to the reference, namely flexural and compressive strength recorded at early ages (7 days) and also the regular age of 28 days. The control mixes (R1 and R2) consist of conventional mortars, while the test mixes incorporate SG materials (SG 1, SG 3 and SG 5) as a partial replacement for sand in the reference mix (R). The substitution is performed at 10%, 30% and 50% by mass, following the standard methodology established in previous studies, and the mixing procedure is in accordance with EN 196-1 and 1015-11.

Raw materials

The Reference and the SG mixes were produced with locally available raw materials (Figure 4):

- Portland Cement, CEM II/A-LL 42.5 R (C) (Figure 4a);
- granular class 0/4 Natural sand (S), (Figure 4b);
- Spent Garnet sand (SG), from by two distinct local sources: SG 1 (Source 1 (ISIM), sampling: April 2022), (Figure 4c); SG 3 (Source 1 (ISIM), sampling: August 2023, (Figure 4d); e) SG 5 (Source 2 (Tim Cut SRL) (Figure 4c), sampling: 2023, (Figure 4e);
- Water (tap water);
- Free additives mixtures.

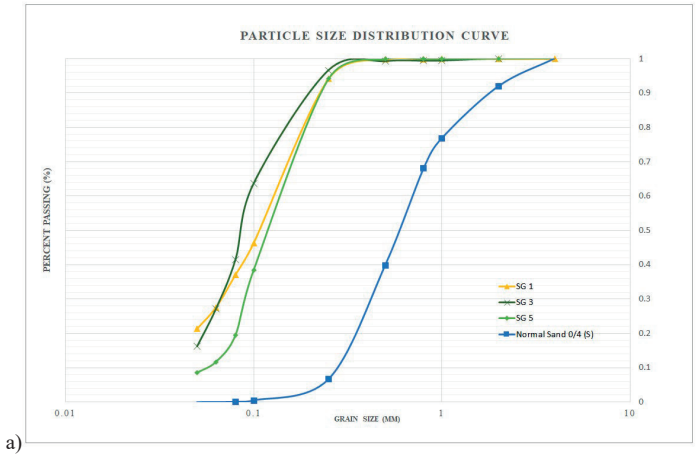

Figure 4. Raw materials: a) Portland Cement; b) Natural sand (0/4), S; c); SG 1 (Source 1 (ISIM), sampling: April 2022); d) SG 3 (Source 1 (ISIM), sampling: August 2023); e) SG 5 (Source 2 (Tim Cut SRL), sampling: 2023)

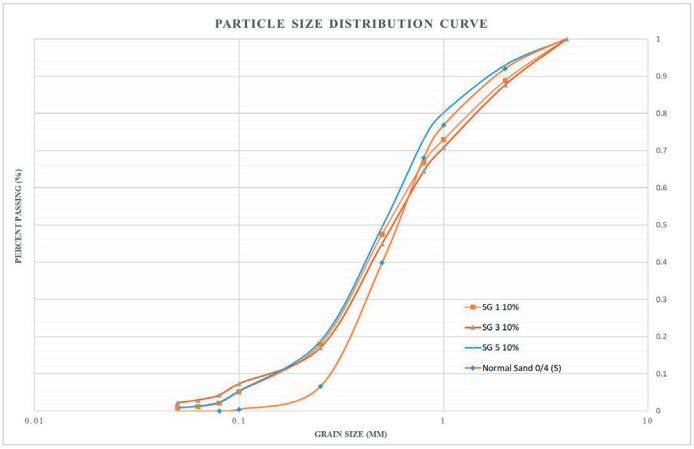
Preliminary experimental procedure - Granulometric analysis



The sieving analysis is performed according to EN 933-1 method for the usual sand 0/4 (S), for the considered substitution SG materials, SG 1, SG 3 and SG 5 and additionally for the S+SG blended aggregate, containing 10%, 30% and 50% replacement levels of the sand (S). The graphical representation of the sieving analysis is presented in Figures 5 and 6 (Vasile et al., 2024).

Mix proportion and specimen preparation

The reference mortar mixes, R1 ((W/C) 0.61) and R2 ((W/C) 0.56), were developed with classic raw materials: regular sand 0/4 (S), cement and water are produced (Cornelia B. et al., 2023; Vasile et al., 2024). The S+SG mortar mixes were produced by SG material incremental replacement, by mass, of the usual aggregate (S), with SG additions (10%, 30% and 50%). The 10% sand replacement presents reduced economic significance for real use purposes, but it serves as important data for completing the perspective regarding the incremental growth and the corresponding mortar performance.

The mortar mix design follows the approach used in the preliminary studies (Cornelia B. et al., 2023; Vasile et al., 2024), the mixing process performed in accordance with the SR EN 196-1 and SR EN 1015-11 standards. Similarly, the casting of prismatic specimens (40 × 40 × 160 mm) and their conditioning before mechanical testing remain consistent with previous research (Baera et al., 2021; 2022; 2023; Vasile et al., 2024). The SG mortars incorporate blended aggregate mixes, with SG materials replacing the natural 0/4 sand at predetermined substitution levels of 10%, 30% and 50%. The water-to-cement (W/C) ratio for SG mortars is maintained at 0.56, aligning with R2. The mix proportions for both the reference mortars (R1 and R2) and the SG-modified mixes are standardized relative to the cement content (C = 1.0) and are detailed in Table 1. Figure 7 emphasises some relevant stages of the mortar specimen development process and testing procedures, as well.

Table 1. Mix proportions of the considered mortar mixtures: References and SG mixtures

Ingredients / Mixtures	C	S 0/4	SG	W/C	A/C

SG 5 30%	1	2.70	0.30	0.56	3
SG 5 50%	1	1.50	1.50	0.56	3

Figure 7. Specimen preparation and testing: a) fresh state aspect of the mortar during mixing sequences; b) fresh mortar casted in the prismatic mold; c) SG 5 50% mix specimen after removal from the mold, 24 h after casting and specific conditioning (air, high moisture (>95%)); d) Specimen placement in the 3PB testing equipment; e) Compression testing; f) Specimens after 3PB and compressive testing

After mixing and fresh state evaluation, the mortars were cast into the 40 x 40 x 160 (mm) prismatic, metallic molds (Figure 7b), cured for 24 h at the temperature T (20±1)°C and relative humidity RH (90±5)%. The hardened specimens (Figure 7c) were removed from the molds after 24 hours, visually evaluated and placed in water at the temperature T (20±1)°C, until the testing age, 7days and 28 days, respectively.

Hardened state evaluation of the SG mixes: validation of early and regular age mechanical performance

The validation stage of the SG substitution mortars (Table 1) is performed based on the mechanical characteristics of the developed mixes, namely the compressive and flexural strength, at early age (7 days) and regular age of 28 days.

The mechanical performance of the mortars is evaluated via bending tensile strength (three-point bending, 3PB) and compression strength, determined on the 40 x 40 x 160 mm prismatic specimens (Figure 7d), at early age (7 day-strength) and further at 28 days, in accordance with EN 1015-11 and EN 196-1 specifications. The flexural strength was determined using the three-point bending (3PB) test performed on whole specimens (Figure 7d), followed by the compression test on the resulting half-prism specimens (Figure 7e).

RESULTS AND DISCUSSIONS

Aggregate grain size distribution

The natural sand 0/4 (S) has a lower fine grain content, as anticipated. Replacing 10% natural sand (S) with SG material does not influence the overall grain size distribution (Figure 6b), but 30% and 50% sand replacement by SG (Figure 6c and 6d) helps balance the aggregate grading curve. All SG materials exhibit a consistent grain size distribution pattern (Figure 6a, Figure 8), with minimal variation, enhancing the reliability of the proposed substitution.

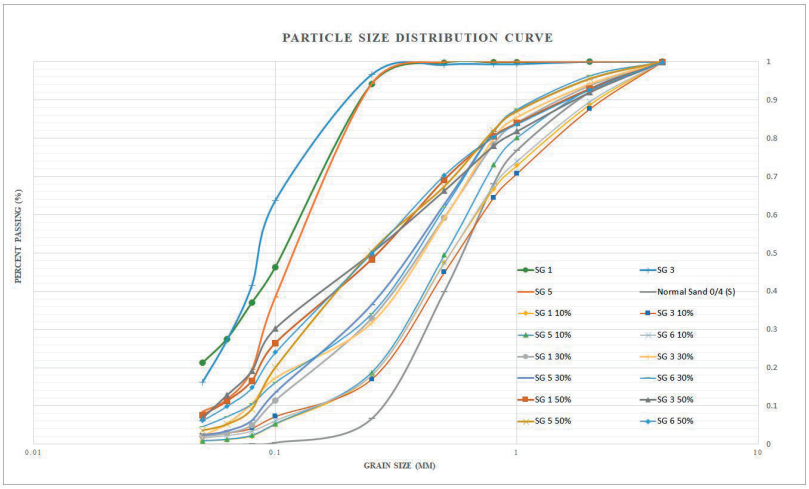

Figure 8. Aggregate grading: Natural sand 0/4 (S), SG 1, SG 3, SG 5 and blended aggregate mixture of S+SG (1, 3 or 5) (10%, 30% and 50%)

Mechanical performance

The physico-mechanical performances at early ages (7 days), bending tensile strength (3PB) and compressive strength, respectively, are essential parameters in evaluating the primary compatibility of the considered SG admixture with the cementitious matrix. Their evaluation, highlighted in Table 2, confirms the previously identified trends of overall improvement in material performance by using SG inert mineral aggregate as a partial aggregate substitute.

- **R1-1 and R2-1:** Reference mortars produced during the initial mechanical testing of SG 1 material (source 1, ISIM Timisoara, initial sampling) – PRELIMINARY STAGE
- **SG 1-1 10%, SG 1-1 30%, SG 1-1 30%:** Substitution mortars produced during the initial mechanical testing of SG 1 material (source 1, ISIM Timisoara, initial sampling) – PRELIMINARY STAGE
- **R1 and R2:** Reference mortars produced during the secondary mechanical testing of SG 1 material (source 1, ISIM Timisoara, initial sampling), SG 3 (source 1, ISIM Timisoara, secondary sampling); SG 5 (source 2, Tim Cut SRL, Timisoara, initial sampling) – VALIDATION STAGE
- **SG 1, SG 2, SG 3 (10%, 30%, 50 %)**: Substitution mortars produced during secondary mechanical testing of SG 1 material (source 1, ISIM Timisoara, initial sampling), SG 3 (source 1, ISIM Timisoara, secondary sampling); SG 5 (source 2, Tim Cut SRL, Timisoara, initial sampling) – VALIDATION STAGE.

The validation phase of the research confirms the initial results and implicitly the derived conclusions regarding the viability of the concept of partial substitution of fine aggregate (sand) in usual cement-based mortars by SG waste derived from AWJ processes. The credibility of the initial studies is confirmed in the secondary stage by the comparative analysis of the R1-1, R2-1 and SG1-1 samples, with similar compositions, developed with the same raw material, but more than 1 year later. The variation of the R1-1 vs R1 and R2-1 vs. R2, respectively, is sensitive for both 3PB flexural strength and compressive strength, at 7 and 28 days, and is within the usual variational limits, typical of cementitious composites, characterized by heterogeneity (Table 2, Figure 9). Simultaneously, the performance of the substitution mortars (SG1-1, SG 1 and SG 3), developed considering the percentage variation of the substitution of 0/4 natural sand 0/4 by SG material, from 10%, to 30% and 50%, confirms the trend traced by the R references, through sensible variations in the comparative analysis in Figure 8. At the same time, the results confirm the similarity of the SG material performance in cement-based material, considering the two distinct sampling

procedures (SG 1 and SG 3), sourced from the same AWJ cutting operator. The variation of the AWJ cutting operations (processed material, equipment processing, conditioning, etc.) seems to produce a negligible effect on the SG waste performance when added to usual mortars. The SG grading curve (SG1 vs SG3), (Figure 6a and Figure 8) also confirms this assumption, in terms of physical characteristics.

The validation conclusions can be further expanded by including the SG 5 material, sourced from Tim Cut SRL Timisoara (Table 2, Figure 10). A common behavior pattern of SG waste in cement-based materials as partial sand replacement can be sketched, due to small variations recorded while comparative analyses are extended by SG 5 mortar inclusions.

CONCLUSIONS

The experimental research program of compositional development of SG partially substituted preliminary mixtures, established in line with previous studies, conducted internationally (Muttashar et al., 2018a; 2018b) as well as in the laboratory (Cornelia B. et al., 2023; Vasile et al., 2024), generated 9 SG compositions, considering the operation of a specific screening in the area of substitution percentages used in the initial studies. This leads to the identification of the following as relevant values for assessing the efficiency of the substitution process:

a) 10% substitution;
b) 30% substitution;
c) 50% substitution.

Hardened state determinations and comparative performance evaluation lead to the identification of SG 30% and SG 50% compositions as prototype SG Mortar. The SG 10% compositions do not offer dramatic changes, and the percentage of substitution, 10% substitution is reduced to generate potential for technology transfer in the compositional area of common mortars and micro mortars. The SG 10% type compositions, though, have the role of confirming the identified trend and identifying possible compositional anomalies that may occur in the mix design.

In addition, the initial SG waste source is extended to a second one. (source 2). At the same time, new samplings are made from the original source 1 (ISIM Timisoara), thus extending the investigation area towards the validation of the initial conclusion and insurance of the robustness of the proposed concept. Ongoing research is offering valuable data regarding the compositional drawbacks and optimisation possibilities, related to the considered direct field of applicability, namely development of paving blocks for the innovative integration of SG into concrete mixes. Development of prefabricated paving products is considered an initial, practical, and more accessible use of SG substitution, with lower health risks for the population due to the outdoor placement of the products.

This field of application is particularly promising given the growing demand for paving products in the local Romanian market, driven by current infrastructure needs in both urban and rural areas. The approach also aligns with Circular Economy principles, by preventing Garnet sand waste and reintegrating it into new life cycles - specifically in building materials and products - while also contributing to the conservation of natural resources such as natural aggregates.

Abstract

The resurgence of earthen construction highlights the environmental, economic, and aesthetic benefits of natural materials. Non-Destructive Testing (NDT) methods are important for assessing the integrity and performance of earthen structures without physical damage. This article reviews key NDT techniques, including ultrasonic testing, electrical resistivity tomography, nuclear magnetic resonance, time domain reflectometry, infrared thermography, and acoustic emission testing, emphasizing their role in evaluating moisture content, mechanical properties, and thermal performance. Despite their advantages, challenges such as material variability, lack of standardized protocols, and specialized training persist. Future efforts must focus on standardization, advanced technologies, and improved data interpretation to maximize NDT's potential. By overcoming these obstacles, the construction industry can ensure the structural integrity and sustainability of earthen materials, promote broader acceptance of earthen construction and foster resilient, eco-friendly building solutions.

Key words*: NDT, Earthen Constructions, Structural Integrity, Structural Health Monitoring.*

INTRODUCTION

Earthen architecture, widely acknowledged as a sustainable and ecologically responsible construction practice, has played a pivotal role in human habitation for millennia, utilizing naturally available soil as a primary building material (Mousourakis et al., 2020). This architectural tradition encompasses a diverse range of construction techniques, including adobe, rammed earth, and compressed stabilized earth blocks (CSEBs), each of which is distinguished by its unique material composition and construction methodology. These techniques have been extensively lauded not only for their minimal environmental impact - characterized by low embodied energy and thermal efficiency - but also for their profound cultural and historical significance in various regions worldwide (Bui & Morel, 2014).

Despite the numerous advantages associated with earthen construction, the long-term structural stability of such buildings remains a significant challenge due to their inherent vulnerability to environmental degradation. Exposure to climatic factors, including fluctuations in moisture levels, temperature variations, and seismic activity, often accelerates material deterioration, compromising the mechanical integrity and durability of these structures over time (Campiani et al., 2019). As a result, the development and implementation of effective assessment methodologies have become imperative to ensure the preservation and continued use of earthen buildings.

Among the various approaches employed to evaluate the condition and mechanical performance of earthen structures, non-destructive testing (NDT) techniques have gained considerable traction due to their ability to provide critical diagnostic insights without inflicting damage on the material. In particular, Ultrasonic Pulse Velocity (UPV) testing has

emerged as a highly effective method for assessing key material properties such as density, porosity, and compressive strength, offering valuable data for both conservation specialists and structural engineers engaged in the maintenance and restoration of earthen heritage and contemporary constructions. This approach not only facilitates the preservation of these culturally significant structures but also enhances our understanding of their material properties and performance over time (Charif et al., 2024).

Ultrasonic Pulse Velocity testing involves sending ultrasonic waves through a material and measuring the time it takes for the waves to travel through it. The velocity of these waves is influenced by the material's density, elasticity, and internal structure, making UPV a valuable indicator of the material's quality and strength. In the context of earthen architecture, the relationship between UPV and compressive strength is particularly significant. Numerous studies have established a correlation between the two, indicating that higher ultrasonic velocities typically correspond to greater compressive strength. For example, Kim et al. (2022) demonstrated that ultrasonic pulse velocity can effectively predict the compressive strength of concrete across varying aggregate types, reinforcing the applicability of UPV in assessing earthen materials. Similarly, Hong et al. (2020) provided empirical evidence of the correlation between UPV and compressive strength, proposing a predictive equation based on their findings.

The compressive strength of earthen materials is an important factor in determining their load-bearing capacity and overall durability. Factors such as the composition of the soil, moisture content, and the presence of stabilizers can significantly influence both the compressive strength and the UPV measurements. For instance, the addition of stabilizers like lime or cement can enhance the mechanical properties of earthen materials, leading to improved performance underload (Mohammad, 2011). Ni et al. (2024) highlighted that various factors, including mix proportions and aggregate types, affect both the strength development of concrete and ultrasonic pulse velocity, emphasizing the need for careful consideration of these variables in earthen architecture.

Recent advancements in ultrasonic pulse velocity (UPV) testing methodologies have significantly expanded its applicability within the domain of earthen architecture, offering enhanced capabilities for the non-destructive evaluation of material properties. In particular, the integration of machine learning techniques into UPV data analysis represents a transformative development, as these approaches facilitate more precise predictive modelling of compressive strength by incorporating a broader spectrum of input variables (Boukhelkhal & Guermazi, 2018). Such advancements not only improve the reliability of UPV-based assessments but also contribute to the refinement of diagnostic frameworks for evaluating structural stability in historical and contemporary earthen constructions.

Moreover, the synergistic application of UPV testing with complementary non-destructive testing (NDT) techniques, such as rebound hammer tests, has been increasingly recognized as a robust strategy for achieving a more comprehensive characterization of material properties (Lee et al., 2014). By integrating multiple diagnostic approaches, researchers can mitigate the limitations inherent in individual testing methods, thereby enhancing the accuracy of assessments related to mechanical performance and long-term durability. These methodological innovations underscore the growing potential of UPV testing as an important tool in the preservation, maintenance, and structural analysis of earthen architecture, reinforcing its role in both academic research and practical engineering applications (Lee et al., 2014).

The use of Ultrasonic Pulse Velocity testing represents an important advancement in the assessment of structural integrity in earthen architecture. By establishing a reliable correlation between UPV and compressive strength, this non-destructive method offers a practical solution for monitoring the health of earthen structures. As the demand for sustainable building practices continues to grow, the preservation of earthen architecture through effective assessment techniques will play an essential role in safeguarding this valuable cultural heritage for future generations.

This research paper explores the potential of

using Ultrasonic Pulse Velocity (UPV) as a dependable method for evaluating the structural integrity of earthen constructions.

MATERIALS AND METHODS

In this study, a series of experiments were conducted to evaluate the mechanical properties of various earthen mixtures, focusing on the relationship between Ultrasonic Pulse Velocity (UPV) measurements and compressive strength. For this purpose, 44 mixtures were developed (Table 1) with materials that included different soil types, sand, water, and various additives such as lignin, deflocculants, and lime. These components were selected based on their potential to influence the mechanical properties of earthen materials, particularly in enhancing compressive strength and durability. The mixtures were cast into 40 x 40 x 160 mm prisms.

The earthen mixtures were formulated using a systematic approach, where different recipes were created by varying the ratios of soil, sand, and water, along with the incorporation of specific additives. The soil used in the mixtures was sourced from local deposits, ensuring that it was representative of typical earthen materials used in construction. The sand was selected for its grain size distribution, which is known to affect the overall strength of the mixture. The water content was adjusted to achieve optimal workability while maintaining the desired consistency of the mixtures.

Additives were introduced to enhance the properties of the mixtures. Lignin, a natural polymer, was included to improve the binding characteristics of the mixtures, while deflocculants were used to reduce the viscosity of the slurry, facilitating better mixing and compaction. Lime was added as a stabilizer, known for enhancing the compressive strength of earthen materials through pozzolanic reactions.

Ultrasonic pulse velocity (UPV)

The initial phase of the experimental investigation focused on the application of Ultrasonic Pulse Velocity (UPV) testing as a means of evaluating the quality, homogeneity, and structural integrity of the prepared earthen material mixtures. This non-destructive testing procedure was conducted utilizing a portable ultrasonic testing device, which was equipped with transducers operating at a frequency of 150 kHz. These transducers were responsible for generating and transmitting ultrasonic waves through the test specimens, facilitating the assessment of their internal consistency and mechanical performance.

The selection of transducers with a 150 kHz frequency was informed by established technical guidelines, which recommend their use for assessing relatively thin structural elements - specifically those with dimensions of less than 50 mm. This frequency range has been demonstrated to provide an optimal balance between wave penetration depth and resolution, thereby enabling the precise detection of internal inconsistencies, voids, or heterogeneities within the tested materials. By employing UPV testing in this manner, the study aimed to generate a reliable dataset for characterizing the physical and mechanical behaviour of the prepared mixtures, ultimately contributing to a more comprehensive understanding of their suitability for use in earthen construction applications (NP137-2014). The time taken for the waves to traverse the material was recorded, and the velocity was calculated. This measurement provided insights into the density and elastic properties of the mixtures, which are closely related to their compressive strength. For these types of specimens with dimensions of 40x40x160 mm, the UPV testing was conducted at two points on each sample, as shown in Figure 1. In Figure 2 a cross section with the positioning of the transducers can be observed. This positioning of the transducers was chosen due to the fact that the specimens were tested destructively to determine the flexural strength, thus each specimen resulting in 2 samples to be tested for compressive strength. Prior to the destructive testing, each specimen was weighed to determine an air-dry density.

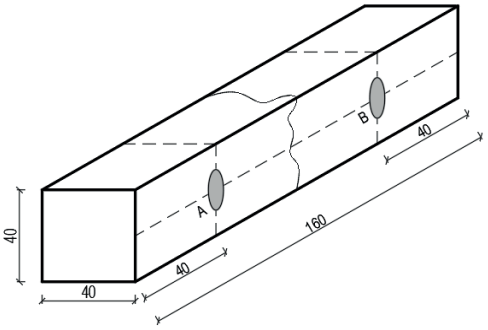

Figure 1. Transducers positioning on the prismatic specimens

Destructive testing for compressive strength

Following the UPV assessments, the same samples were subjected to compressive strength testing to obtain definitive mechanical property data.

The compressive strength tests were performed following standard testing procedures, using a hydraulic press to apply axial loads until failure

occurred. The maximum load recorded during the test was used to calculate the compressive strength of each mixture, allowing for a direct comparison with the UPV results.

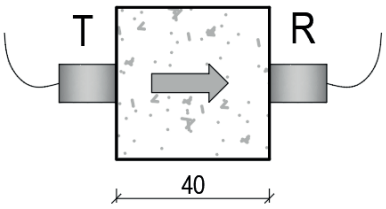

Figure 2. Cross section of the specimens with the positioning of the transducers

RESULTS AND DISCUSSIONS

Correlation between UPV and density

The mean values of the UPV were correlated with the mean values of the air-dry density determined by measuring and weighing each specimen to determine a correlation between them. The UPV values ranged from 0.645 km/s to 1.435 km/s, while density values varied between 1409 kg/m³ and 1782 kg/m³. These measurements indicate a diverse set of materials, with varying degrees of compactness and internal structure. The ultrasonic velocity (UPV) is generally influenced by factors such as elasticity, stiffness, and porosity of the material, while density is determined by the mass per unit volume.

A preliminary dataset analysis suggests a weak correlation between UPV and density, indicating that materials with higher densities tend to exhibit higher ultrasonic velocities. This relationship could be explained by the fact that denser, more compact and cohesive materials offer greater resistance to the propagation of ultrasonic waves. In contrast, lower-density materials, which may contain more voids and less internal cohesion, could allow ultrasonic waves to propagate more easily, resulting in lower UPV values. Figure 3 presents a graphical representation of the correlation between UPV and density. From these values, some trends can be identified:

- Higher UPV values (e.g. 1.252 km/s, 1.383 km/s, 1.435 km/s) are often associated with higher densities (e.g., 1622 kg/m³, 1619 kg/m³, 1603 kg/m³);
- Lower UPV values (e.g., 0.626 km/s, 0.645 km/s, 0.649 km/s) tend to correspond to lower or moderate densities (e.g., 1516 kg/m³, 1591 kg/m³, 1473 kg/m³).

The observed correlation between UPV and density, however, is not linear, as there is some variation in the data. For instance, some samples with relatively high UPV values (e.g., 1.186 km/s) have lower densities (e.g., 1502 kg/m³), which could indicate the presence of other factors influencing the UPV, such as differences in soil composition or structure. Further statistical analysis and experimental studies would be necessary to fully quantify this relationship and account for additional variables.

Correlation between UPV and compressive strength

The ultrasonic velocity values obtained through non-destructive testing (NDT) and the corresponding compressive strength values obtained through destructive testing (DT) were analyzed to identify a correlation between the two (Figure 4). The relationship between ultrasonic pulse velocity (UPV) and compressive strength in the studied soil mixtures reveals significant variations, indicating the influence of material composition and structural characteristics on mechanical performance. The recorded UPV values range from approximately 0.472 km/s to 1.626 km/s, while the compressive strength values exhibit a broader spectrum, from 0.419 MPa to 7.421 MPa.

An initial observation highlights that higher UPV values tend to correspond to increased compressive strength, which aligns with the general principle that denser and more compact materials facilitate faster ultrasonic wave propagation and exhibit greater strength. However, exceptions exist, particularly in cases where relatively low UPV values are associated with remarkably high compressive strengths. For instance, a UPV of 0.759 km/s is linked to a compressive strength of 2.837 MPa, while another instance with a similar UPV of 0.731 km/s reaches 3.970 MPa.

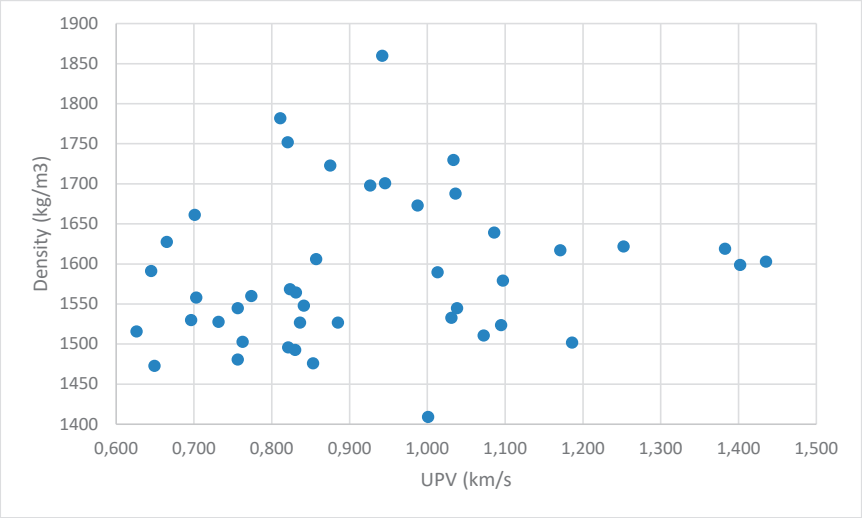

Figure 3. Correlation between UPV and density

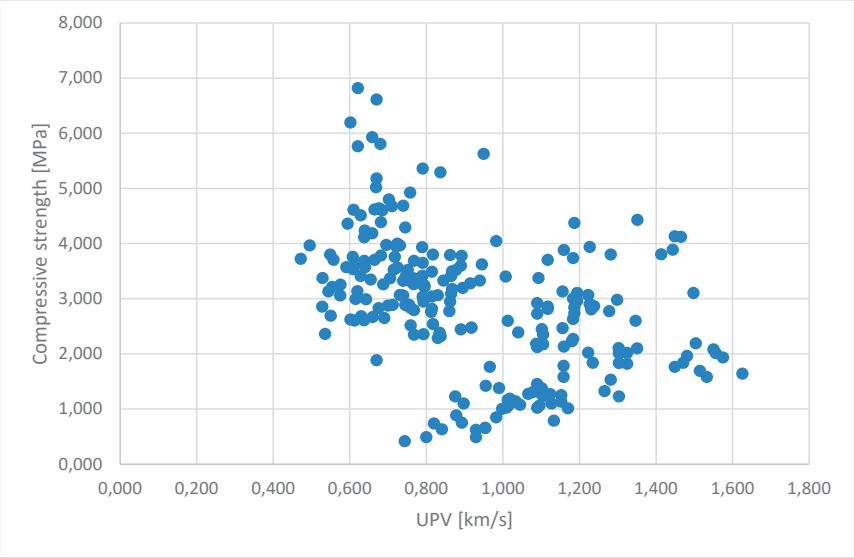

Figure 4. Correlation between UPV and compressive strength

This suggests that factors beyond wave velocity, such as bonding properties and granular arrangement, play an important role in determining compressive strength.

In the lower UPV range (below 0.8 km/s), the compressive strength fluctuates significantly. Some samples exhibit moderate values (e.g., 0.744 km/s corresponding to 0.419 MPa), whereas others demonstrate much higher strengths (e.g., 0.629 km/s associated with 4.513 MPa). These variations imply that certain compositions enable substantial strength development even at relatively low wave velocities, possibly due to optimized particle packing and binder interactions.

Conversely, in the upper UPV range (above 1.2 km/s), compressive strength values remain predominantly higher. For example, a UPV of 1.498 km/s corresponds to a compressive strength of 3.108 MPa, while another instance with 1.303 km/s reaches 2.109 MPa. The consistency in this range suggests that well-

compacted and structurally sound mixtures promote both enhanced wave transmission and mechanical resistance.

Notably, some outliers indicate a deviation from the expected trend. For instance, a UPV of 0.670 km/s corresponds to a remarkably high compressive strength of 6.613 MPa, demonstrating that under specific conditions, even materials with relatively low ultrasonic velocities can exhibit superior values of compressive strength. These anomalies may arise from unique microstructural formations or particular curing processes that enhance cohesion and load-bearing capacity.

Overall, the data suggest a general positive correlation between UPV and compressive strength, albeit with notable exceptions influenced by material-specific properties. The findings highlight the complexity of soil-based materials and underscore the necessity for a comprehensive understanding of both physical and chemical factors when evaluating their mechanical performance.

CONCLUSIONS

The first part of the analysis focused on the relationship between UPV and density. A general trend was observed, where higher UPV values tended to correspond to higher densities. This is consistent with the fundamental principles of material science, as denser materials typically allow sound waves to propagate more quickly due to their compact and homogeneous structure. For example, samples with UPV values above 1.0 km/s often exhibited densities exceeding 1600 kg/m³, while lower UPV values (e.g., 0.626 km/s) were associated with lower densities (e.g., 1409 kg/m³). However, exceptions to this trend were noted, indicating that factors such as soil composition, porosity, and moisture content also play a significant role in influencing UPV independently of density.

The second part of the analysis examined the relationship between UPV and compressive strength. The data revealed a general trend where higher UPV values tend to correspond to higher compressive strengths. This aligns with the fundamental principles of material science, as materials with greater density and compactness typically exhibit faster ultrasonic wave propagation and higher resistance to compressive forces. For instance, samples with UPV values exceeding 1.0 km/s often demonstrated compressive strengths above 1.0 MPa, with some reaching up to 4.136 MPa. This trend supports the hypothesis that UPV can serve as an indirect indicator of compressive strength in soil and similar materials.

Despite the general trend, the dataset exhibited significant variability and several outliers. Some samples with relatively low UPV values (e.g., 0.629 km/s) displayed unexpectedly high compressive strengths (e.g., 4.513 MPa), while others with moderate UPV values (e.g., 0.930 km/s) showed low compressive strengths (e.g., 0.491 MPa). These anomalies highlight the influence of additional factors, such as soil composition, moisture content, curing conditions, and the presence of binding agents, which can significantly alter the mechanical properties of the material independently of UPV.

Combining the insights from both analyses, it is evident that density, UPV, and compressive strength are interrelated but not solely dependent on one another. Higher density generally contributes to both higher UPV and higher compressive strength, but the relationships are not strictly linear or deterministic. For example, some samples with moderate densities exhibited high UPV but low compressive strength, while others with lower densities showed high compressive strength due to factors such as strong internal bonding or optimal moisture content. This highlights the complexity of the interactions between these variables.

ACKNOWLEDGEMENTS

Abstract

The most commonly used material in the construction sector is arguably cement, the production of which generates massive amounts of greenhouse gases, contributing approximately 5-8% of global CO_2 emissions. A potential solution in this context is the use of inorganic binders from local sources, a trend that is gaining momentum in research studies within the construction materials industry. Clay-based masonry mortar represents a viable, eco-friendly, and cost-effective solution, with its components being abundantly available worldwide. Clay has demonstrated its effectiveness as a binder over centuries. In its natural, calcined, or modified forms, clay serves as an important alternative to cement, offering sustainable material development at lower costs and with reduced environmental impact. Clay is a sedimentary rock, whose main ingredient is aluminium silicate, characterized by its colloidal appearance and binding properties. The primary feature of clay is its ability to absorb large amounts of water, transforming into a pasty, ductile mass that can be easily shaped into any form.

Key words*: clay composite, local materials, mortar.*

INTRODUCTION

Global demand for cement and concrete products has increased significantly in recent years, due to the development of economies and the continuous growth of the world population (Kouakou et al., 2009; Berriel et al., 2016). According to the report published by CEMBUREAU (2023), in 2022 about 4.1 billion tons of cement were produced, the largest share being attributed to China - 51.1%.

The total quantity of cement that was imported in 2022 to Europe increased almost fourfold compared to 2016, the values of the quantities of imported tons are illustrated in Figure 1 (Andrew, 2018). Romania has witnessed a 459% increase in cement imports during this period, from 204,264 t in 2016 to 1,142,932 t in 2022 (CEMBUREAU, 2023). This has contributed to the expansion of various concrete-related industries, from the extraction of raw materials to the increased consumption of fossil fuels for material processing and cement production (Memon et al., 2012). At the same time, it should be noted that the impact of increased demand is reflected in the increase in cement prices by over 150% in the last decade and threatens significant environmental impacts, phenomena that need to be mitigated (Ahmad et al., 2011). Thus, improving the sustainability of the construction sector has become a major concern for researchers in this field.

A significant percentage of construction materials contain cement, which represents a hydraulic binder developed through an energy-intensive process. Cement production process emits large amounts of greenhouse gases and contributes approximately 5-8% to global CO_2 emissions.

According to estimates, this share could reach 10-15% if stringent measures are not taken to decarbonize the construction industry (Schneider et al., 2011). In this regard, significant progress has been made in the field of making construction products more efficient and there is a considerable increase in the level of involvement, awareness and engagement in projects to reduce environmental impact

(Kajaste et al., 2016). The automation of lime production in modern kilns and the use of alternative fuel resources represent an important step towards reducing energy consumption and CO_2 emissions (Deja et al., 2010), but these solutions are being outpaced by the exponential growth of demand, which is driving the development of new ways to reduce environmental impact and costs.

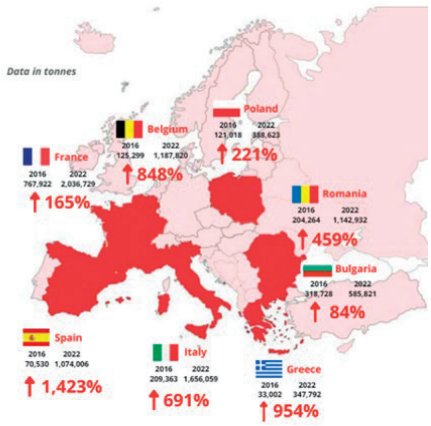

Figure 1. Quantity of tons of cement imported into Europe (CEMBUREAU, 2023)

Among the classic solutions to reduce the need for cement in the shrinkage materials industry, one can mention the partial substitution of cement by using industrial by-products such as fly ash and blast furnace slag, but its applicability is limited by the generation capacity of power plants or blast furnace industries (Alujas et al., 2015; Teklay et al., 2016).

Currently, in the construction sector, there is a growing demand for sustainable materials and products, with ecological characteristics, obtained through non-polluting processes and with increasingly lower energy consumption (Mircea et al., 2021). In order to gain a secure market, being in competition with traditional construction materials/products, made through energy-consuming and polluting processes, materials with ecological properties must have comparable or superior characteristics and durability (Calatan et al., 2020).

The use of natural materials in the production of various construction products is one of the solutions with high potential to achieve the aforementioned goals, and clay is one of these materials (Hegyi et al., 2023).

Clay represents a natural, sustainable, cheap and widely available material worldwide. Since the earliest times of the development of human civilization, clay has been used to obtain various materials and products for construction, either with a non-structural role, such as clay walls and floors, or even with a structural role, namely tiles for making roofs, bricks or clay blocks (Hegyi et al., 2016).

Clay is a sedimentary rock, whose main ingredient is aluminium silicate, characterized by its colloidal appearance and binding properties. The primary feature of clay is its ability to absorb large amounts of water, transforming into a pasty, ductile mass that can be easily shaped into any form (Petcu et al., 2023).

Clay-based construction materials and products are increasingly used at the national level, with the benefits of clay recognized not only for the technical characteristics it imparts to construction materials and products but also for its contribution to enhancing the durability of construction elements over time. The growing adoption of clay in Romanian construction, alongside other traditional natural materials, reflects the industry's alignment with sustainable development principles through the application of environmentally friendly technologies. Additionally, it supports the creation of a healthier environment and contributes to reducing climate change caused directly by human activities.

This study evaluates the influence of aggregate content on the performance of clay-based mortar which can be used to create eco masonry for sustainable buildings.

MATERIALS AND METHODS

The clay composite utilized in this study was prepared using locally sourced materials, including sand fractions of 0-1 mm and 0-4 mm, coarse aggregates of 4-8 mm, and clayey soil characterized by a composition of 53% clay, 44% silt, and 3% sand. The water content required for each formulation was determined experimentally to achieve optimal workability. The compositions analysed in the study are detailed in Table 1.

Table 1. Tested clay compositions

`Constituents	Units	R1	R2	R3
Sand 0-1	g	439	366	293
Sand 0-4	g	4578	3851	3052
Aggregates 4-8 mm	g	4204	3503	2803
Clay soil	g	6148	7684	9221
Water/clay soil ratio		0.52	0.48	0.52
Clay soil/aggregates ratio		0.40	0.50	0.60

The consistency of the fresh mixture was evaluated in accordance with the standard SR EN 1015-3:2001/A2:2007, which specifies the procedure for determining the consistency of masonry mortars using the flow table method. As illustrated in Figure 2, the test involved placing a conical mould on a circular table and filling it with the fresh clay-based mortar in two layers. Each layer was compacted using a standardized metal tamper. Following the removal of the mould, 15 consecutive drops of the table were performed within 15 seconds, after which the average spread diameter of the sample was measured.

Figure 2. Determination of the consistency of the fresh clay mixture

The fresh clay mortar was then cast into standardized metallic moulds with dimensions of 160 × 40 × 40 mm (Figure 3). After a curing period of three days, the specimens were demoulded and stored under controlled laboratory conditions at a temperature of 20 ± 2°C and relative humidity of 65 ± 5% until testing at 28 days.

The performance of the hardened clay mortar was assessed based on density, flexural strength, and compressive strength. The density of the material was influenced by the granulometric distribution, which governed the packing efficiency of the particles and the proportion of voids within the composite.

Figure 3. Casting fresh clay mixture in metal moulds

The internal structure of the clay-based material played a significant role in determining its mechanical performance and durability, as extensively examined in previous studies under various operational conditions.

The density of the hardened mixture was determined with the relationship:

$$D = \frac{m}{V} \qquad (1)$$

where:

D - density of hardened mixture, kg/m^3;

m - mass of the specimen, kg;

V - volume determined by measurement, m^3.

Flexural strength testing was conducted according to the SR EN 1015-11:2020 standard, which outlines the procedures for evaluating the mechanical performance of hardened masonry mortars. The specimens were positioned on support rollers, and a controlled load was applied at a rate of 10-50 N/s until failure occurred within a time frame of 30 to 90 seconds. The flexural strength was determined using the following equation:

$$R_f = \frac{1.5 \cdot F_f \cdot l}{bd^2} \qquad (2)$$

where:

R_f - bending strength, MPa;

b - prism width, mm;

d - prism height, mm;

F_f - load applied in the middle of the prism at rupture, N;

l - distance between the support rollers, mm.

Compressive strength, a fundamental parameter in the assessment of mortars, was also determined in accordance with SR EN 1015-11:2020. The test was conducted on the halves of the specimens obtained from the flexural strength test. Prior to testing, the specimens

were measured to ensure dimensional accuracy, and their surfaces were verified for parallelism to minimize experimental errors. The load-bearing surfaces of the testing apparatus were cleaned using a dry textile before securing the samples. The specimens were positioned to ensure uniform load distribution, with a clearance of 16 ± 1 mm from the nearest support edge. The compressive load was applied gradually, within a controlled range of 50 N/s to 500 kN/s, ensuring failure occurred within 30 to 90 seconds.

Compressive strength was determined with the formula:

$$R_c = \frac{F_c}{1600} \qquad (3)$$

where:

R_c - compressive strength, MPa;

F_c - maximum load at the moment of rupture, N;

1600 - area of the plates (40 x 40 mm), mm^2.

RESULTS AND DISCUSSIONS

The clay-based mortar formulations achieved optimal workability at a spread diameter of 105 ± 1 mm. As illustrated in Figure 4, mixtures with a lower spread exhibited reduced cohesion and workability, forming a stiff, low-fluidity mass. In contrast, mixtures with excessive spread exhibited a paste-like consistency with excessive stickiness.

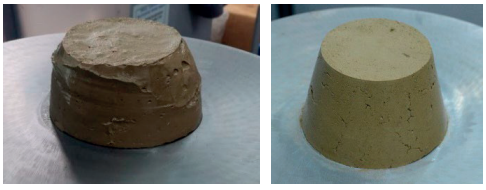

Figure 4. Different consistency of the fresh clay mixture

Density of clay mortar

Higher-density clay mixtures displayed a more compact internal structure, with enhanced particle bonding and lower porosity, whereas lower-density mixtures exhibited improved thermal properties. The uniformity of the clay mortar mixtures was confirmed by the low coefficient of variation (COV), which remained below 1%, indicating a consistent internal structure. The mean density values at 28 days were 1914 kg/m³ for recipe R1 (COV = 0.24), 1939 kg/m³ for R2 (COV = 0.08), and 1961 kg/m³ for R3 (COV = 0.24). The increase in aggregate content led to higher densities due to the greater specific weight of the aggregates compared to the clay matrix, promoting a denser packing arrangement where fine clay particles occupied the voids between aggregates. The aggregate distribution for recipe R2 is depicted in Figure 5.

Figure 5. Aggregate distribution for R2

Flexural Strength

The flexural strength results, determined in accordance with SR EN 1015-11:2020, ranged from 1.06 MPa for recipe R1 (50% clay) to 1.17 MPa for recipe R3 (60% clay). The correlation between density and flexural strength at 28 days is presented in Figure 6. The binding role of clay was evident, as its proportion directly influenced the mechanical performance.

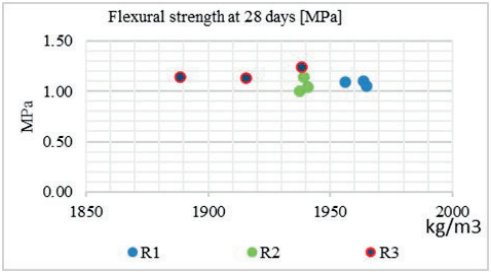

Figure 6. Correlation between density and flexural strength at 28 days

To achieve optimal strength, the clay content must be sufficient to completely coat the aggregate surfaces, facilitating the development of a cohesive and structurally stable matrix. The increased flexural strength observed in mixtures

with higher clay content can be attributed to the formation of silico-aluminate bonds, which enhance the mechanical integrity of the composite. The failure mode of the specimens under flexural testing is shown in Figure 7. The coefficient of variation for flexural strength ranged from 2.19% to 6.53%, further confirming the homogeneity of the material.

Figure 7. The mode of failure of the sample subjected to bending

Compressive Strength

Compressive strength was evaluated using the prism halves obtained from the flexural strength test (Figure 8). The failure mechanism of the material under uniaxial compression was associated with the transverse tensile stresses generated at the aggregate-matrix interface. The primary factors influencing compressive strength included the quality and proportion of the constituent materials, adhesion between the clay matrix and aggregates, compaction state, curing conditions, and specimen age.

Figure 8. Compressive strength of the prism halves

The average compressive strengths recorded at 28 days were 2.98 MPa for R1 (40% clay), 3.72 MPa for R2 (50% clay), and 3.79 MPa for R3 (60% clay), with coefficients of variation ranging from 4.22% to 5.77%. The distribution of compressive strength results is shown in Figure 9. The results indicated that the recipe R3, containing 60% clay marked highest compressive strength, representing a 27% increase compared to the Recipe R1 with 40% clay content. The higher clay content contributed to improved compressive strength due to enhanced bonding between the matrix and aggregates. However, excessive clay content may lead to reduced permeability, which could affect the long-term durability of the material.

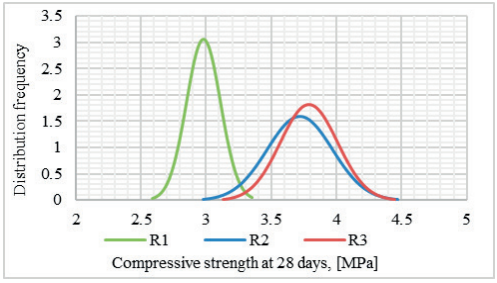

Figure 9. Distribution of 28-day compressive strength results

CONCLUSIONS

The increasing demand for sustainable materials and products in the construction sector contributes to the development of environmentally friendly materials, which contribute to reducing the consumption of natural resources, increasing the energy efficiency of buildings and protecting the environment.

Preliminary results have marked a promising performance of the prototypes, confirming their potential to replace traditional masonry mortar with a high ecological footprint. In addition, the use of local and economically accessible materials supports the development of a circular economy, while contributing to the sustainability of rural communities and reducing production costs

Thus, following the analysis of the results obtained, the R3 recipe containing 60% of the total amount of aggregates showed superior results, both in the case of flexural strength - 1.17 MPa, with a coefficient of variation of

5.19%, and in the case of compressive strength - 3.79 MPa, and a coefficient of variation of 5.77%.

Abstract

The comprehensive mapping and inspection of both underground and above-ground terrain in mountainous environments pose significant challenges for engineering projects, particularly those involving legacy infrastructure. This study presents an integrated geospatial methodology for the rehabilitation and modernization of the Tomesti micro-hydropower station in Timiș County, Romania. By combining GNSS-based control networks, UAV photogrammetry, airborne LiDAR, and handheld SLAM scanning, the project achieved high-resolution data acquisition across complex topographies and inaccessible subsurface structures. Ground control points were established using total stations to ensure millimetric precision and consistent georeferencing of all datasets. The workflow delivered orthophotos, digital surface and terrain models, detailed topographic plans, and 3D reconstructions of the interior hydro-technical gallery. These outputs formed the foundation for updated technical documentation and supported engineering analyses for structural rehabilitation and eco-friendly water intake systems. The results confirm that modern geomatics, when anchored in classical surveying practices, provides a robust framework for accurate assessment, design, and environmental integration. This case study underscores the value of multi-sensor approaches in repurposing abandoned infrastructure for sustainable energy production and demonstrates their practical relevance in mountainous terrain.

Key words*: 3D, LiDAR, SLAM, topographic mapping, UAV.*

INTRODUCTION

Accurate land surveying is a cornerstone of complex engineering projects, especially in rugged or inaccessible terrain (Sestras et al., 2025). Infrastructure and energy development rely on precise topographic data, spatial modelling, and georeferenced planning to minimize risk, control costs, and ensure environmental sustainability. This becomes even more critical in projects involving legacy infrastructure or underground features, where outdated or missing data can cause technical and environmental issues (Langhammer et al., 2018). In response, modern surveying integrates advanced technologies, GNSS, UAV LiDAR, photogrammetry and SLAM, that have reshaped terrain analysis, rehabilitation strategies, and design processes (Nap et al., 2023). These tools not only support but significantly enhance the resolution, speed, and precision of early-stage decision-making.

This study centers on the revival of the Tomesti micro-hydropower station in Timiș County, Romania, combining geospatial innovation with sustainable energy goals. Initially launched before 1989, the site includes upstream intakes, an underground gallery, and a partially built hydroelectric cavern. Work was halted, leaving behind incomplete and poorly documented infrastructure. With renewed emphasis on renewable energy and national energy security, reassessing and completing this project using modern technical and

environmental standards has become a strategic priority.

To guide the design, rehabilitation, and environmental compliance of this complex project, a comprehensive geospatial survey was carried out. The methodology integrated total stations and GNSS-based control networks for spatial accuracy, UAV-based LiDAR for detailed surface modelling, and SLAM technology for high-precision scanning of underground tunnels (Liu et al., 2024). These combined approaches produced orthophotos, DSM/DTM models, topographic plans, and 3D reconstructions of the subterranean system, forming the technical foundation for feasibility assessments and future planning.

While geospatial technologies like UAV photogrammetry, LiDAR, and SLAM have advanced rapidly, classical instruments such as GNSS receivers and total stations remain essential in complex terrain (Sălăgean et al., 2019; Sestras, 2021). Their precision is unmatched when defining geodetic control networks - critical for survey accuracy. GNSS, particularly in RTK or PPK mode, enables fast, accurate 3D positioning across large areas, while total stations offer high angular accuracy in areas with limited satellite visibility, such as valleys or forested regions.

Classical surveying instruments are essential in establishing Ground Control Points (GCPs) and Independent Check Points (ICPs), which are critical for georeferencing UAV imagery and validating products like orthophotos, DSMs, and DTMs (Stöcker et al., 2020). Regardless of technological advancements, airborne systems depend on precise ground data for calibration and accuracy. UAV and SLAM outputs achieve their full potential only when tied to a solid geodetic network established via GNSS and total stations.

As highlighted in both the literature and the present methodology, relying solely on aerial or mobile sensors can lead to positional drift, systematic errors, or reduced accuracy in dense vegetation or occluded zones. Total stations and GNSS provide consistent benchmarks and validation points across the survey area, mitigating these limitations.

Given the complexity of terrain in engineering surveys, no single method suffices in isolation (Bilașco et al., 2021). A multi-sensor approach, especially combining UAV-based LiDAR and photogrammetry, proves far more effective in achieving full spatial coverage and accuracy.

Structure-from-Motion (SfM) photogrammetry reconstructs 3D surfaces from drone-captured images (Khanal et al., 2020), excelling in open areas with visible features like buildings or roads. It offers affordability, high visual detail, and easy interpretation. However, in vegetated areas, it struggles to capture ground surfaces (Popescu et al., 2024). LiDAR, by contrast, penetrates vegetation to provide accurate terrain data, even in low-light conditions (Oniga et al., 2023). Still, it may miss finer architectural elements and demands more advanced equipment and processing (You & Lee, 2020).

By integrating LiDAR and photogrammetry, surveyors harness the strengths of both systems while mitigating their individual limitations. LiDAR accurately captures terrain beneath vegetation, whereas photogrammetry excels at rendering visible structures. Combined, they offer a more complete and balanced view of the landscape (Sestras et al., 2025a).

This integrated approach is especially valuable for infrastructure projects like hydropower development, where natural topography and built features must be mapped with precision. Generating detailed topographic outputs, 3D models, and full site documentation facilitates improved decision-making, risk evaluation, and design planning (Coroian et al., 2024).

Simultaneous Localization and Mapping (SLAM) has become a crucial technology in areas where GNSS or total stations are less effective (Chio & Hou, 2021). Using LiDAR sensors and inertial units (IMUs), SLAM continuously tracks scanner movement while generating accurate 3D point clouds. Its portability allows surveyors to collect data in confined, GPS-denied spaces like underground infrastructure, interiors, or dense forests (Keitaanniemi et al., 2021).

In our case study, SLAM was essential for mapping the abandoned hydro-technical gallery in Tomesti. The underground sewer system, unreachable by GNSS and unsuited for static scanning, was navigated on foot with a handheld SLAM unit. This enabled both 3D data collection and real-time video inspection, producing a reliable model of the tunnel's

condition and revealing critical information for structural evaluation.

The application of SLAM in rugged environments highlights its value in engineering projects where complex geometries, poor visibility, and restricted access make traditional surveying difficult (Urban et al., 2024). In this project, integrating SLAM data with UAV-derived surface models and geodetic networks created a seamless spatial database, essential for feasibility studies and rehabilitation planning. SLAM emerges not merely as a complementary tool, but as a key technology in multi-sensor surveying, enabling accurate and efficient mapping in the most challenging conditions.

The combined use of photogrammetry and LiDAR greatly improves the quality and flexibility of modern surveys, especially in difficult terrain (Rogers et al., 2020). While these technologies increase coverage and speed, classical instruments like GNSS and total stations remain vital for providing the precision needed for georeferencing and validation. This hybrid approach ensures high-resolution, standards-compliant data that supports reliable infrastructure planning and environmental assessment.

The Tomesti project exemplifies how outdated hydro-infrastructure can be revitalized through a balanced mix of advanced geomatics and traditional methods. It addresses both technical demands and broader goals like sustainable energy and responsible land use in mountainous regions. This case stands out for its interdisciplinary methodology, reliance on accurate data, and strong potential for replication. The following sections outline the geospatial workflow, equipment used, survey results, and how this integrated strategy informs rehabilitation and energy planning.

MATERIALS AND METHODS

Study area and desideratum

The study focuses on a hydro-technical site in eastern Timiș County, within the administrative boundaries of Tomești commune, Romania (Figure 1). Timiș is Romania's largest county, covering about 8,696.7 km² or 3.65% of the national territory. Located in the historical Banat region, it borders Hungary to the west and Serbia to the southwest. The county's capital, Timișoara, situated on the Bega River, is the main urban and administrative centre.

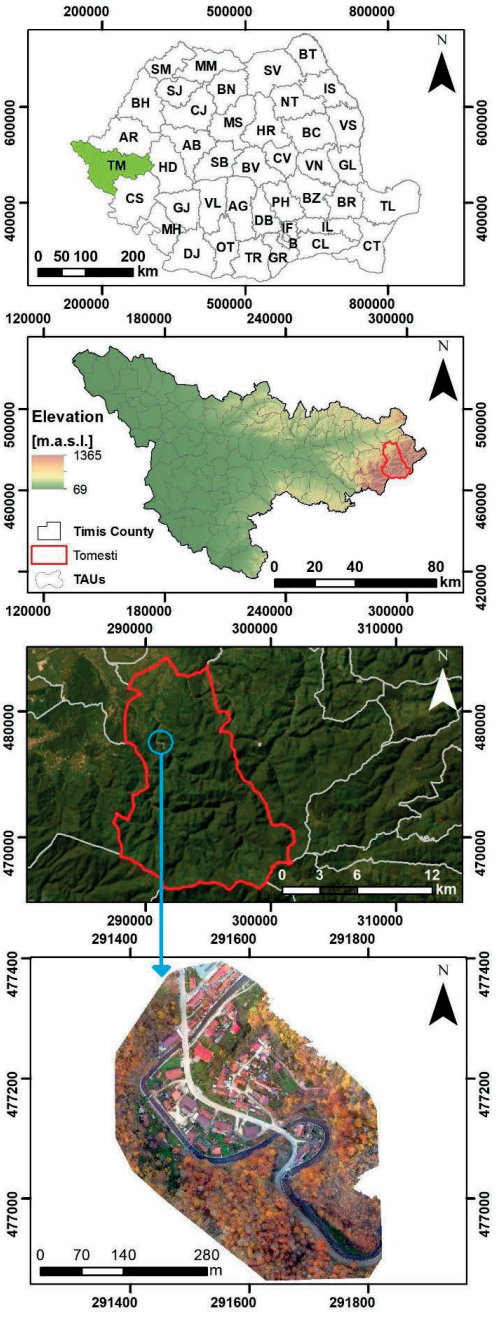

Figure 1. Location of the study area in Timiș County, Romania, showing elevation context, satellite view, and orthophoto of the Tomești micro-hydropower site

Tomești commune lies on the northern slopes of the Poiana Ruscă Mountains, covering 140.94 km² and comprising six villages, including its namesake seat. As of the 2021 census, the population totals 1,879, continuing a declining trend. The area features steep, forested terrain shaped by the upper Bega River and its tributaries, which provide favourable conditions for hydro-technical development due to the region's geomorphological and hydrological profile.

This site was part of a larger hydropower initiative begun during the communist era, which included partial construction of a 9.4 km underground tunnel, two water intakes, and a cavern for a micro-hydropower station. Abandoned before completion, the infrastructure has since deteriorated without maintenance.

The current investment project aims to modernize and finalize the original development using advanced surveying and design tools. Given the complex terrain, outdated documentation, and limited access, technologies such as GNSS, UAV-based LiDAR, and SLAM scanning are essential for georeferencing, surface modelling, and underground inspection.

Aligned with Romania's renewable energy strategy, the project seeks to sustainably harness the site's hydropower potential while ensuring all planning and design stages are based on precise geospatial data. This initiative not only supports technical feasibility and environmental evaluation but also demonstrates how modern methods can breathe new life into legacy infrastructure.

Methodological framework

This study presents an integrated methodological framework for the accurate mapping and inspection of both surface and subsurface components of a previously abandoned micro-hydropower project in Tomești commune, Timiș County. Due to the site's challenging terrain, partial hydro-technical infrastructure, and renewed national focus on renewable energy, the campaign aimed to develop a high-resolution spatial and technical database to support the project's redesign and revitalization.

The need for intervention stems from the deteriorated and outdated state of the original infrastructure. Initially planned before 1989, the project includes two upstream concrete intakes on Bega River tributaries, an underground gallery, and a partially excavated hydroelectric cavern. With no recent surveys or technical evaluations, these structures have experienced extensive environmental and structural degradation. The adopted workflow is outlined in Figure 2.

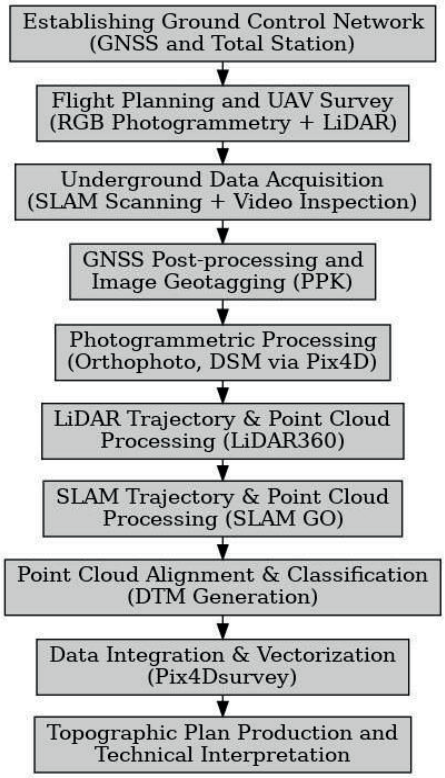

Figure 2. Methodological workflow

To address the complex demands of this project, the methodological framework combined traditional geodetic surveying with advanced remote sensing and 3D scanning techniques. Initially, a ground control network was established using GNSS receivers and total stations, forming a stable reference system for all subsequent data collection and ensuring spatial consistency across datasets.

UAV-based photogrammetry was then performed using drones with high-resolution RGB cameras to produce orthophotos and digital surface models (DSM). These were

refined using LiDAR sensors mounted on UAV platforms, which provided detailed elevation data, even in vegetated or inaccessible zones, enabling the generation of accurate digital terrain models (DTMs) for hydrological and engineering analyses.

To map the underground gallery and associated structures, SLAM (Simultaneous Localization and Mapping) technology was employed. A handheld SLAM unit enabled the collection of 3D point clouds in GPS-denied tunnel environments while also capturing video for visual inspection of structural conditions such as cracks, sedimentation, or collapses.

This hybrid methodology produced robust deliverables tailored for engineering and environmental applications, including:

- High-resolution orthophotos;
- Precise DSMs and DTMs;
- Cross-sectional terrain and tunnel profiles;
- Integrated 3D models;
- Video records of underground conditions.

By providing reliable spatial data, this approach supports feasibility and safety assessments for completing the hydroelectric project in alignment with Romania's energy policy. The method also offers a replicable model for other complex or partially completed infrastructure projects.

Surveying instrumentation and equipment overview

In the Tomești micro-hydropower station rehabilitation project, a suite of advanced surveying instruments was deployed to ensure high-precision data acquisition across diverse terrains and structural challenges. These technologies enabled comprehensive spatial analyses essential for design and planning.

■ GNSS Technology: UniStrong G10 Receiver

To establish the Stereographic 1970 projection, the UniStrong G10 GNSS receiver was used in both static and RTK modes. Supporting GPS, GLONASS, BeiDou, and Galileo constellations, the G10 ensures high positional accuracy. Its tilt compensator auto-corrects based on pole orientation, and its cloud capabilities offer real-time monitoring, updates, and triple data storage for secure acquisition.

■ Total Station: Leica TS16P

In mountainous zones with poor satellite visibility, the Leica TS16P robotic total station was used to densify the control network. This self-learning instrument auto-adjusts to site conditions, offering high-accuracy measurements, a 5-inch touch display, and AutoHeight functionality for automated instrument height reading. It also includes LOC8 technology for remote locking and tracking.

■ UAV-Based Surveying

A DJI Matrice M200 drone with a Zenmuse X4S camera and TOPODRONE 200+ LiDAR system captured aerial data (Figure 3). The LiDAR system, based on the Hesai XT32M2X sensor, offers 200 m range, triple return mode, and 3–5 cm XYZ accuracy. Its built-in 200 Hz IMU and GNSS receiver enable precise georeferencing. Flight planning was performed via Map Pilot Pro, maintaining a steady altitude of 120 m AGL for optimal coverage.

Figure 3. UAV system and GNSS

■ SLAM Technology: Feima SLAM100 Handheld Imaging LiDAR Scanner

The complex water intake structure, which includes underground components, required additional scanning using Simultaneous Localization and Mapping (SLAM) technology (Figure 4). The Feima SLAM100 handheld LiDAR scanner was used for mobile mapping in GNSS-denied environments like tunnels, delivering high-resolution 3D point clouds critical for evaluating the geometry and condition of subterranean infrastructure.

The strategic integration of these advanced surveying instruments ensured the acquisition of precise and comprehensive data, necessary for the effective rehabilitation of the Tomesti micro-hydropower station. Each technology addressed specific challenges posed by the project's diverse terrains and structural intricacies, collectively contributing to a robust

geospatial framework for informed decision-making.

Figure 4. SLAM and TS mapping; video inspection

Geospatial Data Processing and Integration

Following field data acquisition, a structured processing workflow was implemented to ensure data accuracy and integration across UAV photogrammetry, airborne LiDAR, and mobile SLAM sources. Each dataset was processed independently, followed by a unified integration and vectorization stage to produce final deliverables.

UAV imagery was first geotagged using TOPODRONE Post Processing, which synchronized GNSS trajectories with image metadata for high-precision PPK georeferencing. Images were then processed in Pix4Dmapper using a Structure-from-Motion (SfM) pipeline, including alignment, sparse and dense point cloud generation, and surface modelling. The result was a high-resolution orthophoto mosaic accurately referenced to the national coordinate system.

Airborne LiDAR data was refined through several stages to reconstruct the sensor's trajectory and generate a georeferenced 3D point cloud. Using TOPODRONE LiDAR Post Processing, GNSS and IMU data were merged to define the flight path (Figure 5), while the Cloud Generation module converted raw data into spatial coordinates.

To correct internal misalignments, boresight calibration was performed in GreenValley LiDAR360. Manual adjustments of Roll, Pitch, and Heading were made via Stepwise Geometric calibration, using cross-sectional analysis of overlapping flight lines. This was followed by automated strip alignment through least-squares matching for improved spatial coherence.

Ground classification was completed using the Cloth Simulation Filter (CSF), effectively separating terrain from vegetation and infrastructure, resulting in a reliable Digital Terrain Model (DTM).

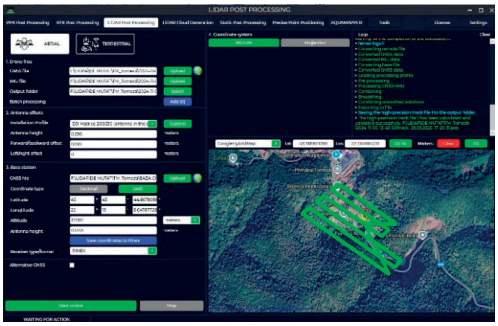

Figure 5. LiDAR postprocessing

SLAM (Simultaneous Localization and Mapping) was performed using the Feima SLAM100 handheld scanner, equipped with a Hensai XT16 LiDAR sensor offering 360° horizontal and 270° vertical coverage. This was essential for mapping the hydro-technical gallery's interior, where GNSS was unavailable. Georeferencing was achieved by aligning SLAM data with Ground Control Points (GCPs) previously measured via total stations, ensuring consistency with the national coordinate system.

Raw SLAM data was processed in SLAM GO software for trajectory reconstruction, noise filtering, and initial alignment. The resulting point cloud was imported into LiDAR360, where the Cloth Simulation Filter (CSF) algorithm classified ground and non-ground points to extract underground terrain and structural elements. All datasets, LiDAR, photogrammetry, SLAM, and total station measurements, were integrated in Pix4Dsurvey, enabling vector extraction and cross-validation. This harmonized geospatial environment allowed accurate digitization of infrastructure features, later exported to AutoCAD for engineering design.

The fusion of classical surveying tools with advanced scanning technologies ensured precise documentation of both surface and subsurface structures, supporting the rehabilitation planning of the Tomesti hydro-technical system.

RESULTS AND DISCUSSIONS

Integrated survey outputs and geospatial products

The integrated survey campaign carried out for the Tomesti micro-hydropower station rehabilitation produced a comprehensive suite of geospatial deliverables essential to the project's technical and environmental planning. These outputs include orthophotos, digital terrain and surface models (DTM/DSM), dense point clouds, topographic layouts, and detailed cross-sections, each contributing to a deeper understanding of both surface and underground conditions.

Figure 6 illustrates a detailed three-dimensional topographic rendering of the Tomesti site, showcasing elevation through dense contour lines. The layout captures the steep and complex terrain of the valley, essential for hydrotechnical planning. Superimposed vector elements such as roads, hydro-technical structures, and land parcel outlines are integrated into the model, allowing for precise spatial analysis and elevation profiling. This visualization supports slope analysis, infrastructure alignment, and drainage assessment, forming a key tool in the rehabilitation planning process of the micro-hydropower system.

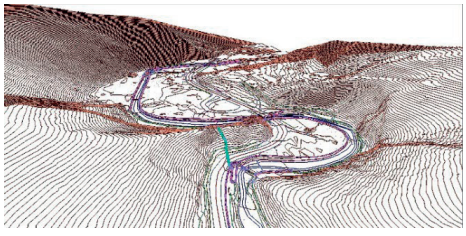

Figure 6. 3D terrain representation with contour lines

Figure 7 presents a high-resolution Digital Elevation Model (DEM) of the Tomesti study area, visualized using a hue-saturation-value (HSV) shader to depict elevation changes. The colour gradient, from red (higher elevations) to blue and green (lower elevations), clearly outlines the valley's terrain morphology, built structures, and hydrological features. The DEM was derived from UAV-based LiDAR data, offering fine detail necessary for slope analysis, hydrological modelling, and infrastructure planning. This product is essential for understanding elevation variability and guiding technical designs within the hydropower rehabilitation project.

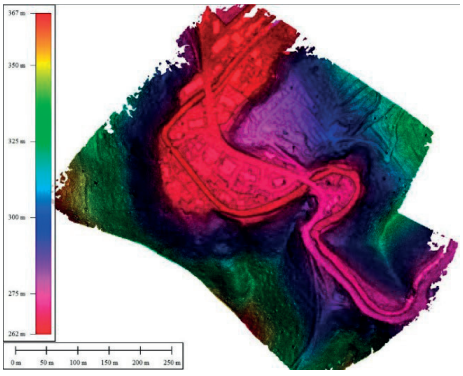

Figure 7. Digital Elevation Model (DEM) with HSV Shading

Figure 8 illustrates a Triangulated Irregular Network (TIN) model overlaid with vector data and geospatial control points. The TIN surface, derived from LiDAR and photogrammetric inputs, represents detailed terrain morphology through irregular triangle meshes. Superimposed vector lines denote features such as roads, hydrological networks, and infrastructure elements, while coloured pins mark field-verified geospatial targets or control points. This combined visualization supports 3D terrain analysis, infrastructure alignment, and engineering planning within the Tomesti hydropower site.

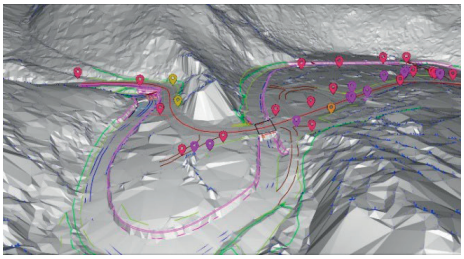

Figure 8. TIN surface with vector overlay and markers

Figure 9 presents a cross-section profile extracted from LiDAR data, corresponding to the yellow transect line shown on the elevation-coloured orthophoto. The upper image provides spatial context within the Tomesti site, while the lower section displays elevation values along the transect. The profile distinctly captures both surface terrain, including road infrastructure and vegetation, as well as the outline of the underground hydrotechnical tunnel. This dual-layer representation offers valuable insights into the vertical spatial relationships between above-ground features and subsurface infrastructure.

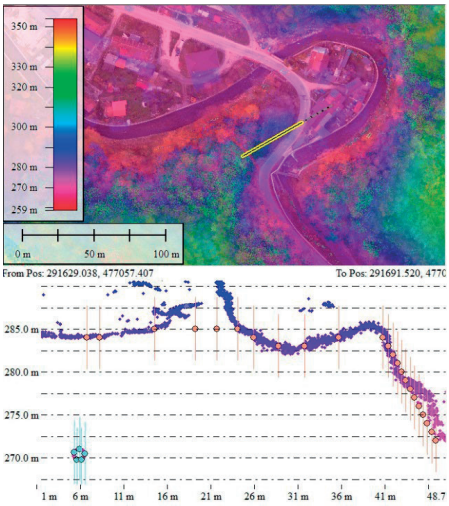

Figure 9. LiDAR and SLAM derived cross-section profile

Figure 10 displays a high-resolution UAV-derived orthophoto of the Tomesti site, overlaid with the traced alignment of the underground tunnel.

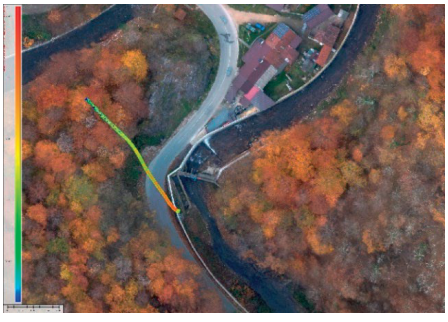

Figure 10. Orthophoto with tunnel overlay

The tunnel path is color-coded by elevation, allowing clear visualization of its trajectory beneath the terrain and infrastructure. The overlay facilitates precise spatial correlation between the subsurface gallery and surface features, proving essential for engineering assessment and future rehabilitation planning.

Topographic mapping and layout plan

Topographic plans are essential tools in civil engineering, infrastructure development, and environmental management. These scaled cartographic outputs accurately represent terrain through elevation contours, hydrography, vegetation, and man-made structures such as roads or utilities. They are critical for understanding slope dynamics, drainage paths, construction feasibility, and site access, particularly in mountainous terrain like the Tomesti study area.

Beyond visual representation, topographic plans integrate data from GNSS, total station, UAV photogrammetry, and LiDAR to provide georeferenced context for all design and modelling efforts.

In modern workflows, these plans are derived from dense point clouds and processed in platforms such as Pix4Dsurvey or AutoCAD Civil 3D, allowing precise integration with engineering and environmental analyses. Their role extends from initial assessment to ongoing monitoring, making them a central deliverable in multidisciplinary survey projects.

The Topographic Plan (Figure 11) marks the culmination of the Tomesti survey campaign, merging LiDAR and photogrammetric data with vector features derived from total station observations. It depicts both natural and built elements, offering a comprehensive layout for hydrotechnical assessment and design. Contour lines extracted from the DTM illustrate slope variations and elevation changes crucial for hydrological planning and infrastructure layout. The alignment of the underground gallery, catchment structures, forested zones, roads, and open terrain are all vectorized and overlaid on an orthophoto mosaic, enabling precise visual correlation with real-world imagery.

This detailed and multi-layered plan provides the spatial foundation for modelling, engineering design, and environmental evaluations, supporting the informed rehabilitation of the Tomesti micro-hydropower system.

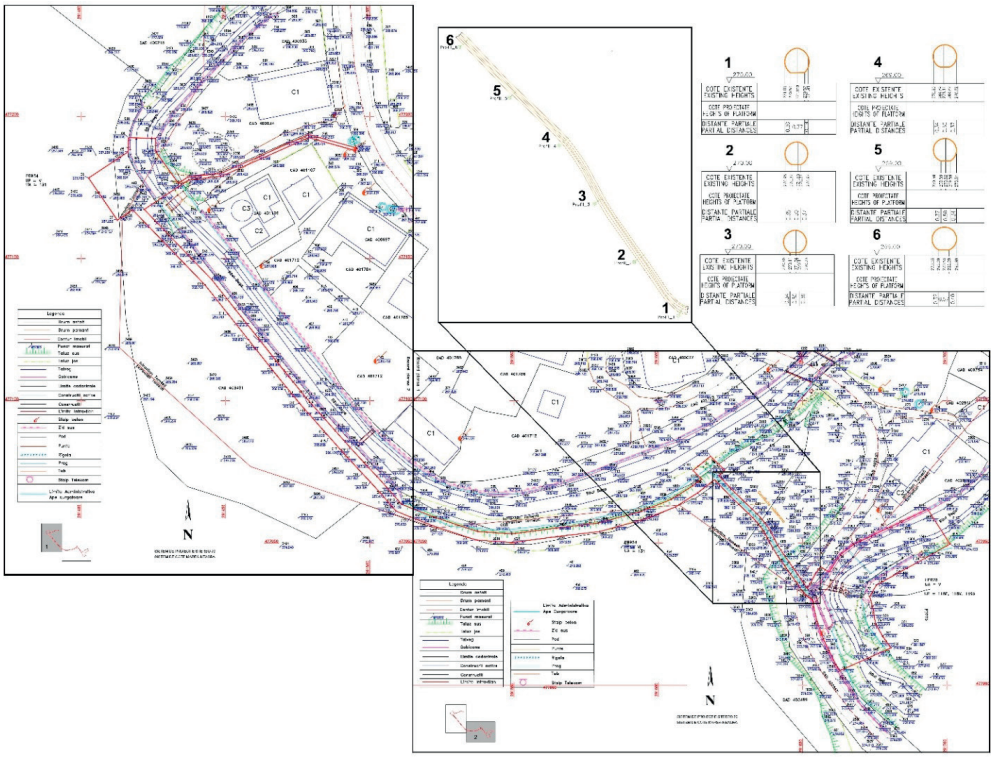

Figure 11. Topographic plan of Tomesti study area with integrated elevation, hydrography, and infrastructure data

SLAM data accuracy assessment and control point validation

Accuracy assessment is a critical element in geospatial data acquisition, especially when merging outputs from multiple sensors like SLAM and total stations (Figure 12). In complex engineering projects, spatial precision underpins reliable design, structural analysis, and implementation. While SLAM excels in GNSS-denied environments such as tunnels, it is prone to positional drift and trajectory errors from motion instability and sensor noise. To ensure spatial integrity, SLAM point clouds must be validated against high-accuracy control points, best obtained using total stations, which offer millimetric precision in areas where GNSS is ineffective. Comparing SLAM outputs with total station-derived control points allows for the identification and correction of spatial discrepancies, ensuring the dataset is accurately aligned within the project's coordinate system. This process is essential for hydrotechnical rehabilitation, where accurate underground alignment and modelling are vital. Ultimately, such accuracy checks enhance the reliability of final products and support confident, data-driven decisions.

Figure 12. SLAM point cloud with GCPs (G6–G11) used for spatial alignment and accuracy validation in the national coordinate system

The table presents an accuracy assessment comparing SLAM (Simultaneous Localization and Mapping) data with control point coordinates measured via total station. It includes six control points (G6 to G11), showing both coordinate sets to evaluate SLAM's spatial precision in inaccessible environments. For each point, residual errors in X, Y, and Z axes are provided (Table 1), with D_{XY} representing horizontal deviation and D_Z the vertical difference. D_{XY} errors range from 0.021 to 0.052 m, while D_Z values remain below ±0.02 m, indicating strong vertical consistency.

Table 1. Residual errors for each GCP, with overall accuracy assessment

Control point (m)				Measurement Coordinates (m)			Residual Error (m)			
GCP Name	East X	North Y	Up Z	Measurement X	Measurement Y	Measurement Z	DX	DY	DXY	DZ
G 8	291671.593	477060.581	272.453	291671.570	477060.582	272.473	0.023	-0.001	0.023	-0.020
G 9	291653.152	477030.348	274.453	291653.147	477030.320	274.469	0.005	0.028	0.029	-0.016
G 10	291664.952	477032.59	272.710	291664.900	477032.587	272.712	0.052	0.003	0.052	-0.002
G 11	291691.226	477045.855	271.724	291691.207	477045.884	271.727	0.019	-0.029	0.034	-0.003
G 7	291661.634	477099.282	270.974	291661.625	477099.263	270.997	0.009	0.019	0.021	-0.023
G 6	291637.355	477123.85	270.088	291637.383	477123.871	270.087	-0.028	-0.021	0.035	0.001
Mean Error							0.013	0.000	0.032	-0.010
RMSE							0.027	0.020	0.034	0.014

Also included are the mean error and Root Mean Square Error (RMSE), with an RMSE of ~0.027 m, validating the system's high accuracy, remarkable for a GNSS-denied, subterranean environment. This confirms SLAM's ability to achieve centimeter-level precision when anchored to total station benchmarks. For the Tomesti project, SLAM delivered reliable 3D documentation that met engineering standards for structural evaluation and design planning.

Rehabilitation strategy and hydro-technical design proposals

The revitalization of the Tomesti micro-hydropower station represents a strategic fusion of modern geospatial technologies and sustainable energy objectives. Originally planned decades ago but left incomplete, the site remains viable due to its existing underground infrastructure and favorable hydrological context. The current project outlines a full rehabilitation strategy, aligning with present-day technical, environmental, and policy standards.

Based on high-resolution topographic and 3D mapping using GNSS, LiDAR, and SLAM, the proposed works address both surface and underground hydro-technical components. This geospatial data provided accurate terrain models, structural detail, and precise spatial alignment to guide engineering analysis and updated documentation.

Rehabilitation efforts focus on the adduction gallery and water intake systems. The pre-existing tunnel, though unused, was digitally reconstructed via SLAM scanning, allowing for condition evaluation and targeted actions such as consolidation, alignment correction, and sealing, ensuring long-term functionality under varying flow regimes.

At the surface, the intake structures on Bega River tributaries will be redesigned to meet modern hydropower standards. The updated system integrates ecological flow control, sediment handling, and durability improvements, using adjustable sluices and fish-friendly features to guide water safely into the rehabilitated gallery.

Further downstream, the incomplete power cavern will be fitted with automated turbines and linked to the national grid. The upgraded facility aims to deliver efficient, low-impact renewable energy, contributing to local sustainability goals.

The 3D rendering of the intake structure illustrates the planned upgrades derived from our integrated survey campaign (Figure 13). Key rehabilitation targets include degraded concrete components such as the overflow weir, sluice niches, retaining walls, and loading chamber. These will be cleaned and reinforced using mesh and sprayed concrete to restore structural integrity.

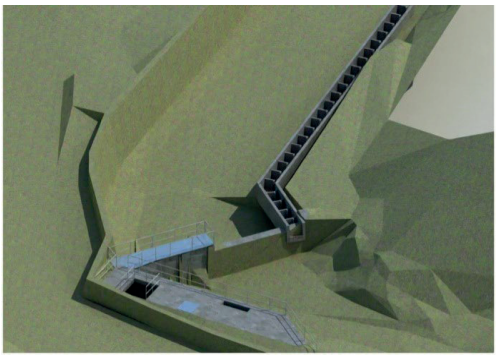

Figure 13. 3D rendering of the rehabilitated water intake structure, designed based on topographic and LiDAR measurements, showing the restored weir, retaining walls, and access elements integrated into the terrain

Interior and exterior reinforcements will be connected to enhance cohesion (Figure 14). The proposed design aligns precisely with terrain data extracted from UAV photogrammetry and SLAM scans, ensuring accurate positioning and minimal landscape alteration.

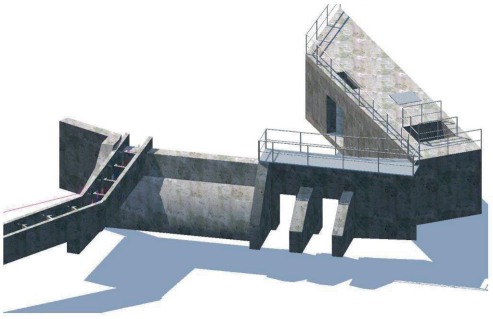

Figure 14. Detailed 3D model of the rehabilitated intake structure, highlighting spillway elements, intake gates, and access platforms, reconstructed based on precise geospatial data

Crucially, all interventions are designed to comply with national energy and environmental regulations. The project embraces a low-impact philosophy, reusing existing structures, minimizing deforestation, and preserving the visual integrity of the mountainous landscape. As such, the Tomesti initiative illustrates how legacy hydro-infrastructure can be repurposed using contemporary tools, offering a replicable model for future sustainable energy projects in similar terrains.

CONCLUSIONS

This study demonstrates the critical importance of integrating modern geospatial technologies with traditional surveying methods for complex infrastructure projects situated in rugged, forested, and geologically challenging environments. The revitalization of the Tomesti micro-hydropower station, a legacy project abandoned decades ago, required not only technical innovation but also methodological precision and environmental sensitivity. Through the combined use of GNSS-based control networks, total station measurements, UAV photogrammetry, airborne LiDAR, and SLAM scanning, a comprehensive spatial dataset was generated, one capable of supporting both engineering design and environmental compliance.

The resulting geospatial products, including orthophotos, DSMs, DTMs, 3D tunnel reconstructions, and a detailed topographic plan, provide a unified spatial framework for decision-making and technical validation. Accuracy assessments between SLAM-derived outputs and total station control points confirmed the reliability of the multi-sensor workflow, with sub-decimetric residuals ensuring confidence in the datasets used for design.

The case of Tomesti highlights how modern geomatics can breathe new life into dormant infrastructure by bridging outdated documentation with current spatial realities. The proposed rehabilitation, grounded in this high-fidelity survey campaign, encompasses both structural restoration and environmentally conscious hydrotechnical design. If implemented, this initiative will not only contribute to local renewable energy production, but also serve as a replicable model for similar projects across Romania and other mountainous regions. This work underlines the evolving role of geomatics in sustainable development, where multi-sensor integration, precision mapping, and terrain intelligence converge to enable resilient, future-ready engineering solutions.

Abstract

The objective of this study was to evaluate the ability of clay (nano- montmorillonite) to the remediation of natural (Ni) rich soils, having the nickel hyperaccumulator Odontarrhena calchidica test plant. The experiment was conducted in a greenhouse in a completely randomized design, with three replicates. The experiment was conducted in 2 kg plastic plot. We used four doses of clays: 0.0, 21.4, 44.3 and 64g kg^{-1}, corresponding to 0, 30, 60 and 90 t ha^{-1}, respectively. Throughout the experiment, the plants were regularly irrigated, and NPK fertilization was applied to ensure optimal growth conditions. After 60 days, the soil analyzed for total nickel in XRF and available nickel $_{DTPA}$ extraction in Atomic Absorption. The BFP and BFR of Odontarrhena chalcidica decreased significantly as a function of increasing doses of nano-montmorillonite, indicating an increase in the adsorption of nickel in the soil. However, the BFP and BFR values were high, indicating hyperaccumulation potential of O. chalcidica. Based on the results, the application of clay in agricultural nickel rich soils favors their improvement.

Key words*: clay, nano-montmorillonite, hyperaccumulator, Odontarrhena calchidica, XRF.*

INTRODUCTION

Nickel (Ni) is an essential micronutrient for plant growth but when present in high concentrations it can become toxic to both plants and the environment (Seregin & Kozhevnikova, 2006; Chen et al., 2009). Serpentine soils, which are naturally rich in nickel and derived from ultramafic rocks are particularly challenging for agriculture (Kazakou et al., 2008). These soils can lead to excessive nickel accumulation in food crops, raising health concerns and reducing agricultural productivity. Excess nickel slows plant growth, lowers yields and decreases the nutritional value of food (Marschner, 2012). Therefore, finding effective strategies to manage nickel-rich soils is crucial for sustainable farming.

A notable example of this challenge is the Tropoja region in northeastern Albania, where serpentine soils contain naturally high levels of nickel, posing risks to both the environment and local agriculture (Bani et al., 2015). Existing remediation methods, such as phytoremediation (using plants to absorb nickel) and chemical stabilization, have limitations.

Phytoremediation is a slow process, while chemical treatments can introduce new environmental risks (Kumpiene et al., 2008). To reduce nickel availability in soil remediation techniques such as the use of adsorbent materials, particularly clay minerals have been explored (Ghorbel-Abid et al., 2010; Uddin, 2017). These materials are readily available, environmentally friendly and effective at immobilizing heavy metals (Uddin, 2017). This occurs through processes such as adsorption and ion exchange, where nickel ions are replaced by other ions on the clay surface (Bhattacharyya & Gupta, 2008).

Nano-montmorillonite, a type of clay predominantly composed of smectite (90%), has proven effective in reducing the bioavailability of heavy metals, thereby limiting their uptake by plants (Wang et al., 2015).

Due to its high surface area and cation exchange capacity, nano-montmorillonite can be incorporated into soil as a conditioner to improve

chemical and physical properties, particularly in sandy soils (Tako, 2015).

The objective of this study was to evaluate the ability of clay minerals to improve naturally nickel-rich soils, using the nickel hyperaccumulator plant *Odontarrhena chalcidica* as a test species. We use as amendment clay minerals extracted from soil of a distinct ultramafic regions of Albania, from Domosdova field, Prrenjas (Tako, 2015).

This research also aims to contribute to the development of sustainable and cost-effective methods for managing nickel-contaminated farmland while enhancing our understanding of nickel dynamics in soil-plant systems.

MATERIALS AND METHODS

Experimental Materials and Treatment

The study was conducted under greenhouse conditions at Sila Company, Fushe-Kruje, Tirane to investigate the effects of clay amendments on nickel availability and plant accumulation. Experiments were performed using the nickel hyperaccumulator plant *Odontarrhena chalcidica* native plant in serpentine soil of Albania. The soil collected from the ultramafic soil of Tropoja region in northeastern Albania (0-20 cm depth). From previous study we know that this soil was rich in nickel. Seeds of *O. chalcidica* came from native plants that grow up in ultramafic site of Tropoja. The experiments were conducted in 2 kg plastic containers. The plots were designed according to a randomized complete block design. The experiment was organized with four replicates for each treatment.

Each experimental unit received four doses of clay: 0.0, 21.4, 44.3, and 64 g kg^{-1}, corresponding to 0, 30, 60, and 90 t ha^{-1}, respectively. The clay was sourced from clayey soil from the main serpentine clay deposit in Domosdova field, southeast of Albania (Tako, 2015). The clay was thoroughly mixed with the soil to ensure uniform distribution (Uddin, 2017). The X-ray diffractogram of the clay minerals was performed in the Institute of Soil Research, University of Natural Resources and Life Sciences, Vienna, Austria and it is presented in Figure 1. The soil was conditioned in plastic containers, irrigated to field capacity, and incubated for 20 days. After incubation, *O. chalcidica* seeds were sown on March 1, 2024. Plant seeds were sown using a broadcast method and covered with a thin layer of soil on the surface. Throughout the growth period, water was periodically supplemented using the weighing method to maintain soil moisture at 60~70% of field capacity. Eight days after emergence, thinning was performed to maintain two plants per container. Fertilization was applied at rates of 3g of 20N: 20P: 20K to ensure adequate nutrient supply.

Soil and plant sample analyses

After 60 days of growth, plants were harvested, and soil and plant samples were collected. The plants aboveground parts and root systems were cleaned and weighed separately. The aerial parts and roots were separated, washed with deionized water, oven-dried at 80°C until a constant weight was achieved, and weighed to determine dry biomass of plants (Kazakou et al., 2008).

The dried soil and plant samples were finely pulverized and ground for subsequent analysis. The soil samples were air dried and passed through a 2 mm nylon sieve to determine soil physico- chemical properties; its pH, organic matter content, cation exchange capacity (CEC), available nickel was analysed in the Laboratory of the Department of Environment and Natural Resources at the Agricultural University of Tirana. Available nickel in the soil was extracted using DTPA and quantified via AAS (Lindsay & Norvell, 1978). Total heavy metals concentrations in soil and heavy metals in plant analyzed using X-ray fluorescence (XRF) in the Laboratory of the Department of Biology at the University of Florence, Italy.

The following parameters were assessed for plants: Bioaccumulation Factor in Plant (BFP) was calculated as the ratio of nickel concentration in the aerial parts to that in the soil (Bani et al., 2024). Bioaccumulation Factor in Root (BFR) was calculated as the ratio of nickel concentration in the roots to that in the soil (Kidd et al., 2018). Translocation Factor (TF) was calculated as the ratio of nickel concentration in the aerial parts to that in the roots (Bani et al., 2015).

Statistical Analysis

Data was analyzed using analysis of variance (ANOVA) with an F-test to assess treatment

effects (Clay doses effects on BFP, BFR and Shoot Dry Biomass) (Kumpiene et al., 2008).

RESULTS AND DISCUSSIONS

Bulk mineralogy of the clay from source Domosdova field, south-east of Albania is dominated by the group of layer silicates.
We count to this group mica and all clay minerals. Accessory minerals are feldspars, pyroxenes, talc, serpentine minerals and traces of quartz (Figure 1). This clay could be the weathering product of ultramafic rocks. Semiquantitative results of clay mineralogy <2µm told us that this clay mineral is a nano-montmorillonite, absolutely dominated by smectite with about 90 %. All the other clay minerals are present in very small amounts. In this sample, the diffractograms from the various treatments are not definitive; some indicate the presence of smectite, while others also suggest the presence of vermiculite. The observed peaks are characteristic of smectite clays, serpentine as well as layer silicates, quartz and feldspars. This mineral will show a very high absorption capacity independently if it is smectite or vermiculite.

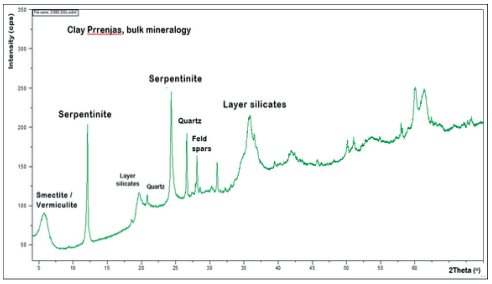

Figure 1: X-ray diffractogram of clay from Domosdova field, bulk mineral composition. The most important peaks are marked

Soil characteristics

The serpentine soil from the Tropoja region was analyzed to determine its physicochemical properties which are essential for understanding its suitability for plant growth, particularly for hyperaccumulator plants. Table 1 presents the soil properties, including pH, organic matter, texture and concentrations of essential nutrients and heavy metals.
The soil pH was neutral (7.0) that is in the adequate range for this hyperaccumulating species (Bani et al., 2014, Kukier et al., 2004). The soil of Tropoja shows a CEC of 20.6 cmol kg^{-1}, this because had a considerable clay content in the soil (27.5%).

Table 1. pH, Physicochemical properties (Mean values ± SD) of serpentine soil of Tropoja

Physicochemical properties	Mean values ± SD
pH	7
Organic matter (%)	4.5
CEC (cmol kg^{-1})	20.6
EC (µs/cm)	27.6
Sand (%)	9.95
silt (%)	62.5
Clay (%)	27.5
K (mg kg^{-1})	1442 ± 330
P (mg kg^{-1})	1859 ± 240
Ca (mg kg^{-1})	8645 ± 250
Mg (mg kg^{-1})	21867 ± 370
Cr (mg kg^{-1})	475 ± 79
Mn (mg kg^{-1})	1728 ± 13
Fe (mg kg^{-1})	96338 ± 3340
Co (mg kg^{-1})	170 ± 33
Ni (mg kg^{-1})	1739 ± 36
Cu (mg kg^{-1})	25 ± 3
Zn (mg kg^{-1})	123 ± 8
Pb (mg kg^{-1})	34 ± 4

*SD - standard deviation

Total P and K concentrations in the soil were low respectively 1442 mg kg^{-1} for P and 1859 mg kg^{-1} for K. In general, serpentine soils are deficient in K and P total contents (Bonifacio & Barberis, 1999), which is a major cause of poor agricultural yields of main crops. The use of fertilizers and organic amendments improved soil fertility.
The organic matter content was 4.5% that is satisfactory for agronomic purposes (Fenton et al., 2008). Total Ca (8645mg kg^{-1}) concentrations in the soil were lower than Mg (21867 mg kg^{-1}), and soil has elevated levels of total metals like Ni, Co, Cr, Mn and Fe that are typical of ultramafic soils. Total Ni concentration is high 1739 mg kg^{-1}, higher than those considered toxic to normal plants by Allen et al. (1974), Kabata-Pendias (1984), and Brooks (1987).

Nickel availability in soil

The application of nano- montmorillonites clay significantly reduced the bioavailability of nickel in the serpentine soil of Tropoja. As

shown in Table 2, the available nickel concentration decreased with increasing clay doses.

Table 2. The available nickel in serpentine soil of Tropoja for the different clay treatments

Treatment (Clay Dose) (g/kg)	Nickel available in soil (mg/kg)
0	88.7
30	69.9
60	33.6
90	27.9

Thus, the available nickel content in the Tropoja soil, where clay from the Domosdova field was applied and nickel hyperaccumulator plants were cultivated, decreased by 68.5%, from 88.7 mg/kg to 27.9 mg/kg.
This reduction is attributed to the adsorption and ion exchange properties of nano-montmorillonites which immobilize nickel ions due to its high surface area and cation exchange capacity (CEC).

Nickel Concentrations in Plants and Roots

The dry biomass of the aerial part (shoot) of the *O. calchidica* was adjusted to a linear model as a function of increasing doses of clay mineral (Figure 2) ranged from 3.1 g (0 t ha^{-1} clay mineral) to 5.4 g (90 t ha^{-1} clay mineral), corresponding to an increase of 1.74 times higher in the highest dose compared to control.

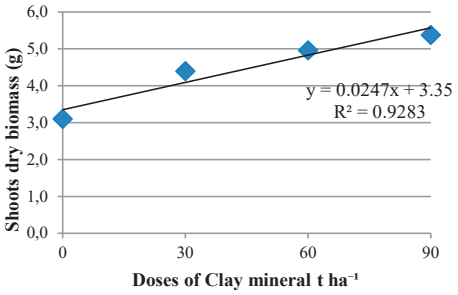

Figure 2. Dry biomass of the shoots for *O. calchidica* cultivated in serpentine soil of Tropoja for the different nano-montmorillonite clay treatments

The positive effect of nano-montmorillonite clay addition on plant growth may be due to its positive effect on the water retention capacity (Wang et al., 2015) and the growth of surface area, increasing the metal cation adsorption capacity present in the soil (Tako, 2015) and consequently decreasing the concentration in the plant parts.
The nickel concentration in the shoot and in the roots of radish was significantly influenced by applying nano-montmorillonite clay (Figure 3). The linear behavior of the nickel concentration in shoots and roots of plants, shows the decrease of Ni concentration with increasing doses of nano- montmorillonite clay ranging from 16545 to 9078 mg kg^{-1} in the shoot (Figure 3A) and ranging to 1993 to 2660 mg kg^{-1} in the roots (Figure 3B) occurring a decrease of 31.47% and 25%, respectively, the control regarding the higher dose.

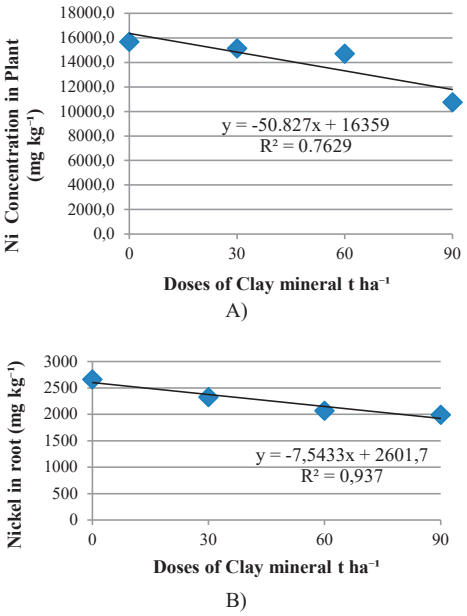

Figure 3. Nickel concentration in the shoots (A) and roots (B) of *O. calchidica* cultivated in serpentine soil of Tropoja for the different nano-montmorillonite clay treatments

The reduction of Ni concentration in this hyperaccumulator plant is explained by the reduction of the availability of the nickel in the soil with the increase of clay doses from 0 to 90 t ha^{-1}. This decrease is likely attributable to the adsorption of nickel by nano-montmorillonite. The ability of a plant to accumulate metals from soil can be estimated using the bioaccumulation potential in plant (BFP) and/or in root (BFR). These factors can be used to estimate a potential

plant for phytoremediation purposes. The BFP and BFR of *O. calchidica* decreased significantly by increasing doses of nano-montmorillonite soil (Tables 1, 3) indicating an increase in the adsorption of nickel in the soil, decreasing the concentration in the plant parts.
This behavior is beneficial since clay minerals such as nano- montmorillonite have a great potential to adsorb pollutants due to their large specific surface area, the layered structure, and high cation exchange capacity (Bhattacharyya & Gupta, 2008).
According to Figure 4, the BFP and BFR ranged from 9 to 6.17 and from 1.52 to 1.14 showing a reduction of 31% and 25%, respectively. The BFP and BFR values were high, indicating high hyperaccumulation potential of *O. calchidica*, for Ni. Application of nano- montmorillonite reduced BFP and BFR values indicating reduced nickel uptake. These results suggest that nano-montmorillonite is an effective amendment for reducing nickel bioavailability in nickel-rich soils.

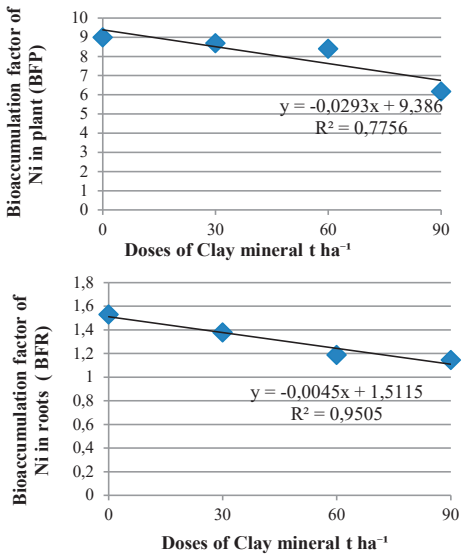

Figure 4. Bioaccumulation factor of nickel in plant (BFP) and in root (BFR) of O. calchidica for the different nano-montmorillonite clay treatments

The translocation factor (TF) gives the shoot/root nickel concentration and showed the ability of our plant for nickel translocation from roots to shoots at our experiment with different doses of clay minerals.

Table 3. Clay doses effects on BFP, BFR and Shoot Dry Biomass tested one-way ANOVA

Variable	F-value	P-value	F crit
BFP	25.61	0.000187	4.066
BFR	118.01	5.82E-07	4.066
Shoot Dry Biomass	46.9	2.02E-05	4.066

The TF varied from 7.1 to 5.89 showing a reduction of 17% depending on Clay doses. However, TF values were high, indicating high nickel translocation potential of *O. calchidica* plant.

CONCLUSIONS

Nano-montmorillonite in nickel-rich soil significantly enhanced the shoot development of *Odontarrhena calchidica* and promoted nickel retention in the soil, as evidenced by reduced nickel concentrations in the plant's shoots and roots. It also contributed to the reduction of bioaccumulation factors of nickel.
This study highlights the vital role of nano-montmorillonite clay in making nickel-rich soils safer and more productive. By applying this clay, the bioavailability of nickel is significantly reduced, protecting crops and the food chain from harmful accumulation.
The notably high nickel concentrations in the aerial parts of *O. calchidica* further confirm its strong hyperaccumulation ability, making it highly suitable for phytoremediation.
These findings are not only scientifically significant but also offer practical solutions for farmers and communities dealing with nickel-rich soils.
By improving soil health and reducing nickel toxicity, this approach supports healthier crops, sustainable agriculture, and public health. Future research should examine the long-term effects of clays and the use of *Odontarrhena calchidica* to enhance remediation efforts.

Abstract

Although the presence of microplastics in the oceans was first reported in the 1970s, the first studies on lakes were published in 2011. This pioneering study aims to determine the presence of microplastics in the Somova-Parches lacustrine complex, situated in the predeltaic territory of the Danube Delta Biosphere Reserve. The Pollution Load Index (PLI) was also calculated to assess the microplastic pollution level in water. The microplastics concentrations in the water of the 6 investigated lakes varied in the 0.15 - 0.65 particles·m^{-3} range. The PLI index values indicated a low level of microplastic pollution (level 1). The results of the micro-FTIR analyses highlighted the predominant presence of polyethylene and polypropylene polymers in the composition of the collected microplastics. The present study contributes to bridging the knowledge gap regarding the occurrence of microplastics in freshwater.

Key words*: emerging pollutant, freshwater, Lower Danube water, micro-FT-IR.*

INTRODUCTION

In recent years, due to their versatility, the production and consumption of plastic products have increased significantly worldwide. According to predictions, global production could reach 25 billion tons by 2050 (Liu et al., 2025). In addition, total plastic waste production could be estimated at 12 000 million tons by 2050 (Zhang et al., 2024). The mismanagement of plastic waste contributes to its release into the environment, where it is fragmented into microplastics (MPs) (Gan et al., 2025). Microplastics are considered hazardous substances in the environment due to their composition (e.g. additives), irregular shape, small size and their ability to carry other pollutants that can have a harmful impact on biota (Nguyen et al., 2023).

Although most research has focused on microplastics in marine ecosystems, recent studies have shown that microplastic pollution in inland waters can be 20 times higher than in marine ecosystems (Horton et al., 2017; Pol et al., 2023). Human activity and terrestrial ecosystems are strongly connected to inland waters. Therefore, their pollution has a direct impact not only on aquatic and terrestrial biota, but also on human health (Luo et al., 2024). Lentic ecosystems serve as indicators of watershed health due to their capacity to accumulate pollutants (Dusaucy et al., 2021). For these reasons, it is essential to monitor microplastics in lakes.

The main aim of this study is to evaluate for the first time the presence of microplastics in six lakes from the Somova-Parcheș aquatic complex, Romania. In addition, the pollution level of lake water with microplastics was determined by calculating the Pollution Load Index (PLI).

Somova-Parcheș lacustrine complex is situated in the western part of the Danube Delta, near Tulcea City. The lakes in this complex are fed with water from the Danube River, especially in high-flow seasons (e.g., spring) (Burada et al., 2015). The water quality of the Danube and its tributaries in Romania has been physico-chemical evaluated in numerous articles by calculating the Water Quality Index (WQI).

According to the obtained results, it was mostly classified in class II - "good" (Frîncu, 2021). Regarding microplastic pollution, according to the study conducted by Procop et al., 2024 the Danube water transports approximately 46-51 tons of microplastics per year on the territory of Romania.

MATERIALS AND METHODS

The area investigated in this study is important because the Danube Delta has been part of the UNESCO (United Nations Educational, Scientific and Cultural Organization) World Heritage Site Biosphere Reserve since 1991 (Popa et al., 2018). In Figure 1, the 6 lakes from which the microplastics were taken can be localized: Morun Lake, Babele Lake, Parcheș Lake, Potica Lake, Câșla Lake, and Somova Lake.

The microplastics were collected from the water with a 150 µm mesh size with a mechanical flow meter that quantifies the volume of filtered water.

The sample preparation, i.e., the isolation of microplastics from organic matter and dense impurities, was carried out according to the method presented in the article by Calmuc et al., 2023.

Microplastics were filtered on Polyvinylidene Fluoride (PVDF) membrane filters with 0.45 µm pore size and 47 mm diameter.

The microplastic filters were analysed using the Spotlight 400 FT-IR Imaging System, PerkinElmer equipment, to identify the polymers in the composition.

The analyses were performed with a resolution of 16 cm^{-1}, a spatial resolution of 6.25 µm, and a spectral range between 4000 -750 cm^{-1}.

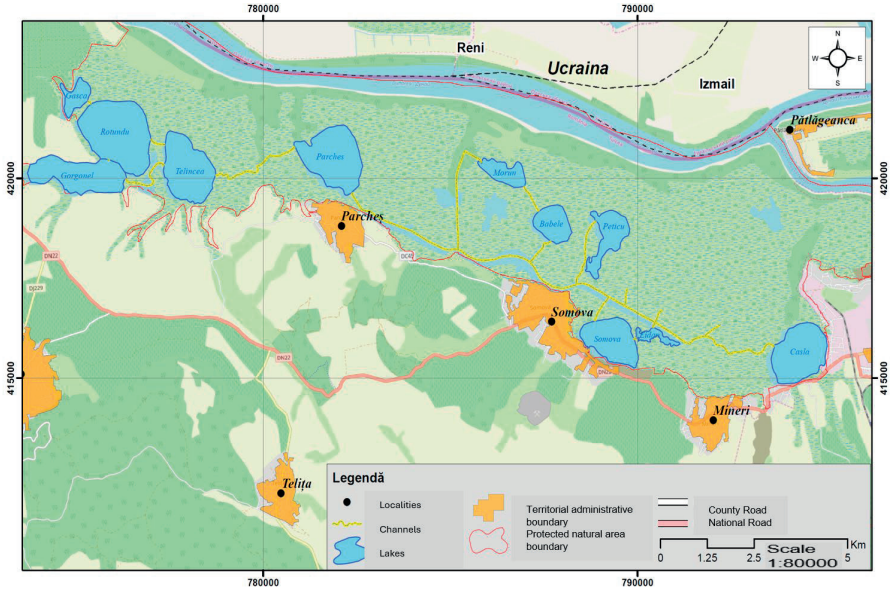

Figure 1. Location of lakes investigated

The Pollution Load Index (PLI) is used to assess the degree of microplastic pollution in the environment and can be calculated according to formulae 1 and 2 (Qiu et al., 2023; Zhou et al., 2024):

$$PLI = \sqrt{CFi} \quad (1)$$

$$CF_i = \frac{Ci}{C0} \quad (2)$$

were:

- CF_i = MPs contamination index;
- C_i = MPs abundance in monitoring stations;
- C_0 = MPs background value (in this study, C_0 represents the lowest MPs concentration recorded in investigated lakes, respectively 0.15 particles·m^{-3}.

According to Table 1, the degree of MPs pollution can be divided into four levels depending on the PLI index score.

Table 1. Pollution Load Index classes
(Qiu et al., 2023; Zhou et al., 2024)

PLI values	Pollution Level
0-10	I – Low
11-20	II – Medium
21-30	III – High
>30	IV – Extremely high

RESULTS AND DISCUSSIONS

Figure 2 illustrates the abundance of microplastic particles recorded in each of the 6 lakes investigated. Particle concentrations ranged from 0.15-0.65 particles·m^{-3}, with the highest abundance recorded in Somova Lake. The main sources of pollution with MPs would be the Danube River that supplies the lakes with water, fishing, tourism, and anthropogenic activities that take place in the localities near the lakes. For example, the village of Somova is located on one of the banks of Somova Lake (where the maximum value was recorded).

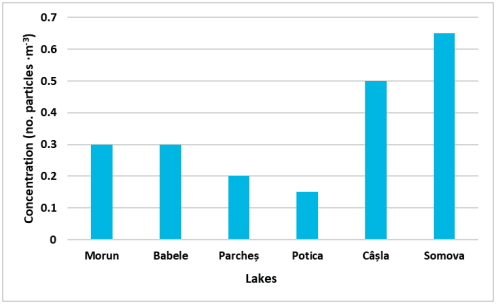

Figure 2. Microplastics concentration in the investigated lakes

Studies showed that MPs concentration in freshwater depends on anthropogenic factors such as population density (Jian et al., 2020). The density of the Somova commune, which includes the villages of Somova, Parcheș, and Mineri, is low, at 33.65 people·km^{-2} (2021) (www.citypopulation.de). Similar results were observed in the study conducted by (Fischer et al., 2016), where concentrations of 2.68 to 3.36 particles·m^{-3} and 0.82 to 4.42 particles·m^{-3} were identified in the surface water from Chiusi Lake and Bolsena Lake, respectively (central Italy). High concentrations of MPs (2425 – 7050 particles·m^{-3}) were observed in the surface water of 20 lakes in the urban area of Changsha, China (Yin et al., 2019).

Based on the morphological classification, MPs collected were film, fragment, and fiber. Fragment and fiber shapes dominate the six lakes, which indicates different sources of pollution (Figure 3) (Li et al., 2021).

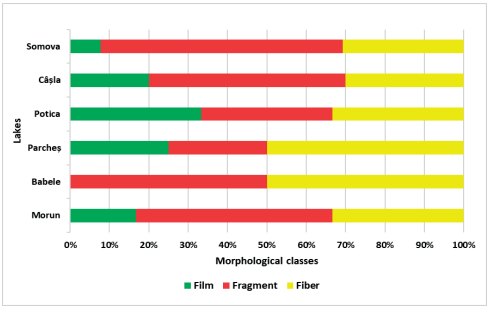

Figure 3. Morphological classification of microplastics

Visible images of MPs particles collected from the six lakes of different colors (green, blue, red), irregular shapes (film - a, fragment - b, fiber - c, d), and sizes are illustrated in Figure 4. An irregular shape suggests that the larger particles' fragmentation can be the source (Rosal, 2021). The sharp edges of irregular shapes can cause physical damage to the stomach wall of fish ingesting MPs (Hossain et al., 2019).

The size classes of microplastics are plotted in Figure 5. In the Somova, Câșla, and Babele lakes, MPs were collected from all four size categories (<150 µm, 150 - 500 µm, 500 - 1000 µm, and 1000 - 5000 µm), while in the Potica and Parcheș lakes, only the 500 - 1000 µm and 1000 - 5000 µm classes were found. The size of microplastics is another important morphological parameter. The presence of larger particle sizes is a source for the secondary of smaller fragments, thus favoring an increase in concentration. Smaller sizes are more bioaccessible and have a higher surface-to-volume ratio, making them more harmful (Sutkar et al., 2023). The polymer composition is another essential parameter of microplastics that provides valuable information for identifying pollution sources. Figure 6 illustrates the image obtained after micro-FT-IR analysis of a microplastic sample on a PVDF filter. Variations in absorbance intensity can be observed, with higher intensities corresponding to greater thickness of the MPs particles.

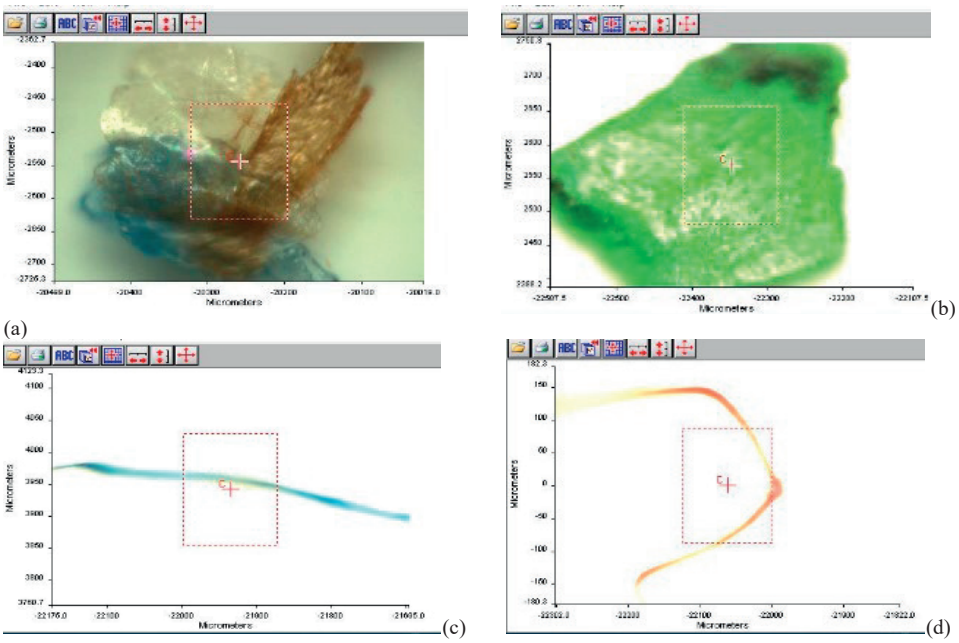

Figure 4. Visible images of microplastics: a) film; b) fragment c); d) fiber

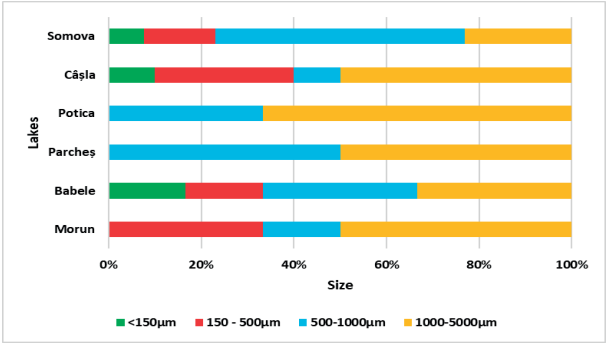

Figure 5. Microplastics size categories

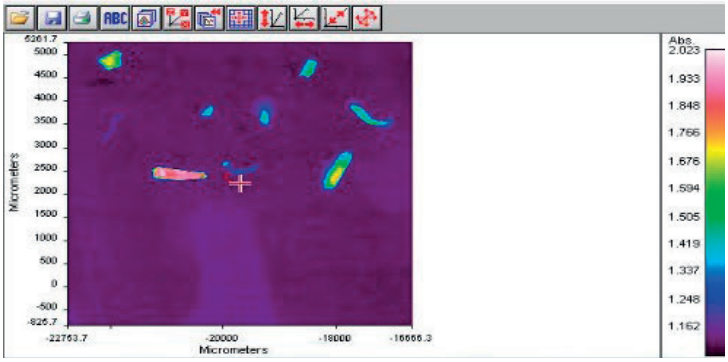

Figure 6. Micro-FT-IR spectral image of microplastics

The IR spectra were extracted from the obtained images (Figure 7) and based on a comparison with the Spectra Databases for Polymers - S.T.Japan Europe GmbH, the polymers composing the microplastics were identified.

The ubiquitous polymer identified in greatest abundance was polyethylene (PE) (Figure 8). The highest polymer diversity was found in Somova and Câșla lakes, where the highest concentrations were recorded. This result is explained by the fact that PE is the most widely used polymer in plastics production (https://www.britannica.com/science/polyethylene.). The second polymer observed was polypropylene (PP), which is one of the most widely used polymers worldwide for packaging (Fernández-González et al., 2021). Polyester (PES), polyacrylonitrile (PAN), and rayon were identified in the fiber composition. Microfiber pollution is caused by fishing nets, rope from lakes, and textiles, in particular by their presence in the air and domestic washing machine effluents (Salvador Cesa et al., 2017).

PVC (polyvinyl chloride) was found in the Somova Lake, which could originate from the degradation of building materials and insulation of cables based on this polymer (Akovali, 2012). In addition, a hydroxyl functional polyester–based paint particle was collected from Somova Lake, which could come from the boat paint. According to the report "Plastic Paints the Environment", published in 2022 by Environmental Action in Switzerland, paints account for 58% of microplastics in the world's oceans and waterways (Paruta et al., 2022).

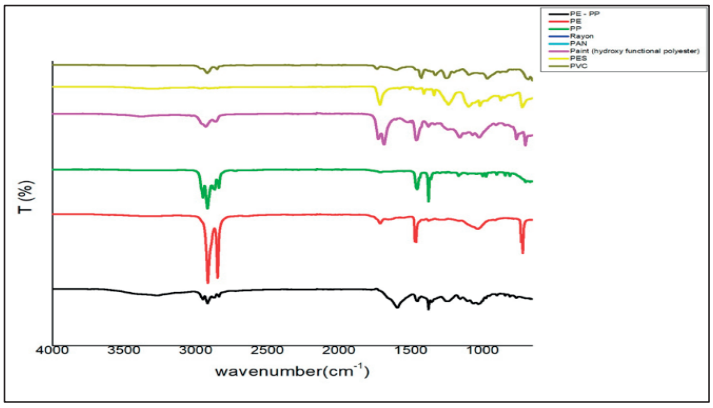

Figure 7. IR spectra of the identified polymers

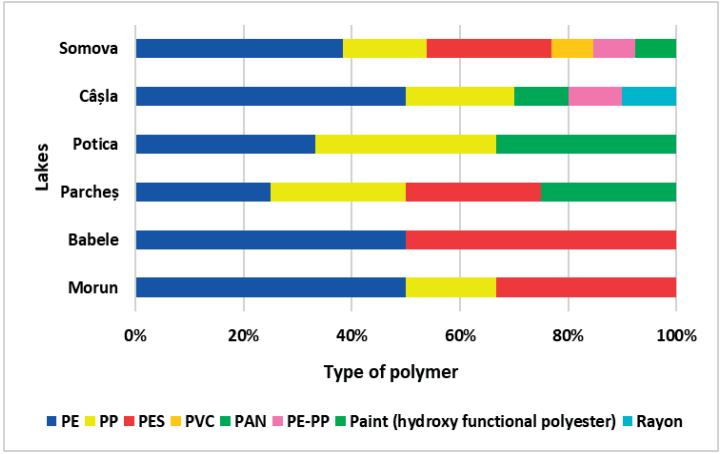

Figure 8. Polymer composition of microplastics

Another aim of the present paper was to assess the level of microplastic pollution in the 6 lakes by calculating the PLI index. The index values are plotted in Figure 9 and are in the range 0.86-1.80, indicating a low level of microplastic pollution (category risk I). Low MPs pollution load was observed in high-altitude glacier lakes in Northern Anatolia, water PLI values ranging from 1.00 to 2.65 (Akdemir et al., 2025).

Figure 9. PLI index values

CONCLUSIONS

In this paper, the presence of microplastics in 6 lakes from the Somova-Parcheș lacustrine complex was studied for the first time. The MPs concentrations in the water of the 6 investigated lakes varied in the 0.15-0.65 particles·m^{-3} range. A variety in the shape, size, and polymer composition of the MPs in the collected samples was observed, indicating the diversity of pollution sources. The MPs shapes identified were fragment>fiber>film. The results of the micro-FT-IR analyses highlighted the presence of PE>PP>PES>PAN>PVC>Paint (hydroxyl functional polyester) polymers in the composition of the collected microplastics. PLI values of all the lakes showed minor contamination with microplastics in the risk I category. This pioneering research fills a knowledge gap, providing valuable information on microplastic pollution of previously unexplored freshwater ecosystems.

Abstract

The Somova-Parcheș Aquatic Complex is part of the Danube Delta Biosphere Reserve and hosts a wide variety of fauna and flora species of community importance. This complex is fed with a significant volume of water from the Danube River, thus influencing the quality of the lake ecosystems. For this reason, the present study aims to investigate the presence of certain classes of pharmaceutical residues in water sampled from 6 lakes, namely Somova, Parcheș, Morun, Potica, Babele, Câșla, as well as their ability to accumulate in the tissues of fish collected from the same study area. Extraction of pharmaceutical compounds was performed using the solid phase extraction method for water samples and the QuEChERS method for fish tissues. Results obtained from analyses using high-performance liquid chromatography coupled with high-resolution mass spectrometry revealed the presence of the pharmaceutical compound caffeine in most water samples and its tendency to accumulate in some fish organs, such as the gills.

Key words*: Somova-Parcheș Aquatic Complex, pharmaceutical residues, water, fish tissue.*

INTRODUCTION

The Danube River supplies water to the Somova-Parches Aquatic Complex, thus facilitating the entry of various contaminants into the lakes. Numerous studies have been carried out on the Danube River, which have shown that, in general, the water falls into class quality II (Good) (Mănoiu & Crăciun, 2021). However, a wide variety of chemical and physical compounds have been identified which, in certain concentrations, can have toxic effects on the aquatic environment, such as: nutrients (Malagó et al., 2017; Popa et al., 2018), gross alpha and gross beta activities (Pintilie-Nicolov et al., 2021), heavy metals (Lazăr et al., 2024; Mîndrescu et al., 2022), pharmaceutical compounds (Chitescu et al., 2015), microplastics (Procop et al., 2024), pesticides (Đurišić-Mladenović et al., 2024), etc.
To date, studies have been conducted in the Somova-Parcheș Aquatic Complex area to evaluate the quality of aquatic ecosystems, considering the common parameters regulated by Order 161/2006. Among the most frequently analyzed compounds in this study area are heavy metals, oxygen regime, and nutrients (Burada et al., 2015; Catianis et al., 2019). This study aims to investigate, for the first time in this area, a class of emerging pollutants represented by pharmaceutical residues. The main pollution sources of the Danube river with pharmaceutical residues are conventional wastewater treatment plants and animal farms (Kock et al., 2023; Radović et al., 2012).
The analysis of this type of contaminants in aquatic environments is very important, as they can have direct toxic effects on aquatic biota and can accumulate in biotic tissues depending on their concentration and the physicochemical properties of each pharmaceutical substance (Khan et al., 2020; Rojo et al., 2021; Williams et al., 2009). For this reason, the present research focuses on investigating the presence of different classes of pharmaceuticals in various organs of the *Carassius gibelio* fish species collected from the Somova-Parcheș Aquatic Complex.

MATERIALS AND METHODS

To study the presence of pharmaceutical compounds in the Somova-Parcheș Aquatic Complex, four water samples were collected

from different areas (inlet, middle and outlet) of each lake, namely Somova, Parcheş, Morun, Potica, Babele and Câşla (Figure 1).

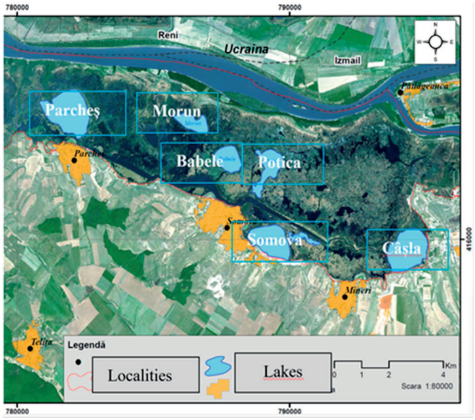

Figure 1. Map of the studied lakes in the Somova-Parcheş Aquatic Complex

Extraction of pharmaceutical residues from water samples was performed with a Dionex AutoTrace 280 Thermo Scientific automated solid phase extraction system (Figure 2).

Figure 2. Automated solid phase extraction system

To extract the target compounds from fish tissues, the QuEChERS (Quick, Easy, Cheap, Effective, Rugged, and Safe) technique was used. This method involved the extraction of contaminants from the matrix into the solvent acetonitrile in the presence of the following salt mixture: 6 g anhydrous magnesium sulfate, 5 g sodium chloride, 1.5 g disodium citrate dihydrate, and 0.75 g trisodium citrate sesquihydrate. To remove fats, lipids, and pigments from the extract, a purification step was performed using the dispersive solid-phase extraction (d-SPE) method in the presence of sorbent materials (PSA – primary secondary amine, C18, and GCB – graphitized carbon) (Figure 3).

Figure 3. QuEChERS extraction steps

The extraction step was followed by the analysis of pharmaceutical substances from the obtained extracts using high-performance liquid chromatography coupled with high-resolution mass spectrometry.

The following pharmaceutical compounds were investigated in water and fish tissue samples: metformin, carbamazepine, clindamycin, ciprofloxacin, clarithromycin, trimethoprim, sulfamethoxazole, amoxicillin, ketoprofen, diclofenac, and caffeine. To quantify these compounds, the internal standards were used depending on the class of pharmaceutical substances they belong to, as follows: enrofloxacin for antibiotics, dihydrocarbamazepine for carbamazepine, fenoprop for anti-inflammatories, phenacetin for metformin and caffeine (Figure 4).

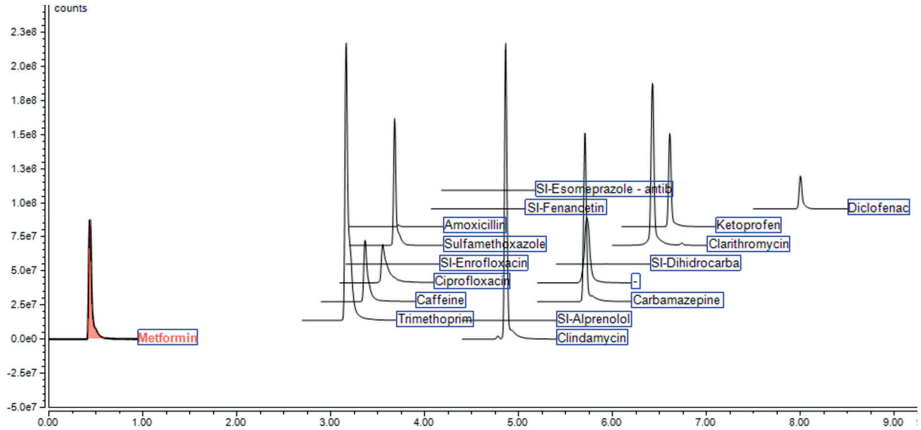

Figure 4. Chromatogram of the analyzed pharmaceutical compounds

RESULTS AND DISCUSSIONS

Spatial distribution of pharmaceutical compounds identified in water samples taken from lakes in the Somova-Parcheş Aquatic Complex

From all the 6 lakes studied in this paper, water samples were taken from 4 different stations, and the presence of different pharmaceutical substances was investigated. Of the 11 compounds monitored in water samples, only caffeine and the internal standards added to the samples for compound quantification were identified in all sampling stations (Figure 5).

Caffeine is found in beverages, foods, and medications that are consumed in significant quantities worldwide. For this reason, it is considered a significant pollutant in the class of active pharmaceutical compounds that is found with high frequency in the environment (Li et al., 2020).

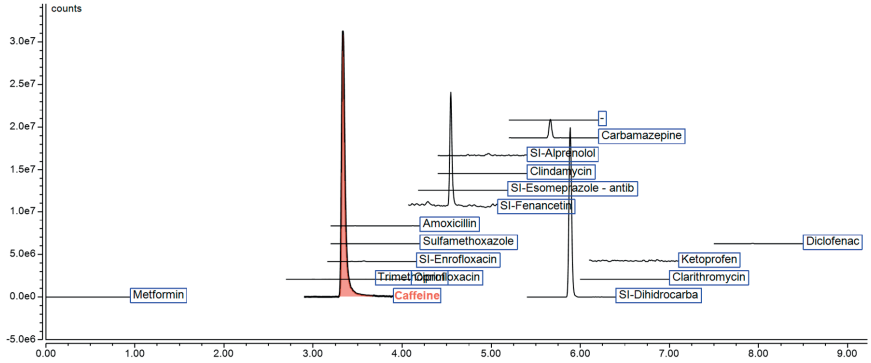

Figure 5. Chromatogram example of compounds in a water sample analyzed from lakes

In the lakes analyzed in the present study, caffeine concentrations varied between 15 ng/L and 65 ng/L. The highest values of the caffeine compound were identified in Somova lake, the mean concentration being 55 ng/L. The lowest concentrations were obtained in water samples collected from Morun lake, where a mean concentration of 20 ng/L was recorded. In most lakes, slight variations in caffeine concentrations were observed from one sampling station to another (Figure 6). The main contamination source of the aquatic environment with this psychoactive compound is anthropogenic,

generally represented by municipal wastewater (Vieira et al., 2022).

The presence of this compound in the aquatic environment can be explained by its pseudo-persistent character, caused by its long half-life. This substance also exhibits high resistance to chemical and biological degradation in the environment, has low volatility, and its low octanol-water partition coefficient (log Kow = -0.07) explains its high solubility in water (Rodrigues et al., 2025). In the aquatic environment, this alkaloid can have direct toxic effects on biota and can even induce behavioral disorders in fish at environmentally relevant concentrations (Cerveny et al., 2022).

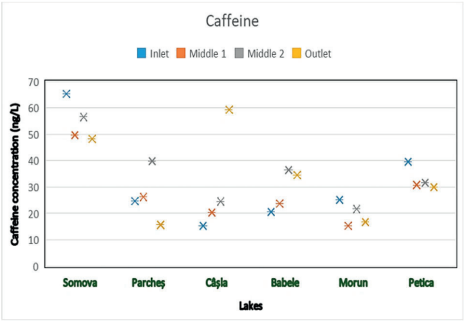

Figure 6. Spatial distribution of caffeine in the Somova-Parcheș Aquatic Complex lakes

The caffeine compound was also identified at high frequency in the Danube River in the territory of the Novi Sad, Serbia with concentrations varying from 3.10 to 621 ng/L (Milić et al., 2018).

On the territory of Romania, there is a limited number of studies that have focused on the analysis of pharmaceutical residues in the aquatic environment.

Chitescu et al., identified the following compounds in water samples taken from the Danube River: sulfamethoxazole, trimethoprim, enilconazole, carbamazepine, and tylosin. Pharmaceutical residues such as sulfamethoxazole, diclofenac, trimethoprim, carbamazepine, piroxicam and ketoprofen were quantified in the Olt, Argeș and Siret tributaries. A smaller number of pharmaceutical substances were identified in water samples taken from the Danube Delta, including sulfamethoxazole and carbamazepine (Chitescu et al., 2015).

Investigation of the pharmaceutical compounds presence in fish specimens of the species Carassius gibelio

The fish species *Carassius gibelio* is found abundantly in the Danube River basin and is considered the most consumed local freshwater fish (Raita and Georgescu, 2019). To identify the presence of pharmaceutical compounds in the species *Carassius gibelio*, 3 fish specimens were taken for analysis and extractions were made from muscle tissue, liver tissue, gills and eggs. Of all the investigated compounds, caffeine was the one that was found in all the organs analyzed from the 3 fish, with mean values ranging from 0.77 ng/g to 2.42 ng/g (Figure 7). Table 1 shows that the highest average concentration of caffeine was identified in the gills. This can be explained by the fact that the gills are in direct contact with water and can more easily accumulate pollutants found in the aquatic environment (Nikolić et al., 2020). However, it can be noted that traces of caffeine were identified even in the fish eggs analyzed in this study.

The obtained results show that the same compound identified in water samples from the Somova-Parcheș Aquatic Complex, represented by caffeine, accumulated also in the organs of fish collected from the same study area.

Table 1. Concentration levels of pharmaceuticals in fish specimens of the species *Carassius gibelio* – the values are expressed as mean ± standard deviation

Pharmaceutical compound identified	Fish organs analyzed	Mean concentration ± std (ng/g)
Caffeine	Muscle tissue	1.04 ± 0.19
	Liver tissue	1.60 ± 0.23
	Gills	2.42 ± 1.10
	Eggs	0.77 ± 0.30

In the literature, there are laboratory studies that monitored the behaviour and physiology of fish exposed to caffeine and it was highlighted that, even in relatively low concentrations, this compound can cause liver enlargement and anxiety of fish (Bikker et al., 2024). There are also studies reporting accumulations of the caffeine compound in the organs of different fish species. For example, Wang and Gardinali reported the presence of caffeine in the fish species *Gambusia holbrooki* at a mean concentration of 1.3 ng/g (Wang & Gardinali, 2012).

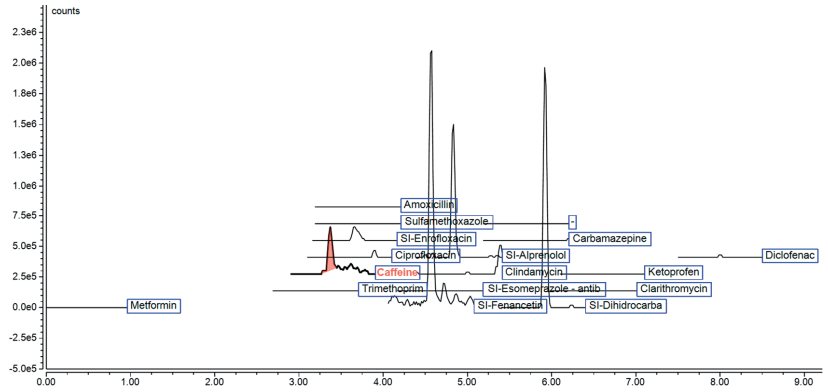

Figure 7. Chromatogram example of compounds identified in fish tissue from the species *Carassius gibelio*

In the panga fish (*Pterogymnus laniarus*) caffeine was detected in the intestine, liver and gills with a concentration of 2.03 ng/g (Ojemaye and Petrik, 2019). Caffeine was also identified in the fish species Common Silver biddy (*Gerres oyena*), Golden snapper (*Lutjanus johni*), Emperor fish (*Lethrinus, nebulosus*), Nile Tilapia (*Oreochromis niloticus*), and Milk fish (*Chanos chanos*) (Ali et al., 2018).
No results have been reported in the specialized literature regarding the presence of pharmaceutical residues in the fish species *Carassius gibelio*.

CONCLUSIONS

Due to their high toxicity, it is important to monitor the emerging contaminant class represented by pharmaceutical compounds in all water bodies.
The present study emphasizes that a wide variety of pharmaceutical substances were not found in the lakes of the Somova-Parcheș Aquatic Complex. This may be due to the fact that there are no direct sources of pollution in the area. This may also be influenced by the low concentrations of these compounds in the Danube water, which may undergo various processes of accumulation, degradation, dilution until they reach the lakes of the Somova-Parcheș Aquatic Complex.
However, the psychoactive substance caffeine was identified in all water samples analyzed. A possible explanation could be that it is generally found in higher concentrations in the aquatic environment compared to the other pharmaceutical compounds analyzed and can therefore reach even areas far from direct sources of pollution.
This study also highlights the ability of the caffeine compound to accumulate in aquatic biota. Low concentrations of caffeine were identified in the organs of the fish analyzed from the species *Carassius gibelio*.

Abstract

PFAS are present in freshwater fish in the Danube River, posing concerns about aquatic ecosystem contamination and adverse effects on human health. These substances also referred to as "forever chemicals" have the potential to accumulate in the food chain and provoke several health issues, including hormonal imbalance and cancer. In this work, the QuEChERS extraction and clean-up method combined with UHPLC-HRMS (Ultra-High-Performance Liquid Chromatography – High-Resolution Mass Spectrometry) was applied for the determination of 18 PFAS in muscle tissue of freshwater fish (European wels catfish – Silurus glanis). The method was validated in terms of Specificity, Linearity, Precision (% RSD), Recovery, and Accuracy (mean spike recovery, %) at two levels of concentration: 0.1 and 5 ng. Additionally, the study assessed the impact of matrix effects on PFAS detection in fish tissue.

Key words*: Danube River, freshwater fish, mass spectrometry, PFAS, QuEChERS.*

INTRODUCTION

Per and poly-fluoroalkyl substances (PFAS) are a class of thousands of environmental contaminants that contain carbon-fluorine bonds, known in organic chemistry as one of the strongest chemical bonds (Figure 1) (*Per- and Polyfluoroalkyl Substances (PFAS) - ECHA*, n.d.). They have been detected in freshwater fish from European rivers, the contamination with these substances is mainly the result of bioaccumulation in aquatic food chains (*PFAS Pollution in European Waters*, 2024). Given the increased anthropogenic pressures on aquatic ecosystems, fish meat and fish products have been observed to accumulate various contaminants, which can pose toxicity risks if transferred to humans via consumption (Panda et al., 2023). PFAS can accumulate in fish via two pathways: direct uptake from contaminated water and indirect uptake through the consumption of contaminated sediments and feed. In time, this can lead to bioaccumulation especially in vulnerable fish species tissue, causing disruption of the aquatic ecosystem.

The Danube River, one of the most important rivers in Europe, has been exposed to environmental pollutants like PFAS mainly through agriculture, industrial processes and wastewater discharges. In the Danube River Basin, a comprehensive study has focused on the occurrence and distribution of 4,777 PFAS in river water, wastewater, groundwater, and biota samples. Results revealed the presence of 82 PFAS, with perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) being widespread in surface water. Furthermore, the risk assessment led to identifying 18 PFAS of environmental concern, highlighting the

ubiquity of these substances throughout the river basin (Ng et al., 2022). Another study conducted in the Lower Danube River region focused on the occurrence of PFAS in surface water and ground water from two sites. PFAS concentrations were mostly low with the exception of PFOA concentrations that exceeded 10 ng/L at one site (Obeid et al., 2023).

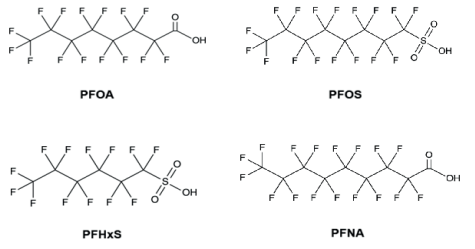

Figure 1. Chemical structure of the most studied PFAS

In the literature (Chaudhary et al., 2024), it is found that the absorption of PFAS at the level of biota depends on several factors that characterize water quality, e.g. heavy metals. It is necessary to associate studies on heavy metals from sensitive areas (Burada et al., 2015) with studies including statistical processing of the results of physicochemical determinations from surface ecosystems (Popa et al., 2018) and determinations of certain pollutants in biota.

As a consequence, regulations regarding PFAS are increasingly strict in Europe due to growing concern about their environmental and health impacts. The European Union has proposed restrictions on the use for specific PFAS under the REACH (Registration, Evaluation, Authorisation, and Restriction of Chemicals) regulation (*REACH Annex XVII: REACH Restricted Substance List 2023*, n.d.). In addition, the European Chemicals Agency (ECHA) is actively identifying and imposing limitations for the use of PFAS substances of high concern (*Per and Polyfluoroalkyl Substances (PFAS) - ECHA*, n.d.). These restrictions will have as an impact an increased demand for targeted assessment of PFAS in different environmental matrices, like water, sediment and biota. Moreover, researchers and environmental agencies will update their monitoring strategies to comply with these regulations with focus on the most harmful and widespread PFAS.

The aim of the present work was to develop and validate a method for the determination of 18 PFAS in fish muscle using QuEChERS (Quick, Easy, Cheap, Effective, Rugged and Safe) extraction and clean-up followed by UHPLC-HRMS (Ultra-High-Performance Liquid Chromatography – High-Resolution Mass Spectrometry) analysis.

MATERIALS AND METHODS

The fish tissue used in this validation study was muscle from three different wels catfish (*Silurus glanis*). The fish were purchased from a local fisherman in the Lower Danube River Region, Galați. 5 grams of each homogenized tissue (wet weight) were submitted to the QuEChERS extraction and dSPE (dispersive solid-phase extraction) clean-up. PFAS compounds were extracted from the fish tissue using acetonitrile and extraction salts (6.0 g $MgSO_4$ and 1.5 g Na-acetate). The resulted extract was submitted to clean-up (150 mg $MgSO_4$, 50 mg Primary and Secondary Amines) and concentrated under a gentle nitrogen flow. All resulted extracts were stored in polypropylene vials to prevent sample contamination. Figure 2 depicts the general workflow for the PFAS analysis in fish samples. For the method validation, spiked samples of 0.1 and 5 ng PFAS were also prepared in triplicate using the same protocol.

The final extracts were separated on Accucore aQ C18 (100 mm x 2.1 mm, 2.6 μm) analytical column in a gradient mode, and the mobile phase consisted of methanol and ultrapure water, both acidified with 0.1% formic acid. The flow rate was 0.5 mL/min. The temperature of the autosampler was 6°C and the analytical column temperature was set to 45°C. Furthermore, the extracts were analysed using a Thermo Fisher Scientific Chromatographic System consisting of Vanquish Flex Liquid Cromatograph coupled to Orbitrap Exploris 120 Mass Spectrometer with heated electrospray ionization (H-ESI II), operated in Full Scan at 120,000 (FWHM) at m/z 200, negative ion mode. The mass measurement accuracy was 5ppm. The chromatographic separation and detection were

performed within 21 min of analysis time. All chromatograms were processed using Chromeleon 7.3 software.

Table 1 contains a list of the target analytes; their acronyms and chemical formula and they are presented in their elution order. Also, the table presents the negative monitored ion (MS Quantitation peak) for each of the 18 PFAS.

The following validation parameters were tested according to Commission Decision 657/2002: specificity, linearity, precision, recovery, accuracy and matrix effects (*Decision - 2002/657 - EN - EUR-Lex*, n.d.). The obtained data represent a helpful tool in evaluating the reliability of the analytical method, in particular for low concentrations quantification of compounds in environmental samples.

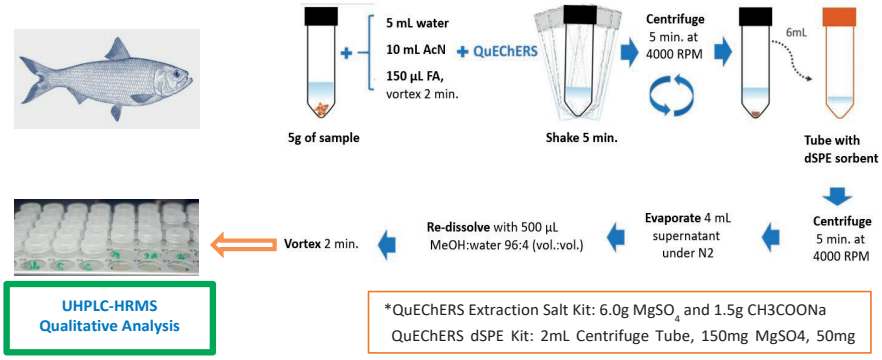

Figure 2. General targeted PFAS analysis workflow in biota samples

RESULTS AND DISCUSSIONS

The specificity of the method was investigated by injecting standard solution and solvent (a mixture of methanol and ultrapure water). Also, a chromatogram of the mobile phase was analysed. The obtained chromatograms demonstrated the absence of interference in the analyte elution. Figure 3 and 4 show a Total Ion Chromatogram (TIC), respectively an Extracted Ion Chromatogram of the PFAS standard mixture at a concentration of 100 ng/mL.

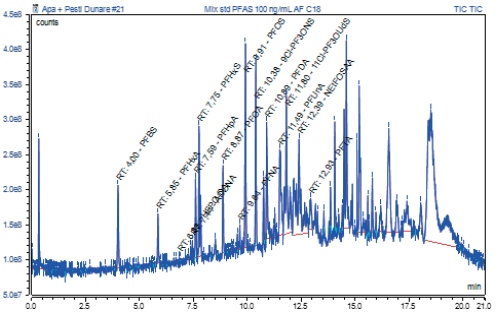

Figure 3. Total Ion Chromatogram of the PFAS standard mixture at 100 ng/mL

They both show a good separation of the compounds which is an indicator for an appropriate choice of the mobile phase, gradient and chromatographic column.

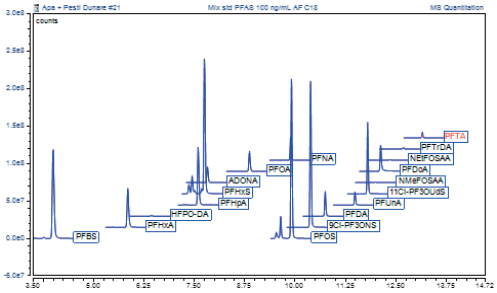

Figure 4. Extracted Ion Chromatogram of the PFAS standard mixture at 100 ng/mL

Linearity of the method was evaluated by testing calibration standards of PFAS on 8 concentration levels. These were prepared by dilutions of the stock standard solution prepared in 96%: 4% methanol: ultrapure water (vol./vol.) and comprise a mixture of target analytes in a calibration range of 0.5-100 ng/mL for most analytes, except for HFPO-DA (5-100 ng/mL).

The coefficient of determination was R^2>0.995, which complies with the acceptance criteria (Table 2). This indicates a strong linear relationship between the measured concentration and expected concentration in the method used for analysis.

Precision was measured as %Relative Standard Deviation. Higher RSD values indicate lower precision, while lower values suggest less variability in measurements. 2 levels of spike were tested: 0.1 and 5 ng. The analysis was performed in triplicate for each spike level. Results for most compounds were reasonably low, especially for the 0.1ng spike. Precision values range from about 2.74% to 18.62% for different compounds and are below 20%. (Tabel 2). For example, PFBS at the 0.1 ng spike has an RSD of 8.14% and at the 5 ng spike of 8.13%, which indicates that the measurements are consistent. Some compounds like PFOS have a relatively low % RSD of 3.11 at 5 ng, indicating good precision, while others like HFPO-DA have higher % RSD values of 18.06 at 0.1 ng, which suggests poorer precision in the measurements at lower concentrations.

Recovery represents a measure of the analytical method efficiency in detecting the spiked compound and it is the measured concentration compared to the spiked concentration, expressed as a percentage. The recovery for some compounds at the 0.1 ng spike is lower than ideal (100%). For example, PFH x A has a recovery of 66.53% at the 0.1 ng spike, suggesting that the method may not be as efficient at detecting lower concentrations. Many compounds (e.g., PFHpA, PFDA, NMeFOSAA) have recoveries slightly lower than 100% at the 5 ng spike, which indicates that the method has good efficiency at higher concentrations.

Accuracy, measured as mean spike recovery %, shows how close a result is to the true value. The obtained results are presented in Table 2. % RSD of the % recovery was within a range of 1.97 to 16.15%.

Matrix effects were significantly reduced by the Orbitrap 120 Mass Spectrometer due to its high resolution, sensitivity, and accurate mass measurements, along with its ability to optimize ionization conditions, whereas in traditional quadrupole MS, matrix effects can lead to ion suppression or enhancement, causing inaccurate quantification and reduced sensitivity due to interference from co-eluting compounds in the sample. Therefore, the proposed method is well-suited for environmental testing, such as analysing fish extracts for contaminants.

The carryover effect was evaluated by injecting two solvent blanks right after the analysis of the highest calibration standard concentration. There was no carryover effect observed.

CONCLUSIONS

An optimized analytical method based on QuEChERS extraction and UHPLC-HRMS analysis of PFAS was successfully validated. However, there are some limitations to this method. While it demonstrates high sensitivity and specificity, it may not detect all PFAS, particularly those with low ionization. Future research could focus on expanding its scope by refining extraction protocols or incorporating complementary extraction techniques. Additionally, further validation on a broader range of environmental matrices would also be valuable for improving the method's practical applications in monitoring PFAS contamination.

The proposed method is highly suitable for the accurate quantification of PFAS in biota samples, offering accurate measurement of these contaminants in fish. This makes it an effective tool for environmental monitoring, risk assessment, and studies on the bioaccumulation and potential health impacts of PFAS exposure in ecosystems and human populations. PFAS determinations in biota are part of the quality indicators for surface aquatic ecosystems and must be included in integrative systems such as the Water Quality Index (Iticescu et al., 2016) due to their persistence, bioaccumulation potential, and widespread distribution in aquatic ecosystems. This will give a correct global picture of the interactions between the different pollutants in complex systems such as the Danube.

Abstract

The ecological reconstruction of degraded lands was based on the predominant use of pine species (Pinus nigra and Pinus sylvestris), resulting in pure stands or sometimes mixed with deciduous trees, with a fragile structure, prone to damage. The research was carried out during 2023-2024, in 18 research areas located on degraded lands in the Vrancea area, in stands of different ages with the aim of the knowledge of compositional and structural indicators that reflect the intensity of competitive processes. The results indicate a pronounced predisposition to disturbances in pure young stands, with a high level of compositional homogeneity and relative abundances of Scots pine. The relationship between the structural diversity index (Gini) and the coefficient of variation allowed the determination of the structure type of the stand, the correlation coefficient being significant (r=0.9923). Research has shown that mixed stands are more structurally stable than pure stands, promoting mixed species being essential in increasing the resistance of stands. The results are useful for decision-makers, the goal being to create stands with structures resistant to the action of damaging factors.

Key words*: structural and compositional diversity, pine species, degraded lands.*

INTRODUCTION

Forest biodiversity is closely correlated with the diversified horizontal and vertical structures of the component stands, and the so-called silviculture (silvotechnics) close to nature is largely based on observations and measurements carried out either in strict research plots located in the improvement perimeters, in the case of degraded stands or in forests affected by disasters (natural disasters due to climatic factors, anthropogenic degradation, etc.) (Seidl, 2017).

Global-scale studies highlight a consistent positive relationship between tree species diversity and productivity, using tree species richness as a proxy for biodiversity, as taxonomic diversity is considered to incorporate other traits, such as those of a functional, phylogenetic, or genomic nature (Liang et al., 2016). Studies from North America and Europe also indicate a positive relationship between species richness and tree productivity, while addressing the influence on the environment and climate (Ruiz-Benito et al., 2017). Other studies highlight that the role of biodiversity tends to be stronger in harsher climates (arid or boreal lands) (Ratcliffe et al., 2017).

Because both productivity and biodiversity depend on a wide range of factors, controlled or not by forest management, the scientific hypotheses of various researchers have mostly supported the role of forests in capturing and storing carbon but also as shelters for the protection of biodiversity (Bodin & Wiman, 2007). An important challenge for forest management and conservation is to achieve an appropriate balance between biodiversity and aboveground biomass in order to support forest managers and decision-makers in developing sustainable management plans in relation to the intended purpose (e.g. conservation, increasing forest resilience, and so on) (Silva et al., 2017).

Within stands on degraded lands, their evolution over time is influenced by harmful abiotic and biotic factors, which destabilize the structure of

the stands and endanger the dynamic balance (Giurgiu, 2004). The ecological reconstruction of degraded lands was achieved through repeated afforestation interventions and the predominant use of pine species (*Pinus nigra* and *Pinus sylvestris*), resulting in stands with a fragile structure, prone to damage, in which there is a risk of diminishing eco-protective functions. (Constandache et al., 2015). The installation of protective forestry crops is made difficult in most situations due to difficult environmental conditions, consisting of lands affected by complex degradation processes, which requires the use of special techniques for arranging/consolidating the respective lands. (Constandache & Nistor, 2008).

The role of forestry crops established through ecological reconstruction consists of limiting surface erosion, increasing infiltration, and improving internal drainage (Sandu et al., 2015), soil improvement and so on. Protective forest crops installed on degraded lands, consisting of pine species, associated with various deciduous species (sycamore, ash, cherry, alder, oak, sea buckthorn, and so on) have demonstrated their hydrological and anti-erosional efficiency, but also their increased resistance to the action of disturbing factors. Many stands are affected by drying, breakage, and so on, due to climate change on the one hand (Vlad et al., 2019), or improper application of silvicultural operations on the other hand (Nistor & Constandache, 2013).

The specific conditions in which each stand develops show that it is necessary to abandon the application of rigid, template measures at stand level. To this end, it is necessary to know the inter- and intraspecific relationships that are established between trees, more precisely, specific indicators, estimators and descriptors of the structure of stands (Ciubotaru & Păun, 2014). These parameters can constitute the basic elements for creating models of stands structures appropriate to environmental conditions, stable and resistant to the action of harmful factors, which can properly fulfill their protective functions (Cristinel et al., 2024).

The research conducted aimed to determine indicators of compositional and structural diversity of stands on degraded lands. These indicators, expressed in measurable/evaluable and comparable units, are necessary to ensure sustainable management of forestry ecosystems installed on degraded lands. The results were obtained based on research on monitoring stands on degraded lands carried out in the period 2023-2024.

MATERIALS AND METHODS

The research was carried out in permanent research plots (SEP), located in representative situations of stands on degraded lands in three experimental perimeters in the Vrancea area (Figure 1):

Caciu-Bârsești (CB), Pârâul Sărat-Valea Sării (PS) and Roșoiu-Andreiașu (RA), located from a phytoclimatic point of view in the hilly storey of sessile oak, beech and sessile oak-beech codified as FD_3.

Figure 1. Location of the study (marked on the map with red dots). Source: www.wikipedia.org

The research consisted in observations, measurements, field data collection, processing and interpretation. The working methodology consisted of applying empirical equations to determine compositional and structural diversity indices at the stand level (Giurgiu & Drăghiciu, 2004; Ciubotaru & Păun, 2014).

In the first stage, to determine the indexes, it was necessary to collect raw field data that include the dimensional characteristics of the trees, which enter into the empirical equations, namely: compositional diversity indices: Shannon index (H), compositional diversity index (A), equity index (Pielou) (E), Simpson index (D); structural diversity indices: Camino index (C), Gini index (G), density index (Id), density index (IG).

The Shannon diversity index (H) measures the diversity of species within a stand.

The compositional diversity index (A) is an indicator of biodiversity, based on the relative abundance of species in a stand (Jaehne & Dohrenbusch, 1997).

The Pielou-Equity index (E). Evenness (E) shows the relationships between the abundances of species or categories of species. In the case of similar relative abundances, the equity will have a unitary value, and if most observations belong to a single category, it tends to value zero. Equity represents a form of standardization of the Shannon index, as the ratio between observed diversity and maximum diversity (Pielou, 1969; Lexerod & Eid, 2006).

The Simpson index (D) expresses the probability that two observations drawn at random from the analyzed perimeter belong to the same category. It is strongly influenced by the abundance of categories and little sensitive to the number of categories (Simpson, 1949).

The analysis of the type of structure and homogeneity of pine stands on degraded lands was carried out using the Camino and Gini indices, which have as their scientific basis the variability of experimental values on Lorenz curves. The indices were calculated using the Gini-Lorenz statistical application (Popa, 1999), implemented through Microsoft Excel. The Camino index shows the trend of structural diversification over time, even for even-aged stands. Research has shown that homogeneity provides information on the type and intensity of interventions in stands: if extractions are performed in the upper storey, homogeneity is reduced, while interventions in the middle and lower storey increase homogeneity (Cenuşă et al., 2002).

The Gini index (G) determined according to the basal area is calculated as the ratio between the area determined by the Lorenz curve and the reference line on the one hand and the area of the triangle formed by the reference line with the abscissa and the parallel to the ordinate through the intersection point between the Lorenz curve and the reference line, on the other hand (Katholnig, 2012; Duduman, 2011). Gini coefficient values range between 0 and 1, with a value of 1 indicating maximum biodiversity or maximum heterogeneity (Roibu, 2010).

The density index (Id) expresses the ratio between the actual number of trees per unit area and the optimal number of trees according to the production tables (Giurgiu & Drăghiciu, 2004) in relation to the species and production class.

The density index (GI), also called the basal area index or area index (Rădulescu, 1956), is calculated as the ratio between the actual basal area per hectare and that in the production tables, considered normal for a stand in conditions similar to the one analyzed. The analysis of the relationships between the dimensional variables was carried out based on modelling the linear regression equations of the form $y = a \cdot x + b$, where y is the analyzed parameter, x-the considered independent variable; a, b- the coefficients of the regression equation. The significance testing of the Pearson r-correlation coefficient was performed at a coverage probability of 95% (α=5%).

RESULTS AND DISCUSSIONS

The trees on the degraded lands (strongly to very strongly eroded and ravined in the analyzed perimeters, are mostly made up of a mixture of Scots pine and black pine (Figure 2), sometimes mixed with deciduous species, with an age between 42 and 69 years (Table 1).

Figure 2. Scots pine grove mixed with black pine, on very heavily eroded land (SEP 11, Caciu-Bârseşti perimeter)

Analysis of compositional diversity indices

Information on the characteristics of the current structure of stands is provided by the *Shannon index (H).*

The H-index is an index of diversity and takes into account species richness and evenness of species distribution (E) (Shannon, 1948), so its value increases with the number of species. At the experimental plot level, calculated in relation to the frequencies of individuals and species (for the tree layer) it is between 0.32 (PS 9) and 1.03 (PS 1). These values, compared to the maximum value that can be reached in each sample area (ln(k) - where k is the abundance of species), signal a high level of compositional homogeneity, the ratio being between 29.13 and 93.75%, this aspect indicating that the differences between the relative frequencies of species in the composition of each stand are relatively small. The most diverse structures are found in mixtures of pine with deciduous trees where this index shows higher values (Table 1). *The compositional diversity (A)* at the experimental surface level is between 1.25 (PS 9) and 2.30 (CB 11). The values within this range are mainly determined by the maximum relative abundance of the main species in the stand composition.

Symbols: PA - improvement perimeter; SEP - permanent experimental plot;.N - number of trees; G - basal area; Id - density index according to number of trees; IG - density index according to basal area; H - Shannon index; A - compositional diversity index; E - equity index (Pielou); D - Simpson index; Composition (forest species) Pi - Scots pine; Pi.n - black pine; Dt - various hardwoods; Pa - sycamore; Ci - cherry; Vi.t - Turkish sour cherry; An.a - white alder; Mj - manna ash; Sc - locust.

The relative abundance of a species represents the proportion between the number and/or biomass of individuals (specimens) of a species in relation to the other species, at a given time. Abundance can be expressed both by the number of individuals and by their biomass, in order to obtain undistorted information regarding the structure of the biocenosis (Sava, 2012).

Evenness (E) ranges between 0.23 (CB 9) and 0.85 (CB 10), indicating that most stands exhibit maximum relative abundances belonging to a single category. For example, in the case of the stand in the Caciu-Bârsești perimeter, SEP 8 (CB 8), Scots pine has maximum relative abundance, the value being close to 0 (zero). The values tend towards the unitary value when there is similarity between the relative abundances. In the case of the stand in CB 10, the similarity is reflected by the close relative abundances of the two pine species (Scots pine and black pine) in the composition.

The Simpson index (D) expresses the probability that two observations randomly drawn from the analyzed surfaces belong to the same category. It ranges between 0.37 (PS 1) and 0.85 (PS 9). Given that the stands are predominantly made up of main species (Scots pine and black pine), there is a high probability that two extracted observations belong to these species, being correlated with their abundance.

Analysis of structural diversity indices

In the case of younger stands less than 50 years old (Caciu-Bîrsești perimeter), *the Camino index (C)* has values ranging from 2.90 (CB 6) to 6.47 (CB 11), which indicates that most of the analyzed stands have an even-aged structure (Figure 4). The exception is the stand in CB 10, where the structure is relatively even aged, and the stands in CB 6 and CB 13, where the structure is relatively plurien.

The types of structure reflected by *the Gini index (G)* are similar. This indicator ranges between 0.25 (CB 5) and 0.46 (CB 6) and additionally indicates the homogeneity of the structures based on the distributions of *the Lorenz curves* (Figure 3 a, b). *The Gini index* was determined separately for each species (Table 2). This results in bimodal structures, with *the Gini index* ranging from 0.17 (CB 9) to 0.36 (CB 12) for Scots pine, and from 0.22 (CB 8) to 0.48 (CB 12) for Scots pine. The closer the *Gini index* values are to the straight line, the more homogeneous the structures are (*Gini* tends to take the value 0 in this case).

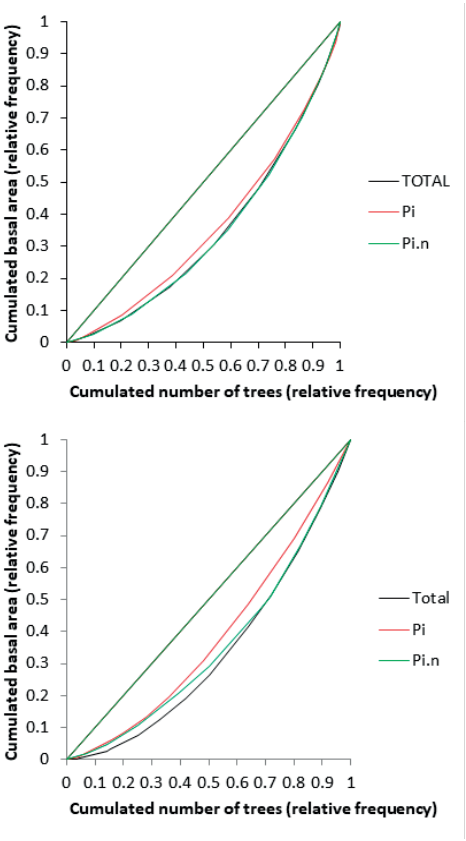

Figure 3. Lorenz curves generated by the Gini index and structural homogeneity analysis after Camino (a - CB11; b - PS1)

The density indexes (ID and IG) (Table 1) reflect the horizontal structure of the stands.

The density index according to the number of trees (Id) is between 0.71 (CB 13) and 2.22 (CB 5), being determined by the actual number of trees per hectare, as well as by the proportion of species in the composition of the stand and the production class. Values lower than 1 indicate a lower number of trees than normal. These indices correspond to a minimum real number of 800 trees per hectare (Id = 0.71), respectively a maximum real number of 3127 trees per hectare (Id = 2.22 which represents a real number of trees, 2.22 times higher than the normal number), the explanation being the dense

planting scheme but also the failure to carry out silvitechnical works.

The density index according to basal area (IG) is between 0.71 (CB 7) and 1.90 (CB 5) and expresses the quality of the stands in relation to the development of their horizontal structure. The basal area expressed per hectare is between 23.30 and 60.37 m^2 (Table 1) indicating a very high variability, especially within stands with a relatively multi-year structure, where the coefficients of variation for the diameter characteristic show high values (CV > 30%) (Figure 4).

Table 2. Structure types according to Camino and Gini indices for young stands predominantly composed of main pine species in the Caciu-Bârsești PA (CB)

Symbols: PA - improvement perimeter; SEP - permanent experimental area; DEG - form and intensity of degradation; R - ravine; E3 - very strong erosion; (C) - Camino index; (G) - Gini index; Pi - Scots pine; Pi.n - black pine; Structure type: E = even aged trees; RP = relatively pluriennial; RE = relatively even

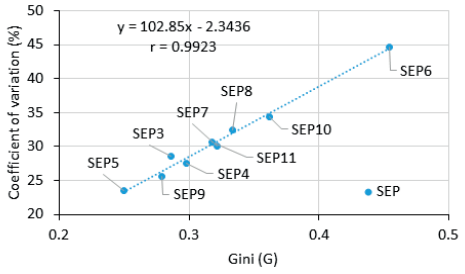

Figure 4. Pearson's r-correlation between the Gini homogeneity index and the coefficients of variation (%)

In the case of older stands (62-69 years old), the Camino index (C) per total stand has values between 2.72 (RA 4) and 4.75 (PS 9), which indicates that most of the analyzed stands present different structures (from even-aged to relatively multi-aged) determined both by the growth conditions and by the action of damaging factors (Figure 5).

The types of structure reflected by the Gini index (G) are similar. This indicator ranges between 0.23 (RA 10) and 0.37 (RA 4). The Gini index determined separately by species indicates bimodal structures, with values ranging between 0.08 (PS 9) and 0.31 (RA 9) for Scots pine, respectively between 0.27 (PS 9) and 0.44 (RA 4) for Scots pine.

The closer the Gini index values are to the straight line, the more homogeneous the structures are (the Gini index tends to take the value 0. In this case, populations formed mainly by Scots pine are more homogeneous than those made up of its competitor, the black pine (Figure 3 a, b).

The density index according to the number of trees (Id) and the density index according to the basal area (IG) reflect the horizontal structure of the stands. *The density index (Id) has ranges between 0.51 (RA 10) and 1.66 (PS 9).* In general, the density of older stands is lower, compared to young ones, the thinning being caused, in most cases, by damage caused by wind and snow at the age of 30-40 years, sometimes by drying but also by natural elimination, etc. These indices correspond to a minimum real number of 470 trees per hectare, respectively a maximum real number of 1515 trees per hectare. The higher values of *the density index* (over-unit) in older stands are the result of the use of small planting schemes (1.0-

1.5 x 1.0 m), the high participation proportion of pine trees (over 90%) but also the failure to carry out silvitechnical works.

The density index (IG) is between 0.66 (RA 10) and 2.29 (PS 9), corresponding to the basal area per hectare, between 26.78 and 81.40 m^2.

These values indicate a reduced variability of stands with even and relatively even structure, where the coefficients of variation for the diameter characteristic show values below 30% (Figure 5).

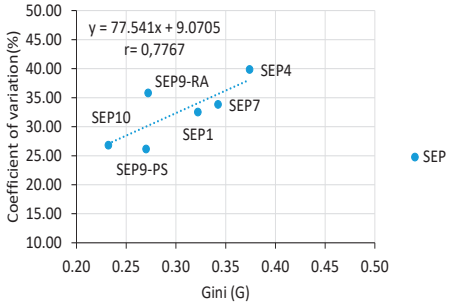

Figure 5. Pearson's r-correlation between the Gini homogeneity index and the coefficients of variation (%)

CONCLUSIONS

The structural and qualitative assessment of stands on degraded lands in the context of climate scenarios provides useful scientific information for the monitoring and sustainable management of forestry ecosystems on degraded lands.

By applying specific data processing methods, indices/parameters regarding the state and structure of stands were obtained. These parameters reflect the intensity of physiological and competitive processes at the tree and stand level (growth, natural pruning, natural elimination, regeneration and so on), having different variability in relation to the composition (component species) and age of the stands, the environmental conditions (form and intensity of degradation) but also to the damage caused by harmful abiotic factors. By the exercise of a optimal functional efficiency throughout their entire evolution period, stands installed on degraded lands require careful supervision and intervention with specific silvotechnical works in relation to their condition, stage of evolution, component species and environmental conditions in which they evolve.

From the point of view of the Shannon compositional diversity index, the analyzed stands present a high level of compositional homogeneity. This aspect derives from the relatively small differences between the relative frequencies of species in the compositions of each stand.

From the point of view of the Gini structural index (G), most of the stands, especially the youngest ones, present an even structure in terms of the distribution of the number of trees and the basal area by diameter classes. The homogeneity of stands is more pronounced especially in stands where the relative abundance of a species (especially Scots pine) is maximum. The exception is made by the older stands with a higher proportion of mixed species (deciduous), where the variability of diameters is high, even if the specimens correspond to the same age class, being determined by competitive and natural elimination processes.

The structure of stands can be easily identified if the coefficients of variation of the actual basal diameters of trees in a population and the Gini index of the respective population are known. From the Gini-coefficient of variation relationship, the correlation coefficients r was obtained, which indicate a high level of significance at a 95% coverage probability, the correlative links being direct and positive for the analyzed cases.

The density indices (Id and IG), determined by the actual number of trees and the basal area per hectare, capture the horizontal structure of the studied stands. In **younger stands**, due to the relatively high number of real trees per hectare and the active development of growth in the basal diameter of the trees, the two indicators present values above unity. In **older stands**, thinned as a result of damage caused by wind and/or snow, the same indicators present values below unity.

Considering the aforementioned conclusions, the following recommendations can be drawn:

1) *Sustainable management of forest ecosystems on degraded lands is ensured by knowing the variability of structural and compositional diversity indices of stands.*

2) *Planning silvicultural works, based on these indicators, establishes urgent measures to*

regulate the homogeneity of stands in order to create optimal and stable structures necessary to ensure resistance to the action of damaging factors.

ACKNOWLEDGEMENTS

Abstract

The participation of the National Network for the Seismic Monitoring and Protection of Building Stock (RNMPSPC) at NIRD URBAN-INCERC in EPOS ERIC, the pan-European Research Infrastructure for Solid Earth Science, requires a rigorous framework for ensuring high-quality seismic data. This paper presents key criteria for seismic data quality assurance and their implementation within RNMPSPC, which operates a strong-motion network of 64 stations across Romania. We detail modern methodologies for seismic data acquisition, processing, and validation, emphasizing compliance with international standards. The practical application of these methods is illustrated using records from a recent ML 5.4 earthquake in the Vrancea seismogenic zone. The study highlights ongoing improvements in equipment, software integration, and data management to enhance the accuracy and reliability of ground motion records. These advancements support seismic hazard assessment and structural safety, reinforcing Romania's contribution to global seismological research.

Key words*: seismic data, quality assurance, seismic network, Romania, research infrastructure.*

INTRODUCTION

Seismic monitoring is a key activity in informing pre-earthquake seismic hazard assessments, rapid identification of seismic damage in instrumented buildings and assisting post-earthquake decision making. From a broader perspective, data acquired from recording ground motions and the response of buildings to these actions provide an essential basis for advancing earthquake engineering science. Seismic networks have already a long history, dating from the late 1800s, when the British geologist, engineer and seismologist John Milne deployed the first international network of seismograph stations, consisting eventually of 30 instruments that recorded ground motion on photographic paper (ISC, 2018; Tripathy-Lang & Bohon, 2022a). Nowadays, seismographic networks maintained by organizations from various countries cover most of the Earth's surface and, given the advancements of sensor technology, not only provide data on ground motions and issue earthquake early warnings, but they are also used in tsunami warning systems (Tripathy-Lang & Bohon, 2022a). Strong-motion networks, equipped with accelerographs and developed from the need of recording potentially damaging ground motions, were first installed in the early 1930s, in the United States (USGS, 2025). Gradually, more and more countries deployed their own strong-motion networks. At present, thousands of accelerographs are deployed all over the world.
In Romania, the first seismographic station was installed in 1895, on Filaret Hill in Bucharest, by the physicist, astronomer and meteorologist Ștefan Hepites (INFP Archive, 2025). The first strong-motion network in Romania was established in 1967 by the National Institute for Building Research, INCERC. Starting from

2009, INCERC is part of the National Institute for Research and Development in Constructions, Urbanism and Sustainable Spatial Development - URBAN-INCERC. This seismic network has been in continuous operation since its establishment and provides ground motion records, as well as data from the monitoring of instrumented buildings. A history of the evolution of strong-motion networks in Romania is provided in (Craifaleanu et al., 2010).

At present, the strong-motion network of URBAN-INCERC consists of 64 digital accelerometers, located according to the main seismicity patterns of the country. Of these, 31 are Kinemetrics (U.S.) instruments and 33 are from GeoSIG (Switzerland), almost 80% being permanently connected online to the Data Center of the seismic network, by using transmission lines from the Romanian Special Telecommunications Service (STS) and from local GSM operators. The URBAN-INCERC seismic network is the central infrastructure of the National Network for the Seismic Monitoring and Protection of Building Stock (RNMPSPC), established in 2017, and which also includes components for experimental testing of building materials, elements and structures. In 2023, in recognition of its importance for a seismic country like Romania, RNMPSPC was granted the status of Infrastructure / Special Objective of National Interest (I.O.S.I.N.), which entitled it for receiving, from the Romanian Ministry of Education and Research, annual funding for maintenance, operation and exploitation.

Given its long existence, the seismic network of URBAN-INCERC has developed, over the years, durable relations with several universities, academic institutions and organizations in Romania and abroad. One of the most significant is collaboration, based on complementarity, with the National Research and Development Institute for Earth Physics, INCDFP, which also owns and operates a large national seismic network, with a focus on seismology. With worldwide recognition in its field, INCDFP is a member of the European Research Infrastructure Consortium EPOS (European Plate Observing System, https://www.epos-eu.org/epos-eric, the pan-European Research Infrastructure for Solid Earth Science), coordinating its Romanian branch, EPOS-RO (https://epos-ro.infp.ro/). EPOS ERIC has currently 19 member countries, and one country, Germany, participating as an observer. The Romanian branch, EPOS-RO, includes five research and development institutes and two universities.

At present, RNMPSPC provides seismic data to the EIDA node (www.orfeus-eu.org/eida) of INCDFP, which is directly connected to the EPOS data portal. The number of connected stations is expected to increase progressively.

Participation in the EPOS Consortium, as well as the need for providing accurate and standardized seismic data, imply, for RNMPSPC, conforming with several requirements, such as hardware and software performance, compatibility with similar worldwide infrastructures, rigorous procedures for seismic data recording, processing and archiving, connectivity with the EPOS data portal, and a structured management of the entire infrastructure. The actions conducted recently in this respect are presented below, with a particular focus on those dedicated to the quality assurance of seismic data. Additional insights into ongoing research and development activities at RNMPSPC can be found in (Dragomir et al., 2023; Mărmureanu et al., 2021).

MATERIALS AND METHODS

In recent years, numerous studies have focused on quality assurance in seismic data, driven by the growing importance of global seismological networks, the interconnection of earthquake monitoring infrastructures, and the increasing demand for high-quality ground motion data. These advancements are essential for seismology, earthquake engineering, and global seismic hazard assessment.

With the advancement of ground motion sensor technology and the automation of recorded data processing, even though human involvement has remained a necessity, the search for methodologies adapted to the automatic screening and quality verification of large amounts of data gained significant momentum. A review of common data processing techniques has revealed several aspects that can lead to distortions or unrealistic features in the

processed signal. Several key studies (Douglas, 2003; Boore & Bommer, 2005; Akkar & Bommer, 2006; Akkar & Boore, 2009; Casey et al., 2018; Ravizza et al., 2019; 2021; Di Giulio et al., 2021) have identified critical issues in seismic data processing and proposed best practices to mitigate these errors. More recently, modern technologies such as machine learning and advanced signal processing techniques have been integrated to assist in the large-scale processing of seismic data (Bellagamba, 2019). Many of the findings of these studies were implemented within complex projects aimed at creating reference ground motion databases and leveraging international collaboration in the field, like RESORCE (https://www.resorce-portal.eu/; Akkar et al, 2013), NERA (Luzi et al., 2016) or SERA (http://www.sera-eu.org/en/home/index.html; Crowley et al., 2018). One of the most significant achievements in the field of seismic data infrastructures is ORFEUS (Observatories and Research Facilities for European Seismology), (https://www.orfeus-eu.org/), the European Infrastructure for seismic waveform data in EPOS. The EIDA data centres connect twelve European data archives, totalling 450 TB of data from almost 300 seismic networks (11000 seismic stations) (Strollo et al., 2021). Within EPOS, seismic data quality assurance is considered an essential prerequisite, covering all steps of the data recording, processing, archiving and distribution. The EIDA nodes and the associated seismological observatories are responsible for implementing their own procedures of data and metadata quality control, complying at the same time with the best international standards and practices (ORFEUS documentation, 2023; Schaeffer et al., 2024).

To comply with the requirements coming from the participation of RNMPSPC in the EPOS-RO/ EPOS ERIC consortium, several actions were taken in the recent period, as presented in the following. These actions are in line with the requirements of the ORFEUS Quality Assurance (QA) documentation (ORFEUS, 2023).

1. Extending and upgrading the infrastructure

a) The seismic network was extended with new stations and accelerometers in existing stations are being gradually replaced with state-of-the-art equipment, with superior capabilities. The accelerometers used in the network come from worldwide trusted manufacturers (Kinemetrics, GeoSIG). Best practices are followed for the placement of accelerometers, typically in small buildings, with low influence on recorded signal. For instrumented buildings, at least two sensors are placed (bottom and top of the building), accompanied, when possible, by a free-field type station, following the COSMOS Guidelines (COSMOS, 2001). It should be noted that instrument deployment must be first agreed with the owner of the space, which induces some restrictions on location selection.

b) Starting from 2023, the year when RNMPSPC received the status of Special Installation/Objective of National Interest (IOSIN), funding for maintenance and reparation of existing equipment, as well as retrofitting of the spaces of the Data Centre is provided, in a large measure, by the Executive Unit for Financing Higher Education, Research, Development and Innovation (UEFISCDI), within the Programme "Research Infrastructures", PN-IV-P5.5-IOSIN-1. Figure 1 shows the newly retrofitted RNMPSPC Data Centre.

c) Most of the data transmission equipment is installed and maintained by the Romanian Special Telecommunication Service. For some additional seismic stations, data transmission is made over GMS lines. All communication channels are functional 24/7 and potential issues are promptly addressed by the providers.

d) The SeisComP (https://www.gempa.de/products/seiscomp/) seismological software for data acquisition, processing, distribution and interactive analysis was implemented at the RNMPSPC Data Centre in Bucharest, starting from 2021. SeisComP uses the SeedLink protocol for communication, a protocol which today practically represents a worldwide standard. With the upgrading of ground motion recording and telecommunication equipment, RNMPSPC stations are gradually connected to SeisComP and to the EIDA node of EPOS. In addition, the *sigma* module (gempa GmbH) is used for advanced data processing, mapping, visualisation and interpretation.

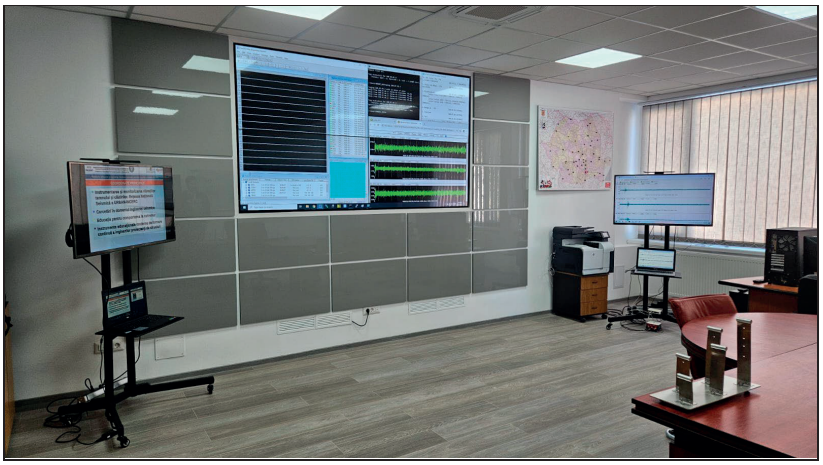

Figure 1. The RNMPSPC Data Centre, with real-time monitoring of seismic activity

2. Seismic data and station metadata curation, storage, archival and dissemination

a) A key condition for data quality assurance is the rigorous specification of station metadata, which ensures accurate interpretation of recorded data. The configuration of stations connected to the SeisComP system was done providing detailed specifications of digitizer and sensor characteristics, locations and orientations. The IRIS DMC Library of Nominal Responses for Seismic Instruments was used, as available in the Station Management Portal created by gempa (https://smp.gempa.de/). The information already available in the seismic station database maintained at the RNMPSPC Data Centre was also used, for all stations. The upgrading and extension of the seismic network were done concomitantly with the upgrading and revision of both databases.

b) The recorded seismic data is stored on NAS (Network-Attached Storage) units and backed-up on a regular basis. In addition, the own data storage system of SeisComP, SDS, is used for the stations connected to this software. Storage capacities are extended as necessary.

c) The seismic network of RNMPSPC was registered at the International Federation of Digital Seismograph Networks, FDSN (https://www.fdsn.org/), with the RQ code (Figure 2).

d) The dissemination of data and research results is done by publishing in peer-reviewed journals, as those mentioned in the "Introduction" section of this article.

3. Structured management of operations

The structured management of seismic network operations was implemented ever since its establishment and evolved continuously with its expansion and modernization. The organization gained additional momentum with the acquirement of the IOSIN status, which imposed the implementation of rigorous procedures for management and reporting.

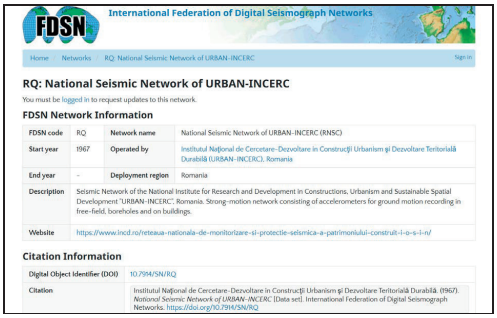

Figure 2. The seismic network of RNMPSPC, as displayed on the FDSN website

An important role in leveraging the activities dedicated to the assurance of the quality of seismic data is played by the various research projects conducted by the RNMPSPC team. The requirements imposed by these projects, as well as the development possibilities they provide, represent an additional incentive. One of the most recent projects is PN 23 35 01 01, aimed at the development of an integrative digital concept for recording, transmitting, processing and analysing data resulting from seismic

monitoring of territory and buildings, based on the implementation of state-of-the-art hardware and software tools, in order to efficiently and operationally identify the destructive potential of earthquakes occurring in Romania and adjacent regions, and at the creation of an open access database for instrumented buildings, set up in accordance with the Open Access, Open Data and FAIR principles and following the best practice models of similar European infrastructures.

RESULTS AND DISCUSSIONS

To demonstrate the practical application of the previously discussed principles, the following section presents examples from recent activities within the seismic network.

Figure 3 displays a screenshot from the SeisComP software, showcasing tests conducted to verify the operational accuracy of seismic stations. The BTH station, featured in the figure, is installed on an instrumented building and is complemented by a free-field accelerometer nearby. This setup is located at the Faculty of Biotechnologies, University of Agronomic Sciences and Veterinary Medicine of Bucharest. Several tests of this type are performed on a regular basis at RMPSPC, for all instruments. For the stations connected to the SeisComP system, values are checked in parallel in SeisComP and in the software applications provided by the instrument manufacturers.

The most important result of quality assurance activities consists in obtaining accurate seismic data and information. The following figures provide an illustration of ground motion records and of seismic data processing and mapping for the largest-magnitude event recorded in Romania in 2024, i.e. the ML=5.4 Vrancea earthquake of September 16th, 14:40:22 UTC.

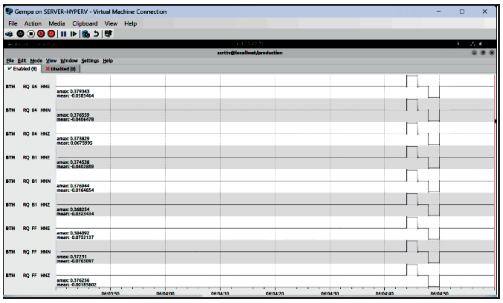

Figure 3. Tests for the verification of station operation. Station BTH (Faculty of Biotechnologies, USAMV, Bucharest). Screenshot taken from SeisComP software

Figure 4 presents a map of the RNMPSPC stations that recorded the ML 5.4 Vrancea earthquake on September 16, 2024, generated using the *sigma* module.

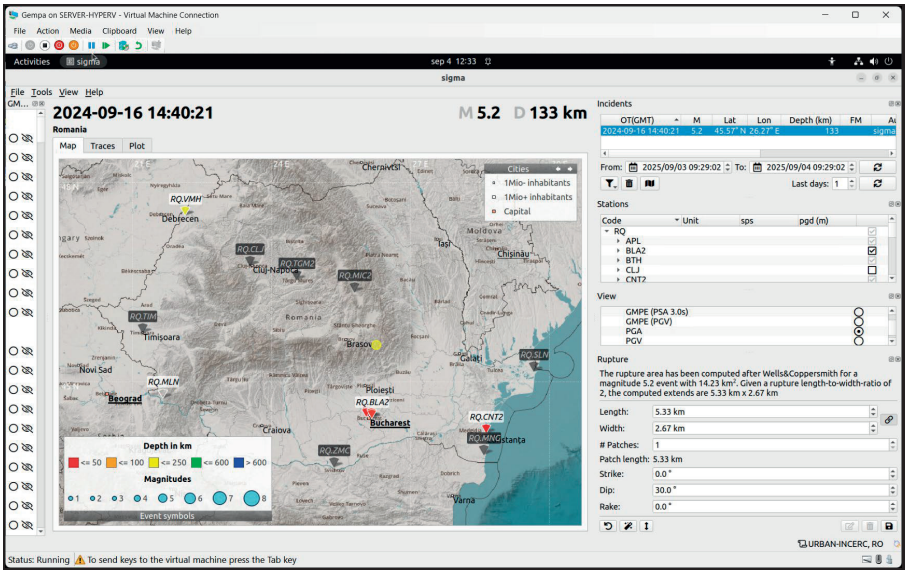

Figure 4. Map of the RNMPSPC stations that recorded the 16.09.2024 Vrancea earthquake, created with the *sigma* module

Figures 5 and 6 display the seismic records from this event and their subsequent processing, both performed with the *sigma* module, ensuring accurate data visualization and analysis. Figure 7 shows the spectrogram representation of the INC6 record from the ML5.4 Vrancea earthquake on September 16, 2024, processed using the *sigma* module. The displayed magnitude is that of the initial estimation in FDSN-SW.

Figure 5. Records of the 16.09.2024 Vrancea earthquake, visualised with the sigma module

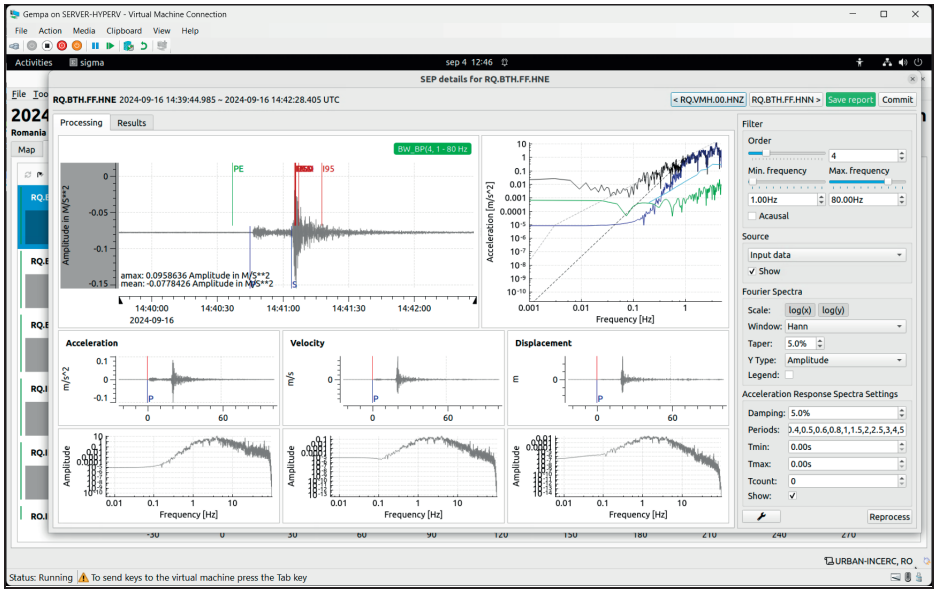

Figure 6. Processing of the 16.09.2024 Vrancea earthquake BTH record, performed with the sigma module

Figure 7. Spectrogram representation of the INC6 record of the 16.09.2024 Vrancea earthquake, obtained with the *sigma* module

Additionally, Figures 8, 9 and 10 illustrate the seismic data recorded at station FOC6, located in Focșani, near the earthquake's epicentre. These figures present the raw seismic record in Figure 8, the acceleration response spectra computed for the three components in Figure 9, and the FFT magnitude plots corresponding to the same record in Figure 10.

The recorded data, acquired using a GMS-18 accelerometer, was processed with the GeoDAS software from GeoSIG, the instrument manufacturer, ensuring high accuracy and compliance with seismic data processing standards.

CONCLUSIONS

This study provided an overview of the fundamental principles of seismic data quality assurance, highlighting their significance in the context of major international research initiatives. The implementation of these quality assurance measures within the National Network for the Seismic Monitoring and Protection of Building Stock (RNMPSPC) at the National Research and Development Institute URBAN-INCERC was examined, detailing compliance with international standards and best practices. The role of RNMPSPC as a Special Installation / Objective of National Interest (IOSIN) within the EPOS European Research Infrastructure Consortium was also emphasized.

Furthermore, the study demonstrated the practical application of these methodologies through the recent ML 5.4 Vrancea earthquake (2024), showcasing the effectiveness of the current seismic monitoring infrastructure, including state-of-the-art software and hardware solutions. These findings reinforce the critical importance of continuous advancements in data acquisition, processing, and validation to enhance the reliability of seismic records and contribute to global earthquake research and hazard assessment.

ACKNOWLEDGEMENTS

Abstract

Fine particulate matter (PM) pollution is a significant environmental and public health concern in urban areas. This study presents an extensive assessment of PM concentrations in Galați, Romania, using the RAPID-E monitoring system. The equipment was deployed at the RI REXDAN (Research Infrastructure REXDAN – George Coşbuc no. 98) to continuously measure PM concentrations at 0.3, 0.5, 1, and 5 µm from December 31, 2023 (22:00) to December 30, 2024 (22:00). The collected data were analysed to determine temporal variations in particulate matter, including monthly means, daily averages, weekday versus weekend patterns, and variations between working days and weekends. By identifying key pollution trends and fluctuations over the monitoring period, this study provides insights into the dynamics of urban air quality and potential emission sources. The findings contribute to a better understanding of PM pollution variability and support the development of effective air quality management strategies in urban environments.

Key words: *air pollution, particulate matter, urban monitoring, RAPID-E, PM variability, temporal analysis, air quality assessment.*

INTRODUCTION

In recent decades, air quality has become a significant global issue, raising concerns about its impact on public health, the environment and ecosystems. The pollutants that influence air quality are SO_2, NO_2, CO, CO_2, O_3 and particulate matter (Constantin et al., 2013; Dragomir et al., 2015; Meier et al., 2017). SO_2, NO_2 and particulate matter arise from the combustion of fossil fuels (Constantin et al., 2020; Merlaud et al., 2018; 2020; Roșu et al., 2020; 2021; 2023). Particulate matter air pollution is a serious problem, especially when we are dealing with fine and ultrafine particles, between 0.3 and 5 µm (Sanda et al., 2023; Iordache, 2017). These particles, often invisible to the naked eye, can penetrate deep into the respiratory tract and even enter the bloodstream, posing significant health risks. Primary sources of these particles include industrial activities, road traffic and natural phenomena such as volcanic eruptions and desert dust (Baldacchini et al., 2019; Lonati & Giugliano, 2006; Ramgolam et al., 2008). The size of these particles determines their ability to reach the lungs and bloodstream, increasing the risk of respiratory and cardiovascular diseases. Prolonged exposure to air polluted with fine particles can exacerbate pre-existing conditions such as asthma and chronic lung disease and may even contribute to reduced life expectancy (Alemayehu et al., 2020; Kelly et al., 2017). Vulnerable groups, such as children, the elderly, and people with compromised immune systems, are particularly susceptible (Kirešová et al., 2023; Pétremand et al., 2022). The economic burden of air pollution, including healthcare costs and loss of working productivity, further underscores the urgency of addressing this issue (Conte et al., 2020; Zoran et al., 2023). Air pollution also has a wider environmental impact, including contamination of water sources, soil degradation, and

disruption of ecosystems. The European Commission has set air quality limit values for particulate matter (PM10) and requires the collection of PM2.5 data to protect public health. However, data on finer particles, such as $PM_{0.5}$, PM_1, and PM_5, are less available. To address this gap, the Rapid E+ equipement, the successor of Rapid E and PA-300, has emerged as a crucial tool for measuring fine particles in the air (Aït-Khaled et al., 2009; Šaulienė et al., 2019). This device uses optical detection technology and laser illumination to measure particles in the 0.3-5 µm range with high accuracy (Boldeanu et al., 2021; Tešendić et al., 2020). Rapid E+ provides a fast and accurate method for continuous monitoring of particle concentrations in a variety of environments, from polluted urban areas to industrial and natural environments (Crawford et al., 2023; Yanagi et al., 2023) . In this study we present the results of one year (2024) of data analysis from our Rapid E+ equipment installed at RI REXDAN (Galați city, Romania).

MATERIALS AND METHODS

Study area and localization

For our study, we conducted continuous dust measurements in the city of Galați, one of the largest urban areas in Romania. The measurements were carried out over a whole year, from January 1, 2024, to December 30, 2024, at the specific location at George Coșbuc Blvd, no. 98 (coordinates: 45°26'6.66"N 28° 2'14.02"E). This location was chosen because it is an area with intense traffic and urban activity. It is also important to note that during this period, significant infrastructure repair works were underway in the area, which could have affected air quality. To collect accurate and reliable data on particle levels, we used the Rapid-E+ equipment, which was placed in the courtyard of the RI Rexdan. The location of the Rapid-E+ device is shown in Figure 1. The aim of this study was to analyse particulate levels in the context of ongoing construction activities and urban development.

Figure 1. Location of the deployment of the measuring equipment (REXDAN)

Equipment and data used

Rapid-E+ is an advanced bioaerosol sensor that uses proprietary laser technology to analyze individual aerosol particles in real time. Its integration with GPU (Graphics Processing Unit) acceleration significantly improves the speed of data acquisition and processing, providing exceptional performance in tracking and identifying aerosols in complex environments. The sensor continuously monitors and characterizes airborne particles ranging in diameter from 0.3 to 100 µm. Values of 0.3 µm indicate particles with sizes between 0.3 and 100 µm, while values of 0.5 µm refer to particles between 0.5 and 100 µm. Also, values of 1 µm cover particles between 1 and 100 µm, and values of 5 µm include particles between 5 and 100 µm. Backed by years of continuous measurements, Plair technology combines scattered light pattern analysis and fluorescence spectroscopy, ensuring reliable, real-time monitoring of ambient air. Rapid-E+ operates

autonomously and remotely, giving users access to data anytime, anywhere. Detailed characteristics of the device (Rapid-E+) are provided in the following table, Table 1, which outlines its specifications and key features of the equipment (https://www.plair.ch/rapid-e.html).

Table 1. Specification of the intelligent bioaerosol sensor Rapid-E+ used for data collection in the city of Galați throughout the year 2024

Parameter	Value	Details
Particle size range, micrometers (µm)	0.3-100	-
UV laser wavelength, nanometers (nm)	337 ± 5	-
Scattering laser wavelength (nm)	447 ± 5	-
Imaging laser wavelength (nm)	637 ± 5	-
Fluorescence spectral range (nm)	390-570 ± 5	12 nm per pixel
Fluorescence spectral ranges of lifetime module (nm)	375-397 ± 5 415-450 ± 5 467-487 ± 5	1 photodetector per spectral range
Fluorescence decay resolution, nanoseconds (ns)	1	For each spectral range
Sample airflow, liters per minute (LPM)	5	-
Maximum counts (scattering only), Maximum counts (fully analysed)	1,000,000 4.800	Particles per minute
Power supply (Volts AC)	90-240	-
Power consumption (watts)	less than 200	Maximum value
Size (H x W x D), centimeters	40 x 34 x 55	-
Operating temperature (°C)	-10 ... +40	Temperature range can be extended with an outdoor box
Humidity (%)	0-95	Without condensation
Weight (kg)	25	-

Rapid-E+ comes with an online platform or dashboard called PlairGrid, which allows users to visualize data collected in the field. PlairGrid is a free, easy-to-use tool that allows users to explore raw data and create a machine learning model capable of classifying particles in real time. This advanced functionality is designed to help users accelerate their data analysis processes, giving them the ability to take full control of their experiments and projects. With these tools, users can start working with their data immediately and easily, without the need for complex setup or additional software. The device was designed to meet the growing need for efficient, accurate, and real-time monitoring of bioaerosols, which include particles such as pollen, bacteria, and fungal spores, among others. By enabling continuous and accurate data collection, Rapid-E+ helps users better understand the dynamics of airborne particles, which can have a significant impact on health, environmental quality, and various research areas. Its design allows researchers, healthcare professionals, and environmental specialists to detect, classify, and analyse these particles in real time, making it a powerful tool for studying air quality, biological hazards, and public health risks. The integration of machine learning and real-time data visualization improves the overall efficiency and effectiveness of experiments, ensuring that users have the flexibility to adapt their approaches and make informed decisions quickly.

Figure 2. Image of REXDAN RI Rapid-E+ equipment

RESULTS AND DISCUSSIONS

Using the detailed data collected by the Rapid-E+ sensor, we have created a series of complex graphs that highlight the average values of airborne particle concentrations throughout

2024. We have separated each category of particles data, so we were able to organize the values so that they showed the values for different categories i.e. 0.3μm (particles between 0.3μm and 0.5μm), 0.5μm (0.5-1μm), 1μm (1-5μm), and 5μm (5-100μm), respectively. These results of data analysis are structured for each day of the week, for particle size interval in the air: 0.3, 0.5, 1 and 5 μm. Analysis of these data allows for a detailed assessment of daily variations in fine particle concentrations, providing valuable information about the behaviour and distribution of aerosols in the atmosphere over an entire year. These observations are essential for understanding the factors that influence air quality that could affect public health and the environment, especially regarding the sizes of respirable particles that can have significant effects on human health. We also present the σ = RMSA to determine the errors that may arise from external conditions, measurement errors, and systematic errors. In this formula, σ represents the standard error, and RMS (Root Mean Square) measures the average magnitude of the errors, calculated by the square root of the average of the squares of the differences between the estimated and actual values. All data representation was created using python code i.e. using matplotlib a native Matlab ploting library implemented with python code via the open-source IDE Spyder (Scientific Python Development Environment).

As can be seen in Figure 3, the values increase exponentially with the size of the particles included in that range. This phenomenon is due to the fact that small particles (below 1 μm) persist longer in the air, due to their small mass and the reduced influence of gravity on them (Casale et al., 2009). Thus, they are suspended for a longer period of time and can be transported over long distances by winds and atmospheric currents. In contrast, larger particles (above 5 μm) settle more quickly due to their greater weight and rapid sedimentation in the atmosphere.

In the analysed graphs, the size range 5-100 μm does not exceed values over 4 thousand per hour, which suggests that larger particles are fewer, because they sediment quickly. In contrast, particles in the range 0.3-0.5 μm can reach concentrations of up to 1.5 million particles per hour, since they are more numerous and remain suspended longer in the air.

As can be seen in the seven graphs presented, the values corresponding to particles of 0.3 and 0.5 μm are represented on the vertical axis on the left, and the data are collected periodically, at one-hour intervals. These values reflect the particle concentrations in a specific period, and the collection interval allows for a detailed observation of their variability over time. On the other hand, the values corresponding to particles of 1 and 5 μm are displayed on the vertical axis on the right, and the scale of this axis varies from one day to the next, depending on the distribution of larger particles. As we progress further into the week, we notice that the values increase slowly but progressively, with Mondays having relatively low values due to the break period of the weekend, when traffic was reduced and work-related activities were at lower end, and Fridays having the highest values of the week and some of the most visible fluctuations in the measured parameters.

On October 19, 2024, between 10:00 and 11:00, a significant and sudden increase in the values of particles in the size range of 1-5 μm was observed in the monitoring carried out on the PlairGrid online platform. This increase was remarkable, with values exceeding by more than 100 times the average values recorded in previous reference periods. Moreover, this fluctuation not only had an immediate impact on the data from that period, but also affected the annual average of Saturday, causing an unusual increase in the values recorded for this day compared to other Saturdays of the year. The significant change in the annual average underlines the importance of a detailed analysis to identify the causes of this abnormal behaviour.

As for the possible causes of this phenomenon, they may include a technical error in the measuring equipment. Another possible cause may be temporary contamination of the environment or equipment. If an external source of contamination was active at that time, this could have led to a punctual accumulation of particles, influencing the measurements, without affecting the entire monitoring time frame.

To facilitate the observation of the differences between weekdays and weekends, we have created two distinct graphs. The first graph includes the average values for weekdays (Monday-Friday), and the second graph presents the average values for weekend days (Saturday and Sunday).

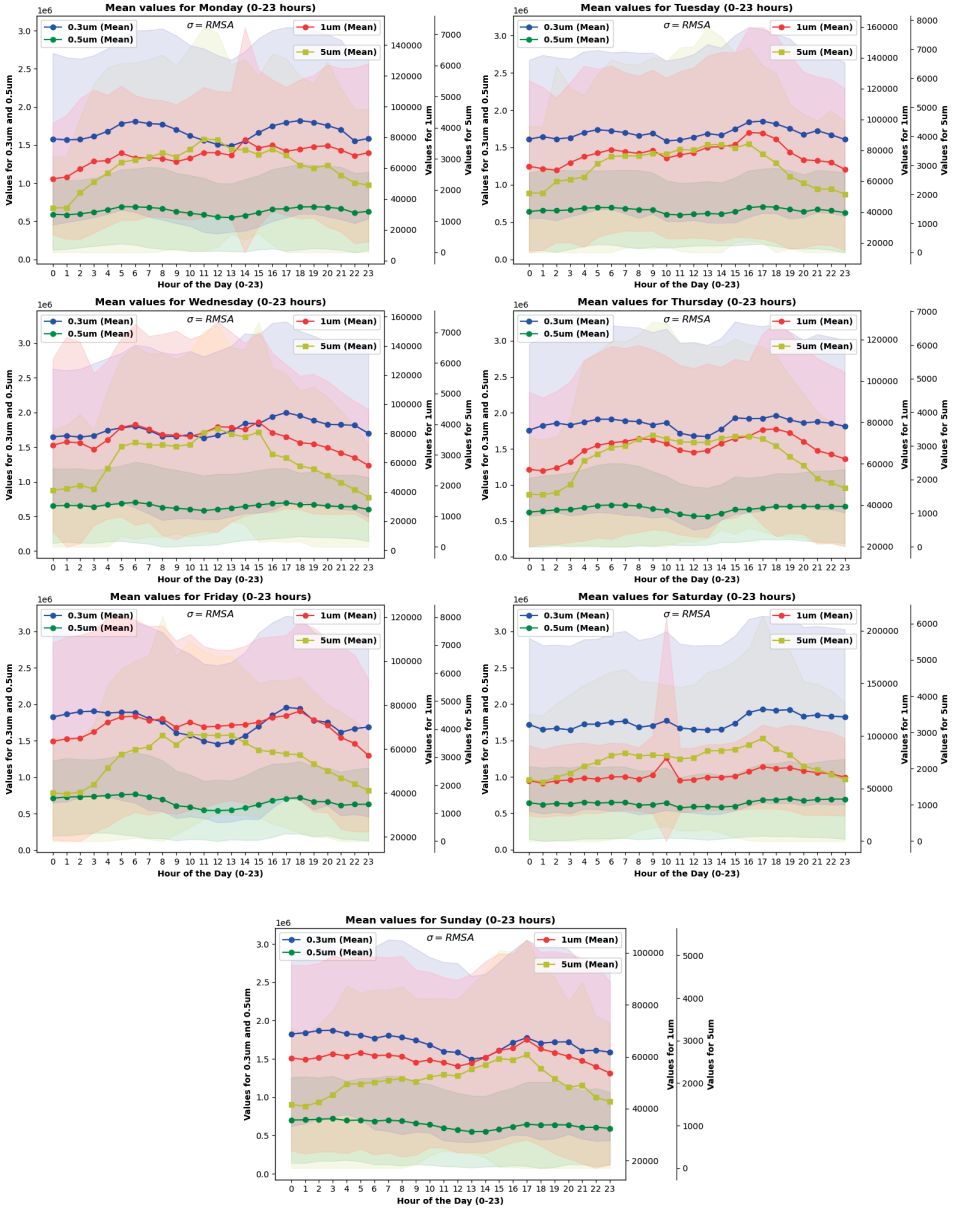

Figure 3. Mean value for each day of the week

These graphs allow a clear visual comparison of the trends and variability characteristic of each category of days, facilitating the identification of possible anomalies or

significant differences in the behaviour of particle values depending on the week period (Figure 4).

By comparing the two data sets, it is possible to observe fluctuations that could be attributed to external factors specific to weekdays or weekends, such as changes in industrial activities, transportation, weather conditions or other environmental influences that may vary depending on the day of the week.

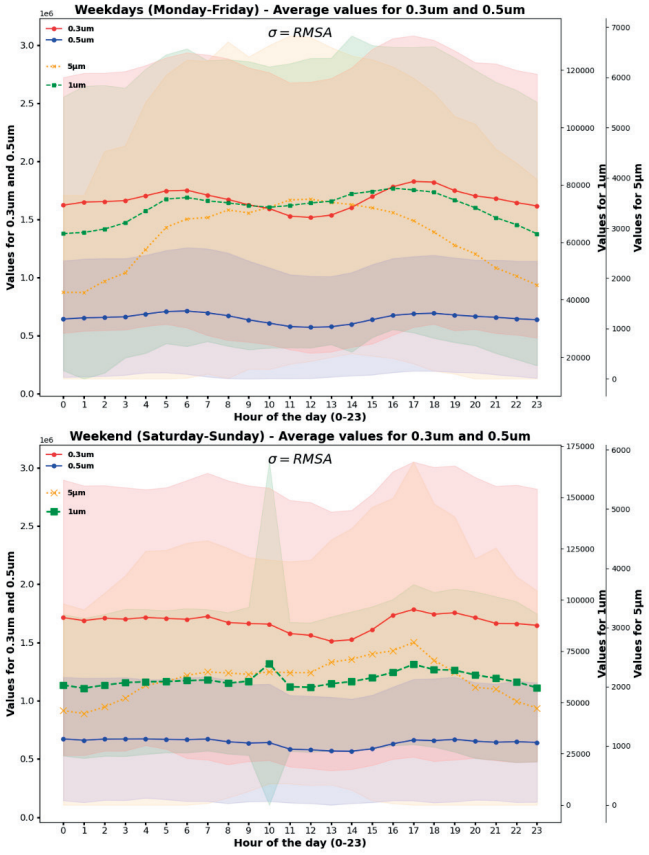

Figure 4. Mean value for workdays and weekend

Analysing the 2 graphs presented in Figure 4, a clear trend of variation of the measured values of particulate matter depending on the time of day is observed, with significant particularities on weekdays compared to weekends. During the week, the data reveal notable fluctuations, with substantial increases in the values around peak hours (6:00 and 17:00), intervals in which, usually, the highest values can be attributed the peak of human activity or intensified traffic. These peaks are significant, indicating moments of increased traffic or other activities related to the daily schedule of employees or workers.

In contrast, on weekends, the data show a relative stability of the values, without notable fluctuations, with only a few isolated exceptions that do not reach the intensity of those observed on weekdays. This behaviour suggests that, on weekends, activity is more constant and less influenced by the rigid schedule of weekdays, making it possible that variation factors are reduced and the activities carried out are more uniform. A significant external factor that can influence these variations on weekdays is represented by the road restoration projects carried out near the measurement area during the respective period.

Considering that infrastructure works involve periodic interventions that can affect the traffic flow or the schedule of activities, we can hypothesize that the significant decrease in the values around 12:00 on weekdays can be attributed to the lunch breaks of the workers involved in these projects. Thus, during the mentioned time interval, the activity of the workers is considerably reduced, which implicitly leads to a decrease in the measured values, even if the values are related to traffic, economic activities or other variables. It can be seen that particles larger than 5 μm do not follow the same rule as particles below 5 μm, as they do not have their maximums during peak hours of the day, but at 12:00 when small particles decrease in number. Another significant difference between weekdays and weekends is made by particles over 1 μm, which during the week reach values of over 80 thousand particles per hour, while during the weekend they do not exceed values of 75 thousand particles.

CONCLUSIONS

The results of this study demonstrate that the Rapid-E+ device is a complex and useful tool for local urban monitoring of airborne particulate matter as we presented in the results of measurements made throughout 2024 at REXDAN RI located at no 98 George Coșbuc Blvd, Galati, Romania. The main advantage of this device is the accuracy of its measurements on an extended scale (0.3-100 μm) and the ease with which the data can be recorded and processed. By making continuous measurements for particulate matter, we can more easily observe the dynamics of these pollutants and determine the factors that influence these parameters and the main sources (traffic, constructions and other natural or anthropogenic factors). The main objective of this research was to determine the average values of some air parameters over a whole year, with a particular focus on monitoring particulate matter. During the analysis, we observed that the factor that most influences the variation of pollutants is human activity, especially construction-related activities. These activities contribute significantly to fluctuations in particulate matter concentrations, especially during peak periods of the day. The most pronounced pollution values were observed during peak hours, when the number of construction sites and associated activities are increasing. This trend suggests that particulate matter emissions generated by such activities have a significant impact on air quality and public health. It is also important to note that these fluctuations are much more evident in urban areas, where economic activity and construction are at a high level. The next study will analyse the diurnal and nocturnal variations of particulate matter, as well as their changes according to the seasons (spring, summer, autumn, winter), using the Rapid-E+ device. This method will provide us with detailed information on how pollutant concentrations fluctuate throughout the day and at different times of the year. Thus, we will be able to observe the differences between day and night, but also how the seasons influence the level of particulate matter in the air. This analysis will contribute to a clearer understanding of the behaviour of pollution under different temporal conditions, providing essential data for long-term air quality management.

Abstract

The identification and assessment of the pressures and threats to which protected areas are subjected is crucial in order to plan, implement and assess conservation actions. Our study aimed to assess the spatio-temporal dynamics of land use/land cover changes that occurred in the Olteț Piedmont between 2012 and 2018 and identify the main threats that anthropogenic activities pose to natural protected areas. The major changes in land use that took place between 2012 and 2018 had a great impact on the landscape. The disappearance of large surfaces of vineyards (–8150 ha), orchards (–2400 ha), watercourses (–700 ha), beaches, dunes and sand plains (–140 ha) and inland marshes (–40 ha) are the most significant. These terrains were occupied by complex crops (+4350 ha), deciduous forests (+2900 ha) and transitional woodland shrub (+750 ha). Also, the built-up areas, especially near cities like Craiova, Filiași, Balș and Drăgășani, had an increase in surface. The results revealed that the expansion of arable land and urban areas have a great impact in the conservation of biodiversity in natural protected areas from the Olteț Piedmont.

Key words*: land use, land cover changes, natural protected areas*, *Olteț Piedmont, Romania*

INTRODUCTION

Land is a three-dimensional, dynamic, and complex system, developed through the interaction of lithology, structure, drainage, climate, vegetation, and geomorphological processes operating over time (Laha, 2023). As a fundamental natural resource, it underpins diverse economic, social, and ecological functions (Phuong & Thien, 2023).

Within this context, land use and land cover (LULC) emerge as interrelated dimensions that describe both the ways land is utilized and the distribution of vegetation and surface features. Transformations in LULC not only reshape landscapes but also intensify global challenges such as climate change, biodiversity loss, and broader environmental crises (Bairwa et al., 2025).

LULC effects and dynamics vary from one region to another according to the type of vegetation cover and activities (Mesmin et al., 2025). Land use and land cover changes (LULCCs), driven by deforestation, forest degradation, and the expansion of human activities - such as agriculture, infrastructure development, and fuelwood extraction - have historically led to widespread land cover loss on both local and global scales (Nkinda et al., 2025). These changes have an impact on a wide range of environmental and landscape attributes, including the quality of water, land and air resources, ecosystem processes and function, and ecosystem quality (Yogesha et al., 2025; Shastri et al., 2020).

Changes in land cover and land use caused by human activities have modified the plant cover (Valea, 2024), forest ecosystems (Prăvălie et al., 2022), deforestation can lead to excessive soil erosion (Nigussie et al., 2025) and even landslide occurrence (Jurchescu et al., 2023).

Protected areas were "invented" and then established all over the world in order to protect the most outstanding values of biological and geological diversity, as well as exceptional cultural values.

The management of protected areas must ensure measures to prevent threats that may

destroy them in the future and if they can reduce the effects of the many pressures that exist today.

The development of urbanization around the world may have a negative impact on some existing plant and animal species (Ives et al., 2016). Nature plays an important role for human health, therefore measures must be taken to preserve biodiversity (Kowarik et al., 2020).

Biodiversity must be approached in relation to the characteristics of the urban and rural environment, plants, animals, the interaction and the pressure people put on nature for their own existence (Elmqvist et al., 2013; Opoku, 2019; Güneralp & Seto, 2013; Aronson et al., 2014).

The role of protected areas in conserving biodiversity and landscape is very important due to global environmental changes and climate change. For an adequate management there is a need to create corridors to link them in order to reduce human impact (Geacu et al., 2012).

In the context of sustainable development of cities and rural communities, it is necessary to find solutions to stop the loss of plant and animal species and maintain restore biodiversity.

Land use change is one of the issues which intensifies environmental problems because of the growing demand for natural capital and the increasingly anthropogenic interference; it threatens ecosystems on which human livelihoods rely upon. So, understanding the magnitude of land use change, drivers, and implications is very crucial in a successful management of land resource (Mekonnen, 2025).

MATERIALS AND METHODS

Study area

The Olteț Piedmont, located in the eastern subunit of the Getic Plateau, represents a geomorphological unit strongly influenced by both morphodynamic processes and anthropogenic activities dating back to the 17th-19th centuries. The region covers approximately 3,771 km² and has a predominant north-south orientation (Figure 1). Intensified human impact, particularly from the late 19th to the early 20th century, disrupted the natural balance through widespread deforestation to create land for cereal crops, orchards, vineyards, pastures, hayfields, as well as through the expansion of rural and urban settlements.

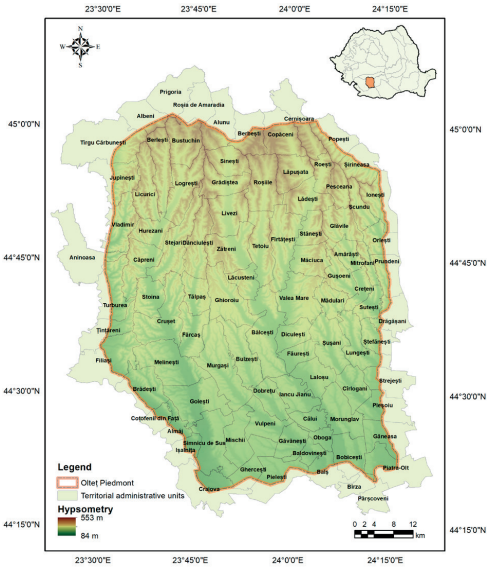

Figure 1. Study area - Olteț Piedmont (Romania)

During the past century, the Romanian agricultural lands underwent deep transformations primarily under the impact of political and socio-economic factors and less, of the biophysical and climatic ones (Bălteanu & Popovici, 2010; Popovici et al., 2013).

Given the major and ongoing spatial, structural and functional transformations of the post-communist period, a substantial body of literature has focused on the social and economic consequences of the Land Reform of 1991 (Urșanu et al., 2024; Dogaru et al., 2024). This reform (Law no. 18/1991) shifted the ownership of land from state to private individuals, small-scale farms appearing and fragmenting the agricultural land, which in time became vulnerable to anthropogenic pressure and climate changes (Prăvălie et al., 2021).

For monitoring land dynamics, the CORINE Land Cover (CLC) project, initiated in 1985, provides a harmonized inventory of land cover across Europe, structured into 44 classes. Building on this, the Copernicus Land Monitoring Service (CLMS), launched in 2012

by the European Environment Agency (EEA) and the European Commission's DG Joint Research Centre, supplies geospatial information on land cover and land-use changes, vegetation state, the water cycle, and Earth surface energy variables for a wide range of terrestrial applications.

In this study, we employed land use/land cover (LULC) databases provided by the EEA for the years 2012 and 2018. This period was selected as it captures the most significant changes in LULC, largely driven by anthropogenic activities. Notably, rising living standards spurred the rapid urbanization of rural areas near cities, where populations increasingly purchased land for residential purposes, particularly secondary homes used on weekends as retreats from urban environments.

Additionally, shapefiles of Romania's natural protected areas were obtained from the Ministry of Environment, Waters and Forests, along with management plans and other relevant data for the five protected areas located within the Olteț Piedmont. These sites were declared under the provisions of OUG 57/2007 and Law 5/2000. Using ArcGIS 10.7, the data for the study area were extracted (via the *Clip* feature), enabling a detailed analysis of how LULC changes affect these protected natural areas.

RESULTS AND DISCUSSIONS

The classified LULC categories comprised built-up areas, farmland, bare land, grassland, forests, wetlands, shrubland, and water bodies. Using ArcGIS 10.7, we extracted and reclassified 21 land use/land cover categories identified within the Olteț Piedmont. The results were represented through cartographic outputs (Figures 2 and 3) for the two reference years of the study, 2012 and 2018.

The period between 2012 and 2018 is marked by major changes in several land use categories (Table 1). Notably, there was a significant reduction in the areas occupied by vineyards (−8,150 ha), orchards (−2,400 ha), watercourses (−700 ha), beaches, dunes, and sand plains (−140 ha), as well as inland marshes (−40 ha). The decline observed in the latter three categories can largely be attributed to flood protection works implemented along most rivers crossing the piedmont.

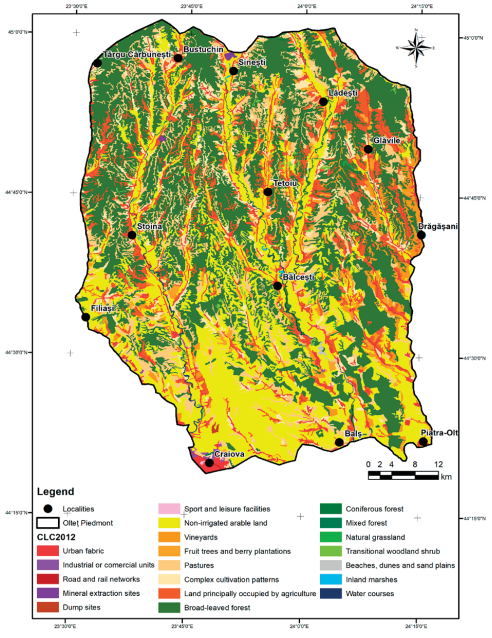

Figure 2. Olteț Piedmont - Corine Land Cover, 2012

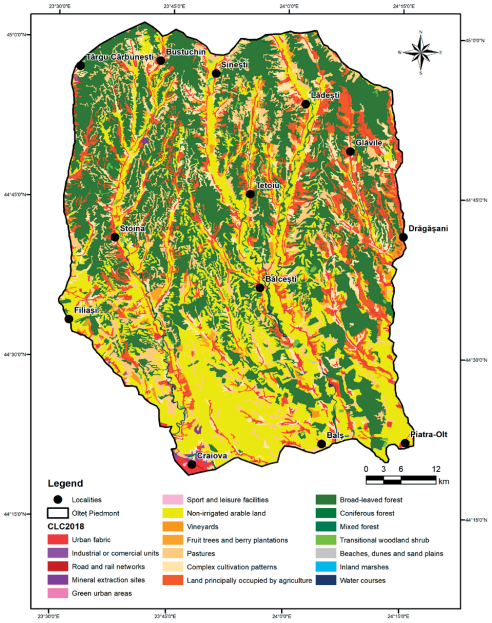

Figure 3. Olteț Piedmont - Corine Land Cover, 2018

The terrains occupied by vineyards and orchards were transformed mainly into areas with complex crops (+4350 ha), deciduous forests (+2900 ha) and transitional woodland shrub (+750 ha). Also, the built-up surface

increased by 610 ha, mainly by the extension of urban areas around major cities like Craiova, Filiași, Balș and Drăgășani.

The constant depopulation of the rural areas within the Olteț Piedmont and the expansion of the periurban areas around major cities have influenced the major changes in land use/land cover between 2006 and 2018. These changes affect not only its population but also the environment.

The influence of human activities has been manifested in all geographical regions of Romania. These have significantly influenced the rate, intensity and pattern of land use/cover changes. Important agricultural areas in the Romanian Plain have become fragmented and gradually abandoned but also subjected to (sub)urbanization processes (Urșanu (Popovici) et al., 2024).

Land use has been seriously influenced by urbanization and by the conversion from one category to another. This has led to the degradation of vegetal associations, the almost destruction of the wild flora and fauna in areas suitable to cultivation (Popovici et al., 2010).

Tabel 1. Land use in the Olteț Piedmont between 2012 and 2018

Land use	Area 2012 (ha)	Area 2018 (ha)
Urban fabric	18105.71	18715.64
Industrial or commercial units	578.45	643.63
Road and rail networks	130.84	130.62
Mineral extraction sites	277.95	237.79
Dump sites	151.62	-
Green urban areas	-	4.40
Sport and leisure facilities	37.44	37.44
Non-irrigated arable land	106522.92	107085.46
Vineyards	12551.88	4370.34
Fruit trees and berry plantations	7894.80	5492.06
Pastures	36379.22	36750.09
Complex cultivation patterns	19823.28	24170.46
Land principally occupied by agriculture	31274.33	33208.10
Broad-leaved forest	139633.92	142516.62
Coniferous forest	142.25	142.25
Mixed forest	53.88	53.88
Natural grassland	96.08	-
Transitional woodland shrub	1257.81	2070.48
Beaches, dunes and sand plains	213.26	77.26
Inland marshes	126.49	85.48
Water courses	1903.59	1363.71

The southern part of Romania was continuously exposed to strong human pressure since early times through extensive/intensive agricultural use, industrialization, urbanization/suburbanization processes. Therefore, the primeval vegetation has been massively transformed, and forests have been significantly fragmented and reduced to even smaller surface (Geacu et al., 2018).

In the study area there are 5 natural protected areas - 3 of national interest and 2 Natura2000 sites (Figure 4): 2.451 Locul fosilifer Valea Desului (1 ha), 2.796 Pădurea Tisa Mare (50 ha), 2.797 Pădurea Silea (25 ha), ROSCI0168 Pădurea Sarului (6768 ha) and ROSCI0296 Dealurile Drăgășaniului (7265 ha).

The International Union for Conservation of Nature (IUCN) defines a protected area as "a clearly delimited geographical space, recognized, designated and managed on the basis of legal acts or by other effective means, with the aim of achieving the long-term conservation of nature as well as of environmental services and associated cultural values".

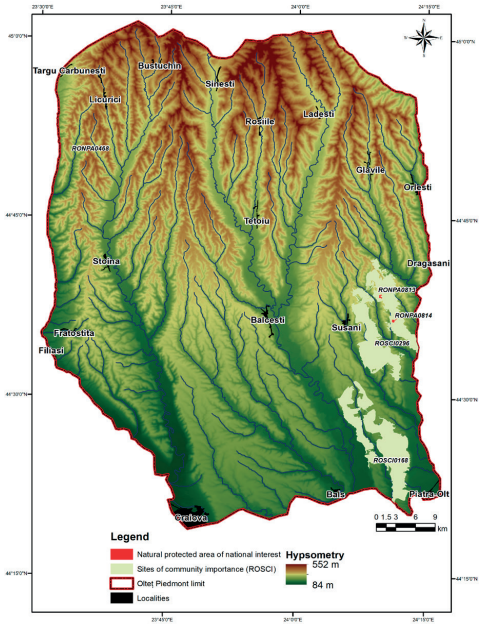

Figure 4. Olteț Piedmont - natural protected areas

Protected areas must guarantee and allow the following:
- conservation of biodiversity by maintaining within the perimeter of protected areas some species and ecosystems in their natural or very close to natural state;
- scientific substantiation of management methods and procedures that allow for the sustainable use of natural resources;
- scientific substantiation of the process of reconstruction and rehabilitation of ecological systems;
- maintenance of ecological services by conserving ecosystems;
- protection of cultural values and landscapes.

2.451 Locul fosilifer Valea Deșului fossil site is a protected area of national interest corresponding to IUCN category IV (paleontological nature reserve), protecting remains of Levantine fossil fauna.

2.796 Pădurea Tisa Mare is a protected natural area corresponding to IUCN category IV (mixed nature reserve) and represents a protection zone for trees of the species sessile oak (*Quercus petraea*) and hornbeam (*Carpinus betulus*) and shrubs of the species tulichine (*Daphne mezereum*) or thorn (of the species *Ruscus aculeatus*).

2.797 Silea Forest is a protected natural area that corresponds to IUCN category IV (mixed nature reserve) and represents the forested area on the two banks of the Silea stream that preserves natural habitats with tree species of sessile oak (*Quercus petraea*) and hornbeam (*Carpinus betulus*), as well as a rare shrub species, known as thorn (*Ruscus aculeatus*).

ROSCI0296 Dealurile Drăgășaniului includes 3 types of protected habitats: 9130, 91M0 and 91Y0.

ROSCI0168 Pădurea Sarului includes only 1 type of protected habitat, 91M0.

These protect a large number of species of conservation importance: over 30 species of mammals, over 90 species of birds, 1 species of plant and 8 species of amphibians and reptiles.

The important changes in land use and the constant increase in urbanization can have a major impact on these natural protected areas by: the use of pesticides and chemical fertilizers in agriculture, in the vicinity of these areas, the existence and spread of invasive plants and water pollution with plastic, glass, household or construction waste. Also, illegal deforestation and poaching represent a major threat to the integrity of natural protected areas.

We have managed to identify the main anthropogenic activities that may have a negative impact:
- harvesting of wild animals (legal/poaching);
- harvesting of mushrooms and berries;
- harvesting of live snails;
- logging activities (legal/illegal) in the funds managed by the Forest Districts;
- development of water and wastewater infrastructure;
- reconstruction works of communal roads, which cross protected natural areas.

These pressures and threats to which protected natural areas are subject must be considered when we study how land use/land cover changes affect the environment because they are an integrant part of a sustainable development for the population in this area.

CONCLUSIONS

The environment constitutes an essential prerequisite for human existence, so its protection and conservation is very important.

The predominance of agricultural activities in the southern part of the Olteț Piedmont, mainly in the rural localities, had a major impact in the land use changes that occurred in the last 20 years.

The major changes in land use, especially after 2012, have put a great pressure on the environment, modifying the landscape and making it more vulnerable to the effects of human activities and even climate change.

To preserve the protected habitats and species in these natural protected areas, administrators and decision-makers should consider the following measures:

- limit the use of pesticides and fertilizers in the vicinity of these sites and using insecticides only in the affected areas, not preventively;
- use of biological control as much as possible and preserve natural regulation mechanisms;
- limit access into the forest only on arranged trails and carrying out picnics and open fires only in designated areas;
- stop illegal deforestation;
- preserve, especially near wetlands, fallen trees or stumps, to boost the biological activity of insects;
- carry out actions to sanitize temporary ponds and waters within the perimeter of these sites;
- preserve open forest areas with shrub and grass vegetation, etc.
- prevent and stop activities with potential negative effects on the natural and cultural values in the protected areas;
- informing and raising awareness among stakeholders and the general public about the importance of biodiversity conservation, by promoting sustainable development models and involving local communities in the management of protected areas.

Future studies should focus on the effectiveness of protected natural areas management and minimizing anthropogenic impact on their territory in order to achieve a better conservation and protection.

Abstract

The production of plastics in the context of global warming contributes to water pollution by microplastic particles. Consequently, a shift towards sustainable practices in the field of plastic production is crucial. This paper aims to address the main concerns related to plastic and microplastic pollution and to identify environmentally sustainable strategies applied in the production sector. A particular focus is placed on biodegradable, eco-friendly materials as alternatives to conventional plastics, with an emphasis on their environmental impact. For example, food waste has emerged as a promising alternative for plastic packaging production, offering a sustainable solution, valorization of by-products, and mitigating environmental impacts. The paper also focuses on the potential of using waste to create biodegradable materials, highlighting the importance of a zero-waste approach to enhance the economic value of by-products, while promoting a cleaner environment and waste management presented in environmental contexts. Through its comparative analysis, this study contributes to a deeper understanding of waste management and supports the advancement of a sustainable circular economy.

Key words: *biodegradable, by-products, microplastics, pollution, sustainable.*

INTRODUCTION

Conventional plastics made from petroleum have a significant impact on the environment, contributing to water pollution, global warming, resource depletion, and the spread of microplastics. This makes the search for durable and sustainable alternatives increasingly critical (Mutmainna et al., 2025; Saleem et al., 2023). Alarmingly, plastic pollution is now ubiquitous - plastic particles have been discovered in the deep sea, rainwater, and even in the human placenta and bloodstream (Stoett et al., 2024). Although the stability of conventional plastics is often cited as an advantage (Xuyang et al., 2025), it also becomes a major drawback due to their persistence and accumulation in the environment.

Globally, the average plastic consumption per person is 20.9 kg per year (Khan et al., 2025), with production projected to rise from 464 Mt in 2020 to 884 Mt by 2050 (Dokl et al., 2024). Equally concerning is that approximately 79% of plastic waste ends up either in landfills or the natural environment, while only 9% is recycled and 12% is incinerated (Kumar M. et al., 2024; Wojnowska-Baryła et al., 2022). Plastics derived from fossil fuels (crude oil, gas, and coal) are a substantial environmental threat, not only due to their long lifespan but also because they emit greenhouse gases, contributing to global temperature rise (Nicholson et al., 2021; Sharma et al., 2023).

Microplastics (MPs), defined as plastic particles smaller than 5 mm, are formed through the gradual degradation of larger plastic items, typically triggered by ultraviolet (UV) radiation (Lee et al., 2025; Niu et al., 2024; Xuyang et al., 2025). Microplastics are a complex pollutant, ubiquitous in freshwater, with negative effects

that can affect the function and health of the entire ecosystem (Garfansa et al., 2025). MP can enter rivers through sources such as atmospheric deposition, surface runoff, in-stream activities, and wastewater discharge (Graham et al., 2024). Also, river receive MP from direct dumping of garbage, the confluence of small streams into the main river, effluents from the cosmetic and textile industries and fishing activities, rivers contribute about 80% of ocean pollution. Rivers also discharge 1.6- 2.3 MMT of MP into the ocean annually (Choudhary et al., 2025). Filtration methods using materials such as sand or activated carbon materials are applied in municipal wastewater treatment to remove MPs. MPs removal efficiency varies depending on particle size, adhesion to the surface of the filter medium, and filtration technique (Garfansa et al., 2025). However, these techniques are largely ineffective at removing MPs, allowing them to continue threatening aquatic environments (Lee et al., 2025; Niu et al., 2024).

In recent years, global attention has increasingly focused on the circular plastic economy and sustainable development. A truly sustainable approach seeks to meet the needs of the present without compromising the resources of future generations - one of the core objectives of of waste management and supports progress toward a sustainable circular economy.

IMPACT OF PLASTIC POLLUTION: ENVIRONMENTAL SIGNIFICANCE AND HUMAN HEALTH

Plastics pose a serious threat to ecosystems, biodiversity, and human health, while also contributing to climate change (Schmidt et al., 2024). Popa et al. (2015) observed that the anthropogenic footprint on the water quality of the Danube, was highlighted in the summer, under the action of the human, trophic factor and the impact of anthropogenic activities. MPs are considered emerging pollutants of increasing concern due to their ubiquitous presence and toxic potential in the aquatic ecosystem (Călmuc et al., 2022).

Water resource management is a major issue, being a very important transporter of pollutants (Pintilie et al., 2016), rivers contributing to approximately 80% of plastic pollution in the oceans, and 20% coming from marine activities sustainable development (Xuyang et al., 2025). Poor plastic waste management exacerbates environmental degradation and health hazards while also contributing to climate change (Roy & Chakraborty, 2024). The growing interest in bio-based alternatives, particularly in the food industry, reflects a shift toward sustainable, efficient, and safer packaging systems compared to those made from petroleum-derived polymers (Dorofte et al., 2023). Biodegradable plastics are now applied across various sectors, and even oil-producing nations are supporting initiatives that promote circularity within the plastic economy (Fei et al., 2024; Saxena, 2025).

The aim of this study is to provide a critical perspective on replacing petroleum-based plastics with sustainable alternatives, while promoting the circular economy and principles of sustainable development. This review offers a comprehensive synthesis of the current literature on the environmental impacts of plastics, as well as strategies for leveraging natural resources and waste to produce biodegradable materials. Emphasis is placed on the zero-waste approach, which adds economic value to by-products and fosters improved waste management. Through a comparative and critical lens, the study enhances understanding (Kumar M. et al., 2024). MPs enter the aquatic environment through wastewater discharges, industrial operations, excessive vehicle use, and human activities (Xuyang et al., 2025). Population and distance from residential areas influence the effects of anthropogenic activity on MPs abundance, urban lakes being more affected by MPs contamination than rural lakes (Anagha et al., 2023; Pierdomenico et al., 2024). China currently records the highest level of surface water microplastic pollution globally, with a concentration of 34 MP/L detected in Lake Poyang (Tran-Nguyen et al., 2024).

In Romania, areas near the confluence of the Siret and Prut rivers with the Danube show particularly high pollutant concentrations, largely due to agricultural and industrial activity and the absence of effective water treatment systems (Iticescu et al., 2014). In marine environments, plastics reduce light and oxygen levels, diminishing biodiversity and affecting marine life through ingestion, suffocation and reduced mobility (Roy & Chakraborty, 2024). Plastics facilitate the bioaccumulation of heavy

metals in aquatic systems. Heavy metals, after being released from microplastics, enter the food chain, accumulating in fish and subsequently affecting human health through biomagnification processes (Bolea et al., 2025). The ecotoxicological effects of MP depend on concentration, types, degradation process, environmental longevity and specific organisms affected (Shi et al., 2024). The presence of MPs has been reported in human saliva, feces, and blood (Saleem et al., 2023). MPs contain harmful chemicals, such as phthalates, bisphenol A (BPA), which can disrupt hormone regulation, interfere with reproductive health and increase the risk of cancer, developmental disorders, and have adverse effects on the immune, nervous, and cardiovascular system (Roy & Chakraborty, 2024; Schmidt et al., 2024). MPs generate toxicity in living organisms by disrupting the defense mechanism against oxidative stress, genotoxicity, neurotoxicity, growth and metabolic diseases, but they can also be vectors of transport in aquatic ecosystems by adsorbing potentially toxic elements (mercury, cadmium, lead and aluminum, copper, nickel, zinc, chromium or arsenic) on their surface (Kumar et al., 2024; Simionov et al., 2023). Exposure and accumulation of heavy metals in the human body has been linked to cognitive impairment, endocrine disruption, developmental abnormalities, and cancer (Simfukwe et al., 2025). As a result, bioplastics have emerged as a promising alternative, offering the potential to mitigate both health risks and environmental degradation associated with conventional plastic use (Kumar et al., 2024).

Biodegradation in soil is considered the best option due to the microorganisms present in the environment. Biodegradation in aquatic environments is usually more complex and limited due to nutrient content, temperature, pH, microbial diversity and density, which reduce the biodegradation capacity of bioplastics (Negrete-Bolagay & Guerrero, 2024).

Biodegradation is a process that depends largely on environmental conditions, such as temperature, humidity, pH, and many other abiotic factors. Biodegradable plastics show mass losses of 23-100%, with higher degradation efficiencies than petroleum- based plastics. PLA biodegradation is complete within 1-3 months in marine environments in Hong Kong, but not all bioplastics degrade completely in these marine environments. Fragmentation of biodegradable plastics requires special attention as it can contribute to microplastic pollution, which is a challenge for in situ studies as the fragments may be too small to be recovered or further biodegraded (Cheung & Not, 2024). Microplastics generated by incomplete biodegradation of biodegradable plastics may persist in environments, affect aquatic microbial communities, plant adaptability, and animal physiology, with their toxicity increasing upon degradation, but knowledge of the effects of biodegradable microplastics, in the aquatic environment remains limited (Shi et al., 2024).

CONVENTIONAL PLASTIC

Conventional plastics, also referred to as petroleum-based, are the most widely used form of plastic. They exist in various physical forms - such as fragments, foams, films, fibers, filaments, pellets, spheres, and particles - and come in a wide range of colors, including red, green, blue, white, transparent, black, and yellow (Chen et al., 2024; de Deus et al., 2024). Depending on size, there are five distinct categories of plastics: nanoplastics (< 0.001 mm), microplastics (0.001-5 mm), mesoplastics (5-25 mm), macroplastics (> 25 mm) and megaplastics (> 1 m) (de Deus et al., 2024).

Microplastics (MPs) are further classified by origin: *primary MPs* are manufactured intentionally for industrial or domestic applications, while *secondary MPs* result from the degradation of larger plastic debris, often due to improper waste disposal or environmental breakdown (Acarer, 2023; Xuyang et al., 2025; Zhuo et al., 2024).

Packaging accounts for approximately 40% of global plastic production, with 60% of that used specifically for food and beverage applications (Ceballos-Santos et al., 2024). Conventional plastics such as polyvinyl chloride (PVC), polypropylene (PP), polystyrene (PS), polyethylene terephthalate (PET or PETE), low-density polyethylene (LDPE) or high-density polyethylene (HDPE) contain additives (stabilizers, plasticizers, foaming agents, colorants, etc.) which, although improving the properties of the material, are known to be

endocrine disruptors and carcinogens (Rajvanshi et al., 2023). Additionally, many plastics contain environmentally harmful compounds such as flame retardants, phthalates, bisphenol A (BPA), and heavy metals (e.g., lead and cadmium), which can leach into the soil, contaminate ecosystems, and bioaccumulate in living organisms (Martínez-Narro et al., 2024).

Conventional plastics are advantageous for storage, use and transport, but not for disposal, as they degrade slowly, in approximately 500 years (Martínez-Narro et al., 2024). Currently, petroleum-based plastics are more cost-effective than those derived from renewable sources, but when external costs and future optimization are taken into account, the price of fossil-based polymers is expected to increase by 44% compared to bio-based polymers (Jiao et al., 2024).

In terms of environmental impact, conventional MPs degrade slowly and thus have a lower immediate impact on soil microorganisms; however, this same persistence increases their potential for long-term bioaccumulation and toxicity in soil fauna (Fei et al., 2024). Although petroleum-based plastics are known for their accessibility, durability, and adaptability, their widespread use continues to fuel the generation of persistent environmental pollutants and the ongoing accumulation of plastic waste (Jiao et al., 2024).

BIOPLASTIC, AN ALTERNATIVE TO CONVENTIONAL PLASTICS: SUSTAINABLE STRATEGIES

Recognizing the complexity and emerging concerns surrounding biodegradable microplastics, it is important to understand their impact on the environment (Shi et al., 2024). Bioplastics are polymers derived from natural or renewable sources that can be either *biodegradable* or *non-biodegradable* (Kumar et al., 2024). Importantly, bioplastics are not exclusively based on biological sources; they may also originate from fossil fuels. As such, there are four main categories (Jiao et al., 2024; Vigneswari et al., 2024):

- Bio-based biodegradable;
- Bio-based non-biodegradable;
- Fossil-based biodegradable;
- Fossil-based non-biodegradable.

Not all bioplastics are entirely composed of natural materials or guaranteed to be biodegradable. Therefore, understanding their classification is essential when evaluating their environmental benefits. An overview of the major classes of bioplastics is presented in Figure 1, which summarizes their source materials and degradation characteristics.

The four major bioplastic categories include:

- Bio-based biodegradable bioplastics such as polylactic acid (PLA), polyhydroxyalkanoates (PHA), polyhydroxybutyrate (PHB), and starch blends.
- Fossil-based biodegradable bioplastics such as poly(butylene adipate-co-terephthalate) (PBAT), polycaprolactone (PCL), poly(butylene succinate) (PBS), poly(butylene succinate-co-adipate) (PBSA), and polyvinyl alcohol (PVA).
- Bio-based non-biodegradable bioplastics including bio-based polyethylene (PE), polyethylene furanoate (PEF), polytrimethylene terephthalate (PTT), and polyethylene terephthalate (PET).

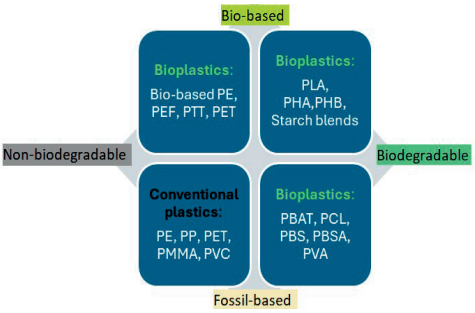

Figure 1. Classification of plastics based on their origin and degradability. Adapted from Shi et al. (2024) and Vigneswari et al. (2024)

In line with current trends, the development of eco-friendly plastics increasingly focuses on low-cost and renewable raw materials as a sustainable alternative to conventional petroleum-based plastics. These bio-based materials show great potential for application across multiple sectors, including packaging, agriculture, and biomedical industries (Rajvanshi et al., 2023).

Table 1 summarizes various biodegradable alternatives to conventional plastics, outlining their applications, key advantages, and limitations.

The primary advantages of bio-based polymers stem from their renewable and low-cost sources. However, cost feasibility is a challenge for the commercial viability of bioplastics. For example, the use of PHA in various applications remains limited due to the high production costs and the high cost of substrates for PHA production (refined carbon origins, sugars, oils, organic acids and fatty acids). Current studies present methods to reduce the cost of PHA production such as the use of renewable substrates, the use of cheaper carbon sources from industries (biodiesel, agriculture, dairy and animal processing). Less expensive substrates for PHA synthesis must be accessible, available in sufficient quantities, stable and resistant to microbial spoilage, and easy to store (Hadri et al., 2025).

Bioplastics derived from biological materials—such as starch, cellulose, vegetable oils, fats, and microorganisms—are generally non-toxic, easier to recycle, and faster to degrade than conventional plastics. They contribute to energy savings, reduce waste volume and landfill space requirements, and help lower greenhouse gas emissions, making them promising solutions due to their abundance and biodegradability (Khan et al., 2025; Mutmainna et al., 2025; Vigneswari et al., 2024).

Table 1. Alternative bio-based for conventional plastics

Biodegradable materials	Advantages	Disadvantages	Applications	References
PLA	Biocompatibility, resistance to fragmentation and good processability, good mechanical properties, simple and rapid degradation mechanism, gas barrier comparable to that of polystyrene and low-density polyethylene (LDPE).	Low degradability in water. Can increase oxidative stress of organisms, cause metabolic disorders, growth limitations; can adsorb heavy metals; higher gas barrier than PET. The cytotoxicity in human cell lines remains limited.	Packaging materials, tissue engineering, drug delivery, 3D printing, face masks.	(Burada et al., 2015; Fei et al., 2024; Hadri et al., 2025; Jiao et al., 2024; Kumar S. et al., 2024; Niu et al., 2024; Rajvanshi et al., 2023; Wen et al., 2025)
PBS	Crystallinity, mechanical performance equivalent to PP/PE, good processability, thermal stability, simple and rapid degradation mechanism.	Requires specific conditions for biodegradation. Weaker mechanical and physical properties. The cytotoxicity in human cell lines remains limited.	Packaging materials, compost bags, biomedical materials and hygiene products.	(Fei et al., 2024; Hadri et al., 2025; Kaur et al., 2025)
PCL	Elastomeric, relatively crystalline and suitable for modification, mechanical properties comparable to other basic plastics.	Requires specific conditions for biodegradation.	Mulch films, tissue engineering, dressings, drug delivery.	(Fei et al., 2024; Hadri et al., 2025; Kaur et al., 2025)
PBAT	High flexibility and toughness, biocompatibility, good processability.	Requires specific conditions for biodegradation. The cytotoxicity in human cell lines remains limited.	Mulch sheets, packaging materials and shopping bags.	(Fei et al., 2024; Mutmainna et al., 2025; Wen et al., 2025)
PHA	Eco-friendly, biocompatible, biodegradable, moisture and heat resistant, good gas barrier properties, rigid.	Requires specific conditions for biodegradation.	Packaging, bags, containers, drug delivery, pens and hygiene products.	(Mutmainna et al., 2025; Vigneswari et al., 2024)
PGA (Polyglycolic acid)	Crystalline, thermal stability, good degradability and biocompatibility.	The cytotoxicity of new degradable polymers in human cell lines remains limited.	Materials for drug delivery and packaging.	(Chia et al., 2020; Hadri et al., 2025; Mogany et al., 2024)

One of the disadvantages of biodegradable MPs is that they can accumulate cadmium, could support certain microbial communities or could inhibit microbial activity, could negatively affect plant adaptability and animal physiology, and their toxicity may increase with their degradation (Shi et al., 2024). In addition, biodegradable plastics require specific conditions for their mineralization (humidity, temperature, pH, oxygen, light and the presence of functional microorganisms) (Rajvanshi et al., 2023), and failure to meet the conditions turns bioplastics into a source of pollution (Shi et al., 2024), with prolonged periods being required for the biodegradation process (Fei et al., 2024). Biodegradable MPs have a higher adsorption capacity and exhibit greater mobility than conventional MPs, thus they promote the transport of contaminants, affecting ecosystems (Fei et al., 2024). Compared to conventional plastics, bioplastics have poorer mechanical and barrier properties, which limits their commercial use (Dorofte et al., 2025; Kumar et al., 2024).

Recent studies also challenge the notion that all bioplastics are inherently biodegradable. They emphasize limitations such as the need for

equivalence in production volumes relative to conventional plastics and the requirement of specific conditions for effective degradation. Nevertheless, microbial degradation technologies offer promising, environmentally friendly avenues for managing bioplastic waste sustainably (Roy & Chakraborty, 2024).

WASTE MANAGEMENT AND FOOD PACKAGING INNOVATION FOR SUSTAINABILITY

Urbanization has led to a significant increase in food waste generation from various sources. In this context, biomaterials derived from food waste have emerged as promising alternatives for plastic production due to their biodegradability, biocompatibility, bio-stability, and biofunctionality. Adopting a zero-waste approach enhances both the sustainability and the economic value of these by-products, while contributing to a cleaner environment through more effective food waste management (Mutmainna et al., 2025).

One such example is vegetable starch, a biodegradable biopolymer presents in various food waste streams, which can be processed into functional, environmentally friendly bioplastics such as PLA (Hadri et al., 2025; Li & Chen, 2024; Mutmainna et al., 2025). Similarly, whey proteins, a by-product of the cheese manufacturing industry, are being utilized to develop biodegradable packaging materials. Their low cost, high biodegradability, flexibility, and neutral taste and aroma make them ideal for food applications (Dorofte et al., 2025).

Waste from the meat and poultry processing industry (bones, blood, eggshells, skin, tendons, etc.) is used to produce polymers such as collagen, chitin, PHA and gelatin, and waste generated from dairy processing, grain processing and fruit and vegetable processing industries are also widely used for PHA production (Rajvanshi et al., 2023). Also, food waste from agriculture, fruits, vegetables and plant by-products (banana peels, pineapple peels, avocado seeds and durian seeds) offer a sustainable solution to reduce plastic pollution (Mutmainna et al., 2025). Other industrial by-products such as glycerol, cellulosic materials, molasses and waste oil are also used as alternative raw materials for bioplastic production (Rajvanshi et al., 2023).

The research trajectory is moving towards new biodegradable and sustainable food packaging solutions as alternatives to conventional packaging, which can provide safe and quality food, so mixing essential oils with bioplastics, alternative to chemical preservatives, is a growing trend for creating antimicrobial films to conventional plastic used as packaging in the food industry (Dorofte et al., 2024; Kumar et al., 2024). Whey films functionalized with essential oils have high potential for use on various foods due to their antimicrobial and antioxidant activities (Lanciu Dorofte et al., 2023). Microbial polymers such as yeast and fungal biomass, exopolymers such as kefiran from kefir culture, bacterial cellulose, gellan and levan, are capable of forming films, being used as packaging materials (Bleoanca et al., 2025).

Despite their benefits, bioplastics derived from plant waste often exhibit inferior mechanical properties compared to conventional plastics. However, these limitations can be mitigated through innovative enhancements, such as the incorporation of materials like chitosan, polyvinyl alcohol (PVA), nanoparticles, or the application of ultrasound treatments, which significantly improve the structural and functional performance of bioplastics (Mutmainna et al., 2025).

CIRCULAR ECONOMY, SUSTAINABILITY AND PLASTIC POLLUTION MANAGEMENT STRATEGIES

Plastic waste management is one of the imperative components of the circular economy concept. This model seeks to transform the traditional linear plastic economy - characterized by a "take, make, dispose" approach - into a more sustainable system by eliminating unnecessary plastic use, fostering innovation, and promoting material recirculation. This transformation aims to reduce plastic leakage into the environment while enhancing long-term sustainability (Mehta et al., 2025).

The efficiency of the circular economy is supported by the integration of recyclable materials and the transition to a circular

economy is a central pillar of European sustainable development to achieve successful European goals (Georgescu et al., 2025). Among its key objectives is tackling plastic pollution by promoting recycling and reducing waste generation (Buruiana et al., 2023).

The linear economy model is one in which products are manufactured, used and disposed of as waste, but the circular approach emphasizes the importance of closing the loop by recycling and reusing at every stage, to create a sustainable system that maximizes resource efficiency and minimizes environmental pollution (Saxena, 2025).

Currently, mechanical recycling is still the main plastic recycling process in Europe (Hsu et al., 2022). Although waste-to-energy processes (pyrolysis and gasification) convert plastic waste into fuels or chemicals, promoting a circular economy, the disadvantage is that they generate carbon, a solid residue often deposited (Khan et al., 2025). Compared to conventional plastics, bioplastics can be completely degraded under controlled conditions, reducing CO_2 emissions. Recycling helps conserve resources, reduce energy consumption and minimize the carbon footprint associated with plastic production (Fayshal, 2024).

However, several barriers hinder the widespread adoption of recycling and circular strategies. These include techno-economic challenges such as the high cost and reduced quality of recycled plastics, as well as legislative, social, and cultural obstacles (Xuyang et al., 2025). An emerging solution is the biodegradation of plastics using microorganisms isolated from landfills, which can break down plastics into carbon dioxide, water, and biomass in an environmentally friendly manner (Hsu et al., 2022; Roy & Chakraborty, 2024).

Although recycling recovers valuable petrochemicals, recycled plastics have disadvantages, such as significant emissions that could be produced during transportation, lower quality compared to new products, and energy consumption. By using bioplastics, reducing the use of unnecessary packaging, and adopting environmentally friendly materials, the negative environmental impact caused by plastics can be effectively mitigated (Jiao et al., 2024).

Circular approach measures such as using reusable products, transforming plastic waste into value-added products to improve socio-economic conditions, or adopting a "zero waste" lifestyle contribute to the transition towards adopting sustainable practices, which is a complex but necessary one (Bertolazzi et al., 2024; Kaplan Sarısaltık et al., 2025; Roy & Chakraborty, 2024).

CONCLUSIONS

Plastic and microplastic pollution in the aquatic environment are one of the most urgent global challenges, as it represents an undeniable threat to marine ecosystems and human health. This study presents an overview of the use of sustainable bioplastics over conventional plastics, with the aim of reducing the total consumption of fossil-based plastics and their waste, minimizing the devastating impact on the environment and mitigating the harmful effects of microplastic pollution.

Implementing sustainable strategies for the use and disposal of synthetic polymers is essential, as these materials are major contributors to environmental contamination through the continuous release of microplastics. While bio-based materials offer a promising solution - being more sustainable, durable, and aligned with the zero-waste approach - their widespread adoption still faces significant hurdles.

Addressing the challenges related to the properties of bioplastics, their costs and their biodegradability are essential for their widespread adoption.

This review highlights both the advantages and limitations of conventional plastics and bio-based alternatives. Future research and innovation in the field of bioplastic development, biodegradation technologies, and circular economy practices will be critical for improving bioplastics' market performance and environmental impact. These efforts will play a pivotal role in tackling the global plastic pollution crisis and in advancing the broader goals of sustainability and circular economy adoption. Based on this review work, the following ideas for future work are recommended: exploring the development of biodegradable plastic formulations with better degradation efficiency in various environments, streamlining the production costs of bio-based

materials, and improving waste management systems.

Abstract

Monitoring landfill stability is critical in mining operations to prevent failures that could have significant environmental and safety implications. Site characterization is a comprehensive approach to monitoring landfill stability in order to conduct detailed geological assessments to understand the composition, structure, and physical properties of the tailing material, to perform laboratory tests to assess the engineering properties, all these correlated with geodetic repeated measurements. Techniques and instruments used in geodetic monitoring are chosen depending on the type of surveyed displacement and level of accuracy required. Photogrammetric and remote sensing technologies play an essential role in the detection and monitoring displacements and deformations, providing crucial support in the rapid and effective management of these emergencies. These techniques allow for large-scale, continuous monitoring of slope movements without requiring direct contact with the slope. This way, it ensures precise deformation monitoring, validates theoretical models, enhances predictive capabilities, and supports safety, regulatory compliance, and environmental protection efforts. A well-designed monitoring system not only ensures compliance with environmental regulations but also provides valuable insights for designing effective mitigation and rehabilitation strategies.

Key words*: displacement and deformation, environmental protection, geotechnical assessment, monitoring landfill stability, photogrammetric and remote sensing technologies.*

INTRODUCTION

Precise spatial measurement, a surveyor's most traditional and well-known expertise, is crucial not only for monitoring climate change impacts but also for developing adaptation strategies. Detailed topographic mapping, fundamental for land use planning and deformation monitoring, can be achieved through conventional surveying techniques, laser scanning, or digital image analysis. The construction of new engineering infrastructure to support climate change adaptation depends on geodetic measurements - such as levelling, total stations, and GNSS technologies – complemented by visual assessments and geotechnical data (Hannah et al., 2014).

At the 2002 World Summit on Sustainable Development, nine key societal benefits of Earth observations were identified (United Nations publication, 2002): disaster management (minimizing loss of life and property from natural and human-made disasters), health (analysing environmental factors affecting human well-being), energy resources (enhancing energy resource management), climate (assessing, predicting, mitigating, and adapting to climate variability and change), water (improving water resource management by understanding the water cycle), weather (enhancing forecasting and warning systems), ecosystems (better management and protection of terrestrial, coastal, and marine ecosystems), agriculture (promoting sustainable farming and combating desertification), and biodiversity (monitoring, preserving, and understanding biodiversity).

Romania adheres to Decision No. 766 of November 21, 1997, which governs the monitoring of construction behaviour during operation, investment phases, and post-usage. Published in the Official Gazette No. 352 on December 10, 1997, this law applies to all types of constructions and aims to evaluate their technical condition while ensuring their continued suitability for use. In the field of construction and civil engineering, a tailings landfill is a designated site for storing mine

tailings, which are the residual materials left after valuable minerals have been extracted from ore. These tailings, typically consisting of fine rock particles, water, and chemicals, are often disposed of in large, controlled piles or ponds.

Monitoring the stability of tailings landfill slopes is essential in mining operations to prevent failures that could lead to severe environmental and safety consequences. Quality in the construction sector is maintained through the following measures (Hannah et al., 2014; Caldera et al., 2016):

- Monitoring construction behaviour during operation to ensure structural stability and enable early detection of potential degradations.
- Interventions involving construction work aimed at maintaining or enhancing operational efficiency.
- Post-usage management, including safe demolition or in-situ abandonment, efficient material recovery, environmental restoration, and sustainability assurance.

The security and sustainability of a tailings landfill are evaluated based on two key engineering and environmental factors (Hannah et al., 2014; Caldera et al., 2016; CRED, 2016; VicRoads, 2021):

- Geotechnical stability: Engineering design must ensure that the tailings landfill remains structurally safe, preventing catastrophic failures such as tailings dam collapses.
- Environmental impact: Effective management of tailings landfills is crucial to prevent pollution of nearby water sources, soil contamination, and harm to wildlife. In some cases, monitoring is necessary to detect the release of hazardous substances like heavy metals or cyanide.

A comprehensive approach to assessing landfill slope stability involves site characterization (Hannah et al., 2014; Caldera et al., 2016; CRED, 2016; VicRoads, 2021):

- Geological surveys: Conducting thorough geological assessments to determine the composition, structure, and physical properties of the tailing's material.
- Soil and rock testing: Performing laboratory analyses (e.g., shear strength, consolidation, and permeability tests) to evaluate the engineering properties of the tailings.

MATERIALS AND METHODS

Monitoring tailings landfills – large accumulations of waste materials from mining operations – is essential to ensuring environmental safety, structural stability, and regulatory compliance. Slope stability assessment relies on two complementary approaches: the geotechnical approach (analytical) and the parametric approach (measurable). A comprehensive and realistic evaluation of tailings landfill stability requires considering both perspectives (Caldera et al., 2016; CRED, 2016; Gilbert Gedeon, 2021; VicRoads, 2021). Slope stability and landslide monitoring involve identifying specific parameters and tracking their variations over time. The two primary factors in this process are groundwater levels and displacement. Slope displacement is analysed based on failure plane depth, direction, magnitude, and rate, with one or more of these aspects being continuously monitored.

Traditional slope monitoring employs either a single method or a combination of techniques. Piezometers measure water levels, while tools such as surveyed surface monuments, extensometers, inclinometers, and tiltmeters provide insights into slope movement direction, rate, depth, and failure plane extent. Extensometers specifically help quantify displacement magnitude. For long-term slope monitoring, manually operated probe inclinometers are the most widely used instrument (Caldera et al., 2016; CRED, 2016; Gilbert Gedeon, 2021; VicRoads, 2021). Effective waste landfill management requires a combination of monitoring activities and interventions to ensure both stability and sustainability.

These approaches are divided into invasive and non-invasive methods. Invasive methods involve direct physical interaction with the landfill mass, such as drilling, excavation, or other intrusive processes. Non-invasive methods enhance and assess landfill stability without disturbing the waste mass, using remote sensing, surface-based techniques, and indirect monitoring measures. By integrating both invasive and non-invasive strategies, tailings landfills can be efficiently monitored and stabilized, promoting long-term environmental

and structural sustainability (Caldera et al., 2016; CRED, 2016; Gilbert Gedeon, 2021; VicRoads, 2021).
The typical workflow for tailings landfill monitoring focuses on:

1. PLANNING AND PREPARATION
The monitoring of tailings landfills starts with a site assessment, which involves identifying specific risks related to the landfill, such as its composition, size, slope, and proximity to sensitive areas like water bodies or nearby communities. This phase also includes defining the monitoring objectives, which may focus on detecting seepage, evaluating slope stability, tracking dust emissions, or ensuring compliance with safety regulations (Popa, 2012; CRED, 2016).

2. DATA COLLECTION
The data collection process employs a combination of manual and automated techniques to monitor various environmental and structural conditions of the tailings landfill (Figure 1). Routine monitoring is a systematic process focused on assessing the technical condition of the land or structures. Its primary goal is to ensure stability during operation. If certain parameters exceed predefined thresholds, special monitoring must be implemented. This involves conducting regular, periodic investigations on specific parameters to assess deformations in the land, structures, or specific components. Special monitoring activities are typically defined during the project planning phase or determined through technical expertise (UTCB, 2009; Popa, 2012; Buchmayer et al., 2021).

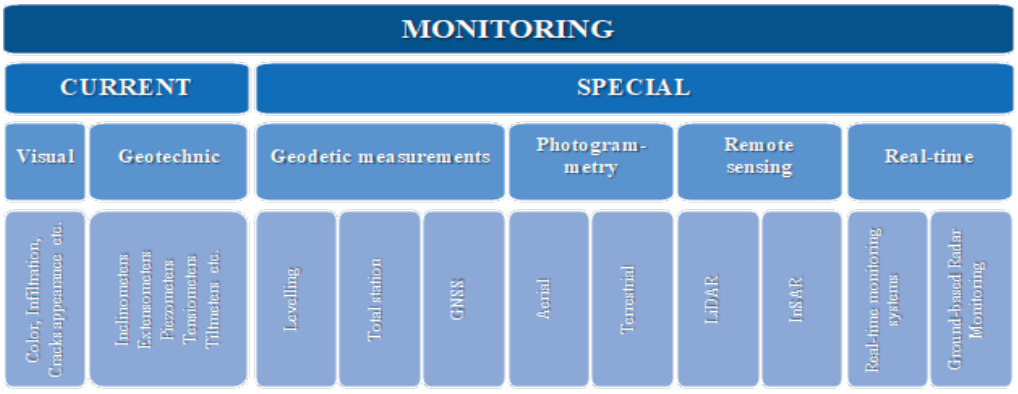

Figure 1. Monitoring methods and instruments - classification by monitoring aspects

Visual Monitoring
Regular field inspections and surveys play a crucial role in supplementing instrument-based monitoring. Visual inspections help identify early warning signs of instability, such as the formation or expansion of surface cracks, changes in vegetation or water drainage patterns (which may indicate subsurface movement or shifts in stability), and surface subsidence or slumping. These issues are particularly common in carbonate deposits due to karst features or weathering (UTCB, 2009).

Geotechnical Monitoring
Geotechnical monitoring utilizes various instruments to continuously or periodically measure ground movements, stresses, and other factors influencing slope stability.
The geotechnical parameters essential for ensuring construction stability and safety can be categorized into two main groups (UTCB, 2009):

- Environmental factors: These include water levels, air temperature, water temperature at various depths, solar radiation, and seismic activity.
- Structural response measurements: These depend on the type of construction. For tailings landfills, key monitored parameters include: absolute and relative displacements of the landfill and geotechnical characteristics, particularly vertical settlements during construction and operation, displacement between structural

elements, temperature variations within the landfill body, deformation and stress conditions, crack development, infiltration rates and the position of the infiltration curve, pore water pressure within earthen sealing elements, effective and total stress conditions, and slope displacements and infiltration through slopes.

Monitoring instruments must be deployed in adequate numbers and at appropriate intervals to detect abnormal behaviour. When irregularities are observed, the data collected – combined with field inspections – should enable the identification of underlying causes. In some cases, additional monitoring tools may be required (UTCB, 2009).

Advancements in technology, particularly the Internet of Things (IoT), have significantly enhanced traditional monitoring methods, overcoming challenges such as low measurement frequency and time-intensive data collection. IoT-based systems enable real-time and precise tracking of changes in enclosure structures, allowing for dynamic adjustments to construction parameters and techniques (Figure 2). This adaptive monitoring approach provides critical technical support by assessing the stability of surrounding rock formations, evaluating the reliability of primary supports and secondary linings, refining support system designs based on real-time data, determining optimal timing for secondary lining installation, and adjusting construction methods to enhance overall structural safety and efficiency. By integrating modern monitoring technologies, construction teams can proactively address stability concerns, ensuring the long-term safety and sustainability of tailings landfills (Buchmayer et al., 2021).

Global investigations focus on determining the geophysical structure and geotechnical characteristics of a tailings landfill, as well as detecting water circulation within the landfill and its surrounding environment. Piezometers are used to measure pore water pressure within weak soil layers, particularly inside slopes. Installed in boreholes within the landfill or slope, these instruments monitor fluctuations in water pressure within carbonate rock formations. Elevated pore pressure can reduce effective stress, potentially leading to slope instability. In carbonate deposits, water infiltration through fractures or karst formations can further contribute to slope failures. Piezometer data is essential for tracking groundwater conditions and assessing stability risks (UTCB, 2009; Buchmayer et al., 2021.

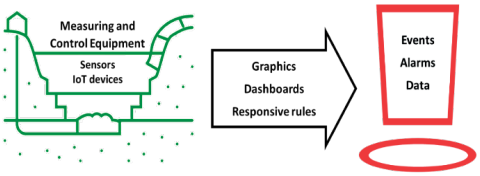

Figure 2. The use of modern technologies in monitoring activities

In addition to geotechnical monitoring instruments, seismic activity monitoring is critical for tailings landfills. Seismometers record ground movement, measuring velocity and acceleration, while seismographs track acceleration over time. For comprehensive seismic monitoring, devices should have three measurement components and be installed at three levels at least: the crest elevation of the tailings landfill, the foundation level, and the open field reference point. The interpretation of seismic data and application of results must be conducted by qualified specialists to ensure accurate risk assessments and effective mitigation strategies (UTCB, 2009; Buchmayer et al., 2021).

Geodetic Measurements

Field surveys are commonly conducted using geodetic methods and instruments such as levelling, total stations, and GNSS systems, which enable the detection of surface movements over time. The Monitoring Geodetic Network (MGN) consists of two main categories of points (Figure 3) (Popa, 2012):

- Reference points: These are further classified into three types: survey points – directly used for monitoring the targeted structure, control points – assess the stability of survey points, and orientation points – provide geodetic network alignment. Reference points must meet several essential criteria: ensure long-term stability and reliability, be strategically positioned to enable precise and accurate data collection, be placed on solid, stable geological formations to prevent movement-related distortions, and be located in areas

where groundwater levels do not compromise stability.

- Object points: These points must also fulfil specific requirements: they should be embedded within the load-bearing components of the structure, and their placement should align with the foundation's geometry and load distribution to ensure accurate monitoring.

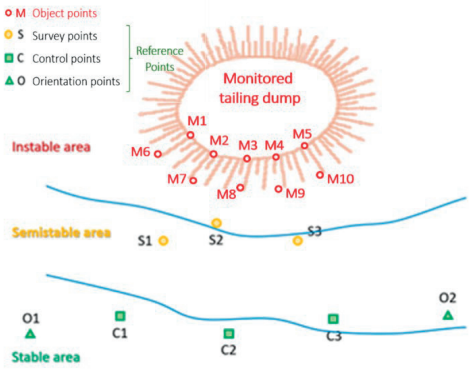

Figure 3. The monitoring geodetic network

Techniques and instruments used in geodetic monitoring are chosen depending on the type of surveyed displacements and deformations, and level of accuracy required.

Photogrammetry

Photogrammetry plays a significant role in slope stability monitoring by providing accurate, detailed, and often real-time measurements of changes in the surface geometry of slopes, being preferred over traditional methods. Photogrammetry contributes to surface change detection (comparing models over time, deformations, cracks, subsidence, or bulging can be revealed – key signs of instability). Photogrammetry allows the surveying of extensive or dangerous terrains without needing physical access, ensuring safety while capturing critical data. The outputs of repeated surveys can be integrated into Geographic Information Systems (GIS) for more advanced geotechnical analyses and risk mapping. Photogrammetry is an effective method for monitoring terrain displacement, particularly useful for generating 3D models of slopes through photographic imagery. Multiple aerial or ground-based photos are combined to create detailed models of the landfill slope. By comparing models taken at different times, any changes in the slope can be identified. This technique is particularly useful for detecting surface cracks, erosion, and slumping in carbonate deposits (Hannah et al., 2014; Dimen et al., 2024).

Photogrammetry combines precise visual data with geospatial analysis, making it ideal for both large-scale and localized environmental monitoring projects (Hannah et al., 2014; Dimen et al., 2024).

Photogrammetry and unmanned aerial vehicles (UAVs) are closely linked, with UAVs enhancing photogrammetry by providing a versatile and efficient platform for capturing aerial imagery, which serves as the foundation for photogrammetric analysis (Hannah et al., 2014).

A UAV (drone) can operate autonomously or be controlled remotely. Equipped with technologies like GNSS, cameras, sensors, and specialized software for tasks such as collecting data from hard-to-reach areas, UAVs are increasingly utilized in monitoring (Hannah et al., 2014).

The imagery captured by UAVs is processed using photogrammetry software to create 3D models, orthomosaics, and contour maps. Advanced algorithms use overlapping images to triangulate points and generate accurate spatial data, which is then correlated with other field-collected information (Hannah et al., 2014).

Though, there are a few challenges which should be kept in mind. Photogrammetry requires good lighting and clear views (vegetation can be a problem), while accuracy depends heavily on ground control points and the camera quality and processing software. Photogrammetry mostly tracks surface movement, not internal slope deformations (for subsurface issues, photogrammetric surveys still need to be correlated with geotechnical measurements).

Remote Sensing

Modern remote sensing technologies play a crucial role in detecting and monitoring displacements and deformations in tailings landfills. These technologies support rapid and effective management, enabling large-scale, continuous monitoring of slope movements without direct contact. This is especially

valuable for monitoring expansive landfill slopes in mining operations (Hannah et al., 2014; Dimen et al., 2024).
When satellite data is combined with aerial imagery and field measurements, it provides an accurate and comprehensive view of the monitored area. This data is crucial for coordinating adaptation strategies, responding to emergencies, and optimizing resource allocation. It also aids in planning operational measures and predicting future behaviour (Dimen et al., 2024).

Real-time Monitoring

A real-time monitoring system continuously collects data and provides alerts for any significant changes. The goal of such systems, especially for mining waste landfills, is to ensure safety, environmental compliance, and operational efficiency. Real-time data helps detect even small, progressive slope movements before they escalate into major failures, allowing for prompt mitigation actions in cases of structural instability, excessive seepage, or environmental contamination (UTCB, 2009; Buchmayer et al., 2021).
In addition to geotechnical, hydrological, and environmental sensors, real-time monitoring systems should include GNSS and total stations for precise surface movement monitoring.
These sensors continually collect data on various parameters, with wireless communication networks (e.g., 4G/5G, LoRaWAN, or satellite links) transmitting the information in real-time to central monitoring stations or cloud-based platforms. Specialized software analyses incoming data to identify anomalies and trends. Machine learning algorithms or predefined thresholds can trigger automated alarms when critical conditions are detected (Buchmayer et al., 2021).
The data is displayed on user-friendly dashboards featuring charts, maps, and 3D visualizations. Stakeholders are notified via SMS, email, or other notification systems when thresholds are exceeded. Real-time data is also integrated with weather monitoring, geological models, and remote sensing data (such as from drones or satellites) for a comprehensive analysis (UTCB, 2009; Buchmayer et al., 2021).
Interpretative algorithms are absolutely crucial when it comes to predicting landfill slope failures, especially when working with large, complex datasets. Modern monitoring methods produce huge datasets (e.g. point clouds, images, displacement maps). Algorithms process, analyse, and filter this data efficiently, identifying meaningful patterns or anomalies that humans would miss. There could be early warning signs, like subtle slope movements (millimetres of displacement), that can be an early indicator of impending failure. Algorithms can detect these small changes over time, often earlier and more accurately than manual inspections. By learning historical deformation patterns, algorithms can predict future behaviour, recognizing acceleration trends that precede a collapse. Moreover, algorithms can combine various factors (e.g. displacement rates, rainfall data, soil type, slope angle) to quantify failure probabilities, turning subjective assessments into objective risk metrics, aiding decision-making. Interpretative algorithms interpret incoming data in real time. If critical thresholds are crossed (e.g. displacement rate suddenly doubles), the system can trigger alarms immediately (Buchmayer et al., 2021).
By continuously monitoring the landfill, real-time systems enable proactive risk management, providing ongoing insights into structural, environmental, and operational conditions. This technology supports sustainable, safe management practices, reduces risks to human life and the environment, and improves decision-making (Caldera et al., 2016; CRED, 2016).

3. DATA TRANSMISSION AND MANAGEMENT

Data from different type of sensors and monitoring devices are consolidated within a centralized system, often referred to as a Supervisory Control and Data Acquisition (SCADA) system or a similar platform. This system enables real-time monitoring and triggers alerts in response to abnormal readings, such as unusual seepage or deformation (Figure 4) (Buchmayer et al., 2021).

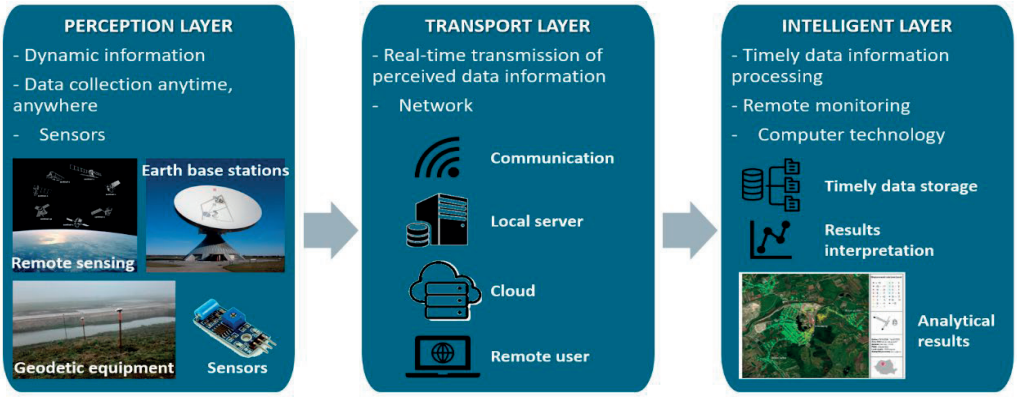

Figure 4. Layers of a real-time monitoring system

4. DATA ANALYSIS

For thorough analysis and interpretation, field-collected data is integrated by combining outputs from various instruments using specialized software designed for analysis and stability assessments. The data is then processed and interpreted to uncover patterns, trends, and potential issues. To create a 3D model of the tailings landfill for further analysis, the collected data must be processed using specific modelling software. Interpolation techniques are often required due to challenges in data acquisition and the limited number of measurement points. Most modelling software provides users with various interpolation methods to choose from. Before selecting the most suitable spatial interpolation technique, it is essential to evaluate the assumptions and characteristics of each approach, along with the spatial properties and analysis of the data (Herban & Alionescu, 2012).

Several factors influence the accuracy of Digital Elevation Models (DEMs), including sampling density for contour derivation, the vertical spacing of contours, the grid cell size of the DEM, field complexity, and spatial filtering. Advances in terrestrial measurement technology have significantly improved accuracy, enabling the development of models that can be utilized in deformation analysis and predicting the future behaviour of the tailings landfill (Figure 5) (Herban & Alionescu, 2012).

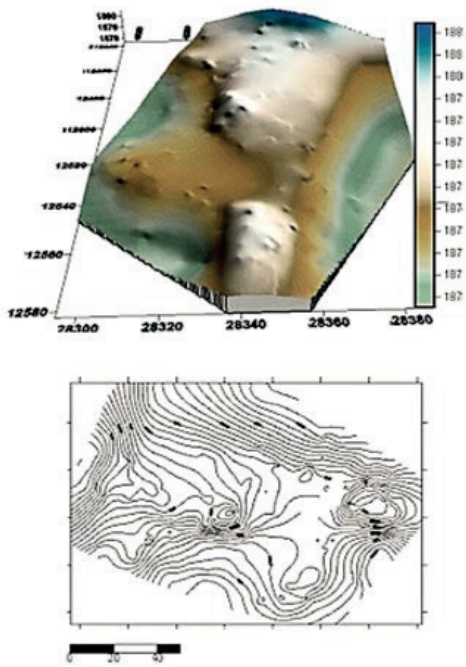

Figure 5. Digital elevation model and contour lines (Herban & Alionescu, 2012)

Data Quality Control

Data cleaning is essential to eliminate outliers or erroneous values, often caused by sensor malfunctions. The validated data must align with known benchmarks and expected ranges for parameters like pH, temperature, and deformation (Welsch & Heunecke, 2005; Popa, 2012).

The relation between geotechnical parameters (e.g., pH, temperature) and landfill slope stability is indirect but significant, because they influence the geotechnical behaviour of the waste material, leachate chemistry, and biological activity, all of which affect how stable the landfill slope is. Low pH accelerates the breakdown of organic materials leads to weaker waste material, and, therefore, higher risk of slope failures. On the other side, a neutral or high pH leads to more chemically stable environment and more stable slopes. High temperatures are more often met in case of waste weakening and could be an early sign for slope instability.

Statistical and Geospatial Analysis

Statistical methods, such as regression and trend analysis, are applied to detect significant changes in tailings behaviour, including gradual slope shifts or sudden seepage spikes. Environmental conditions, like rainfall or temperature, are correlated with variations in tailings characteristics, such as water chemistry and seepage rates. Geographic Information System (GIS) software enables mapping of monitoring points to visualize spatial patterns, like areas of excessive settling or deformation. By overlaying environmental data—groundwater and surface water quality—onto topographical maps, risks of contamination can be assessed (Welsch & Heunecke, 2005; Popa, 2012).

During analysis, the tailings landfill is treated as a unified system, fully monitored to identify displacements and deformations over time. Repeated measurements relative to the surrounding environment form the basis for determining absolute displacements (Welsch & Heunecke, 2005; Popa, 2012).

To forecast future evolution with maximum accuracy, displacement and deformation models are developed by analysing changes over time and space. These models incorporate causal forces, such as internal or external stresses, which drive the displacements and deformations (Nikolić, 2009).

A practical method involves integrating observation-based analyses to study displacements and deformations. This includes geometric state analysis and physical interpretations that identify dynamic processes. "Integrated analysis" refers to merging geometric evaluations with predictive models (Welsch & Heunecke, 2005).

The synergy between geodetic repeated measurements and parametric modelling is pivotal for effective tailings landfill monitoring and management. Geodetic measurements yield high-resolution spatial data on deformations, while parametric models contextualize these measurements, integrating geotechnical and environmental factors. By combining these approaches, deformation trends can be precisely analysed, risks predicted, and future behaviours simulated under varying conditions (Welsch & Heunecke, 2005; Popa, 2012).

This integrated framework validates theoretical models while enhancing safety compliance and environmental stewardship. It enables proactive identification of hazards - like seepage or slope failures - that may lead to contamination or ecological damage. Ultimately, the correlation fosters a robust risk assessment strategy, supporting informed decision-making and resource optimization to protect human lives, infrastructure, and the surrounding ecosystem (Welsch & Heunecke, 2005; Popa, 2012).

Predictive Modelling, Alarm Systems and Thresholds

Historical data is utilized to develop predictive models that can anticipate issues such as tailings dam failure, seepage migration, or structural shifts. These models support proactive management and the establishment of early warning systems. Key parameters, such as maximum allowable pore pressure or ground displacement, are assigned thresholds. If these thresholds are exceeded, alarms are triggered to alert the management team to potential risks (Welsch & Heunecke., 2005).

5. REPORTING AND DECISION MAKING

Reporting involves generating regular summaries of monitoring data and analysis. These reports typically include visual representations, such as graphs, charts, and maps, alongside an assessment of trends and anomalies. Recommendations for mitigation measures or further monitoring are also provided. Ensuring regulatory compliance involves meeting environmental regulations, standards, and submitting the necessary reports

to local authorities or regulatory bodies (Welsch & Heunecke, 2005; Caldera et al., 2016; CRED, 2016).

Based on these analyses, the management team may implement actions such as modifying the operation of the tailing's facility, strengthening the structure, or initiating deeper investigations. After each monitoring cycle, it is crucial to review the system's effectiveness. This review assesses whether the data collected is sufficient and accurate, prompting adjustments to the monitoring strategy where needed—for example, adding sensors or altering data collection intervals (Welsch & Heunecke, 2005; Caldera et al., 2016; CRED, 2016).

As technologies advance, adopting new monitoring tools and analytical techniques should be considered to enhance accuracy and efficiency in the monitoring process.

RESULTS AND DISCUSSIONS

Ensuring the stability of landfill slopes in carbonate deposits requires a combination of instrumentation, remote sensing, and geotechnical modelling. The unique characteristics of carbonate formations - such as fractures, karst features, and susceptibility to water infiltration - necessitate a comprehensive monitoring approach to maintain safety and stability. Continuous data collection from these methods enables the early detection of potential failures, allowing for proactive mitigation (Welsch & Heunecke, 2005; Caldera et al., 2016; CRED, 2016).

A multi-faceted approach is essential for monitoring tailings landfill slope stability, integrating traditional geotechnical techniques with modern technology. By implementing a robust monitoring program, mining operations can significantly reduce risks associated with tailings storage, enhancing both safety and environmental protection (Welsch & Heunecke, 2005; Caldera et al., 2016; CRED, 2016).

Integrating geodetic repeated measurements with parametric modelling plays a critical role in monitoring tailings landfills, which serve as storage areas for mining waste. This integration delivers precise, timely, and actionable insights into the structural stability, integrity, and environmental impact of the landfill. Key advantages of this correlation include (Welsch & Heunecke, 2005; Caldera et al., 2016; CRED, 2016; Gilbert Gedeon, 2021; VicRoads, 2021):

- Geodetic measurements provide high-precision spatial data on geometric displacements, while parametric modelling aids in understanding the behaviour of the landfill. Together, they enable the detection of deformation trends and early identification of anomalies signalling potential instability. Combining high-precision geodetic tools (e.g. GNSS, LiDAR) with robust modelling and uncertainty analysis is crucial in early warning systems. Thus, minor inaccuracies in measurement or modelling can mask critical pre-failure displacements, especially in systems like landfills where early deformations may be subtle but significant. Small but persistent inaccuracies can lead to misinterpretation of long-term trends, such as poor resolution or incorrect model calibration that may suggest stability even when precursors to failure exist.
- Discrepancies between observed measurements and model predictions can highlight areas for model improvement or uncover hidden risk factors. Geodetic deformation analysis helps validate parametric models, while tailings landfill conditions and responses are simulated based on their characteristics.
- Localized geodetic displacements may indicate risks, such as slope failures or seepage. By considering material properties, loading conditions, and environmental factors, this approach develops a complete risk profile, combining empirical observations with theoretical assessments for more informed decision-making.
- Regular monitoring and reporting are often required to meet regulatory standards. Incorporating geodetic monitoring within parametric models enhances communication with regulators and stakeholders by providing evidence-based assurances of safety and stability. This practice minimizes the risk of overdesigning stabilization measures or underestimating risks, ensuring optimized resource allocation.
- A general monitoring strategy for tailings landfills should support sustainable mining by addressing environmental hazards proactively. Monitoring displacement

patterns can reveal potential pathways for seepage or contamination. Simulating environmental impacts enables the development of effective containment strategies, further reinforcing environmental stewardship.

CONCLUSIONS

Romania complies with legislation regarding the monitoring of construction behaviour throughout all phases of its life cycle – pre-usage, exploitation, and end-of-life. In case of inactive landfills, as construction in the third life cycle phase, a long-term stability assessment is still required, in order to ensure residual waste continuity to settle safely without causing surface deformation or failure, while environmental monitoring involves continuous tracking of groundwater, air quality, and leachate for decades.

Therefore, monitoring through all life cycle phases ensures the landfill does not become a long-term environmental or structural hazard. It protects ecosystems, human health, and investments while enabling informed decision-making.

Monitoring a landfill using both geodetic methods and geotechnical parameter measurements is essential because each approach provides complementary information crucial for understanding and managing stability risks. This approach brings more benefits, such as a comprehensive understanding of landfill stability, early warning and risk mitigation, improvement in data reliability and confidence in decision-making, more accurate predictive modelling for stability assessments, and ensuring compliance and enhancing public and environmental safety.

A range of sensors, including vibrating wire piezometers, electrolytic bubble inclinometers, and tiltmeters, are commonly used to monitor groundwater levels and ground movement for slope stability assessments. Recent advances in electronic technology, coupled with reduced costs, have made remote monitoring a highly efficient and cost-effective tool for evaluating slope stability.

The workflow for monitoring tailings landfills is a multi-step process involving meticulous planning, the use of advanced monitoring equipment, systematic data collection, comprehensive analysis, and ongoing reporting. This structured approach helps identify risks early, enabling prompt action to prevent environmental damage and ensure community safety.

In summary, the integration of geodetic repeated measurements with parametric modelling establishes a synergistic framework for tailings landfill monitoring. This integration provides accurate deformation assessments, validates theoretical models, improves predictive capabilities, and bolsters efforts in safety, regulatory compliance, and environmental protection.

Environmental monitoring for water, air, and soil should follow an integrated approach rather than operating separately. This ensures a holistic management strategy through:

- Identifying relationships between pollutants across water, air, and soil systems.
- Utilizing real-time data to detect contamination at an early stage and prevent its spread.
- Implementing actions like containment barriers for water and soil, dust suppression systems for air, water treatment methods such as filtration, reverse osmosis, or chemical neutralization, and soil rehabilitation through phytoremediation or amendments.

Monitoring tailings landfills is crucial for minimizing environmental and public health risks. A thoughtfully designed monitoring system not only ensures compliance with environmental regulations but also provides valuable insights to develop effective mitigation and rehabilitation strategies. Continuous evaluation of environmental conditions allows stakeholders to preserve ecological balance and promote sustainable mining practices.

Abstract

Carbon capture and storage (CCS) is a technology designed to reduce greenhouse gas emissions by capturing CO_2 from industrial processes or power generation and securely storing it in geological formations. Băile Lăzărești serves as a promising natural laboratory for studying the environmental effects of potential CO_2 leakage from an anthropogenic CO_2 storage site and for testing monitoring solutions. One effective method for environmental monitoring of CO_2 geological storage involves soil flux and soil gas surveys, which can identify potential CO_2 leakage points by determining the natural variability of CO_2 flux. Since 2019, several soil flux surveys have been conducted at Băile Lăzărești across different seasons, combined with soil-gas measurements. By analyzing seasonal CO_2 variation along with geological knowledge, we have determined the natural variability of post-volcanic emissions and important for monitoring CO_2 geological storage sites, aiding in the identification and understanding of potential leakage in the near-surface environment.

Key words: *CO_2 geological storage, monitoring, natural laboratory, soil flux surveys, soil gas-surveys, leakage detection.*

INTRODUCTION

Carbon capture and storage is an important tool for reducing CO_2 emissions (IPCC, 2022; IPCC, 2023) and it is expected to be deployed large-scale to achieve the climate targets. From all the components of the CCS chain, the storage seems to be the most debated since there are some public concerns related to the risks of storing CO_2 underground, although the storage occurs in the deep environment at more than 800 m depth. Environmental monitoring in this respect is very important since it can easily demonstrate the absence of leakage and its undesirable effects in the environment (West et al., 2005; Beaubien et al., 2008; Ziogou et al., 2013). One important monitoring method which has been successfully applied at all the current and past storage projects is soil flux monitoring (Beaubien et al., 2008). Its application was also demonstrated on natural laboratories (Beaubien et al., 2008; Ziogou et al., 2013), sites where CO_2 is leaking naturally, mostly related with volcanic or post-volcanic activity. The study of these sites can provide valuable insights on the natural variability of soil fluxes and on the migration pathways of CO_2 in the near-surface (Beaubien et al., 2008).

In Romania, a promising natural laboratory can be considered Băile Lăzărești site (Harghita County). The site is located at approximately 16 km north-east from Băile Tușnad and it is renowned for its post-volcanic activity (Pricăjan, 1974; 1985; Karátson et al., 2022).
The site was selected for further research as a natural analogue for CO_2 leakage in 2019 (Dudu et al., 2021; Dudu et al., 2024) in the context of a national research project. Several soil flux and soil gas surveys have been conducted in the following years in order to determine the natural variability of CO_2 soil fluxes and concentrations and to highlight migration pathways, contributing to the understanding of CO_2 leakage mechanisms in the environment and therefore to the design of monitoring for future CO_2 storage sites. During the last 6 years, the site underwent significant landscaping projects, which also complicated its assessment.

MATERIALS AND METHODS

Study area

The Gurghiu-Harghita post-eruptive chain represents the most intense post-volcanic manifestation in the Eastern Carpathians, with a significant release of gases. The ascent of

volcanic gases to the surface is favoured by deep tectonics, through a complex crustal, regional, and local fracture system, of which regional and local fractures have different degrees of current mobility (Airinei & Pricăjan, 1972). The post-volcanic emissions in the Lăzărești area propagate along a system of deep fractures, which are then taken over by surface faults. These emissions are redistributed with varying intensity throughout the entire sedimentary volume of the Cretaceous flysch (Airinei & Pricăjan, 1972).

From a lithostratigraphic perspective, the post-volcanic emissions in the Lăzărești area traverse a series of deposits, starting with the Cretaceous flysch (Sânmartin-Bodoc strata, Barremian-Albian) at the base, continuing with terrace deposits (Mutihac, 1990). The Cretaceous flysch (Barremian-Albian) is characterized by accentuated flysch features (pronounced rhythmic alternations of rusty grey sandstones, often bituminous, and shales), while lacking marl-limestones. The flysch, with its low permeability due to the alternating layers of shale and sandstone, can act as a barrier, limiting the free migration of gases. However, tectonic activity and the presence of fractures within the flysch can create pathways for volcanic emissions to reach the surface. These fractures and fault systems essentially create a "stratigraphic screen," which can either trap or channel gases depending on their alignment and mobility. Quaternary deposits are terrace deposits, composed of coarse sediments, locally or at the base of the slopes covered with finer alluvium, such as fine sands and sandy shales, marls, and grey shales. The formation of carbonated mineral water deposits in the region results from the interaction of moffetic carbon dioxide with the aquifer layers within the mentioned geological formations. Additionally, the specific hydrodynamic characteristics of the known springs (sulfonated, ferruginous, etc.) are directly influenced by the chemical composition of the volcanic, flysch, Neogene and Quaternary formations through which the groundwater flows.

In 2019 several gas measurements were made near important elements such as the dry and wet mofettes, mineral spring and therapeutic bath. The level of CO_2 emissions was determined to reach more than 85% inside the dry mofette cabin (Dudu et al., 2021). From the measurements made across several location across the site, it was decided to divide it into two perimeters, completely different considering the level of emissions and the presence and number of the gas vents (Figure 1).

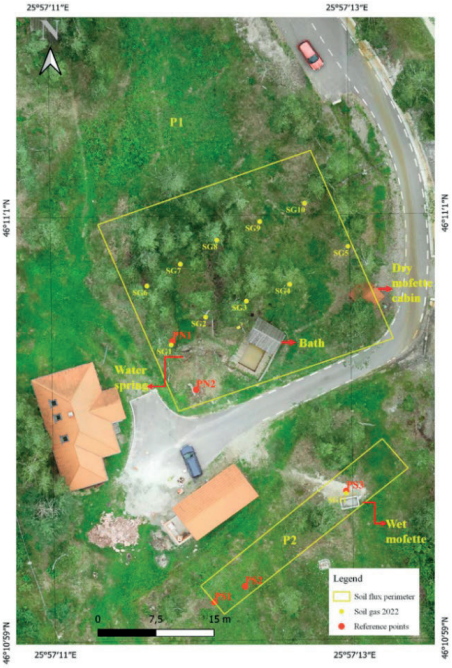

Figure 1. Location of study perimeters, reference points, soil gas sample points and touristic features

The northern perimeter (P1) presents high CO_2 emissions and many wet and dry gas vents, including most of the touristic features such as the baths used for therapeutic purposes and the dry mofette. The southern perimeter (P2) presents much lower emissions and includes a wet mofette and some dry gas vents reduced in intensity and area. This perimeter also was mostly affected by an extensive landscaping process over the years (see example in Figure 2 and Figure 3).

Figure 2. Wet mofette from P2 (PS3) in 2020

Figure 3. Wet mofette in P2 (PS3) in 2024

Soil flux surveys

Starting with 2020, several field campaigns of soil flux measurements have been conducted in the dry (summer) and wet (autumn and spring) seasons of 2020, 2022 and partially in 2024 (after the site underwent an extensive landscaping project).

The most extensive surveys were made in 2022 (Figure 1). Several key points (reference points in Figure 1) were monitored during all this time to see the flux variation in time and its dependence on hydrological regime. The soil flux measurements were made using the closed chamber accumulation method and were conducted with a West Systems portable fluxmeter equipped with CO_2, H_2S and CH_4 sensors (Figure 4).

Figure 4. Soil flux survey conducted with West Systems portable fluxmeter in October 2022

The raw data was processed with FluxRevision software and the calculated flux values were interpolated using ArcGIS software to obtain the maps showing the flux variation.

Soil gas surveys

Soil gas surveys were also implemented on selected sample locations in 2020 and 2022.

In 2020, the soil gas measurements were done during July and focused mainly around the identified wet and dry mofettes of the site.

In 2022, the soil gas measurements were done mostly on 2 selected profiles from P1 (including a reference point) and on a reference point from P2 located around the wet mofette. The measurements were done using the Gas Data GFM 436 portable gas analyser coupled with a hardened steel probe from Durridge (Figure 7). This ensemble allows measuring CO_2 concentrations at different depths, in this case 25, 50 and 75 cm.

RESULTS AND DISCUSSIONS

Soil flux surveys

The extensive soil flux surveys from 2022, conducted in the summer (dry) and autumn (wet) season, shown a significant difference in the level of CO_2 fluxes, most probably due to the difference in the hydrological regime.

In the summer (July for P1 and August for P2), the CO_2 flux varied on P1 between 0.43 and 185 mol/m^2/day and on P2 between 0.20 and 178 mol/m^2/day (Figure 5). The highest CO_2 fluxes

on P1 were measured next north of the therapeutic bath (where several smaller baths exist), near the water spring and on the alignment of the dry mofette cabin. On P2 the maximum CO_2 fluxes were measured near the wet mofette and on the alignment of the water spring.

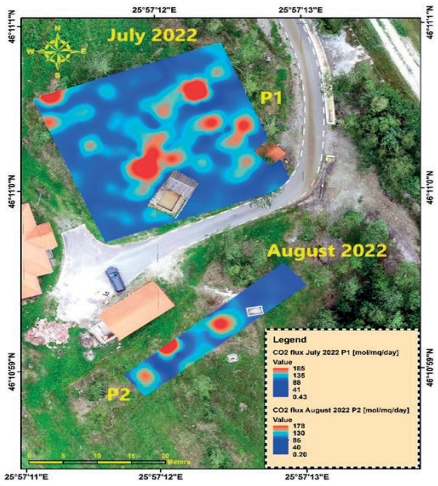

Figure 5. CO_2 soil flux variation in July and August 2022

In October 2022 (Figure 6), CO_2 flux shows much larger values, between 0.17 and 893 mol/m^2/day on P1 and between 0.27 and 625 mol/m^2/day on P2. The maximum values are located, as in the summer, around the water spring, wet and dry mofettes on P1 and on the alignment of water spring and bath and near the wet mofette on P2.

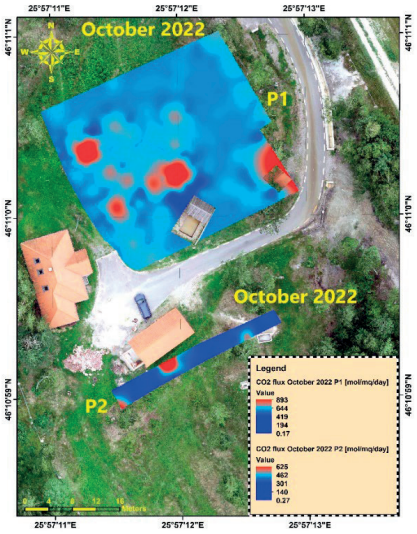

Figure 6. CO_2 soil flux variation in October 2022

The variation of fluxes recorded for the reference points in 2020, 2022 and 2024, show a clear difference between summer and autumn seasons (Table 1).

Table 1. CO_2 flux values in the reference points measured in the surveys from 2020, 2022 and 2024

Ref. point	CO_2 flux October 2020 (mol/m^2/day)	CO_2 flux July/August 2022 (mol/m^2/day)	CO_2 flux October 2022 (mol/m^2/day)	CO_2 flux September 2024 (mol/m^2/day)
PN1	130.2	1.994	262.1	323.3
PN2	32.25	1.898	51.71	60.64
PS1	2.092	3.017	3.17	9.985
PS2	6.688	2.309	12.29	13.78
PS3	1.532	0.939	4.103	2.877

Soil gas surveys

As mentioned before, soil gas surveys from July 2020 have focused around the wet and dry gas vents identified at the site. Two of the sample stations measured then are corresponding with the reference points PN2 (near the water spring) and PS3 (near the wet mofette). For PN2, the measured CO_2 concentrations were 30.6% at 25 cm depth, 16.8% at 50 cm depth and 13.4% at 75 cm depth. For PS3, the measured CO_2 concentrations were 33.3% at 25 cm depth, 31.5% at 50 cm depth and 4.7% at 75 cm depth. The drop in CO_2 concentration with depth, opposite to what have been expected, can be explained with the water ascension in the steel probe. At 25 cm depth, the measurement time was stopped at 2 minutes, but for larger depths, the measurement was stopped at 1 minute due to water intake.

The same situation was encountered also in October 2022 (Table 2), especially near the water spring (SG 1), the smaller wet mofettes (SG2 and SG3) from P1 and near the wet mofette from P2 (SG11).

Table 2. CO_2 soil concentrations in October 2022

Point	CO_2 conc. (%) 25 cm depth	CO_2 conc. (%) 50 cm depth	CO_2 conc. (%) 75 cm depth
SG1	95.6	97.1	n.d.
SG2	9.5	2.2	95.9
SG3	97.2	22	4.6
SG4	1	16.8	2.4
SG5	11.9	2.7	3.6
SG6	0.7	0.3	80
SG7	8.7	96.3	96.7
SG8	13.3	96	27
SG9	35.8	38.8	11.8
SG10	2.3	7.2	12.3
SG11	71.2	0.3	0.1

For SG1, due to water intake, the CO_2 concentration could not be measured at 75 cm depth, considering the specifics of the used equipment. For SG6 and SG7, located north of the water spring and very close to PN 1 (where large CO_2 fluxes have been measured), the increase of CO_2 concentration with depth is clear, having a normal variation in the absence of water at depth.

For SG8 and SG9, the increase of CO_2 concentration was measured at 50 cm depth, but decreased rapidly at 75 cm depth together with the water ascension. SG10, located north of the dry mofette cabin, shows an increase of CO_2 concentration with depth in the absence of water. The most drastic drop of CO_2 concentration with depth can be seen for SG11 (Figure 7), where water intake was higher than in any other point.

Figure 7. Soil gas survey using Gas Systems portable gas analyser and Durridge hardened steel probe next to a wet mofette (SG 11) in October 2022

CONCLUSIONS

During the 2022 campaign, measurements highlighted significant fluctuations in CO_2 flux, both in terms of intensity (concentration) and diffusion area. During the dry season (July-August), CO_2 emissions were relatively low. In contrast, during the wet season (October), CO_2 fluxes increased significantly.

These measurements suggest a correlation between CO_2 emissions and the water regime, with higher emission tendencies in the wet season and lower ones in the dry season. The diffusion of carbon dioxide occurs both at the level of Cretaceous aquifer complexes (a succession of sandstones, marls, and clays) and Quaternary formations, as well as in non-aquifer levels that generate dry mofettes.

Soil moisture plays an important role in how CO_2 diffuses through the soil. In wetter soils, water aids in CO_2 transfer, as moisture appears to facilitate CO_2 mobility, allowing it to migrate more easily to the surface. In wet soils (such as the marshy areas in the northern perimeter - P1), porosity is higher, enabling better CO_2 circulation. As a result, CO_2 concentrations in the soil can increase since it can migrate more easily to the surface. Conversely, in dry soils (during the dry season), porosity may be lower, restricting CO_2 mobility, which leads to the accumulation of CO_2 at deeper levels.

The arrangement of the maximum fluxes mapped, could be possibly associated with migration pathways of CO_2 in the near environment. Possible paths are distinctly highlighted on a north to south direction on the alignment of the water spring, of the therapeutic baths and on the alignment of the dry mofette cabin.

The soil gas surveys revealed a rather strange correlation of CO_2 concentration with depth. In the dry sample locations, the CO_2 concentration increased with depth. In wet locations, the water intake at 50 to 75 cm depth in soil decreased due to water intake.

The studies conducted so far showed the importance of determining the seasonal variability of CO_2 fluxes and concentrations for establishing future monitoring solutions. Apart from this seasonal variability, the hydrological regime and landscaping can play very important roles.

ACKNOWLEDGEMENTS

The research leading to these results was made within the projects PN19 20 05 03 "The study of natural CO_2 emission sites in Banat and Harghita for accession to the European ECCSEL network (Studiul siturilor cu emisii naturale de CO_2 din Banat și Harghita în vederea aderării la rețeaua europeană ECCSEL)" and PN 23 30 04 04 "Development of an environmental monitoring methodology for potential CO_2 storage sites in Romania (Dezvoltarea unei metodologii de monitorizare de mediu pentru potențialele situri de stocare de CO_2 din România)", both financed by the Ministry of Research, Innovation and Digitalization of Romania through the Core Program.
The authors would like to acknowledge and to thank for the support of town hall of Cozmeni who facilitated the access to the site and the smooth running of the campaigns.
We also thank the anonymous reviewers for all suggestions provided for improving the manuscript.

Abstract

Agricultural activities generate substantial volumes of waste and by-products annually, primarily of plant origin, which are either underutilized or not utilized at all. Through partial pyrolysis, these waste materials can be transformed into a product known as "biochar (BCH)," which has potential applications in both agriculture and innovative construction materials. This paper presents a comparative study examining the impact of BCH utilization in these two fields. Research findings demonstrated beneficial effects on soil quality and crop yield improvement. Additionally, studies conducted on cementitious composites incorporating 5-15% biochar revealed reduced density, increased open porosity, maintained mechanical strength parameters, and thermal conductivity values that suggest the possibility of developing innovative mortars with enhanced thermal resistance or suitable for manufacturing paving elements. Through this dual approach, this paper aims to highlight the potential of transforming agricultural waste into valuable materials that benefit both agriculture and the development of new, innovative, and environmentally friendly construction materials.

Key words*: agricultural sub-products, benefits for agriculture, biochar, innovative cementitious composites.*

INTRODUCTION

Globally, there is an ongoing transition from the linear economic model of "EXTRACT – PRODUCE – CONSUME – DISPOSE", now considered obsolete, to a circular model. This new approach focuses on reintegrating industrial and agricultural waste and/or by-products into the production cycle, emphasizing increased product durability and extended operational lifespans (Ricciardi et al., 2020; Kebaili et al., 2022). This transition addresses two key challenges: first, the need to find valorization solutions for the large volume of biomass generated by agricultural activities, and second, the necessity to develop new, innovative, and environmentally friendly sustainable materials and technologies to reduce the construction industry's environmental impact (Androutsopoulos et al., 2020). Using agro-industrial waste, which would otherwise be destined for landfills or incineration (Madurwar et al., 2013), presents an opportunity to prevent increased greenhouse gas emissions. The International Biochar Initiative (IBI) defines biochar (BCH) as "a solid material obtained by biomass carbonization" (Cha et al., 2016). Specifically, BCH is a sterile vegetable charcoal produced through thermochemical biomass processing – pyrolysis at 400-900ºC under limited oxygen conditions – which could address both identified challenges. BCH contains 75-90% carbon and is characterized by extremely high porosity and superior adsorption capacity. Its applications include use as an agricultural soil amendment to enhance fertility, an additive in animal feed, and a filtering medium for air, gases, and water (Chan et al., 2007).

Currently, researchers are investigating BCH's potential in developing carbon-neutral concrete, leveraging its ability to store atmospheric CO_2 (Winters et al., 2022; Gupta & Kua, 2018a; Choi et al., 2012; Zhao et al., 2019; Cuthbertson et al., 2019; Gupta & Kua, 2017).

Some research shows that the rich pore structure of BCH causes it to absorb a large amount of water during the concrete preparation stage, which it then releases during the cement hydration-hydrolysis stage. This process

promotes the secondary hydration reaction and additional hardening, thereby increasing the mechanical performance of cementitious composites (Maljaee et al., 2021; Gupta et al., 2018b; Chen et al., 2022a).

However, international research results remain controversial.

Generally, it is reported that the beneficial effect of biochar-type materials in cementitious composites is optimal at a maximum addition of 5% in the composition, with higher quantities hurting the composite's performance (Song et al., 2023).

Some studies limit the mass percentage of BCH addition in cementitious composites to 2% (Maljaee et al., 2021), while others suggest that it's possible to partially substitute up to 10% of cement with BCH while maintaining the physical-mechanical performance indicators of both the cementitious composite (Hylton et al., 2024) and cement-based agglomerated boards (Chen et al., 2022b).

Regarding the effect of using BCH in agricultural soils, studies have shown that poor nutrient content and accelerated mineralization of soil organic matter are the two major constraints currently encountered in sustainable agriculture (Zheng et al., 2010).

In recent years, there has been much evidence that BCH is not only more stable than other soil amendments but also that soil nutrient content is higher compared to the effects of other fertilizers (Lehmann & Joseph, 2009).

Numerous studies have reported improvements in water capacity and retention when a rate of 0.5% BCH was applied, modifying porosity and facilitating the formation of bonds and complexes of cations and anions with metals and elements in the soil, which improves nutrient retention capacity (Suarau et al., 2016), while reducing soil density (Mukherjee & Lal, 2013).

The increase in soil fertility also results from the fact that the basic cations contained in BCH are discharged into the soil, replacing Al and H+ and thus improving the cation exchange capacity (CEC) of the soil (Cha et al., 2016), but also through the influence on the dynamics of Soil Organic Carbon (SOC), inhibiting the degradation process and increasing the mean residence time (MRT) in which organic carbon remains in the soil, respectively, increasing the processes of stabilization and retention of SOC (Suarau et al., 2016). At the same time, studies have reported an increase, from 50% to 72%, of biological nitrogen fixation in the soil and increases in the yield of agricultural crops (Suarau et al., 2016).

A recent statistical meta-analysis of global results (Hartley et al., 2016; Zhang et al., 2016) indicates a significant positive effect on agricultural production yield, namely an increase of 12%, simultaneously showing a significant impact on soil performance indicators (Schmidt et al., 2016).

For example, an analysis carried out on the use of inorganic fertilizers in the cultivation systems of small farmers in Africa shows that they often become ineffective due to increased sensitivity to fertilizer application.

The use of BCH, alone or in combination with classical fertilizers (urea or di-ammonium phosphate), had no effects on macrofauna, such as beetles, centipedes, millipedes, termites and ants, but attracted earthworms and led to taxonomic enrichment of species as well as increased corn production yield in the first 2 growing seasons, with no subsequent significant effects in seasons 3 and 4 (Kamau et al., 2019).

Other studies (Mikajlo et al., 2024; Kammann et al., 2016) indicate that good results were obtained for soil treatment intended for lettuce growth. Thus, it is shown that BCH applied by simply spreading on the surface does not necessarily lead to an improvement in soil quality, but composted BCH, or BCH applied in a mixture with compost, can lead to 3-6 times higher growth of lettuce plants compared to untreated soil. The study also indicates more obvious results in soils with lower iron content.

Therefore, in recent years the use of BCH in agriculture has become increasingly common, as evidenced by countries such as Portugal, Spain, Germany, Austria and Switzerland (Calotescu, 2016; Zmaranda, 2019; Schmidt et al., 2016), where very large quantities of biochar are used to replace chemical fertilizers and pesticides. Countries such as Belize, Cameroon, Chile, Costa Rica, Egypt, India, Kenya, Mongolia, and Vietnam are implementing similar projects as discussed at the Biochar 2018 conference (IBI, 2018).

In this context, the purpose of this paper is to present a parallel study on the possibilities of using BCH in two apparently unrelated fields

which, in this case, have in common the possibility of implementing circular economy principles on biomass residues.

MATERIALS AND METHODS

The research methodology followed two parallel directions. Thus, on one hand, cementitious composites with BCH addition were prepared, and on the other hand, the development of three plant species was monitored: radish (*Raphanus sativus*), spinach (*Spinacia oleracea*), and garden lettuce (*Lactuca sativa*) on a plot of land located in Sălaj County, where the soil was enriched with BCH. The BCH used was obtained from vegetable waste, produced by Explocom GK through the slow pyrolysis process (temperature of 500ºC, residence time of 15 minutes) and is characterized by the following parameters: granulation 0-20 mm, pH 9, carbon content 70-76%, volatile substances content 8-19%, ash content 3-6%, and water content max. 12%. To analyze the influence of BCH addition on the performance of cementitious composites, 4 compositions were prepared: one control and three compositions with BCH addition, using Portland cement CEM I 52.5 R, water, and standardized polygranular sand (Table 1).

Table 1. Ratio of raw materials for the preparation of cementitious compositions

Sample code	Cement (g)	Ratio water/ cement	Polygranular sand (g)	BCH (% based on cement quantity)
R-M	450	0.5	860	0
R-5BCH				5
R-10BCH				10
R-15BCH				15

The indicators for quantifying the influence of BCH on the performance of cementitious composites were: density in the hardened state, according to EN 1015-10:2002+A1:2007; water absorption according to EN 1339:2004+AC:2006; compressive strength and flexural tensile strength determined according to EN 1015-11:2020; and wear resistance (EN 1339:2004+AC:2006). At the same time, an analysis of the influence of BCH on the durability of cementitious composites was carried out, namely an analysis in terms of behavior after 25 freeze-thaw cycles (EN 1339:2004+AC:2006) and 25 wet-dry cycles (a wet-dry conditioning cycle was performed by completing 8 h of air conditioning at a temperature of 21±2°C and 16 h of immersion in 3% NaCl solution at a temperature of 21±2°C). All tests were performed under laboratory conditions, on sets of 3 prismatic specimens 40x40x160 mm each, made by casting in metal molds. After casting, the samples were kept for 24 h in high humidity conditions (90%), at room temperature (23°C), then demolded, deburred, and kept under controlled temperature and humidity conditions in the climatic chamber until reaching the age of 28 days from casting. Finally, the influence of BCH on the thermal performance of cementitious composites was evaluated by following the variation of the thermal conductivity coefficient λ (W/m·K). For this purpose, 300x300x20 mm plates made by casting from cementitious composites and conditioned under conditions similar to the prismatic specimens were used. Using the hot plate method, a FOX 314 conductivity meter was used for testing at a temperature difference between the plates of 10°C, according to EN 12667:2002.

The research conducted to identify the influence of BCH on plant growth performance was carried out using soil collected from an agricultural area in Sângeorgiu de Meseș locality, Buciumi commune, Sălaj county. The soil falls into the class of clinohydromorphic black soils, with a concave appearance, having a high humus content, a dark brown to black color, and being slightly stony. This soil was prepared for planting seeds of radish (*Raphanus sativus*), spinach (*Spinacia oleracea*), and garden lettuce (*Lactuca sativa*), by adding 5%, 10%, 15%, and 20% BCH (mass percentages in relation to the amount of soil). BCH was used in the soil in combination with Bio-pyrolytic condensate - a biopyrolytic distilled product, representing a solution of organic fertilizer (pyrolinic acid - humic acid), a commercially purchased nutrient intended for use on all soil types, dosed at 1ml/l water/container, applied in odd weeks of growth. An experimental greenhouse-type stand was built in which containers with a capacity of 1l were placed, 3 for each type of plant and each type of soil sample, with a set of 3 containers for each type of plant being filled with soil without the addition of BCH and considered as control. In each container, purchased commercially, 5 seeds of the same type were planted and watered

with 100 ml of water. Subsequently, at equal intervals of 2 days, each sample was watered with 50 ml of water, continuously monitoring the temperature in the greenhouse, which was kept constant at 25±2ºC, and the degree of sunlight was ensured equally for all samples by their location. Plant growth monitoring was carried out for 9 weeks from planting until they reached a degree of development that no longer allowed cultivation in the containers used. The quantifiable monitoring indicator was the height of the plants, measured using a graduated ruler with a minimum division of 1 mm, reporting average values of all plants of a species developed in the 3 pots with the same type of soil. The samples were assigned codes (Table 2).

Table 2. Sample coding system for plants grown with different BCH concentrations

	BCH 0%	BCH 5%	BCH 10%	BCH 15%	BCH 20%
Radish	CR	R5	R10	R15	R20
Spinach	CS	S5	S10	S15	S20
Garden lettuce	CSV	SV5	SV10	SV15	SV20

RESULTS AND DISCUSSIONS

Regarding the influence of BCH addition on the performance indicators of cementitious composites, the experimental results indicate a progressive reduction in apparent density, with an increase in the amount of BCH, by 4.8%-5.8% compared to the control sample.
Based on these results, a first benefit of using BCH can be identified: reducing the mortar density (Figure 1) therefore, in the case of its use as a construction material, reducing the load on the construction's resistance structure.

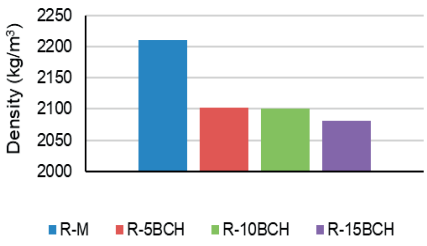

Figure 1. Hardened bulk density of cementitious composites

Regarding water absorption (Figure 2), the results indicate increases in this indicator following the addition of BCH, without being able to identify a direct correlation with the amount of BCH added to the composite.

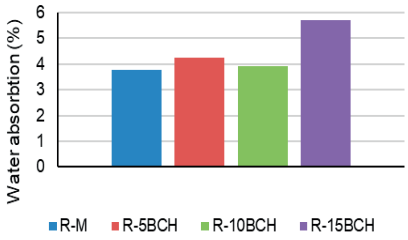

Figure 2. Water absorption of cementitious composites

However, correlating this information with the variation of apparent density in the hardened state, it can be concluded that both directions provide indications leading to the hypothesis of increased open porosity in mortars with the introduction of BCH in the composition.
On the other hand, correlating the experimentally obtained results with the references in standards EN 1338, EN 1339, and EN 1340, which indicate a maximum water absorption of 6% for prefabricated elements such as tiles, pavers, and curbs, it can be noted that, from this point of view, the analyzed mortars successfully satisfy the condition of resistance and durability to climatic factors required for use in the production of such elements.
These results correlate with the literature which indicates the possibility of increasing the total water absorption by up to 28% compared to the control samples (Song et al., 2023).
From the point of view of BCH addition's influence on the mechanical strengths of cementitious composites (Figure 3) the results indicate reductions of 30-40% in tensile bending strength (from 10.4 N/mm² to min. 6.2 N/mm²), and 26-47% in compressive strength (from 71.3 N/mm² to min. 37.9 N/mm²), while maintaining sufficient performance to be classified as M35 or M50 masonry mortars according to EN 998-2 specifications.
Comparing the experimental results with other findings reported in the literature (30-50 N/mm²) (Roychand et al., 2023), it can be said that they are consistent, with some cases where the compressive strength of the laboratory-tested cementitious composite is even better.

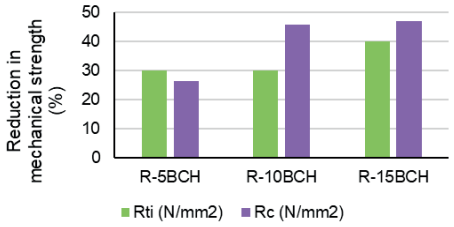

Figure 3. Reduction in mechanical strength of cementitious composites with BCH, compared to the control sample

Although negative influences of BCH addition on mechanical strength are identified under laboratory conditions when cementitious composites are subjected to freeze-thaw cycles (Figure 4), a first beneficial effect is observed: the reduction in mechanical strength following freeze-thaw action occurs only in the control composition, while composites with BCH show slight increases in strength indicators. This behavior suggests the possibility of improving the durability of cementitious composites through BCH addition.

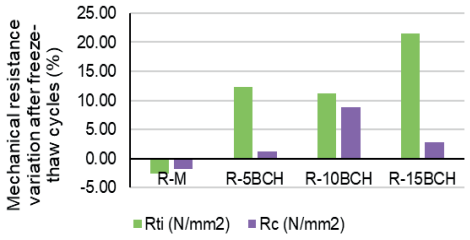

Figure 4. Increase in mechanical strength of control and BCH cementitious composites after 25 freeze-thaw cycles

Similarly, the action of wet-dry alternation cycles combined with the action of chlorine ions in the immersion phase (wet), leads to a reduction in mechanical strength only for the control composition, supporting the possibility of improving durability by using BCH (Figure 5).
According to the literature (Chen et al., 2023), a possible explanation for this phenomenon could be found as a result of several processes that occur when BCH is introduced into the composite matrix:
- the incorporation of biochar into the cementitious composite improves the pore structure, dimensions, and distribution, which leads to a reduction in capillary porosity. At the same time, the macropore structure becomes more independent, providing more space for frozen water (this being the main factor that induces internal stresses in the composite matrix upon freezing), thus reducing the internal stresses in the freezing phase and the loss of mechanical strength (Gupta et al., 2020; Jia et al., 2023; Qin et al., 2016);

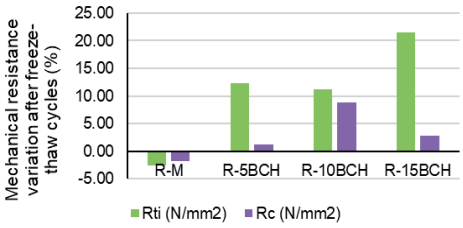

Figure 5. Increase in mechanical strength of control and BCH cementitious composites after 25 wet-dry cycles

- on the other hand, the porous structure of BCH can store and, when necessary, slowly release an amount of water necessary to reduce the self-shrinkage of the cement paste, promoting the hydration reactions of the partially or unreacted cement granules, densifying the material and thus improving long-term properties and durability (Mo et al., 2019). Additionally, it has been shown that the BCH-cement paste transition zone (ITZ) can be superior to that characteristic of sand particles, which increases the yield of hydration product formation (Mrad & Chehab, 2019);
- at the same time, studies have shown that the incorporation of BCH into the composite matrix strongly contributes to increasing the possibilities of storing CO_2 and forming stable calcium carbonate precipitates through rapid reaction with the main compounds of non-hydrated cement, tricalcium silicate (C_3S) and calcium hydrogen silicate (C-S-H) inside the cement matrix, while promoting the process through its function as a nucleating agent. Subsequently, through the precipitation of calcium carbonate, BCH will cause the filling of pores and the reduction of the carbonation depth (Liu et al., 2022), a similar effect being probably possible on the penetration of liquids in the freeze-thaw or wet-dry process in the presence of chloride. This CO_2 absorption capability could also improve indoor air quality, as recent

studies have shown that CO2 levels in multifamily buildings often exceed recommended thresholds for a health-safe indoor environment (Magurean & Petran, 2023). The mass loss due to abrasion stresses is reduced by modifying the mortar composition as a result of the addition of organic waste subjected to thermal treatments (mass loss of 13.6-17.2% for samples with BCH, compared to 19.6% for the control sample). However, given that the addition of organic waste subjected to thermal treatments results in a reduction in the density of the material, it is considered that this indicator is inconclusive and could lead to an erroneous conclusion indicating an increase in wear resistance. Therefore, two other indicators were analyzed: the height loss of the sample and its volume loss (Figure 6).

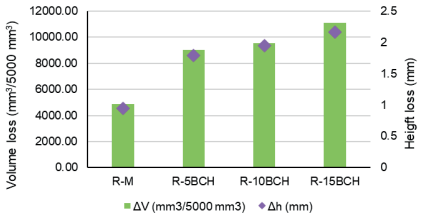

Figure 6. Height/volume loss of specimens subjected to abrasion stress

It is thus demonstrated that with the addition of BCH, the wear resistance of the mortars decreases, increasing the height losses and volume losses of the specimens. However, analyzing the experimentally obtained results in correlation with the series of standards EN 1338, EN 1339, and EN 1340, specific to prefabricated elements such as tiles, pavers, and curbs, it can be said that mortars with the addition of BCH meet the acceptability criteria in terms of wear resistance, with maximum height and volume loss limits being 2 mm and 11080 mm^3 / 5000 mm^3, respectively.

It should be noted that the specialized literature restricts the amount of heat-treated organic waste to 1-2%, a maximum 5% mass percentage, and the tests carried out addressed substantially larger amounts of used waste. This approach, assuming the risk of reducing some physical-mechanical performance indicators, allowed demonstrating the achievement of the acceptability criteria specific to a specified field of use, in this case, masonry mortars or compositions intended for the manufacture of paving elements. At the same time, corroborating the indicators relating to the apparent density and water absorption that lead to an increasing porosity with the addition of BCH, with the thermal conductivity coefficient (Figure 7), it is appreciated that the addition of BCH contributes to improving the thermal performance of the composites. Thus, a possibility is foreseen to produce cementitious composites similar to adhesive mortars intended for the production of ETICS thermal insulation systems whose thermal conductivity coefficient generally falls within the range of 0.08-0.11 W/mK. At the same time, for cementitious composites containing BCH, the mechanical strength indicators support this possibility of defining a field of use in the area of adhesive mortars intended for the creation of ETICS thermal insulation systems.

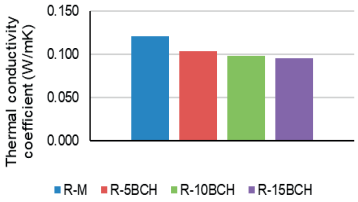

Figure 7. Thermal conductivity of cementitious composites

Regarding the results of the program analyzing the influence of BCH on plant growth, several key elements were highlighted. After the first week following seed planting (Figure 8), it was observed that the control containers showed a germination rate of 60% (3 shoots out of 5 seeds), while in containers with BCH-enriched soil, the germination rate was 80-100% (4-5 shoots out of 5 seeds).

Figure 8. Plant development - week 1

During the 9 weeks of monitoring, more accelerated plant development was recorded, regardless of plant type, in the soil enriched with BCH (Figures 9-11).

Figure 9. Plant development - week 5

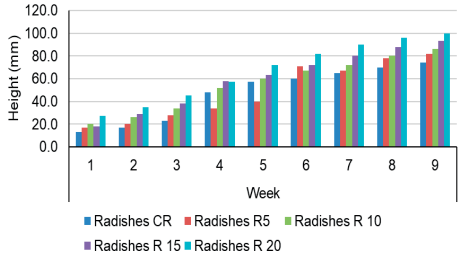

Figure 10. Plant development - week 9

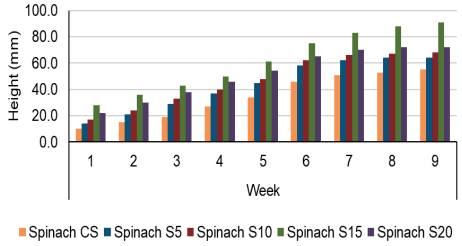
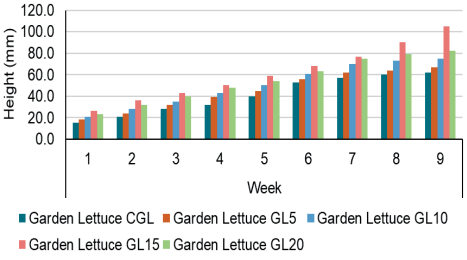


Compared to the control sample, radishes showed a 6-fold more intense growth after 9 weeks with just 5% BCH addition, and for additions of 10-20% BCH in the soil, the height increase was 16.2%, 25.7%, and 35.1% more intense.

In the case of spinach, a Gaussian evolution of the benefit was observed, quantified by the increase in plant height. In the range of 5-15% BCH addition to the soil, after 9 weeks, compared to the control, the plants were taller by 16.4%, 23.6%, and 65.5%, respectively, while for soil with 20% BCH, this indicator was 30.9%. This Gaussian evolution was maintained throughout all weekly measurements, indicating that a 20% BCH addition to the soil is not beneficial, with the limit in the analyzed case being 15% BCH.



A similar evolution to spinach development was also recorded in lettuce plants. For 5-15% BCH, the plant heights were 8.1%, 21%, and 69.4% higher compared to the control after 9 weeks, while for soil with 20% BCH, this indicator was 32.3% higher compared to the control. Again, this Gaussian-type evolution was maintained throughout all 9 weeks, similarly indicating a limitation of 15% for BCH addition to the soil.

Figure 11. Evolution of plant height during the 9 weeks of analysis, based on the amount of BCH used: a) radishes (R); b) spinach (S); c) garden lettuce

Similar results were also obtained by Goldan E. and Nedefe V. (Goldan & Nedeff, 2020) in their experimental research on winter barley plants in open fields.

CONCLUSIONS

The purpose of this study was to analyze, in parallel, possible directions for using plant waste treated by partial pyrolysis, specifically a biochar-type product, in two independent fields: construction materials and agriculture. Based on the experimental results presented, regarding the

influence of BCH addition in cementitious composites, the following can be stated:
- reductions in apparent density in the hardened state were recorded simultaneously with increases in water absorption, which could be considered indicators suggesting an increase in open porosity. Additionally, reductions in mechanical resistance to compressive, flexural, and abrasion stresses were recorded. However, by correlating the obtained results with the specific conformity indicators for tiles, pavers, and curbs specified in the product standards EN 1338, EN 1339 and EN 1340, a preliminary direction for identifying the field of use can be determined, as cementitious composites with BCH addition satisfy these criteria;
- analyzing the durability indicators, namely the loss of mechanical resistance following exposure to freeze-thaw cycles and wet-dry cycles under the action of chlorine ions, the experimental results indicate a performance improvement. More specifically, mechanical resistance increases in cementitious composites with BCH addition, unlike the control sample whose mechanical performance is, as expected, reduced following exposure to the test cycles. Possible explanations can be found in the scientific literature, which identifies a significant influence of BCH on the porosity of cementitious composites, on the hydration-hydrolysis mechanism of cement granules, on the structure of the interfacial transition zone (ITZ) between the cement paste and BCH granules, and the potential for CO_2 storage and formation of stable calcium carbonate precipitate. This precipitate forms through rapid reaction with the main compounds of non-hydrated cement and could fill the pores or even the microcracks that appeared during the stress period of the test cycles;
- regarding the influence of BCH on the thermal conductivity coefficient, this indicator showed improvement compared to the control sample, which, correlated with the reduction in apparent density and sufficient mechanical resistance, can support the identification of a new research direction, namely, the development of adhesive mortars intended for ETICS thermal insulation systems of building facades.

Therefore, although the literature restricts the amount of heat-treated organic waste to 1-2%, with a maximum of 5% mass percentage, the tests carried out addressed substantially larger amounts of waste. This approach, while assuming the risk of reducing some physical-mechanical performance indicators, allowed the demonstration of achieving acceptability criteria specific to a particular field of use, in this case, masonry mortars, compositions intended for the manufacture of paving elements, or even adhesive mortars specific to ETICS thermal insulation systems.

Based on the experimental results presented, regarding the influence of BCH addition to agricultural soil, a positive influence was also identified on the development of some food consumption plants: radish (*Raphanus sativus*), spinach (*Spinacia oleracea*), and garden lettuce (*Lactuca sativa*). The experimental results indicated an increase in germination rate from 60% recorded for the control samples to 80-100% recorded for the soil samples with BCH addition. Additionally, more accelerated plant development was recorded, regardless of plant type, in the soil enriched with BCH, noting that, for the same development time interval, the evolution of plant height depending on the amount of BCH used in the soil can be Gaussian-type, depending on the cultivated plant type. Overall, a maximum limit of 15% BCH amount is recorded, exceeding it (samples with 20% BCH) may lead to reduced benefits in terms of plant development (spinach and lettuce).

In conclusion, based on the experimental results, in addition to several benefits that prove the possibility of valorizing plant waste and using BCH in construction and agriculture, several future research directions can be identified:
- analysis of the influence of introducing BCH into cementitious composite matrices not as an addition but as a raw material substitute;
- identification of maximum acceptable limits for BCH use in cementitious composites, depending on the expected field of use;
- identification of correlations between soil nature and characteristics, plant type, and optimal BCH amount used to obtain maximum benefits.

Abstract

Urban air pollution poses significant public health risks, with airborne microorganisms contributing to air quality concerns and respiratory illnesses. This study investigates the distribution of airborne microflora using a six-stage cascade impactor. Samples were collected from three urban hotspots, three park areas, and a natural control site in Sofia, Bulgaria. Microbial counts were analyzed across six particle size fractions to determine spatial distribution patterns. Hotspots showed significantly higher microbial loads, especially in larger particle fractions (>7 µm, 4.7- 7 µm), whereas densely forested green areas exhibited lower microbial levels with a shift toward finer fractions (2.1- 3.3 µm, 1.1-2.1 µm). Parks with minimal vegetation showed microbial patterns similar to hotspots. These findings underscore the role of urban vegetation in mitigating microbial air pollution and highlight the importance of incorporating forested green spaces into urban planning to enhance air quality and public health.

Key words*: air microorganisms, air microflora, cascade impactor, green zone, hotspots.*

INTRODUCTION

Clean air is essential for human and environmental health. Urbanization and anthropogenic activities have significantly degraded air quality, with particulate matter (PM) serving as an indicator of complex pollutant mixtures. Recent studies suggest a correlation between PM levels and airborne microbial content (Mansour et al., 2014; Palladino et al., 2021). Historically, air quality studies focused on inorganic contaminants due to their abundance; however, interest in organic components, including airborne microbial biota, has grown (Friedlander et al., 2000).

Airborne microorganisms - including bacteria, micromycetes, actinomycetes, and viruses - can remain suspended either freely or attached to dust particles (Stetzenbach, 2009; Lighthart, 1997). Larger dust particles tend to harbor more microorganisms (Meklin et al., 2002). Research conducted by Tignat-Perrier et al. (2019) has shown that airborne microbial communities are influenced by ecosystem types and meteorological conditions. Their concentrations vary with air pollution levels, influenced by factors such as dust storms, fog, biomass burning, and traffic emissions. Seasonal and diurnal patterns in bioaerosol levels often reflect human activity, and studies have found correlations between microbial concentrations and the Air Quality Index (AQI). Shammi et al. (2021) observed distinct seasonal and diurnal variations in bioaerosol concentrations that closely reflect patterns of human activity in densely populated urban areas. Similarly, Yan et al. (2019) reported a strong correlation between bacterial and micromycete concentrations and the Air Quality Index (AQI). Their findings indicated that micromycete concentrations gradually increased when the AQI was below 200, whereas bacterial concentrations rose when the AQI exceeded 200. However, the mechanisms underlying the increase in bioaerosols - particularly aerophilic microorganisms - in response to air pollution remain unclear. One hypothesis is that elevated or extreme pollution levels primarily influence the diversity and composition of airborne microbial communities (Fan et al., 2019). The viability of microorganisms within bioaerosols depends on various environmental factors, including climate and atmospheric chemistry (Gong et al., 2020). Consequently, understanding the microbiological structure and composition of particulate matter is essential for identifying potential disease transmission pathways and assessing risks to human health (Wang et al., 2019).

The primary objective of this study is to examine the dynamics of airborne microflora across three urban hotspots and three park areas in Sofia,

Bulgaria, along with one control site located in the Vitosha Mountain. Specifically, the study quantifies the total number of airborne microorganisms in each sample and assesses their distribution across six particle size fractions, as determined by a cascade impactor.

MATERIALS AND METHODS

The study was conducted in early November 2024 at various locations in Sofia, Bulgaria, and the Vitosha Mountain region. Three urban park areas, their adjacent hotspots, and one site in Vitosha Mountain were selected to compare the composition of airborne microorganisms across different environments. The Vitosha Mountain site was chosen based on Kadinov's research, which highlighted its exposure to anthropogenic pollution - particularly during summer, when slope winds transport pollutants from Sofia (Kadinov, 2021a). However, Kadinov (2019) also reported that the fine dust in Vitosha originates mainly from background sources, with less than 1% attributed to Sofia, and that particulate matter (PM) deposition remains below critical levels. Seasonal PM trends show summer peaks in Vitosha Mountain, in contrast to the winter peaks observed in Sofia (Kadinov, 2021b).

The sampling sites included:

- TA1: Borisova Gradina – green area; coordinates: 42°41′15″N, 23°20′16″E
- TA2: Orlov Most intersection – hotspot; coordinates: 42°41′23″N, 23°20′17″E
- TA3: Voenna Academia Park – green area; coordinates: 42°41′30″N, 23°20′42″E
- TA4: Voenna Academia intersection – hotspot; coordinates: 42°41′33″N, 23°20′39″E
- TA5: Studentski Grad Park – green area; coordinates: 42°39′09″N, 23°21′09″E
- TA6: 8 Dekemvri St. and Rosario St. intersection – hotspot; coordinates: 42°39′06″N, 23°21′16″E
- TA7: Vitosha Mountain – nature park; coordinates: 42°36′34″N, 23°19′34″E

The geographic distribution of all sampling locations is illustrated in Figure 1, providing a visual overview of the selected green areas, urban hotspots, and the control site in Vitosha Mountain.

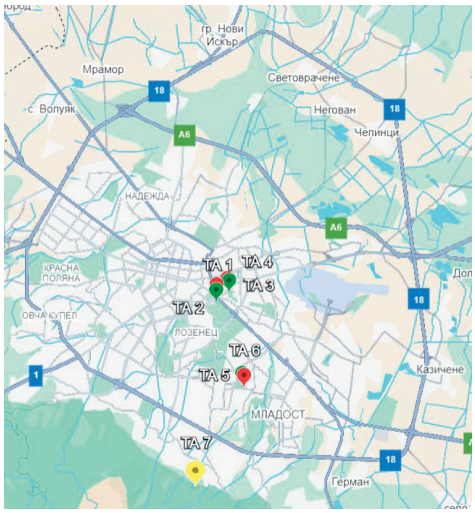

Figure 1. Map of the sampling locations

Air microflora sampling and analysis

Airborne microbial abundance was analyzed using a six-stage cascade impactor, which separates particles by aerodynamic diameter as follows:

- Stage 1: > 7 µm;
- Stage 2: 4.7-7 µm;
- Stage 3: 3.3-4.7 µm;
- Stage 4: 2.1-3.3 µm;
- Stage 5: 1.1-2.1 µm;
- Stage 6: 0.65-1.1 µm.

Petri dishes with appropriate nutrient media were placed on each stage. One cubic meter of air passed through the impactor at a constant flow rate. The microorganisms collected on each plate were then cultured and counted.

Microbial cultivation and identification

Microbial colonies were cultured under controlled conditions using the following nutrient media:

- Meat-Peptone Agar (MPA): bacterial growth at 28°C for 48 hours.
- Starch-Ammonia Agar (SAA): bacterial growth at 28°C for 10 days.
- Czapek Dox Agar Medium: fungal growth at 28°C for 7 days.

Sampling conditions and data processing

Sampling was conducted on a dry day following five consecutive precipitation-free days to minimize the influence of weather on airborne microbial concentrations.

Average atmospheric conditions during sampling:

- temperature: 4°C;
- relative humidity: 92%;
- atmospheric pressure: 1009 millibars;
- wind speed: 9 km/h (southwest direction).

Statistical analysis of the microbiological data was performed using StatSoft Statistica 12. Results are presented as the means of three replicates with corresponding standard deviations. A 95% confidence level was used to determine statistical significance.

RESULTS AND DISCUSSIONS

The results of the experiments are presented in colony-forming units (CFU) × 10²/m³. The total levels of airborne microorganisms are shown in Figure 2, while Figure 3 illustrates the distribution of microorganisms across the different stages of the cascade impactor. Unlike our previous studies (Peshev et al., 2024), the current study revealed that not all green areas exhibited lower microbial loads compared to their adjacent hotspots.

Table 1 provides a summary of microbial abundance across various particle size fractions for each location. The overall microbial load observed in this study is notably lower than that reported in studies conducted during the winter season. This difference is likely related to the increased concentration of fine particulate matter (PM) in winter. As Azis et al. (2018) noted, fine PM serves as a core for the accumulation of airborne microorganisms. Accordingly, microbial levels are expected to increase during the winter months, driven by increased PM concentrations due to the continued widespread use of solid fuels for heating in Sofia.

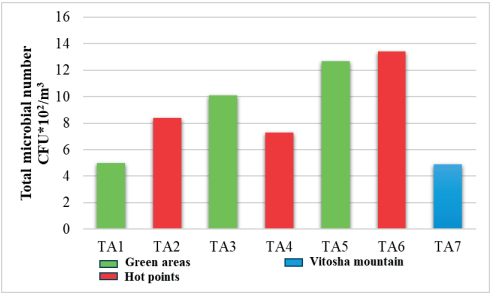

Figure 2. Total number of airborne microorganisms (CFU × 10²/m³) measured across all sampling sites

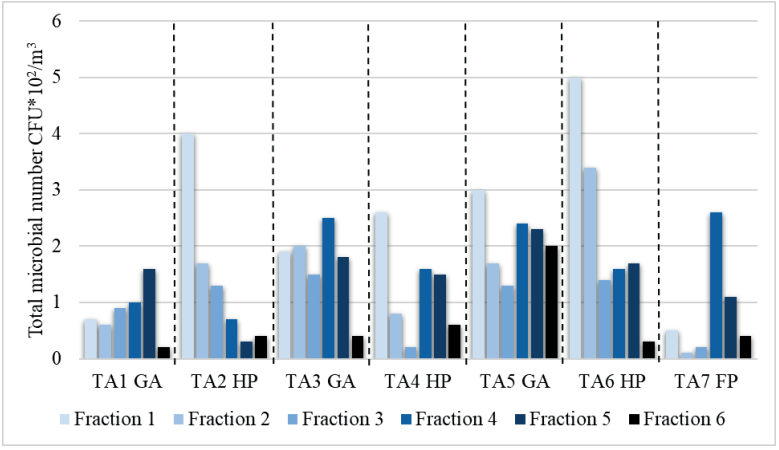

Figure 3. Total microbial number of airborne microorganisms from each of the stage of air Separator

According to the World Health Organization (WHO), air pollution is the greatest environmental health risk globally, affecting both developed and developing countries (WHO, 2017). However, no current WHO guideline specifically addresses the health impacts of airborne microorganisms in outdoor environments. Most WHO documentation on air quality and respiratory health focuses on non-organic hazards such as ozone, carbon dioxide, and fine particulate matter.

Table 1. Microbial abundance at different sites (CFU $\times 10^2/m^3$)

Location	Microbial count (CFU x $10^2/m^3$)	Dominant particle size fraction	Observations
Hotspot (TA2-Orlov most)	8.4 ± 3.25	>7 µm, 4.7-7 µm	Hight traffic, PM accumulation
Hotspot (TA4-Voenna Academia	7.3 ± 3.25	>7 µm, 4.7-7 µm	Hight vehicle emissions
Hotspot (TA6 – Studentski grad	13.4 ± 3.25	>7 µm	Construction activities contributing to PM
Green Area (TA1 – Borisova Gradina)	5.0 ± 3.92	2.1-3.3 µm, 1.1-2.1 µm	Dense tree cover, reduce PM levels
Green Area (TA3 – Voenna Academia Park	10.1 ± 3.92	3.3-4.7 µm, 2.1-3.3 µm	Lower elevation, direct PM exposure from traffic
Green area (TA5 – Studentski grad Par)	13.4 ± 3.92	> 7 µm, 4.7-7 µm	Minimal tree cover, resembling hotspots
Vitosha mountain – Nature Park	4.9	2.1-3.3 µm, 1.1-2.1 µm	Nature forest, the lowest load with microorganisms

When microorganisms are considered, the emphasis is typically on indoor air quality. Nevertheless, the 2021 WHO guidelines on particulate matter acknowledge the importance of analyzing the effects of organic aerosols on human health, alongside combustion particles and secondary inorganic aerosols (WHO, 2021). Many studies highlight the role of green spaces in mitigating air pollution (Givoni, 1991; Cohen et al., 2014). Chiesura (2004) found that urban parks improve air quality, particularly in large cities, while Dadvand et al. (2023) documented the positive health effects of tree vegetation.

Our study clearly shows that the location and forest cover of park areas matter.

Our study clearly demonstrates that both the location and forest cover of park areas significantly influence airborne microbial levels. TA1 – Borisova Gradina, one of the largest parks in Sofia with dense tree and shrub vegetation, recorded the lowest levels of airborne microorganisms. These findings are consistent with previous research (Mhuireach et al., 2016). The timing of the sampling - late autumn - likely contributed to these results, as trees retained a substantial portion of their leaf mass, aiding in particle filtration.

Interestingly, TA3, another green area, showed higher microbial concentrations than its adjacent hotspot, TA4. This discrepancy underscores the importance of both vegetation and location. TA3 is situated at a lower elevation than the nearby boulevard, making it more susceptible to direct dust and PM exposure from traffic. This highlights the need for careful urban planning that incorporates principles of "Environmental Hygiene". As Robinson et al. (2019) suggest, expanding research in this area is vital given the growing recognition of urban green spaces as essential to public health.

The data for TA5 further emphasizes the importance of vegetation type. This green area, dominated by grass with minimal tree cover, exhibited microbial levels comparable to its nearby hotspot, TA6. These findings, supported by the trends in Figure 2, suggest that grassland-type parks do not effectively reduce PM or associated microbial loads.

In hotspots, microorganisms were primarily concentrated in the upper stages of the cascade impactor (Stage 1: >7 µm; Stage 2: 4.7-7 µm), indicating association with larger PM particles. In contrast, green areas with substantial woody vegetation exhibited a greater concentration of microorganisms in the finer particle stages. TA5 again deviated from this trend due to its lack of trees, resulting in microbial distributions more similar to those observed in hotspots.

Moreover, notable differences in microbial loads among hotspots were observed. TA2, despite being one of the busiest intersections in Sofia, had lower microbial concentrations than TA6, a residential neighbourhood. This can be attributed to the influence of wind and air mass

movement. Additionally, ongoing excavation work in the TA6 area at the time of sampling likely increased dust levels, contributing to higher microbial counts. These findings support the conclusion that construction and renovation activities significantly deteriorate ambient air quality by increasing both PM and microbial content.

Our study reinforces the need for more urban green spaces that mimic natural forests, rather than purely aesthetic, meadow-type landscapes. Tree vegetation, even with reduced leaf mass during autumn, remains effective in capturing particulate matter and the microorganisms it carries. In hotspots, microbial concentrations were highest in the coarser PM fractions, whereas in green areas with tree cover, microorganisms were more prevalent in finer fractions (Stages 4 and 5). The control site in Vitosha Mountain demonstrated the lowest microbial levels, comparable only to Borisova Gradina, further affirming the role of dense forest vegetation in limiting airborne microflora.

CONCLUSIONS

The main objective of this study was to conduct a preliminary analysis of airborne microbial abundance across selected urban and natural locations and to assess the distribution of microorganisms in relation to different particulate matter (PM) size fractions. The results revealed that green areas do not always exhibit lower microbial loads than their adjacent urban hotspots. This variation is largely influenced by the type of vegetation cover and the specific location of the green spaces.

Park areas dominated by grass and with limited woody vegetation displayed microbial patterns similar to nearby high-traffic zones. In contrast, parks with dense tree covers showed a more favorable profile, with lower microbial concentrations. Additionally, areas with strong air mixing due to moving air masses demonstrated a reduction in microbial presence, even in busy hotspots.

Our findings suggest that both busy intersections and green spaces situated near active construction or renovation zones should be approached with caution, as they pose elevated health risks due to increased microbial and particulate loads. In hotspots and grass-dominated green areas, microorganisms were mainly associated with larger PM fractions. Conversely, in tree-rich parks, microbial abundance shifted toward finer particle fractions.

These insights underscore the importance of integrating principles of "Environmental Hygiene" into urban planning. Efforts should focus on minimizing particulate and microbial exposure to improve respiratory health among urban populations. This study provides a foundation for further research and can inform the development of detailed urban design strategies aimed at optimizing air quality and public health outcomes.

ACKNOWLEDGEMENTS

This research work was carried out with the support of Research Fund of Ministry of Education and Science in Bulgaria, project №: КП-06-Н74/5 „Relationships between the amount of fine particulate matter and airborne microorganisms in "hot spots", park areas, urban background areas and control forest areas''.

Abstract

One of the key challenges associated with traditional buildings constructed from vernacular materials is their response to climatic agents and microorganisms. These present a significant challenge also for the surface of constructions based on unbaked clay elements. This paper presents the possibility of creating plasters based on clay, lime and other additives, their behaviour in response to mould growth, and the potential for coating treatments to enhance their resistance to the harmful action of microorganisms. The antifungal treatment was conducted with the objective of exploring the potential for recycling expired non-food household and medical products. The experimental results indicated the initial development of colonies of Penicillium notatum and Aspergillus niger and subsequently demonstrated the potential for enhancing resistance to mould action through pellicular treatment and/or surface impregnation. It can therefore be concluded that not only is it possible to create clay-based plasters with enhanced performance, but also that this represents an original contribution to the implementation of the concept of the circular economy.

Key words*: antifungal treatment, circular economy, clay soil, plaster mortar, vernacular constructions.*

INTRODUCTION

Vernacular architecture is a foundational model for contemporary energy-efficient construction, given its capacity to adapt to local microclimates and environmental conditions. Recent studies have demonstrated its exceptional energy conservation performance, often exceeding initial scholarly assumptions (Abdelrazek & Yılmaz, 2020; Martinovic et al., 2023). In Romania, earth-based constructions, primarily adobe and wattle-and-daub, account for approximately 32.9% of buildings nationwide, predominantly as single-story structures built before 1992, with a higher prevalence in lowland counties where timber resources are less abundant compared to hilly and mountainous areas (INCD URBAN-INCERC). Structures built with unfired loamy soil represent some of the earliest forms of building technology. A variety of construction techniques have been utilised across the globe over time, including the construction of rammed earth walls, cob walls, and walls constructed from naturally dried unfired clay bricks. These techniques have been preserved and continue to be employed in various regions, exhibiting regional variations influenced by local resources and traditional building practices. These constructions present numerous advantages: they contribute to a healthy indoor environment by maintaining thermal stability and consistent humidity levels, while emitting no toxic substances - a critical factor in reducing the risk of respiratory diseases and allergies, they are cost-effective to construct, require minimal specialist labour, have a low environmental impact due to the limited use of raw materials, integrate harmoniously with local architectural traditions, and have a minimal impact on the surrounding landscape. These specific elements have the capacity to exert a considerable influence on the enhancement of hygiene and health standards for occupants, whilst

concurrently effecting the mitigation of energy consumption and pollutant emissions. This, in turn, results in a contribution to environmental sustainability (Androutsopoulos et al., 2020; Măgurean & Petran, 2023). There are many studies in the literature that demonstrate the benefits of building with clay using indigenous techniques in different geographical and climatic conditions (Minke, 2006; Bui, 2009a Ciurileanu & Bucur, 2011). However, the main challenge with these constructions is the high risk of cracking during the drying process and their low resistance to water and weathering, which often requires frequent surface repairs and maintenance (Vural et al., 2007; Bui et al., 2009a; Kiroff & Roedel, 2010;). The scientific literature indicates that clay soils used for earthworks must contain a minimum of 15-16% clay to ensure the plasticity and workability required for proper handling (Vural et al., 2007; Kiroff & Roedel, 2010). In addition, to effectively control the risk of cracking, the acceptable linear shrinkage should be in the range of 3-12% for soft mixes and 0.4-2% for drier mixes (Minke, 2006; Jayasinghe & Kamaladasa, 2007). A variety of organic or inorganic additives of plant, animal or industrial origin may be used to achieve these indicators (Bahobail, 2012). However, increasing the resistance of the exposed surface to climatic or biological factors remains a challenge, although these additives can significantly improve the bulk performance of the clay composite. Research aimed at identifying surface treatment solutions for clay surfaces has been reported in the literature, with some researchers analysing the possibility of developing sol-gel solutions based on TiO_2 (Calabria et al., 2010) while others have focused their attention on more traditional solutions, such as natural oil-based waterproofing agents of vegetable or animal origin, sodium silicate, silicon nanoparticles, titanium dioxide, silica nanoparticles, silane-siloxane, beeswax, ethyl silicate, organic polymer products, lime-based paints and others (Ferron, 2007; Li et al., 2009; Ferron & Matero, 2011; Pacheco et al., 2016; Stazi et al., 2016; Lanzón et al., 2017; Camerini et al., 2019; Elert et al., 2019; Rescic et al., 2023**)**.

On the other hand, the cosmetics, pharmaceuticals and other non-food household products industries are experiencing rapid growth in correlation with the demands of modern society. The cosmetics market tends to grow year on year, making it the third fastest growing market, with the global beauty and self-care industry estimated to be worth USD 341 billion in 2020, USD 565 billion in 2022, USD 758 billion in 2025 and USD 480.4 billion in 2030 (Nciri et al., 2022; Morganti et al., 2023). It is therefore of interest to find solutions for the recovery and recycling of expired non-food household products, cosmetics, pharmaceuticals, various aromatic oils, etc., so that they no longer pose a pollution risk when disposed of in sewers or landfills (Juliano & Magrini, 2017; Cinelli et al., 2019; Bashir et al., 2021; Silletta et al., 2024**)**. Research has shown that, in addition to specific functional ingredients, cosmetic products, for example, are rich in phenolic compounds, flavonoids and organic acids known for their antimicrobial properties, preservatives and bioactive molecules for the treatment of skin conditions (such as dermatitis, atopic eczema, atopic dermatitis or acne) (Varvaresou et al., 2009; Houston et al., 2017; Halla et al., 2018; Hamrita et al., 2022; Sandle, 2022).

A distinctive attribute of cosmetic products is the homogeneity of their component formulations, which is characterised by minimal variation in size, extending down to the nanometric level, even for mineral-derived products (Silletta et al., 2024).

The utilisation of non-food household products in the domain of construction has been documented in the extant literature. For instance, a group of researchers from the Department of Civil Engineering, PVPIT Budhgaon, Maharashtra, India (Patil et al., 2021) demonstrated the potential use of an aqueous soap solution to induce a high volume of pores in the cementitious matrix, enabling the production of concrete with a density lower than 1000 kg/m³, commonly referred to as "floating concrete". Moreover, other studies have emphasised the advantageous properties of soap, along with soap precursors such as oils or fats, in enhancing the performance of unfired clay bricks, particularly in terms of their resistance to water (Browne, 2009; Bahobail, 2012).

A group of researchers from Korea University of Technology & Education (Nciri et al., 2022)

demonstrated that cosmetic waste can be integrated into the creation of green, sustainable road pavements. Specifically, the incorporation of cosmetic waste, such as lipstick (completely soluble at temperatures above 50ºC) or other cosmetic products containing oils, fats, emulsifiers, wax, fillers, mica, silicon, titanium oxide, or zinc oxide, into asphalt mixtures can act as additive materials that improve rheological properties, viscosity, and elasticity. This contributes to reducing fatigue-induced cracking, enhancing aging resistance, and improving durability, including through the influence of crystallization/hardening mechanisms.

This exploratory study aims to assess the potential reuse of expired cosmetic-pharmaceutical products for protecting clay surfaces against mould growth, which can act as a trigger for allergies. While the permeability of these compounds through clay materials represents an important consideration that may affect treatment effectiveness and durability, this initial investigation focuses on surface application effects. The method employed for repurposing these expired products involved their integration as functional additive raw materials in formulations designed for surface application, resulting in a protective coating with increased resistance to microbial activity. It is important to note that the scope of this research does not extend to evaluating the potential health implications associated with the utilisation of these products for construction purposes beyond the specified scope, nor does it include in-depth analysis of treatment permeability through the clay matrix - aspects that deserve further investigation in future studies. Therefore, the aim of the present study is to analyse the feasibility of recycling non-food household waste (namely cosmetic-pharmaceutical products) through the development of a protective and finishing coating aimed at enhancing the resistance of unfired clay construction surfaces to biological agents.

MATERIALS AND METHODS

The raw materials utilised in the fabrication of clay-based plaster mortar composites for the protection and finishing of vernacular construction surfaces comprised the following: clay soil (named "clay") extracted from Valea Drăganului, Cluj-Napoca, Romania, hydraulic lime with the commercial designation RÖFIX NHL5, with an apparent density of 520 kg/m³ and a minimum compressive strength of 5 N/mm², river sand with a maximum grain size of 4 mm, and water.

To characterise the clay that was utilised in this study, an XRF analysis was conducted (Table 1).

Table 1. The oxide composition of the clay, determined through XRF analysis

Oxides	SiO_2	Al_2O_3	Fe_2O_3	CaO
Content [%]	74.17	12.74	4.38	0.7
Oxides	MgO	K_2O	Na_2O	TiO_2
Content [%]	1.0	1.43	0.73	0.05

This non-destructive analytical technique utilises the measurement of characteristic secondary X-rays to determine the elemental composition and concentration of materials, through the exposure of a sample to high-energy X-rays or gamma rays, which results in the emission of secondary X-rays due to the excitation of inner-shell electrons. The subsequent analysis of the resultant data enabled the determination of the clay's oxide composition and enabled prediction of its classification according to the standard mineralogical nomenclature. The analysis revealed that the clay in question belonged to the clay loam domain (Figure 1), as indicated by its specific mineralogical composition (Figure 2).

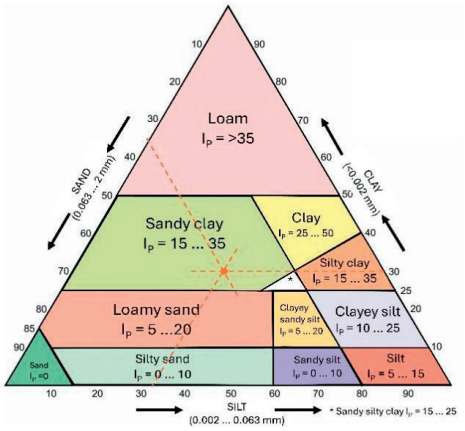

Figure 1. Characterization of the clay as a raw material – classification within the ternary diagram

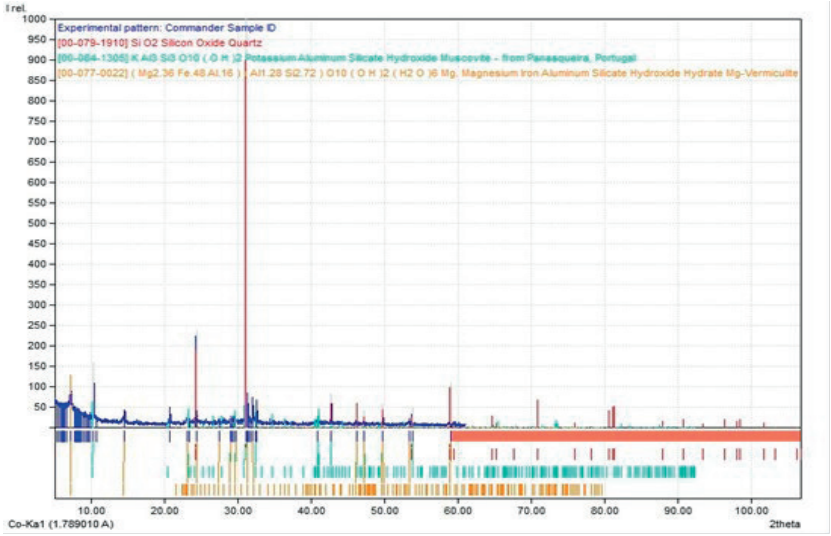

Figure 2. Mineralogical analysis of the clay used as a raw material

From a mineralogical perspective (Figure 2), experimental tests revealed the presence of predominant minerals, including quartz with approximately two-thirds of the composition, muscovite accounting for nearly one-third, and a minor fraction of vermiculite, along with montmorillonite, illite and kaolinite. (Minke, 2006; Niroumand et al., 2013; Dormohamadi & Rahimnia, 2020; Muñoz et al., 2020; Ige & Danso, 2022). In accordance with existing literature on the subject, these characteristics support the assessment that this raw material is suitable for use in the construction sector.

The selection of the hydraulic binder (hydraulic lime) was based on preliminary experimental tests and existing literature highlighting its beneficial effects (Minke, 2006; Pacheco-Torgal, 2015; Ige & Danso, 2022; Rescic et al., 2023) particularly the additional contribution of calcium oxide in mitigating drying shrinkage and reducing the risk of cracking. The water used in the preparation process was carefully dosed to maintain a consistent fresh mix consistency within a controlled range of 95 ± 5 mm.

In order to evaluate and analyse the performance of clay-based compositions intended for plastering applications, a series of mixtures were formulated and prepared under controlled laboratory conditions.

The proportional composition of the raw materials, together with the corresponding sample codes, is shown in Table 2.

Table 2. The ratio of raw materials in composites intended for use as plaster mortar

Sample code	Clay (%*)	Hydraulic Lime (%*)	Sand (%*)
P1	60	0	40
P2	57	3	40

P8	30	30	40
P9	25	35	40
P10	20	40	40
P11	10	50	40
P12	0	60	40

*Note: It should be noted that the percentage indicated is that by weight of the total dry material.

For each clay-based composite, a number of indicators were evaluated to characterise the material and confirm its suitability for use as a rendering mortar, in particular:

- apparent density in the hardened state, according to the standardised method EN 1015-10;
- axial shrinkage, according to the standardised method STAS 2634;
- presence of drying cracks, assessed on visual inspection;
- flexural tensile strength and compressive strength, according to the standardised method EN 1015-11;

- adhesion to the substrate, tested on ceramic bricks and unfired clay masonry units, according to the standard method EN 1015-12.

The experimental evaluation of the physical and mechanical performance was conducted under laboratory conditions using prismatic specimens of 40×40×160 mm, formed in metal moulds and demoulded 72 hours after preparation. To assess substrate adhesion, flat specimens were prepared by applying a 3-5 mm thick layer of the clay-based composite to the selected substrates. All samples were stored for 40 days until a constant mass was reached, which was taken as an indicator of full maturation and drying of the material. The samples were stored under controlled laboratory conditions at 23±2°C and 65±1% relative humidity, and then subjected to experimental testing. In order to ensure the repeatability of the experimental determinations, a minimum of three samples were prepared for each case and the values reported represent the arithmetic mean of the individual measurements.

Subsequently, to analyse the resistance to microbiological attack, a test scheme was designed for four clay-based composites selected on the basis of their physical and mechanical performance. The test procedure consisted of three stages:

- evaluation of the behaviour of plastering mortars in an environment contaminated with mould spores;
- design, preparation and application of a protective product on the clay surface;
- validation of the antifungal performance by evaluating the behaviour in an environment contaminated with mould spores.

Samples were selected on the basis of minimum thresholds for four indicators identified in correlation with references from the literature: (Minke, 2006; Pacheco-Torgal, 2015; Muñoz et al., 2020; Eslami et al., 2022; Azalam et al., 2024):

- absence of drying cracks;
- adhesion to substrate: minimum 0.5 N/mm²;
- compressive strength: at least 2.5 N/mm²;
- bending tensile strength: minimum 1.5 N/mm².

In addition, a batch of clay-based composites without hydraulic lime content (P1) was subjected to a comparative analysis.

The analysis of the resistance of the clay-based composites to microbiological attack was carried out by exposing the samples to a highly contaminated cross-infection environment with *Penicillium notatum* (PN) and *Aspergillus niger* (AN) spores. For this purpose, individual culture systems were prepared for each sample type. A disc-shaped specimen, 15 mm in diameter and 3 mm thick, prepared in the same way as the prismatic specimens used for the determination of physical and mechanical tests, was placed in a Petri dish on a potato dextrose agar (PDA) nutrient substrate (prepared by dissolving 39 g/L of granular substance in warm water). The test sample and the culture medium were sprayed vertically from a distance of 100 mm with a solution containing *Penicillium notatum* (PN) and *Aspergillus niger* (AN) spores (10 µl PN + 10 µl AN/20 ml distilled water). The entire system was then sealed and incubated at a constant temperature (23±1°C) in a BIOBASE BOV-D30 incubator. At predetermined time intervals, the systems were evaluated by observing the appearance and development of mould and the degree of surface coverage on the material sample. The evaluation was performed by microscopic examination using a LEICA SAPO microscope. The results were quantified using two indicators: one to assess fungal growth (Table 3) and the other to estimate product performance (Table 4).

Table 3. Fungal growth assessment

Class	Fungal Growth Evaluation
Class 0	No fungal growth is visible upon microscopic examination.
Class 1	The growth is invisible to the naked eye but is clearly visible under a microscope.
Class 2	Visible growth to the naked eye, covering up to 25% of the surface area that was tested.
Class 3	Visible growth to the naked eye, covering up to 50% of the surface area that was tested.
Class 4	Visible growth to the naked eye, with a surface coverage of more than 50%.
Class 5	Heavy growth, with complete coverage of the tested surface.

Table 4. Product performance estimation

Category	Product Performance Estimation
0	The material is characterised as being inert or fungistatic, thereby serving as an unsuitable nutrient medium for microorganisms.
1	The material contains minimal nutrients or is minimally contaminated, resulting in restricted microbial growth.
2-3	The material demonstrates susceptibility to microbial attack and contains nutrients that facilitate microorganism growth.

The surface treatment solutions were prepared using expired non-food household products (cosmetic-pharmaceutical products) together with dispersion matrices. The raw materials used were:

- dispersion matrices:
  - commercially available liquid wax, natural beeswax dispersed in water, manufactured by Borma Wachs, Italy;
  - rabbit skin glue solution, made from rabbit skin glue granules (manufacturer: Divolo, Italy, commercially available) dissolved in warm water at a ratio of 1:10 by mass (one part glue to ten parts water).
- cosmetic-pharmaceutical products:
  - liquid pharmaceutical product for the treatment and prevention of fungal infections of the mucous membranes, particularly in the oral cavity, based on glycerine. It is an over-the-counter solution available in pharmacies that combines the properties of glycerine, borax (B) (sodium tetraborate, a substance with antiseptic and antifungal properties) and nystatin (NT) (a broad-spectrum antifungal agent that inhibits the growth and spread of fungi by disrupting their cell membrane);
  - liquid antifungal pharmaceutical product for the treatment of fungal infections of the skin and nails. It is available over the counter and contains the active ingredient naftifine (NF), which belongs to the class of allylamines with antifungal and antimicrobial properties. Naftifine inhibits enzymes involved in the formation of fungal cell membranes, thereby affecting their growth and survival. It is effective against several types of fungi, including yeasts and moulds;
  - hand cream for dry skin, made in Romania (contains 15% glycerine);
  - lipstick, produced in Romania (contains 50% glycerine);
  - lavender oil, produced by Ecoland Production SRL, Romania.

The selection of these raw materials was driven by the following criteria:

- representation of waste materials for which potential reuse solutions are being explored;
- affordability, accessibility, and absence of health risks to users;
- capability to serve as natural treatment solutions suitable for vernacular construction applications;
- liquid wax has been demonstrated to reduce the water sensitivity of clay surfaces by filling pores and forming a water-repellent sealing film, thereby enhancing resistance to water exposure and climatic agents. When utilised in an efficient manner during the mixing process, it functions as an effective dispersion medium for fine powdered substances and lavender oil;
- rabbit skin glue solution is recognised as an effective surface treatment material, frequently used in furniture and painting restoration, as well as in traditional and eco-friendly construction works. The formation of a varnish-like film is the result of the interaction of the glue with the substrate, and this results in strong adhesion. It is expected that this will enhance surface resistance to water exposure and climatic agents. The solution's application as an aqueous medium facilitates the dissolution of other raw materials (e.g., expired pharmaceutical products) while ensuring the effective dispersion of fine powdered substances;
- lavender oil is renowned for its antiseptic, antifungal, antimycotic, and antibacterial properties, as well as its effectiveness as a natural insect repellent. Its efficacy in treating contamination caused by *E. coli*, *P. aeruginosa*, *S. aureus*, *P. vulgaris*, *E.s faecalis*, *L. monocytogenes*, *B. subtilis*, *A. niger*, *P. chrysogenum*, and *C. albicans* has been well-documented (de Elguea-Culebras et al., 2016; Vasileva et al., 2018; Silletta et al., 2024);
- the improper disposal of expired cosmetic pharmaceutical products in household settings represents a significant environmental concern, as these materials have the potential to contaminate water sources and soil. The selected products are intended for external use, are available without medical restrictions, and do not present risks associated with use by children, pregnant women, or breastfeeding individuals. Furthermore, the glycerine content present in these products has been demonstrated to

enhance the flexibility of the protective film (for rabbit skin glue film, the required glycerine content is 5%). Finally, while some of these materials function exclusively as treatment agents to enhance resistance to mould growth, others can readily serve as pigments, thereby enabling a broad spectrum of colours and shades in the protective coating.

The evaluation of coating coverage uniformity was conducted by applying the treatment solutions to a white cementitious substrate characterised by a smooth surface (specimens fabricated from white cement paste, aged two years post-casting). Preliminary tests demonstrated that, under constant exposure and lighting conditions, the coatings were more visible on the white cementitious substrate compared to the clay substrate. The coding and composition of the treatment solutions are presented in Table 5.

Following the preparation stage, the treatment solutions were applied by brushing onto the surface of the selected clay-based composite specimens in two layers, with a 24-hour interval between applications.

Table 5. Ratio of raw materials utilised in the formulation of clay surface treatment solutions.

Sample code	Liquid wax (ml)	Rabbit skin glue solution (ml)	B+NT+NF Total content (%)	Cosmetics (g hand cream/g lipstick)	Lavender oil (ml)
S1	100	-	0.0017	10/7	1
S2	50	50			
S3	-	100			

Following the application of the second layer, the specimens were left to dry for a period of seven days. Thereafter, the contamination exposure procedure described earlier was employed to test the specimens. Figure 3 provides a schematic representation of the experimental research methodology.

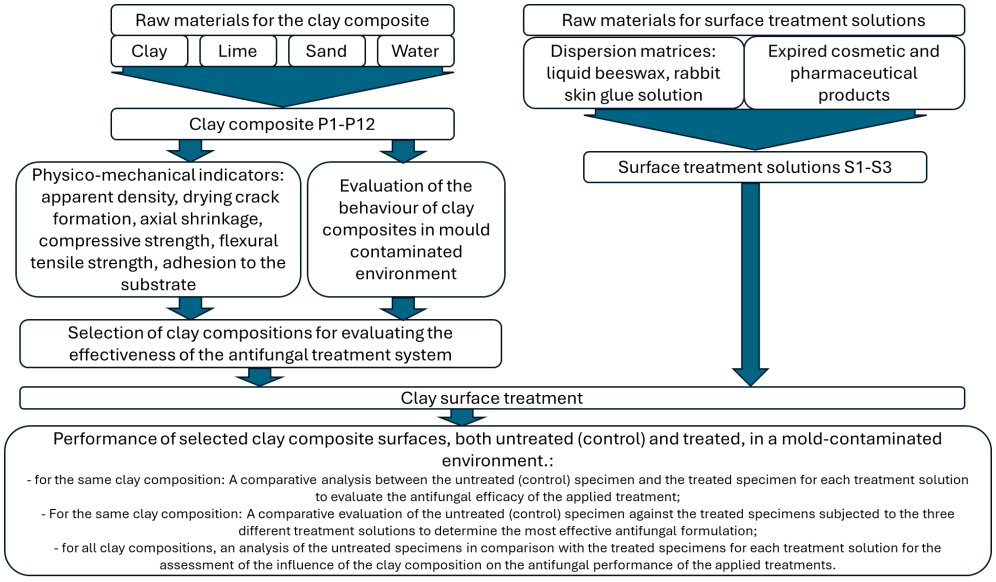

Figure 3. Schematic representation of the experimental research methodology

RESULTS AND DISCUSSIONS

The experimental results obtained in this study demonstrate that, in relation to physical and mechanical indicators, an increase in the hydraulic lime content in the composition results in a decrease in apparent density (Figure 4) and a reduction in axial shrinkage (Figure 5). These outcomes are particularly favourable for such materials, as they are accompanied by the absence of cracks.

However, it is crucial to acknowledge the unfavourable consequence of elevated hydraulic lime content, namely the decrease in mechanical strength, both in compression and flexural tensile resistance, which underscores the

necessity for the identification of the optimal hydraulic lime content in each instance where the composition of the clay material is subject to alteration (Figure 6).

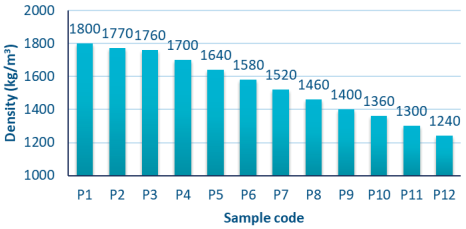

Figure 4. Bulk density of clay composites in their hardened state

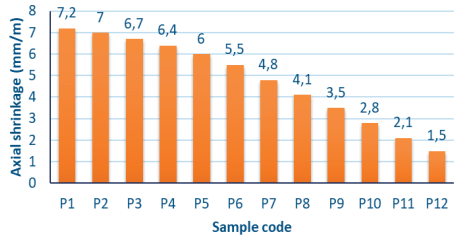

Figure 5. Axial shrinkage of clay composites

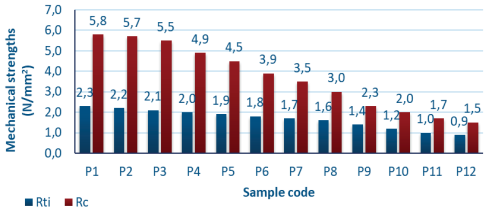

Figure 6. Mechanical strengths of clay composites

Concerning the adhesion of clay-based composites to the substrate, a Gaussian trend was observed (see Figure 7).

In particular, an increase in hydraulic lime content, coupled with a reduction in clay content (while maintaining a constant sand proportion in the total dry mix), resulted in enhanced adhesion to both adobe brick and fired ceramic brick surfaces. This adhesion exhibited a peak at composition P8 (30% clay, 30% hydraulic lime, 40% sand). Conversely, compositions where the lime content exceeds the clay content (P9-P12) exhibited a decline in adhesion to the substrate. It is therefore essential to establish the optimal hydraulic lime content to achieve a sustainable balance between its benefits and potential drawbacks.

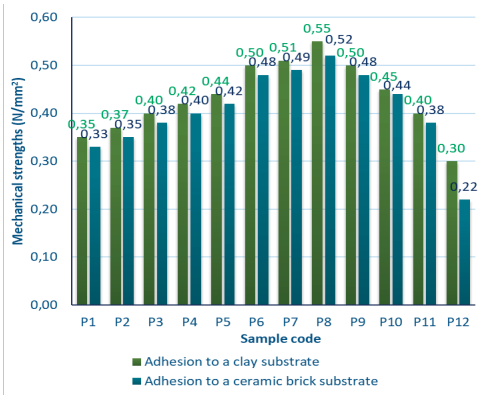

Figure 7. Adherence of clay composites to the substrate

The experimental results regarding the evaluation of the resistance of clay-based compositions under cross-contamination conditions with *Penicillium notatum* and *Aspergillus niger* revealed the following:

- All clay-based compositions invariably allowed the growth of one or both types of mould on their surface, although at different rates. The initial indications of mould growth (3 days after contamination) manifested in compositions with a reduced lime content, thereby validating the advantageous and sanitizing effect of lime.
- Following a period of seven days of exposure to the contaminated environment, all compositions exhibited indications of fungal growth, which was classified as Class 1 according to the classification system (i.e. invisible to the naked eye but clearly visible under a microscope). According to the performance estimation indicator (Table 4), all compositions were categorised as Category 1 (i.e. the material contains very few nutrients or is minimally contaminated, allowing only very limited fungal growth).
- During the exposure period of 7 to 33 days in the contaminated environment, visual and microscopic evaluations of the clay surfaces indicated varied behaviours. Some compositions exhibited a more intense development of PN (*Penicillium notatum*) colonies, while others showed a more pronounced growth of AN (*Aspergillus niger*) colonies. Additionally, the extent of

surface coverage by the microbiological film varied depending on the composition. Consequently, the analysis of the results has not permitted the establishment of a clear correlation between the clay composition and the predominant type of mould growth.

- The final evaluation, conducted 33 days after exposure to the contaminated environment (see Figure 8), revealed the following classification based on fungal growth: Class 1 (invisible to the naked eye but clearly visible under a microscope) for compositions P8-P12 (minimum 30% lime content), Class 2 (visible growth covering up to 25% of the tested surface) for compositions P3-P7 (minimum 5% lime content), and Class 3 (visible growth covering up to 50% of the tested surface) for compositions P1 and P2 (0% or 3% lime content in the dried material). In terms of product performance estimation, the P3-P12 compositions were classified as Category 1. The rationale behind this categorisation is that these materials contain negligible nutrients or minimal contaminants, which precludes substantial fungal growth. Conversely, the compositions with minimal or no lime content (P2 - 3% lime and P1 - 0% lime) were classified as Category 2. This classification is attributed to the fact that these materials lack the resilience to microbial attacks and contain nutrients that facilitate microorganism growth. One potential explanation for these results is the presence of residual organic content in the clay soil, despite the processing of the soil through sorting and sieving to remove vegetative materials prior to use. Consequently, in order to enhance the durability and hygienic properties of clay surfaces, the implementation of an appropriate surface treatment is considered beneficial.

The selection criteria for the clay-based compositions (absence of drying cracks; adhesion to the substrate of at least 0.5 N/mm²; compressive strength of at least 2.5 N/mm²; flexural tensile strength of at least 1.5 N/mm²) as identified in Figure 9 were applied, and three compositions that met all these requirements were selected for validation testing of the antifungal treatment through surface coating. These selected compositions are: P6 (40% clay, 20% lime, 40% sand), P7 (35% clay, 25% lime, 40% sand) and P8 (30% clay, 30% lime, 40% sand).

The protective and surface treatment solutions for clay-based surfaces, as prepared (Figure 10), were found to be homogeneous, easy to apply by brushing, and demonstrated good surface coverage. The most homogeneous solution was the one prepared with liquid wax (S1). However, with the addition of rabbit skin glue, the dispersion of raw materials derived from the recycling of expired cosmetic products became more challenging.

Despite this, the resulting coatings were found to be smooth, continuous, and uniform, ensuring adequate surface coverage. However, it was observed that the presence of rabbit skin glue in the treatment solution had a slightly negative effect on coating coverage capacity. This effect was particularly noticeable on the white cementitious substrate, which remained slightly visible beneath the treatment film, especially in the case of solution S3, where rabbit skin glue was used exclusively as the dispersion matrix (Figure 10d).

In relation to the investigation of the resistance exhibited by clay-based composites following treatment with a liquid beeswax-based solution, observations made after a seven-day exposure period (see Figure 11) indicate that the surface remains impermeable when exposed to a mould-contaminated environment. The moisture generated by the mould's metabolic processes manifests as water droplets, thereby supporting the hypothesis of the surface's hydrophobic nature. No signs of mould growth were present on the surface of the specimens. Furthermore, the testing systems exhibited a slight inhibition halo around the clay-based specimens, with the halo size ranging from 1 to 5 mm from the edge of the specimen, forming a circular pattern around it, as exemplified in Figure 11b-c. In accordance with the fungal growth evaluation system and product performance estimation criteria (Tables 3 and 4), it can be concluded that treating clay surfaces with solution S1 resulted in their classification under: Class 0 (No signs of fungal growth upon microscopic examination),
Category 0 (The material does not serve as a nutrient medium for microorganisms – it is inert or fungistatic).

The results of the 7-day exposure period in a highly contaminated environment demonstrated

the treatment solution's high efficacy and a significant improvement in fungal resistance. The treatment of clay surfaces with solution S2, which uses a liquid beeswax and rabbit skin glue mixture (1:1 mass ratio) as the dispersion matrix, resulted in a loss of surface hydrophobicity compared to specimens treated with solution S1 after seven days of exposure to a contaminated environment (Figure 12).

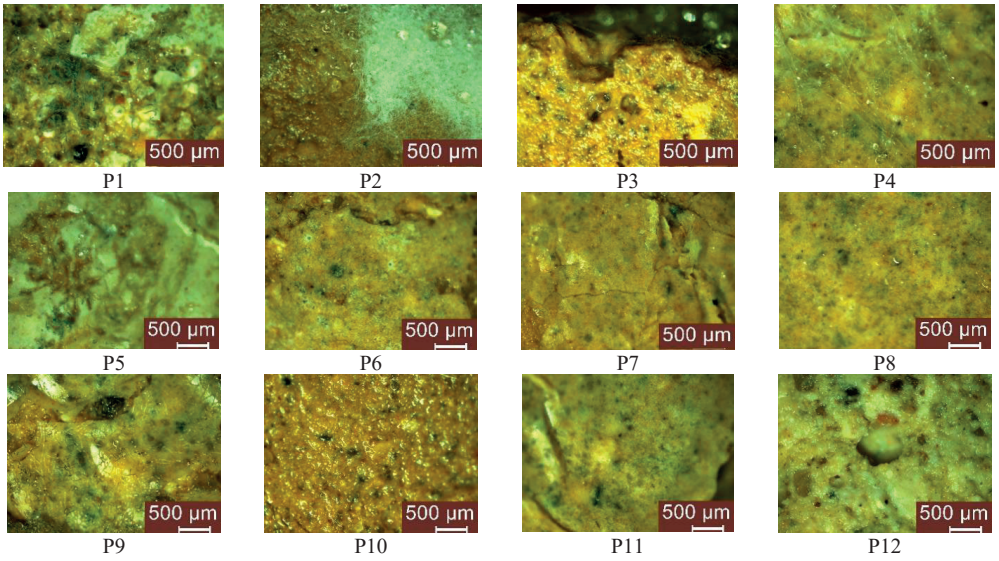

Figure 8. Optical microscopy images depicting the behaviour of clay composites in a mould-contaminated environment following 33 days of exposure.

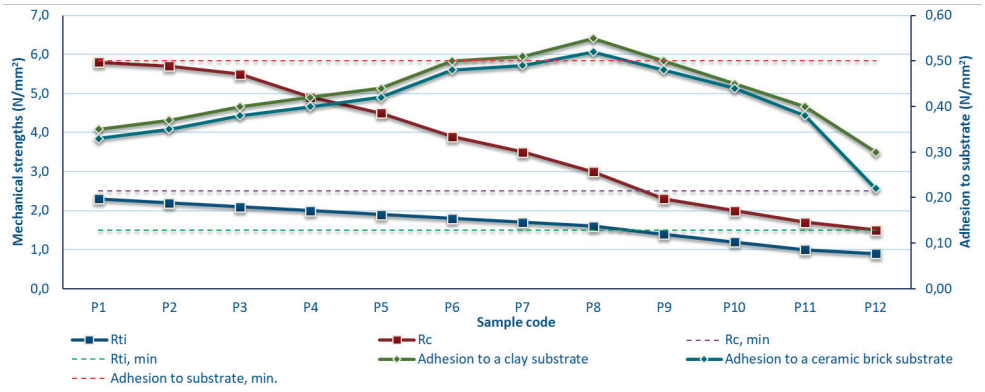

Figure 9. Selection of compositions for testing the efficacy of the antifungal treatment system.

It is noteworthy that no mould development was detected on the surfaces of any of the specimens. According to the fungal growth evaluation system and product performance criteria (Tables 3 and 4), treatment with solution S2 classified high-lime-content compositions (P7 and P8) in Class 0/Category 0 (no fungal growth detected, inert or fungistatic).

In contrast, the control (P1) and the 20% lime composition (P6) were placed in Class 1/Category 1 (microscopic fungal growth with minimal contamination).

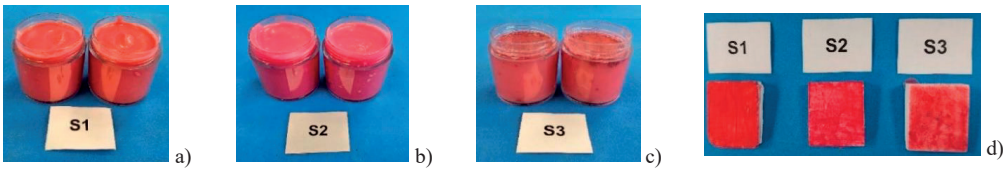

Figure 10. Representative images of protective and surface treatment solutions and their coating appearance on a white cementitious substrate

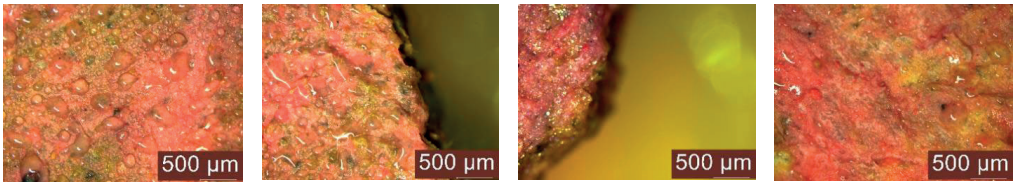
Therefore, the efficacy of solution S2 was clearly influenced by the nature of the clay substrate to which it was applied. The treatment of clay surfaces with solution S3, in which rabbit skin glue was used exclusively as the dispersion matrix, yielded the poorest results in terms of protection and coating durability after seven days of exposure in a contaminated environment (Figure 13). Exposure to moisture from mould growth compromised the integrity of the rabbit skin glue matrix, leading to the softening, dissolution, and absorption of the coating into the clay substrate. Consequently, only minimal traces of glycerine-based cosmetic products remained on the surface, appearing as dispersed lipstick residues. Additionally, a mucilaginous layer formed on the clay surface, with a more distinct and continuous film observed in compositions with higher lime content. This suggests that the mucilaginous film, likely containing traces of glycerine and rabbit skin glue, was less readily absorbed into the clay matrix as the lime content increased.

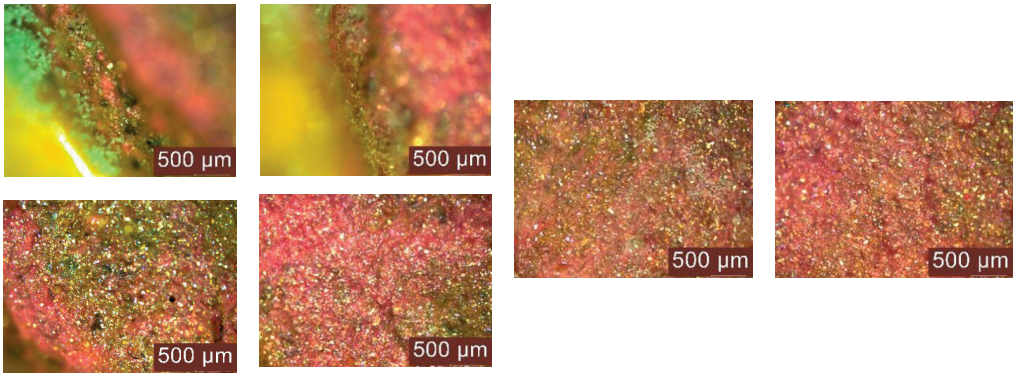
The analysis revealed the loss of inhibition halo formation, surface hydrophobicity, and visible moisture, suggesting its absorption into the system, which contributed to the dissolution of the rabbit skin glue coating and the formation of a mucilaginous film.



Clear signs of mould proliferation were observed, particularly in specimens with lower lime content, such as the control (P1) and sample P6. Quantitative evaluation based on fungal growth assessment criteria and product performance indicators confirmed the ineffectiveness of solution S3, with specimens classified as Class 1 (microscopic fungal growth) and Category 1 (minimal contamination allowing limited growth).

The final evaluation of the clay specimens treated with solutions S1-S3, conducted 33 days after exposure in a contaminated environment, demonstrated good resistance in the specimens treated with the beeswax-based solution (S1) (Figure 14). No fungal growth was observed on the specimens, and the coating maintained its hydrophobic properties. Although the inhibition halo previously observed at shorter exposure durations was no longer present, microscopic evaluation of the specimen surfaces confirmed their classification as: Class 0 (no signs of fungal growth under microscopic examination), Category 0 (the material does not serve as a nutrient medium for microorganisms – it is inert or fungistatic).

As rabbit skin glue was incorporated into the dispersion matrix (S2 and S3), the coatings on the clay specimens demonstrated diminished resistance to the contaminated environment (Figures 15 and 16). In the case of treatment solution S2, a decline in hydrophobicity was observed, accompanied by distinct indications of mould growth on the control specimen (P1) and the low-lime-content clay specimen (P6). Furthermore, the presence of fungal growth was detected in the cracks that formed on the surfaces of the high-lime-content specimens (P7 and P8). Utilising the product performance estimation criteria outlined in Tables 3 and 4, the treatment of clay surfaces with solution S2 led to the classification of the high-lime-content compositions (P7 and P8) as: Class 1 (Growth invisible to the naked eye but clearly visible under a microscope), Category 1 (The material contains very few nutrients or is minimally contaminated, allowing only very limited fungal growth). In contrast, the control composition (P1) and the composition with 20% lime content (P6) exhibited behaviour classified as Class 2 (visible growth covering up to 25% of the tested surface) and Category 2 (the material does not resist microbial attacks; it contains nutrients that support microorganism growth).



For treatment solution S3 (100% rabbit skin glue dispersion matrix), microscopic examination confirmed significant mould growth on all clay surfaces, resulting in a loss of colour and a transition to a mucilaginous state. The

classification results are outlined below: P1: Class 3/Category 2 (Visible growth covering up to 50% of the tested surface; material supports microbial growth); P6-P7: Class 2/Category 2 (Visible growth covering up to 25% of the tested surface; material allows microorganism development); P8 (highest lime content): Class 1/Category 1 (Growth invisible to the naked eye but clearly visible under a microscope; very limited fungal development). As illustrated in Table 6, a comprehensive overview of the temporal progression of quantification indicators, contingent on the nature and implementation of treatment, was provided. It is evident that surface treatment resulted in an enhancement of resistance within the contaminated environment, with an increase ranging from 1 to 3 classes and 1 to 2 categories, depending on the treatment modality and the clay composition. This is particularly influenced by the presence and proportion of lime in the mixture.

	Category	2	0	2	2	1	0	2	2	1	0	1	2	1	0	1	1

Although equal amounts of expired non-food household cosmetic-pharmaceutical products were used in all three prepared solutions - some selected for their fat content, others for their antifungal properties, and some only as colour pigments - only the beeswax-based solution proved fully effective. This solution imparted hydrophobic properties to the clay surface and utilised the antifungal effect of the non-food household additives, as evidenced by the formation of an inhibition halo around the specimen in the test system.

The beeswax-based surface treatment resulted in more favourable classifications in both fungal growth evaluation and product performance estimation compared to untreated surfaces. In contrast, the rabbit skin glue solution reduced the antifungal efficiency of the non-food household products.

The addition of rabbit skin glue to the mixture, even when combined with beeswax, resulted in only modest outcomes in terms of clay surface protection. The nature of the clay substrate also influenced the outcomes, with a higher lime content in the clay composition contributing to slightly improved outcomes.

CONCLUSIONS

Vernacular constructions, which frequently comprise unfired clay walls, offer a number of advantages, including enhanced indoor air quality, minimal environmental impact, and a beneficial role in preserving and promoting local identity. However, these structures are not without vulnerability; a primary concern pertains to their diminished resilience to Vernacular constructions, which frequently comprise unfired clay walls, offer a number of advantages, including enhanced indoor air quality, minimal environmental impact, and a beneficial role in preserving and promoting local identity. However, these structures are not without vulnerability; a primary concern pertains to their diminished resilience to biological and environmental factors. The objective of this experimental research was to investigate the feasibility of repurposing non-food household waste and minimally processed products through the development of surface treatment solutions aimed at enhancing the durability of unfired clay-based wall surfaces against mould growth.

The experimental research yielded the following conclusions:

- The composition and ratio of raw materials utilised in clay-based composites significantly impact the physical and mechanical performance, resistance, and durability. Among the 12 analysed clay compositions, three were identified as having the most suitable clay-to-lime ratio for the intended application: P6, P7, and P8, which are characterized by the following ranges of raw materials: 30-40% clay, 20-30% lime, and 40% sand.
- With regard to resistance to mould growth (*Penicillium notatum* and *Aspergillus niger*), it was found that all clay compositions ultimately permitted the development of one or both types of mould on their surface. The initial signs of mould appeared earliest (3 days after contamination) in compositions with lower lime content, thereby confirming the beneficial and sanitizing effect of lime.
- The efficacy of surface treatment in enhancing the resistance of clay surfaces to contamination is dependent on the nature of the treatment solution.
- The enhancement of clay surfaces through surface treatment has been shown to occur within a range of 1 to 3 classes and 1 to 2 categories. The most effective performance was observed in the clay composite with the highest lime content (P8), treated with the solution using a 100% liquid beeswax dispersion matrix (S1). The replacement of beeswax with rabbit skin glue (S2) led to a reduction in the antifungal efficacy of the surface treatment for all clay surfaces that were tested, including the composition with the highest lime content (P8). Furthermore, when beeswax was entirely substituted with rabbit skin glue (S3), this decline in antifungal protection persisted.
- Rabbit skin glue (S3) functions as a dispersion matrix, yet it does not yield a substantial beneficial effect in terms of enhancing mould resistance on clay surfaces. In comparison, liquid beeswax has been demonstrated to be a significantly more effective dispersion matrix.

In conclusion, based on the findings presented, new research hypotheses can be formulated, focusing on the use of liquid beeswax as a dispersion matrix while exploring and identifying new expired non-food household products that could be repurposed to develop surface treatment solutions for unfired clay surfaces in construction, with the aim of enhancing their resistance and durability.

Abstract

Since time immemorial, mankind has sought solutions to the problem of creating sustainable living spaces that provide thermal comfort and good indoor air quality. One of the most prevalent techniques has been the construction of buildings from clay-based materials. Nevertheless, even at the present time, this method is still insufficiently regulated by generalised regulations. The principal issue is the diversity of raw material characteristics, which necessitates a considerable number of preliminary tests and a lengthy period of time. This paper puts forward an interdisciplinary methodology for the analysis of clayey earth, with a view to determining the potential applications of this material in the production of adobe-brick masonry elements and plastering mortars for vernacular construction. The research methodology entailed a pedological analysis of 30 clay soil samples sourced from Mârgău and Ciucea region, Cluj, followed by an evaluation of their suitability for construction applications. The experimental findings have indicated the potential for establishing limiting conditions regarding the clay, sand, and dust content of the soils, in conjunction with pH, humus, and carbonate levels.

Key words*: vernacular constructions; clay soil; pedological analysis; adobe-brick, plaster mortar*

INTRODUCTION

The construction sector is responsible for approximately 40% of global energy consumption, 40% of raw material usage, 50% of greenhouse gas emissions, and 60% of total waste generation, with only 20-30% of this waste being recycled (Măgurean & Petran, 2023; Papadaki et al., 2022; Asif et al., 2007; Santamouris et al., 2015; Papadaki et al., 2019; Mollaei et al., 2023; Munaro et al., 2020). This issue has been widely recognised on a global level, leading to an increased focus on identifying strategies to mitigate and reduce its adverse environmental impact (Androutsopoulos et al., 2020), a significant initiative in this regard being the European Green Deal (Ak et al., 2024; Montanarella & Panagos, 2021; Kotseva-Tikova & Dvorak, 2022).

Recent studies have increasingly concentrated on formulating solutions that support sustainability objectives in the construction industry. One such approach involves the resurgence of traditional construction practices, with a focus on the development and optimisation of clay-based building techniques to preserve their benefits while mitigating their limitations.

A substantial body of documenttation on this subject is available in the scientific literature. Evidence of the growing research interest in this field is illustrated by a query of the Web of Science Core Collection using the keyword "adobe brick", which yielded 518 publications, of which 39% were classified under Construction Building Technology, 38.8% under Civil Engineering, and 25% under Materials Science Multidisciplinary.

This distribution underscores the increasing emphasis on the development of environmentally sustainnable construction materials, with a notable surge in research publications after the year 2000 (Figure 1).

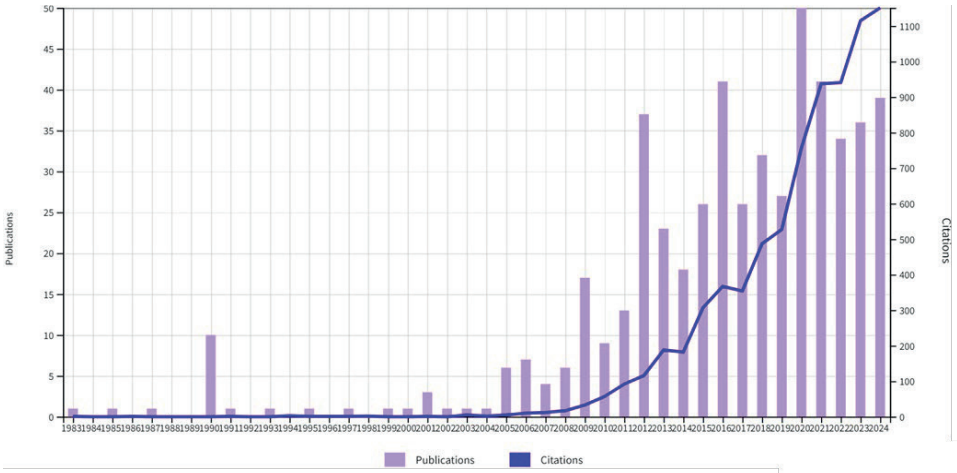

Figure 1. Evolution of publications and citations, according to WOS, of scholarly works identified using the keyword "adobe brick"

Notwithstanding the advantages inherent in unfired clay-based constructions, it is important to acknowledge their inherent limitations. Niroumand et al. (Niroumand et al., 2013) emphasise that one of the most critical drawbacks of earth-based structures is their inadequate mechanical strength, which hinders their utilisation to the same extent as conventional construction materials. However, contemporary research endeavours are actively addressing this limitation by enhancing the mechanical performance of these materials through the application of composite material principles. These advancements involve the incorporation of additive raw materials, such as lime, fly ash, bitumen, asphalt, or dispersed reinforcing fibres, to improve their structural integrity and durability.

Despite the fact that the field of earth-based construction remains a minimally regulated and standardised field, largely due to the high heterogeneity of its primary raw material, clay soil, a review of the scientific literature identifies several guiding principles that support its potential for sustainable building applications. The most notable regulatory frameworks include the German Earth Building Code, which was established in 1944 and laid the foundation for the development of DIN 18951. In addition, New Zealand has introduced relevant standards (NZS 4297:1998; NZS 4298:1998; NZS 4299:1998), and specific regulations exist in Australia, New Mexico and Zimbabwe. Furthermore, various guidelines, instructional documentation and specialised educational programmes have been developed, particularly within Europe, to promote and standardise earth-based construction practices (Pacheco-Torgal & Jalali, 2012). Therefore, given the existence of regional variations based on geographical location, several criteria have been established to determine the suitability of clay soil for the production of adobe bricks. The most fundamental requirements, irrespective of the geographical location of the experimental area, include the absence of organic matter (Pacheco-Torgal & Jalali, 2012) and the implementation of a sampling method that ensures soil collection from a minimum depth of 150 mm below the surface. This approach is designed to minimise the presence of organic residues, such as vegetal or animal matter (Giada et al., 2019). Furthermore, G. Minke advances the argument that a minimum sampling depth of 400 mm may be required to ensure the material's suitability for construction applications (Minke, 2005). From a chemical, oxide, and mineralogical composition standpoint, which are challenging to assess in the field without access to specialised laboratories, the scientific literature (Salih et al., 2020) highlights a predominance of silicon dioxide (SiO_2) in the range of 50-60%, followed by aluminium oxide (Al_2O_3) at approximately 10%. These elements contribute to the structural quality of adobe bricks. Additionally, the presence of ferric oxide

(Fe_2O_3), generally not exceeding 10%, is noted, with its hydrated form responsible for the characteristic brown-reddish soil colouration. However, ferric oxide has also been implicated in the development of efflorescence, which may have a detrimental effect on the material's durability and performance.

Limitation of the calcium oxide (CaO) concentration to a maximum of 10% is another critical aspect. When not chemically bound to SiO_2, CaO can have detrimental effects, including swelling in the presence of water and carbonation, which leads to the formation of $CaCO_3$, a compound characterised by low mechanical strength and reduced durability. In terms of granulometric composition, clay functions as the primary binding agent, while silt, sand, and aggregates act as fillers that influence the material's mechanical and structural properties. The scientific literature suggests that the aggregate fraction should not exceed 10% for particles larger than 2 mm, while the sand content should range between 40% and 80%, with particle sizes between 0.063 and 2 mm. Furthermore, the recommended silt content varies between 10% and 30%, with grain sizes between 0.002 and 0.063 mm, whereas the clay fraction typically ranges from 20% to 50% (grain sizes between 0.002-0.063 mm) (Salih et al., 2020; Giada et al.,2019). However, older references indicate that clay content should not fall below 15%, as it plays a crucial role in maintaining the structural integrity and cohesion of the material (Laaroussi et al., 2013; Boduroglu, 1989). From a mineralogical standpoint, the predominant minerals present in clay soils may be associated with a high silicon content or be characteristic of clay-rich compositions. The most commonly identified minerals include quartz, calcite, feldspars, illite, kaolinite, chlorite, smectite, and montmorillonite. The presence of calcite is often indicative of soil alkalinity (Dormohamadi & Rahimnia, 2020; Demir, 2008).

From a physico-mechanical perspective, the assurance of optimal thermal insulation and substantial thermal inertia - facilitating the accumulation of heat during warm periods and its subsequent release during colder seasons – necessitates that the bulk density of the mixture falls within the range of 1800-2000 kg/m³ (Burroughs, 2008). From a structural performance standpoint, the ASTM D1633-00 standard (New Mexico) stipulates a minimum compressive strength of 2.07 N/mm² for earthen wall materials. In a similar fashion, the Zimbabwean code for rammed earth walls establishes a minimum compressive strength of 1.5 N/mm² for single-story structures with 400 mm thick walls and 2.0 N/mm² for two-story buildings. In Australia, the relevant standard prescribes a minimum compressive strength of 1.15 N/mm², while the ASTM International E2392/E2392M-10e1-2010 standard mandates a threshold of 2.068 N/mm². Additionally, the ACI Materials Journal Committee has reported that compressive strength varies based on soil composition, with values ranging from 2.76 to 6.89 N/mm² for sandy soils and from 1.72 to 4.14 N/mm² for clay-rich soils. Moreover, the Peruvian Standard E.080 stipulates a minimum compressive strength of 1.2 N/mm² and a minimum tensile strength of 0.4 N/mm², thereby underscoring the heterogeneity of regulatory approaches to earthen construction materials (Pacheco-Torgal & Jalali, 2012; Vega et al., 2011).

During the preparation process, clay soil is typically mixed with water, thereby initiating the delamination of clay particles. Ensuring adequate plasticity and workability is crucial; however, it is important to recognize that an excessive water content increases the risk of cracking and significant axial shrinkage. Achieving crack-free final elements is imperative, and it is considered acceptable for bricks produced using soft mixture technologies to exhibit a linear shrinkage between 3% and 12%. Conversely, drier mixtures should exhibit a linear shrinkage ranging from 0.4% to 2% (Minke, 2005).

The physico-mechanical properties of clay-based materials vary significantly depending on the characteristics of the clay soil, the preparation and testing methods employed, and the type and proportion of additives incorporated. The scientific literature reports a wide range of values for these parameters, reflecting the diversity of experimental approaches1. Specifically, the compressive strength has been documented to range from 0.5 MPa to over 7 MPa (Dormohamadi & Rahimnia, 2020), while the flexural strength has been reported to vary between 0.25 MPa and 1.25

MPa (Dormohamadi & Rahimnia, 2020). Furthermore, Silveira et al. (Silveira et al., 2013) reported a tensile strength of 0.16 MPa for adobe bricks. The parameters under consideration – namely, particle size distribution, density, mixing water content, and consistency – are relatively straightforward to analyse and assess, particularly in situ, where access to a specialized laboratory for chemical and mineralogical analysis may be limited. However, for a comprehensive evaluation, it is essential to incorporate both physical and chemical testing methodologies to ensure a thorough characterization. The objective of this study was to assess, through chemical and pedological analysis, the potential suitability of clay soils from the Mârgău and Ciucea regions in Cluj County for the production of adobe masonry elements.

MATERIALS AND METHODS

The study aimed to assess the feasibility of rapidly determining the suitability of clay soils from the selected locations – Mârgău, Cluj County (46°44′35″N 22°57′51″E), and Ciucea, Cluj County (46°57′13″N 22°48′27″E) – for construction applications through chemical and pedological analysis methods was carried out by collecting soil samples at variable depths, up to a maximum of 1200 mm, using a transversal sampling method with a soil probe. The sampling process was carried out while maintaining the depth of the pedogenetic soil horizon in order to preserve the integrity of the analysed profiles. The soil sample batch was selected on the basis of pedological analysis requests submitted to OSPA (Office for Soil and Agrochemical Studies) by external clients, specifically landowners, in 2024. Each collected soil sample was assigned a unique identification code and subjected to pedological analysis under controlled laboratory conditions using standardized methods recognised in Romania. The analysis focused on key soil properties, including texture and skeletal fraction, clay content, sand content and granulometry, determined according to STAS 7184/10-79, pH value, determined according to the standardized method described in SR 7184-13:2001, humus concentration, determined according to STAS 7184/21-82, and $CaCO_3$ content determined according to the standardized method described in STAS 7184/16-80. 169 samples were collected from the Mârgău and Ciucea areas and coded as follows: M1–M114 for those collected from the Mârgău area, C1–C55 for those from the Ciucea area, and VD for the sample collected from Valea Drăganului.

In order to evaluate the potential applicability of the selected clay soils, a series of working hypotheses were formulated based on insights from the scientific literature (Figure 2). Following the pedological characterisation of the collected clay soil samples, a systematic multi-step selection process was implemented (Figure 3), wherein samples that did not meet the predefined criteria were excluded.

This methodological framework was applied to both the clay soil samples collected from the Mârgău area, Cluj County, and those from the Ciucea area, Cluj County. Subsequently, the selected soil samples were subjected to laboratory analysis in order to evaluate their physico-mechanical properties and to compare them with a reference set of indicators derived from specimens produced using clay soil collected from the Valea Drăganului area, Cluj County (46°54′10″N 22°49′53″E).

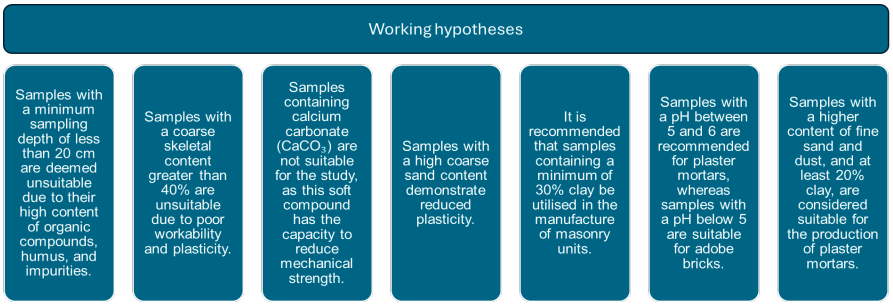

Figure 2. Working assumptions based on references found in the literature

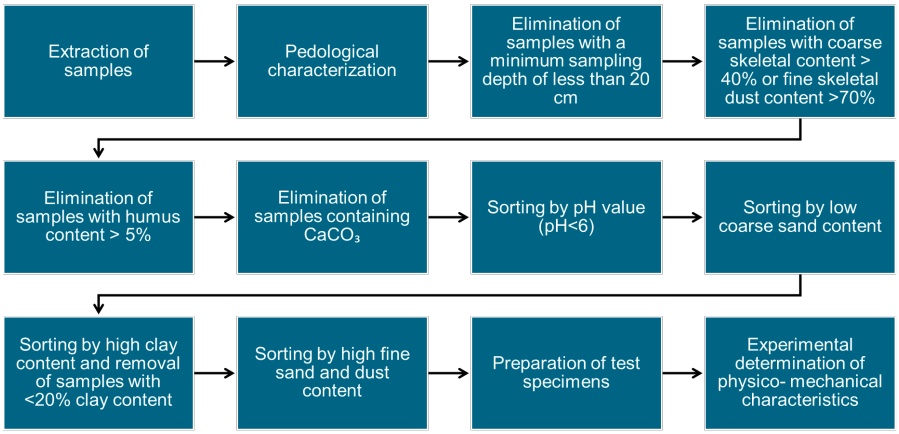

Figure 3. Clay soil sample selection scheme

The suitability of Valea Drăganului soil for adobe brick production had previously been established through experimental testing and documented findings in the scientific literature (Calatan et al., 2017; Hegy et al., 2016; Hegyi et al., 2023; Calatan et al., 2016; Călătan et al., 2020).

The present study therefore set out to validate the selection methodology applied through a comparative assessment of the soil samples.

The physico-mechanical performance of the specimens was assessed by the fabrication of prismatic specimens (40×40×160 mm) from each batch of collected and selected clay soil, as detailed below:

- the clay soil was mixed with a precise quantity of water in order to maintain consistent workability, as measured by a spread diameter of 95±5 mm;
- the freshly prepared clay-water mixture was subsequently introduced into metal moulds, with the internal dimensions of 40×40×160 mm;
- the moulded specimens were stored under controlled laboratory conditions at a temperature of 23 ± 2°C and a relative humidity of 65 ± 2% for a period of three days, after which they were demoulded for subsequent analysis;
- the clay-based specimens were then subjected to the same temperature and humidity conditions until they had attained a constant mass, which was considered an indicator of uniform drying;
- for each clay soil type selected for laboratory analysis, a set of three identical specimens was prepared to ensure the repeatability and reproducibility of the experimental results.

The physico-mechanical performance characterisation tests were conducted under controlled laboratory conditions using standardised methodologies. Thus, the analysis included the determination of apparent density in the hardened state, in accordance with EN 1015-10, and axial shrinkage, as specified by STAS 2634. Axial shrinkage represents the reduction in a material's length along its longitudinal axis during the processes of drying or curing, flexural tensile strength is defined as a material's resistance to bending stress before fracture, and compressive strength is represented as its ability to withstand axial loads without failure. Furthermore, flexural tensile strength and compressive strength were evaluated following the procedures outlined in EN 1015-11. The risk of cracking was monitored through visual examination throughout the conditioning and drying process in order to assess the material's structural integrity.

The experimental results were analysed comparatively, in relation to existing data reported in the scientific literature, as well as to the findings obtained for clay soil samples collected from the Valea Drăganului area (VD).

RESULTS AND DISCUSSIONS

In the course of the study, 114 soil samples were collected in the Mârgău area. Following the application of the sampling depth criteria, 52 samples were excluded. A similar process was followed in the Ciucea area, where 18 out of 55

samples were excluded after meeting the same selection criteria (Figure 4).

The experimental analysis of the soil texture from the predefined sampling locations revealed a wide distribution on the ternary diagram (Figure 5). As evidenced by the analysis, the soil samples from the Valea Drăganului area are classified within the L (loam) zone, having a medium-textured (M) profile.

In contrast, the soil samples collected from the Mârgău area displayed a heterogeneous distribution, with a predominant LP (loamy sand) texture, though some samples were also situated within adjacent zones, including S (sand), SS (sandy loam), SP (sandy clay loam), TP (clay loam), and AP (silty clay loam).

A similar distribution of soil samples was observed in the Ciucea area, with the majority of samples falling within the LP zone, and a smaller number positioned in the SS, SP, TP, and AP zones.

Following the selection process based on soil texture, an additional seven samples from the Mârgău batch were excluded due to their classification within the AP zone. Furthermore, ten additional samples were eliminated as they had a dust content exceeding 70%, coupled with a low clay content. Similarly, within the Ciucea batch, one additional sample (C9) was removed, as its fine particle composition rendered it more suitable for plaster mortar or finishing coat preparation rather than for adobe brick production.

Following the elimination of samples that did not meet the sampling depth criteria, the texture analysis of the remaining soil samples revealed the necessity for further exclusions. Specifically, additional samples (M14, M20, M52 from the Mârgău batch and C19, C43, C54 from the Ciucea batch) were excluded on the basis that their coarse skeletal content exceeded 40% (Figure 6).

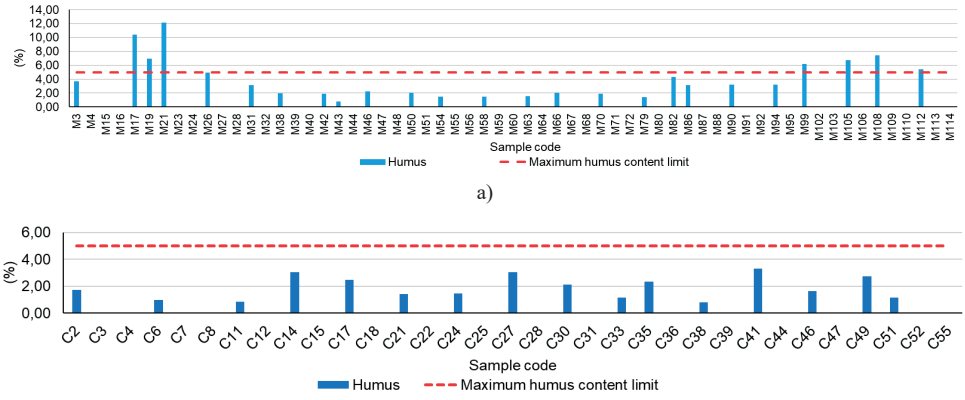
b)

Figure 6. Comparative soile texture analysis for: a) samples procured in the Mârgău area; b) samples procured in the Ciucea area

From a chemical analysis perspective, the experimental results indicated that the remaining soil samples from the Mârgău batch, after selection based on textural criteria, had a humus content ranging between 0% and 12.16% (Figure 7a). Moreover, a total of 12 samples were found to have CaCO3 concentrations ranging from 0.06% to 10.19%, which consequently prompted the exclusion of an additional 19 soil samples from the batch. Conversely, the Ciucea batch had a humus content ranging from 0% to 3.32%, with no

detectable levels of $CaCO_3$ in any of the samples. Consequently, all soil samples from this batch were retained for subsequent analysis (Figure 7b).

The analysis of acidity revealed that the pH values of the Mârgău soil samples ranged between 4.12 and 6.73 (Figure 8a), while those of the Ciucea soil samples varied from 3.75 to 5.50 (Figure 8b). Following the analysis, the distribution of pH values exhibited by the clay soils under consideration enabled the grouping of the samples into three categories.:

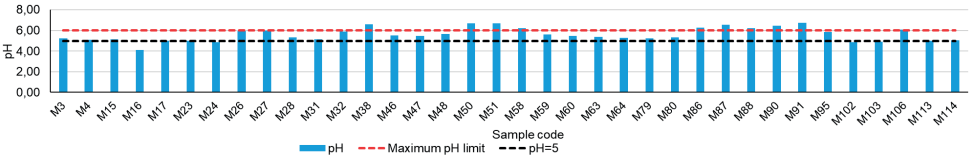


I. soil samples with a pH greater than 6 – excluded at this stage of the analysis;

II. soil samples with a pH ranging between 5 and 6 – deemed suitable for use in plaster mortar production but not recommended for adobe brick manufacturing;

III. soil samples with a pH of 5 or lower – identified as being appropriate for adobe brick production.

Following this analysis, the Mârgău batch was reduced to 25 soil samples with a pH below 6, of which six samples had a pH ranging from 4.12 to 4.99 (≤5).



A similar reduction process was applied to the Ciucea batch, which was reduced to 21 soil samples, all with a pH between 3.75 and 4.99 (≤5).

b)

Figure 8. Comparative pH valuea analysis for: a) samples procured in the Mârgău area; b) samples procured in the Ciucea area

A subsequent evaluation of the clay content and its proportional relationship to sand and silt, conducted as part of the selective elimination process, revealed that an additional nine samples from the Mârgău batch did not meet the established criteria. These samples (M16, M113, M4, M15, M64, M43, M60, M46, and M48) had clay content values ranging from 12.32% to 19.75%, rendering them unsuitable under the predetermined selection parameters.

A similar analysis of the Ciucea batch indicated that two of the remaining 21 samples had a clay content below 20% (C17: 19.05% and C44: 18.30%). As a result, these samples were excluded from further evaluation.

Following the selection process, 16 samples remained from the Mârgău batch. Of these, two samples (M24: 31.27% clay content, pH 4.87; M102: 30.8% clay content, pH 4.88) had a clay content exceeding 30% and a pH below 5, making them suitable for adobe brick production. The remaining 14 samples had clay contents ranging from 20 to 30%, with fine sand content exceeding 40%, making them more appropriate for plaster mortar and finishing coat applications (Figure 9a). Of particular note were samples M102 and M103, which had a coarse sand content below 10% (9.48% and 6.58%, respectively). Of additional significance is the observation that sample M102, in addition to having a pH below 5, also had a clay content in excess of 30%, thus rendering it suitable for utilisation in adobe brick production. Similarly, sample M103 had a clay content close to 30% (29.70%) and a pH below 5, which also suggested its suitability for adobe brick manufacturing.

Of the 19 remaining samples from the Ciucea batch, two samples (C8: 38.7% clay content; C7: 37.05% clay content) had a clay content of at least 30%, rendering them suitable for adobe brick production (Figure 9). Among the remaining 17 samples, which contained 20–30% clay, all had a fine sand content exceeding 50%, suggesting their compatibility for use in plaster mortar and finishing coat production (Figure 10). However, particular attention is drawn to samples C2, C3, C6, C7, C14, and C15, which were characterized by a coarse sand content ranging from 4.51% to 7.86%, with sample C14 having the lowest coarse sand content at 4.51%. Moreover, sample C7 is noteworthy for its low coarse sand content (6.44%), high fine sand content (56.51%), and clay content exceeding 30% (37.05%). These characteristics suggest that this clay soil has the potential to be utilised for the manufacturing of adobe bricks and plaster mortar.

Following the stepwise selection process, the soil samples selected for further investigation and physico-mechanical performance analysis were as follows: from the Mârgău batch: M24 (31.27% clay, 28.51% coarse sand), M102 (30.8% clay, 9.48% coarse sand), and M103 (29.7% clay, 6.58% coarse sand) and from the Ciucea batch: C7 (37.05% clay, 6.44% coarse sand) and C8 (38.7% clay, 10.82% coarse sand). The selection of these samples was based on their compositional properties, ensuring their suitability for subsequent experimental analyses. In consideration of the findings presented, and given the number of soil samples collected from a minimum depth of 20 cm at each location (62 samples from the Mârgău batch and 37 samples from the Ciucea batch), as well as the fact that, following the selection process, it was found that only three samples from Mârgău and two samples from Ciucea met the predefined criteria for adobe brick production. This indicates that the Ciucea area exhibits slightly greater potential than the Mârgău area in terms of identifying clay soils with properties that are compatible with the intended application. A subsequent investigation into the properties of the sample batch, with a focus on its compatibility with plaster mortars, fine plasters, and finishing coats, revealed that the 15 selected samples from the Ciucea batch exhibited higher compatibility with these applications when compared to the 14 samples selected from the Mârgău batch, indicating a potentially superior performance in these specific contexts.

The experimental results of the physico-mechanical tests conducted on prismatic specimens, produced by casting the selected soil samples, demonstrated that, in terms of apparent density (Figure 11), the recorded values were higher than those observed for the reference sample from Valea Drăganului.

In addition, these values correspond to the optimal range suggested in the scientific literature (1800-2000 kg/m³) to ensure adequate thermal inertia (Burroughs, 2008).

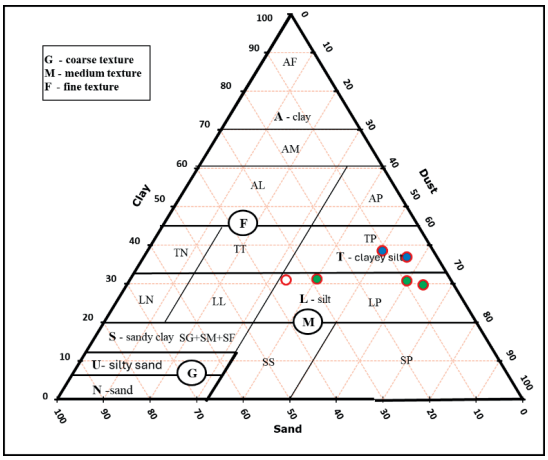

Figure 9. Humus content for: a) samples collected from Mârgău area; b) samples collected from Ciucea area

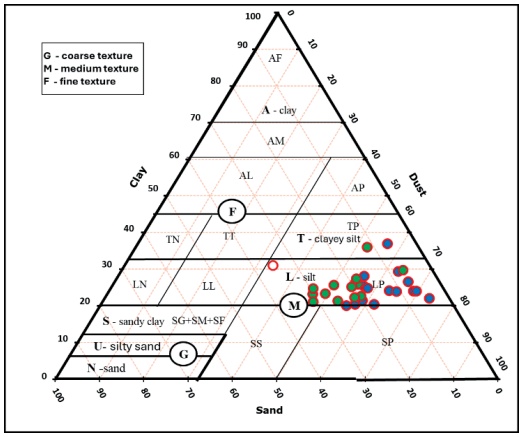

Figure 10. Texture of the soils sampled for analysis, selected for the realization of mortars for plastering, tinctures or plasters, Mârgău (green), Ciucea (blue), compared with the texture of the soil sampled in Valea Drăganului

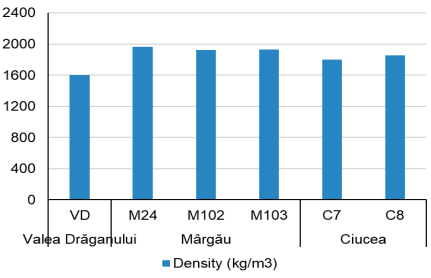

Figure 11. Graphical representation of the apparent density for a reference sample from Valea Drăganului, compared to samples M24, M102, and M103 (from Mârgău), and samples C7 and C 8 (from Ciucea)

With regard to axial shrinkage, the selected clay soil samples exhibited values within the recommended range of 3-12%, as documented in the scientific literature (Minke, 2005) (Figure 12). However, it was observed that sample M102 exceeded the upper limit of this range by 15%, suggesting an increased susceptibility to cracking during the drying process. In order to mitigate this risk, the scientific literature indicates that various additive materials, such as bone glue, salt (NaCl), or vegetable oils, may be employed to improve the material's dimensional stability.

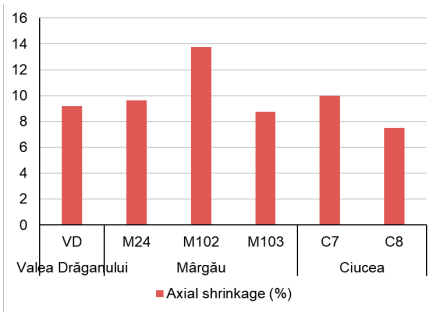

Figure 12. Graphical representation of the axial shrinkage for a reference sample from Valea Drăganului, compared to samples M24, M102, and M103 (from Mârgău), and samples C7 and C 8 (from Ciucea)

The analysis of mechanical strength under compressive and flexural tensile stresses indicates that the performance of the selected clay soil samples is comparable in magnitude to that of the reference sample from Valea Drăganului (Figure 13). Considering the previous experimental studies conducted on clay soil from Valea Drăganului (Calatan et al., 2017; Hegyi et al., 2016; Hegyi et al., 2023; Calatan et al., 2016; Călătan et al., 2020), it can be inferred that the selected clay soils from the Mârgău and Ciurila batches could also be effectively utilised for a variety of applications. These include the development of fiber-reinforced compositions incorporating dispersed vegetable fibers, as well as compositions intended for the production of construction elements, plaster mortars, and masonry mortars. Furthermore, these materials may serve as a base for incorporating performance-enhancing additives or for the integration of waste-derived raw materials, thereby contributing to the exploration of novel recycling strategies.

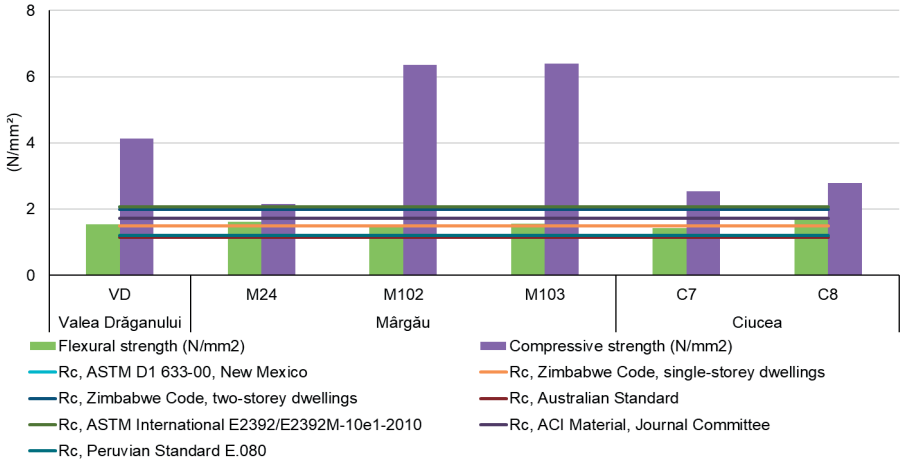

Figure 13. Analysis of flexural strength and compressive strength for a reference sample from Valea Drăganului, samples M24, M102, and M103 (from Mârgău), and samples C7 and C8 (from Ciucea), compared to relevant standards from New Mexico (ASTM D1 633-00, blue), Zimbabwe (dark blue - two stories' dwellings and orange - one story dwellings), ASTM International E2392/E2392M-10e-1-2010 (dark green), ACI Material (purple), and the Peruvian E.080 Standard (turquoise)

Furthermore, a comparison of the mechanical strength indicators with the minimum thresholds established by international standards, including ASTM D1633-00 (New Mexico), the Zimbabwean Code for Rammed Earth Walls, ASTM International E2392/E2392M-10e1-2010, and Peruvian Standard E.080, indicates that the selected and analysed samples satisfy the requirements for use in the construction of residential building walls. The findings of this study suggest that the materials can be effectively utilised in various construction techniques, facilitating the development of both single-story and multi-story structures.

CONCLUSIONS

The objective of this study was to assess the viability of utilising chemical and pedological analysis techniques to determine the prospective

suitability of clay soils from the Mârgău and Ciucea regions in Cluj County for the fabrication of adobe brick masonry components. The experimental research programme was conducted on two distinct batches of soil samples: one collected from the Mârgău area and the other from the Ciucea area, both of which are located in Cluj County. The study was designed to encompass two primary phases:

I. Selection of clay soil samples, conducted in accordance with a set of predefined criteria, which were established in alignment with the specifications outlined in the scientific literature.

II. Validation of the clay soil selection methodology is based on physico-mechanical indicators obtained through experimental testing, with a comparative analysis against references from the scientific literature. The characteristics of a clay soil sample from Valea Drăganului are also presented, and this sample had previously been investigated in a comprehensive experimental research programme.

The selection process involved the reduction of the initial 62 soil samples from the Mârgău batch and 37 soil samples from the Ciucea batch, all collected from a minimum depth of 20 cm at each location, to a final selection of three soil samples from the Mârgău batch (M24, M102, M103) and two soil samples from the Ciucea batch (C7, C8).

The validation phase, which was conducted via experimental testing, established that the selected clay soil samples had an apparent density ranging from 1798 to 1965 kg/m^3, thereby satisfying the critical mass criterion necessary to ensure optimal thermal inertia. The axial shrinkage values generally fell within the recommended range of 3-12%, with the exception of sample M102, which exceeded the upper limit by 15%, indicating a heightened risk of cracking during the drying process. The mechanical strength assessments yielded values that exceeded the minimum thresholds stipulated by international standards and were comparable in magnitude to those of the reference sample from Valea Drăganului, with compressive strength ranging from 2.54 to 6.39 N/mm² and flexural tensile strength between 1.43 and 1.69 N/mm².

In conclusion, the proposed methodology for assessing the suitability of clay soils for adobe brick production demonstrates promising potential benefits. While further refinement of the experimental protocol is necessary to fully validate the soil selection approach, it is anticipated that by integrating current knowledge in the field with rapidly obtainable data through fundamental laboratory testing in soil pedology or cost-effective on-site evaluations, the following advantages can be realised:

- enhanced comprehension of a soil horizon's capacity for a specific application;
- reduced evaluation times in comparison to conventional methodologies. In the case of conventional methods, clay soil undergoes processing, adobe bricks are fabricated, and a prolonged conditioning period is required (achieving constant mass necessitates several days under controlled temperature and humidity conditions) before being tested using physico-mechanical methods;
- the mitigation of risk associated with the selection of soil with unsuitable properties for the intended application, with a consequent minimisation of resource inefficiencies and the reduction of material and time wastage.

Abstract

Asbestos water supply networks are not believed to represent a significant hazard to public health in normal use. However, repair, rehabilitation and removal of asbestos pipes involve cutting, and demolition, can release asbestos fibers into the air, posing risks to public health. Many water utilities currently have significant portions of their water mains composed of asbestos pipes that need to be rehabilitated. This paper focuses on the evaluation of four different alternatives to rehabilitate/remove of asbestos pipes, considering the impact on the environment, respectively the total air emissions generated by the activities involved in this rehabilitation. A very performant model, EMEP/EEA air pollutant emission inventory guidebook 2023, was used for this assessment. Results indicate that the replacement of asbestos-cement pipes with no-dig, pipe-bursting technology, which involves laying the new pipe on the inside of the existing pipe, which is broken but remains underground, will have the lowest environmental impact.

Key words*: water supply networks, asbestos-cement pipes, emissions of pollutants.*

INTRODUCTION

Produced and widely used in the construction of water supply networks, asbestos cement pipes were, during the 1950s-1970s, the main type of material used for the design and execution of water distribution networks (Coufal et al., 2014).

Asbestos is an extremely cost-effective material with high tensile strength and good compressive strength. It can withstand alkaline environments, corrosion, heat, electrical conductivity, and bad weather (Pini et al., 2021). The reinforcing properties of Chrysotile fibers greatly increase durability and allow thinner and lighter pipes to be made (World Health Organization, 2011).

The use of asbestos-cement pipes brought several advantages for water operators, thus explaining the wide development of asbestos-cement networks:

- reduced production costs;
- easy installation;
- low weight compared to steel or cast iron;
- resistance to electrochemical erosion;
- relatively low roughness, so low hydraulic load losses;
- low thermal conductivity;
- durability, relatively long-life span.

However, over time it was found that using this material in water supply networks also has some disadvantages, among which are significant:

- risk to human health due to the content of asbestos fibers;
- fragility of pipes; tendency to crack under bending stress;
- difficulties in repairing degraded pipes;
- reduced resistance to vibrations generated by traffic.

Although exposure to asbestos is potentially dangerous, health risks can be minimized. In most cases, the fibers are only released if the asbestos-containing material (asbestos cement) is broken or crumbled (Logsdon, 1983). The product, non-crushed materials containing asbestos, such as water pipes, do not pose health risk. The mere presence of asbestos does not mean that the health of people working with asbestos is threatened. Asbestos is harmless in water because the problem is not ingesting the fibers but inhaling them (Qldwater, 2014).

The natural dissolution of asbestos-containing minerals in the surrounding environment implies the existence of asbestos fibers in water, and research has indicated that most waters, distributed or not through asbestos-cement pipes, contain asbestos fibers (Qldwater, 2014).

Fiber in drinking water consists almost entirely of short fibers, which are considered to pose little risk to public health.

Compared to the reduced health risk associated with the ingestion of asbestos released into drinking water, the repair, rehabilitation and replacement of water mains is of increased health concern as it involves pipe cutting, demolition, transport and disposal, resulting in emissions of very fine asbestos particles into the atmosphere, that could be inhaled (Wang et al., 2010).

Currently, within the urban water infrastructure, the problem of the existence of asbestos-cement pipes is increasingly topical, from the perspective of restrictions on use but also related to the difficulties of decommissioning them from drinking water transport and distribution systems, in which asbestos-cement pipes have been used a long time (Zavašnik et al., 2022). The fact that many of these works have reached the end of their life cycle requires their replacement and rehabilitation.

Asbestos pipe replacement technologies

The potential technologies considered for the replacement of asbestos pipes, which are the subject of this study, are:

- T1 - Replacement of asbestos pipes by placing the new pipe in an open excavation on a route parallel to the replaced pipe and leaving the existing pipe underground by filling it with concrete.
- T2 - Replacement of asbestos-cement pipes by supported open excavation and laying of the new pipe on the same route as the replaced pipe, using a temporary pipe until the new pipe is put into operation; this technology involves the evacuation of the existing pipe from the ground and its transport to an authorized waste landfill having a waste storage cell containing asbestos.
- T3 - Replacement of asbestos pipes by laying the new pipe through horizontal drilling directed along a route parallel to the replaced pipe and leaving the existing pipe underground by filling it with concrete.
- T4 - Replacement of asbestos pipes by no-dig, pipe-bursting technology, which involves laying the new pipe on the inner area of the existing pipe, which is broken, but remains underground.

The carrying out of the works to replace the asbestos-cement pipelines constitutes, on the one hand, a source of dust emissions, and on the other hand, a source of emissions of pollutants specific to the combustion of fuels (distilled petroleum products – petrol and diesel) both in the engines of the necessary machines carrying out the works, as well as the vehicles used to transport the materials (Gottesfeld, 2024).

Dust emissions, which occur during the execution of works specific to the four technologies for replacing asbestos-cement pipes, are generally associated with excavation works, transportation and putting into operation. Dust released into the atmosphere often varies substantially from day to day, depending on the level of activity, specific operations, and weather conditions (Zhang et al., 2002). The temporary nature of the asbestos pipeline replacement works, the specifics of the various execution phases, the continuous modification of the work fronts clearly differentiate the emissions specific to these works from other undirected sources of dust, both in terms of estimation and control of emissions.

The main pollutants associated with the release of dust into the atmosphere from the execution of the construction works are suspended dust - TSP, PM_{10} and $PM_{2.5}$.

As regards the emission sources of pollutants specific to the combustion of fuels, they are differentiated, according to the specifics of the machines, into two categories: heavy construction equipment (construction machinery) and material transport vehicles.

The activity of heavy construction equipment includes, in general, the work that is performed on the pipeline section that is being rehabilitated. The pollution specific to the activity of the machines is assessed according to their type, fuel consumption, period of operation and the area in which they carry out activities.

The main pollutants associated with fuel combustion in engines are CO, NMVOC, NO_x, N_2O, NH_3, SO_2 (Mitra et al., 2002). The amounts of pollutants emitted into the atmosphere by construction machinery depend mainly on the following factors:

- technological level of the engine;
- engine power;
- fuel consumption per power unit;
- machine capacity;

- age of engine/machinery, equipped with pollution reduction devices.

It is obvious that pollutant emissions decrease as the performance of the engine is more advanced, the trend in the world being the manufacture of engines with the lowest possible consumption per unit of power and with the most restrictive control of emissions. It is estimated that the pollution specific to the activities of refueling, maintenance and repair of machinery is reduced because these activities will be carried out mainly in filling stations and specialized repair bases.

The circulation of material transport means can represent an important source of pollution associated with asbestos-cement pipeline replacement technologies. Pollution specific to vehicle traffic is assessed by fuel consumption (polluting substances - NO_x, CO, NMVOC, NO_x, N_2O, NH_3, SO_2, material particles from fuel combustion, etc.) and the distances traveled.

MATERIALS AND METHODS

The evaluation of pollutant emissions into the atmosphere from the activities of replacing asbestos pipes was carried out starting from a series of general calculation assumptions or associated with each technology of replacing pipes separately.

Thus, it was considered:

- the length of the replaced asbestos-cement pipe: 100 m;
- several connections on the new pipe: 10 connections;
- an average transport distance of earth from excavations for disposal: 20 km (round trip);
- an average transport distance of construction materials: 15 km (round trip);
- an average transport distance of asbestos cement waste disposed of at the hazardous waste landfill: 220 km - nearest hazardous waste landfill from Bucharest (round trip);
- fuels used for heavy construction equipment/construction machinery (bulldozer, motor compressor, generator, horizontal directional drilling machine, etc.) and transport vehicles (dump truck, concrete mixer, etc.): diesel (density 860 kg/m^3) and/or gasoline (density 750 kg/m^3);
- fuel consumption was evaluated depending on the transport distances, the volumes of transported materials and the number of operating hours of each construction machine;
- location of construction works – Bucharest, Romania.

As a function of the rehabilitation technology profile, for heavy construction equipment/construction machinery and material transport vehicles used for the replacement of asbestos-cement pipelines, their number and operating time were considered within the activities carried out for each of the four technologies presented. The duration of the works to replace the asbestos-cement pipes, as well as the volumes of excavated earth and the volumes required to restore the filling layers for the length of 100 linear meters of replaced pipe are presented in Table 1.

Table 1. Durations of execution, volumes of excavated earth and volumes required to restore fill layers

Potential technologies	T1	T2	T3	T4
Construction period (days)	3	3	4	4
Volume of excavated soil (m^3)	164	160	92	64
Sand (m^3)	49.2	48	22.8	17.76
Gravel (m^3)	8.2	8	3.8	2.96
Crushed stone (m^3)	8.2	8	3.8	2.96
Asphalt mixture (m^3)	8.2	8	3.8	2.96

Based on the assumptions and the data presented, the emissions of pollutants into the atmosphere were calculated for the four categories of emissions:

- dust/particle emissions resulting from the construction activity itself;
- emissions of dust/particles resulting from the transport of materials;
- emissions of pollutants resulting from the combustion of fuels in the engines of construction machinery;
- emissions of pollutants resulting from the combustion of fuels in the engines of material transport vehicles.

Emissions associated with asbestos pipe replacement technologies

The dust/particle emissions from the asbestos-cement pipe replacement activities themselves, for 100 linear m of asbestos-cement pipe replaced, were calculated with the relation (U.S. E.P.A., 1986):

$$EM_{PM_{10}} = EF_{PM_{10}} \times A_{affected} \times d \times (1 - CE) \times \frac{24}{PE} \times \frac{s}{9\%}$$

where:

$EF_{PM_{10}}$ - the corresponding emission factor for PM_{10}

$A_{affected}$ - the area affected by the works

d - the duration of construction works, d = *3 days = 0.00822 years*

CE - coefficient regarding the efficiency of emission control works, *CE = 0*

PE - the Thornthwaite coefficient of precipitation-evapotranspiration, *PE = 49.47*

s - the dust content of the soil, s = *32%*.

The results of calculations for dust/particle emissions from the actual asbestos pipe replacement activities, for 100 linear m of asbestos pipe, by the four technologies are presented in Table 2.

Table 2. Dust/particles emissions from asbestos-cement pipe replacement activities

Technology	T1	T2	T3	T4
Affected area [m^2]	320	300	176	162
Duration [days]	3	3	4	4
Total suspended particles – TSP [kg]	1.316	1.234	0.965	0.888
Suspended particles with d<10 µm – PM_{10} [kg]	0.390	0.366	0.286	0.263
Suspended particles with d<2.5 µm – $PM_{2.5}$ [kg]	0.039	0.037	0.029	0.026

Dust/particle emissions from the transport of materials on public roads were calculated per km traveled by a transport vehicle, using the formula (European Environment Agency, 2023):

$$E = k \times 1.7 \times \left(\frac{s}{12}\right) \times \left(\frac{S}{48}\right) \times \left(\frac{W}{2.7}\right)^{0,7} \times \left(\frac{w}{4}\right) \times \left(\frac{365-p}{365}\right)$$

for which it was considered:

- multiplication factor for the particle size:
  - 0.35 for PM_{10};
  - 0.053 for $PM_{2.5}$.;
- s - dust content of the road surface, s = *3*;
- S - average speed of vehicles, S = *30 km/h*;
- W - weight of vehicles, $W \approx 20$ *t*;
- w - number of wheels, w = *6*;
- p - number of dry days, p = *132* (for Romania).

The results of the calculations for dust/particle emissions from the transport of materials on public roads, for the four technologies, are presented in Table 3.

Table 3. Emissions of dust/particles resulting from the transport of materials on public roads

Technology	T1	T2	T3	T4
Distance [km]	575	745	330	240
Suspended particles with d<10 µm – PM_{10} [kg]	207.93	449.02	119.34	86.79
Suspended particles with d<2.5 µm – $PM_{2.5}$ [kg]	31.49	67.99	18.07	13.14

The total emissions of pollutants resulting from the combustion of fuels in the engines of heavy construction equipment and in the engines of vehicles transporting construction materials, used for the replacement activities of asbestos-cement pipes (100 linear m of pipe) were calculated based on the "EMEP/EEA" guide air pollutant emission inventory guidebook 2023, 1.A.3.b. Combustion - Road transport, with the relationship (European Environment Agency, 2023):

$$E_i = \sum_j \left(\sum_m \left(FC_{j,m} \times EF_{i,j,m} \right) \right)$$

in which:

E_i - emission of the pollutant i [gr];

$FC_{j,m}$ - fuel consumption of vehicle category j using the fuel m [kg];

$EF_{i,j,m}$ - emission factor for the pollutant i, for the vehicle of category j using the fuel m [gr/kg].

The results of the calculations for the total emissions of combustion fuels in the engines of construction machinery and in the engines of construction material transport vehicles for the four technologies are presented in Table 4.

Table 4. Total emissions resulting from the combustion of fuels in the engines of construction machinery

Technology	T1	T2	T3	T4
NMVOC [kg]	5.107	5.201	1.493	1.340
NO_x [kg]	15.320	16.955	11.759	11.173
PM [kg]	0.497	0.543	0.343	0.325
N_2O [kg]	0.0250	0.0275	0.0183	0.0173
NH_3 [kg]	0.0078	0.0084	0.0049	0.0047
SO_2 [kg]	0.0030	0.0033	0.0022	0.0021
CO [kg]	19.48	19.85	5.76	5.18
CO_2 [kg]	1536.8	1692.0	1132.5	1074.6

RESULTS AND DISCUSSIONS

Following the calculations performed and the results obtained and represented graphically in Figure 1, it is found that the emissions of dust/particle matter for T4 technology for the

replacement of asbestos-cement pipes are lower than in the other three technologies, as follows:

- T1 – 1.48 times higher than T4;
- T2 – 1.39 times higher than T4;
- T3 – 1.09 times higher than T4.

This is mainly due to the smaller land areas affected by T4 technology.

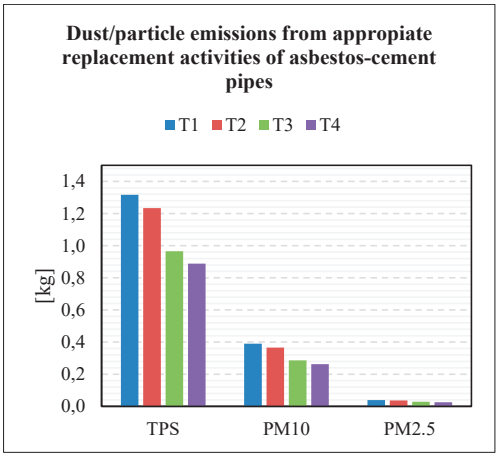

Figure 1. Emissions of dust/particles from the activities of replacing the appropriate asbestos-cement pipes, through the four technologies

For the emissions of dust/particle matter in suspension, generated from the transport of construction materials, shown graphically in Figure 2, it is found that the values obtained for the T4 technology for the replacement of asbestos-cement pipes are lower than the values obtained for the other three technologies, as follows:

- T1 – 2.40 times higher than T4;
- T2 – 5.17 times higher than T4;
- T3 – 1.38 times higher than T4.

The value of dust/particle emissions from the transport of construction materials for T2 technology for the replacement of asbestos-cement pipes, are very high due to the disposal of the disused asbestos-cement pipe at a hazardous waste landfill.

In terms of total emissions of combustion fuels in the engines of heavy construction equipment and construction material transport vehicles, they also vary from one technology to another for the replacement of asbestos-cement pipes, but also from one activity to another.

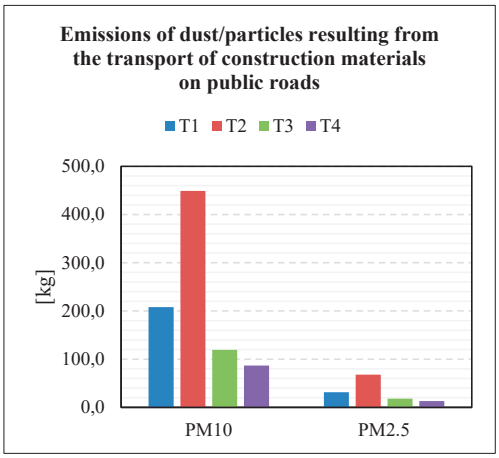

Figure 2. Emissions of dust/particles resulting from the transport of construction materials on public roads, through the four technologies

In comparison, Figure 3 and Figure 4 show, for the four technologies of replacing asbestos-cement pipes, the main emissions (NMVOC, NO_x, PM, N_2O, NH_3 and SO_2) from combustion in the engines of heavy construction equipment.

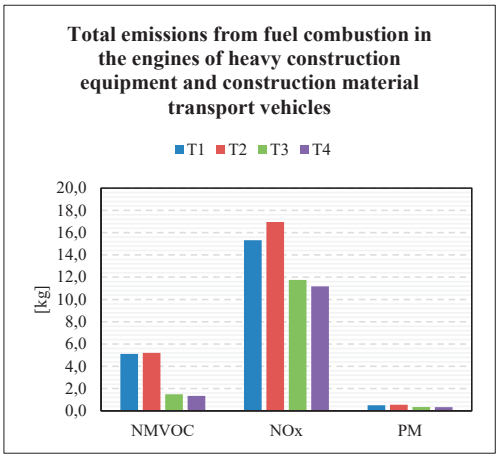

Figure 3. Total NMVOC, NOx and PM emissions resulting from fuel combustion

Analyzing the obtained values, it is found that again the technology with the lowest level of pollutants resulting from fuel combustion is T4 technology (smaller volumes of excavations, shorter transport distances, non-recovery of the replaced asbestos-cement pipe).

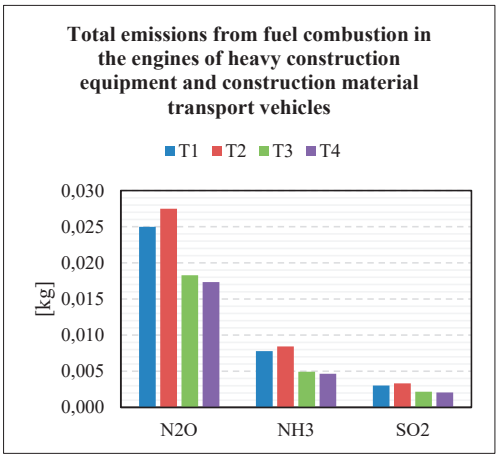

Figure 4. Total N_2O, NH_3 and SO_2 emissions from fuel combustion

It is also found that T4 technology has the lowest levels of pollutants, for the same reasons, both for the CO emission values represented graphically in Figure 5 and for the CO_2 emission values graphically represented in Figure 6.

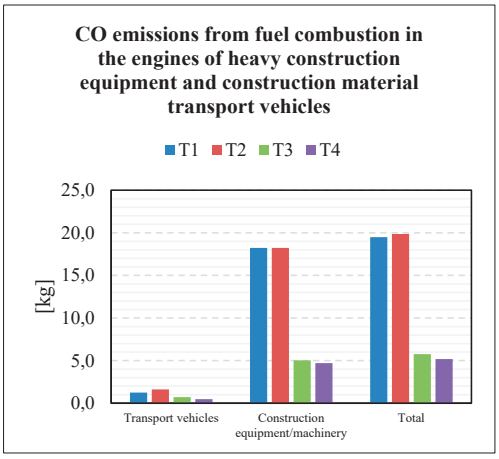

Figure 5. CO emissions [kg], resulting from fuel combustion

The comparative analysis of dust/particle emissions from the actual asbestos pipeline replacement activities, through the four technologies, highlights for any of the four evaluated factors, namely TSP, PM_{10}, $PM_{2.5}$, the fact that the lowest values of them are recorded for T3 and T4 technologies. Technologies T1 and T2 have high values, in the order in which they are listed. Overall, dust/particle emissions for the T4 asbestos-cement pipe replacement technology are lower than the other three technologies.

The emissions of dust/particle matter (PM_{10}, $PM_{2.5}$) from the transport of construction materials for the T4 technology are lower than in the other three technologies.

Emissions from the transport of construction materials for the T2 technology are very high, this fact results from the need to dispose of asbestos pipe waste at a hazardous waste landfill.

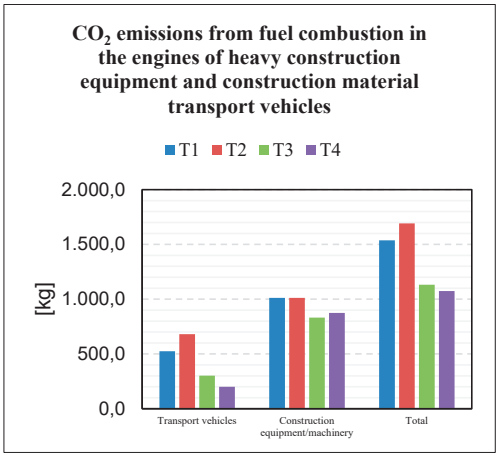

Figure 6. CO_2 emissions [kg], resulting from fuel combustion

NO_x emissions from the combustion of fuels in the engines of heavy construction equipment/construction machinery and vehicles transporting construction materials (NMVOC, NO_x, PM, N_2O, NH_3 and SO_2) also vary from one technology to another, proposed to replace pipelines of asbestos, but also from one activity to another.

The emissions resulting from the combustion of fuels in the engines of heavy construction equipment, for technologies T3 and T4 have the lowest values.

The level of emissions associated with the T2 technology for replacing asbestos pipes is 3.41 times higher than that of the technology with the lowest levels of NO_x emissions T4.

The other two technologies, T1 and T3 record values of 2.63 and 1.51 times higher than technology T4, respectively.

Table 5. Air pollutant emissions associated with the four asbestos-cement pipe replacement technologies

Type of emissions	Emissions			
	T1	T2	T3	T4
Dust/particle emissions from the appropriate asbestos pipe replacement activities, for 100 linear m of asbestos pipe [kg]				
Total suspended particles – TSP	1.316	1.234	0.965	0.888
Suspended particles with d < 10 µm – PM_{10}	0.390	0.366	0.286	0.263
Suspended particles with d < 2.5 µm – $PM_{2.5}$	0.039	0.037	0.029	0.026
Emissions of dust/particles resulting from the transport of materials on public roads [kg]				
Suspended particles with cu d < 10 µm – PM_{10}	207.93	449.02	119.34	86.79
Suspended particles with d < 2.5 µm – $PM_{2.5}$	31.49	67.99	18.07	13.14
Total emissions of pollutants resulting from the fuel combustion in the engines of heavy construction equipment and vehicles transporting construction materials [kg]				
Carbon monoxide – CO	19.48	19.85	5.76	5.18
Non-methane volatile organic compounds – NMVOC	5.107	5.201	1.493	1.340
Nitrogen oxides – NO_x	15.320	16.955	11.759	11.173
Suspended particles – PM	0.497	0.543	0.343	0.325
Nitrous oxide – N_2O	0.0250	0.0275	0.0183	0.0173
Ammonia – NH_3	0.0078	0.0084	0.0049	0.0047
Sulfur dioxide – SO_2	0.0030	0.0033	0.0022	0.0021
Carbon dioxide – CO_2	1536.78	1692.00	1132.53	1074.60

The emission levels of the four technologies were compared by assigning standardized scores to each emission type.

These scores were normalized to a common scale within the [0,1] interval using the following formula:

$$Score_{[0,1]} = 1 - \frac{E - max(E_i)}{max(E_i) - min(E_i)}$$

in which:

E - the emission for a certain type of pollutant;

max(Eᵢ) - the maximum value of the pollutant emission, from the four technologies;

min(Eᵢ) - the minimum pollutant emission value, from the four technologies.

A value of "0" was assigned to the highest emission level, while a value of "1" was assigned to the lowest. Based on this approach, Table 6 presents the standardized scores for each technology and type of atmospheric emission, corresponding to the four asbestos–cement pipe replacement methods.

Table 6. Standardized scores by technology and type of atmospheric emissions associated with the four asbestos-cement pipe replacement technologies

Type of emissions	Standardized scores according to technology and type of emissions			
	T1	T2	T3	T4
Dust/particulate emissions from appropriate asbestos pipe replacement activities, for 100 linear m of asbestos pipe				
Total suspended particles – TSP	0	0.19	0.82	1
Suspended particles with d<10 µm – PM_{10}	0	0.19	0.82	1
Suspended particles with d<2.5 µm – $PM_{2.5}$	0	0.19	0.82	1
Final grade (arithmetic average):	0	0.19	0.82	1
Emissions of dust/particles resulting from the transport of materials on public roads				
Suspended particles with d<10 µm – PM_{10}	0.67	0	0.91	1
Suspended particles with d<2.5 µm – $PM_{2.5}$	0.67	0	0.91	1
Final grade (arithmetic average):	0.67	0	0.91	1
Total emissions of pollutants resulting from the fuel combustion in the engines of heavy construction equipment and vehicles transporting construction materials				
Carbon monoxide – CO	0.03	0	0.96	1
Non-methane volatile organic compounds – NMVOC	0.02	0	0.96	1
Nitrogen oxides – NO_x	0.28	0	0.90	1
Suspended particles – PM	0.21	0	0.92	1
Nitrous oxide – N_2O	0.25	0	0.91	1
Ammonia – NH_3	0.17	0	0.92	1
Sulfur dioxide – SO_2	0.24	0	0.91	1
Carbon dioxide – CO_2	0.25	0	0.91	1
Final grade (arithmetic average):	**0.18**	**0**	**0.92**	**1**

CONCUSIONS

The analysis elements presented for the four options highlight the diversity of rehabilitation technologies, respectively their impact on the environment, in particular the emissions of pollutant substances and particles in the atmosphere. At the same time, it was noted that there is still no definitive (dominant) opinion at the international level regarding the solutions applied, or applicable, each country oscillating between various possible options.

Synthesizing the results obtained based on the calculations performed for the emissions of pollutants in the atmosphere highlights the fact that the T1 and T2 technologies have major effects on the environment. However, it can be noted that the T2 technology has higher values of emissions compared to the T1 technology by approximately 18%. T3 and T4 technologies have relatively equal minimum values (slightly better for T4 technology, but the difference is insignificant).

Comparing the scores obtained for the four technologies based on the standardization and normalization of atmospheric emissions in the interval [0,1], various rankings can be made, giving different weights to the three categories of emissions:

- dust/particle emissions from the actual asbestos pipeline replacement activities,
- emissions of dust/particles resulting from the transport of materials on public roads,
- total emissions of pollutants resulting from the combustion of fuels in the engines of heavy construction equipment and vehicles transporting construction materials,

all considered for the replacement of 100 linear m of asbestos-cement pipe.

Regardless of the weightings chosen, technology T4 – replacement of asbestos pipes by no-dig, pipe-bursting technology will get the highest score, and technology T2 – replacement and removal of asbestos pipes by supported open excavation and laying the new pipe on the same route as replaced pipe – will get the lowest score.

AFFORESTATION OF SANDY SOILS OF OLTENIA - A REVIEW -

Paula IANCU, Marin SOARE, Mariana NICULESCU

University of Craiova, 13 Libertății Street, 200583, Craiova, Romania

Corresponding author email: soare_marin@yahoo.com

Abstract

Oltenia is the region in southwestern Romania facing significant challenges related to desertification, especially in Dolj County. Sandy soils from this area present specific characteristics due to the low water retention, low nutrient content and limited organic matter typically found in these types of soils. Afforestation could be an essential solution to prevent desertification in this region, which faces significant risks related to land degradation. Afforestation of sandy soils, however, requires a multifaceted approach, combining soil improvement techniques, careful species selection, water management and continuous monitoring. With the right strategies, it is possible to restore ecological functions and to improve fertility of these types of soils. The key to success lies in understanding the specific challenges of sandy soils and adapting techniques accordingly to promote the growth and sustainability of forested areas.

Key words*: afforestation, aridity, desertification, Oltenia region, sandy soils.*

INTRODUCTION

Afforestation is the process of planting trees on lands that were not previously forested. Key features of afforestation refer to the plantation of entirely new forested areas and often involve the use of native or fast-growing species. In the context of Oltenia, where there are challenges like sandy soils, desertification, and degraded agricultural land, afforestation could address land degradation and create new forest ecosystems in areas which became unsuitable for agriculture.

Agroforestry is also a technique which could be effective in the area because utilizes the integration of trees with farming systems to stabilize soils and improve livelihoods. This system has considerable potential to mitigate climate change (Doelman et al., 2020).

The afforestation projects of degraded terrains must be carried out in accordance with the technical norms issued by the ministry responsible for forest management. Afforestation can bring numerous ecological and economic benefits, contributing significantly to their stabilization.

Afforestation of sandy soils is an essential measure to combat desertification and stabilize affected lands. Oltenia is facing an alarming phenomenon of desertification, which is seriously affecting which once were fertile soils. Oltenia is the region in southwestern Romania that encompasses a varied relief and diverse soils, influenced by specific climatic and geological conditions. This area is characterized by a combination of plains, hills and mountains, which significantly influences the types of soils and their use in agriculture. It is also home to the largest area of sands and sandy soils. These are arranged in longitudinal dunes oriented from west to east, in the direction of the dominant wind (Prioteasa, 2021). Yield potential of these soils is low and requires measures to stem deflation, increase in the content of humus in the soil, mineral and organic fertilizer application and preservation of forest areas (Stanila et al., 2020). Fertilization becomes essential for sandy soils, the main practice being inorganic fertilization, but also organic manures can supply nutrients in slowly available forms which improve soil physico-chemical properties. The incorporation of organic manures deeper into the soil or spreading a carpet-like layer (at least 1 cm thick) improves water storage, biological activity, and nutrient status (https://www.fao.org/soils-portal). Under current conditions (drought and extreme temperatures), fertilization combined with appropriate irrigation practices, becomes even

more important to ensure a constant supply of nutrients, thereby ensuring good crop development (Nițu et al., 2024). Another technique is applying mulch in order to reduce evaporation. Crop residues from the soil surface reduce evaporation losses, decrease the range between maximum and minimum soil temperature, and wind erosion. There are authors which sustain that mulching improves yield (ex. sweet potato) by maintaining soil temperature and moisture, increasing plant growth, and leading to higher tuber numbers and weight. Also, influence their quality, by increasing total soluble solids, starch, and vitamin C content in the tubers. But, the effectiveness of mulching can vary depending cultivar and mulch type (Dinu et al., 2022).

To combat the advance of sand and revitalize this type of soil, planting trees or forest curtains to stabilize them and create a favorable micro-climate can be a solution. The implementation of new agricultural technologies based on reducing resource consumption contributes to reducing the impact of agriculture on the environment (Coca et al., 2020).

As in the specific context of Oltenia, afforestation is a key strategy to combat soil desertification, the purpose of this work is to present the advantages of this action and how it can help reduce the vulnerability to the drought and to the current or future climatic changes.

MATERIALS AND METHODS

The sandy soils occupy a significant surface in Oltenia, especially in its south and have become difficult for agriculture due to the high permeability and the low water retention capacity. However, their afforestation can transform this useless land into some productive ones, income generators. The presentation of this process was carried out by consulting relevant materials, such as books, scientific articles, conference works, reports or online databases. The objectives of the documentation focused on identifying the context of desertification, the benefits and challenges of afforestation actions in the context of current climate change by attempting to address the following aspects:

- advantages;
- challenges;
- techniques;
- recommended trees.
- afforestation projects in Oltenia region.

RESULTS AND DISCUSSIONS

Advantages of afforestation action

- *Reducing soil erosion*. Forests help to fix the soil through tree roots, which hold soil particles together. This reduces the risk of erosion, a common phenomenon in areas with sandy soils, where wind and water can quickly carry soil particles (Akca et al., 2010). Erosion usually affects soil fertility because removes the fertile layers in the upper horizons, which contain a large amount of organic matter and nutrients (Bălan et al., 2024).
- *Improving soil quality and structure*. Afforestation helps improve soil structure and fertility. Fallen leaves and organic matter in the forest decompose, enriching the soil with essential nutrients and increasing its water-holding capacity. Tree roots help form a dense root system, which can improve the texture of sandy soil by creating channels for water and other components.
- *Regulation of the hydrological cycle*. Forests positively influence the local hydrological regime. They contribute to increasing soil moisture and reducing flood risks by absorbing excess water. This is crucial in areas with sandy soils, which have a low water retention capacity.
- *Creating a favorable microclimate*. By shading the land and through plant transpiration, forests contribute to creating a more stable microclimate, which can favor the development of other plant and animal species. This microclimate helps maintain humidity and reduce extreme temperatures. Forests contribute to better infiltration of water into the soil, which helps prevent droughts and improve the availability of water for crops and other plants.
- *Diversification of fauna and flora*. Planting tree species contributes to creating a habitat for various animal and plant species, increasing local biodiversity (Jorge et al., 2022).
- *Carbon sequestration*. Forests are essential in sequestering carbon, thus contributing to combating climate change. Through the process of photosynthesis, trees absorb carbon dioxide from the atmosphere, which helps reduce greenhouse gases.

- *Economic and social benefits*. Afforestation can generate economic opportunities through the development of eco-tourism and sustainable forestry activities. Local communities also benefit from the creation of jobs in forest management and sustainable agriculture (Akca et al., 2010). Afforestation of degraded land is not an end in itself but a national necessity (Crăciunescu et al., 2014).

Challenges regarding afforestation

- *Low precipitation*. Oltenia is characterized by a low annual precipitation rate, which has been recorded as low as 262.7 mm in certain years.
- *Water scarcity*. Sandy soils typically have low water retention capacity, making it challenging to sustain newly planted trees during dry periods. Effective water management practices are essential for success (Mingyuan, 2024).
- *Drought sensitivity*. In southern Romania, frequent droughts can affect the success of tree planting and development, necessitating additional irrigation and seedling protection strategies. Oltenia region is highly sensitive to drought conditions, which are exacerbated by climate change.
- *Soil characteristics*. Sandy soils in Oltenia are prone to erosion and have poor nutrient retention capabilities. These factors make it challenging for trees to obtain the necessary nutrients for growth, leading to higher mortality rates among afforested species.
- *Long-term maintenance*. Continuous monitoring and management are required to ensure the health of afforested areas, especially in terms of pest control and competition among species (Jorge et al., 2022).
- *Conflict with agricultural land use*. In areas where sandy lands are used for agriculture, afforestation may conflict with economic interests related to crops.
- *Lack of funds and infrastructure*. Afforestation projects can be expensive and require considerable financial resources for implementation and long-term maintenance.

Recently, the Ministry of Environment has launched initiatives to expand the forested area in southwestern Romania, with the aim of combating desertification and improving the local ecosystem.

Afforestation of the sands in this region can bring numerous ecological, economic and social benefits, essential for combating desertification and improving living conditions in the region.

As afforestation techniques, the following can be used:

- **planting on degraded lands**: in the plain regions of southern Romania, it is essential to plant forest species on lands degraded due to erosion or excessive exploitation. Planting should be done in a way that maximizes the success of the seedlings (e.g., using irrigation systems, protecting the seedlings from strong winds);
- **silvopasture**: this involves combining forest with animal grazing, with the aim of conserving the soil and efficiently using natural resources. Also, in some areas, to increase the efficiency of afforestation, methods such as mixed plantations (using combinations of tree and shrub species to create a stable and diversified ecosystem) or the use of local species (in some cases, native plants are preferred to ensure better adaptation to the ecological conditions in Oltenia) can be used;
- **Miyawaki method**: this technique involves planting a dense mix of native species in a small area, which helps create a self-sustaining forest ecosystem quickly. The method emphasizes biodiversity and can improve soil quality rapidly;
- **patch planting**: instead of uniform planting, creating patches of vegetation can help gather surface runoff and improve local moisture levels, facilitating better growth conditions for the trees (Mingyuan, 2024).

Tree species suitable for afforestation of sandy soils

For the afforestation of sandy soils, several species of trees and shrubs are recommended that adapt well to the specific conditions of these soils. These are:

- Acacia (*Robinia pseudoacacia*) is a drought-resistant species that grows well on sandy soils and helps fix nitrogen in the soil.
- Oak (*Quercus robur*) is a hardy tree that can help stabilize soils and can grow on poorer soils. In the Oltenia Plain the Turkey Oak occupies 10061.9 ha, and the Hungarian Oak 4655.0 ha (Cojoacă et al., 2020).
- Poplar (*Populus* spp.). Poplars are often used in reforestation projects in lowland areas

because they grow quickly and can tolerate sandy soils.

- Pine trees (*Pinus* spp.). Various species of pine are well-suited to sandy soils due to their deep root systems and drought tolerance. Research from Turkey demonstrates that afforestation of sand dunes with pine (specifically Stone Pine, *Pinus pinea*), along with other species, increases soil organic matter, phosphorus content, and socio-economic value within several decades. Pines not only stabilize sandy soils and reduce erosion but can also serve as sources of timber, nuts, and other products, benefiting local communities (Akca et al., 2010). Planting trees such as *Pinus sylvestris* and *Ulmus pumila* has been shown to enrich soil nutrients in the surface layers, improve soil structure, and reduce bulk density, which enhances overall soil health (Guo et al., 2024).
- *Casuarina* spp. (Sheoak). These trees are drought-resistant and can fix nitrogen, improving soil quality.
- *Hakea* spp. An Australian native that adapts well to sandy soils and is drought-tolerant.
- *Grevillea* spp. Another Australian native that flourishes in sandy conditions, known for its unique flowers and deep root system.
- Olive Tree (*Olea europaea*). Drought-tolerant and well-adapted to nutrient-poor soils, making it ideal for sandy environments.
- *Telopea* spp. (Tree Waratah): Known for vibrant flowers and hardiness in poor soil conditions.
- Bald Cypress (*Taxodium distichum*): Thrives in wet or dry sandy conditions and is known for its resilience.
- Sand grass or perennial grass species - they can be used as short-term cover plants to help stabilize the soil until the trees become mature enough.

In addition to these, a number of other species can also be used such as: juniper, sea buckthorn, willow, weeping willow, etc., and shrubs that can also be used for the afforestation of degraded lands (Enescu, 2015, 2018). Among best shrubs or other plants:

- *Lavandula angustifolia* (Lavender): Excellent for sandy soils due to its drought resistance and ability to thrive in poor nutrients.
- *Rudbeckia* spp. (Black-Eyed Susan): A flowering plant that does well in full sun and sandy conditions.
- *Salvia* spp.: These plants are hardy and can tolerate dry, sandy soils.
- *Buddleja* spp. (Butterfly Bush): Thrives in sunny, dry locations with sandy soil.
- *Juniperus* spp. (Junipers): Adaptable shrubs that can withstand drought and poor soil.

Choosing the right species for afforestation in sandy soils is essential for ensuring successful growth and sustainability of the forest ecosystem. The mentioned species are well-suited to cope with the challenges posed by sandy environments, making them ideal candidates for afforestation projects (https://www.rhs.org.uk/plants/for-places/sandy-soils).

The lands from the Oltenia area were gradually subjected to changes induced by intensive agricultural use, so that on large areas of forest it was intervened in numerous stages of afforestation and deforestation (Iordache & Ciuinel, 2013). In the last three decades over 4300 hectares of forests and vineyards areas in sandy dunes perimeter were lost (Prăvălie, 2013). The absence of irrigation and the uncontrolled deforestation of protection belts accelerated the extension of desertification of sandy soils, leading to depleted arable-land productivity and, in time, abandonment of these lands (Bălteanu et al., 2013). The impact of climate change in the sandy soil areas of Sadova, Bechet, Corabia, Apele Vii, etc. leaded to intense aridity phenomena and tends to enhance desertification on larger surfaces. Therefore, there is an urgent need to cover and protect the soil from Apele Vii, Mârşani, Daneţi, Celaru, Castranova, etc. communes which also falls into the high drought-affected sandy soils of the Leu-Rotunda Plain. Recent studies suggest that the combination of black locust (*Robinia pseudoacacia*) and bird cherry (*Prunus padus*) is optimal for afforestation in this region. These species are favored due to their rapid growth rates and ability to stabilize shifting sands within five years. They are also economically viable, as their seedlings are easy to produce and affordable (Enescu, 2019; Răducă et al., 2022). Black locust is an important non-native tree species used mostly for sandy soil and sterile dump afforestation for its ornamental role, but also for its wood (lumber, poles, firewood) and honey production (Buzatu-Goanță et al., 2020).

Few years ago, in Radovan (medium fertility soil), Tâmburești (sandy soil, irrigation) and Işalnița (antropomorphic soil formed from coal ash), an experiment with SRC willow crop of was initiated considering the specie a sustainable source of biomass because of its potential to fix carbon (C) in the soil and also, short-term crops could be an option for solving the demand for bioenergy (Păniță et al., 2017).
Salix genus includes many species with various uses - wood production, biomass, animal feed, source of salicylic acid, land reclamation, biofuel, etc. (Corneanu et al., 2022).
In Dolj county there is a natural forest in Bratovoiești, which occupies a large part Oltenia Plain, of the Valley Jiu with three types of natural habitats and plant communities rich in mesophyle, mesohygrophyle and hygrophyle species (Cojoacă & Niculescu, 2018).
Juglans regia L. is also a specie which is growing well in temperate climate areas. Oltenia is a region known for walnut diversity because its various eco-geographical areas (Cosmulescu & Botu, 2012).
The challenges of afforestation of Oltenia region necessitate careful planning and the selection of drought-resistant tree species for afforestation projects. Strategies must include efficient water management practices and soil improvement techniques to enhance the viability of afforestation efforts in this vulnerable region.
The zoning and micro-zoning of the potential forest vegetation can be the base of the selection of species that optimally harness the stationary potential in the case of the extension of the forest land to the agricultural land unfit for agricultural use, and the extension of forest protection curtains in territories where their design has not been carried out (Bercea & Dinucă, 2018).

Recent afforestation initiatives

The increase of areas covered by forest vegetation and the necessity to take actions against drought, aridity and land degradation is a priority of the national strategy for preventing and control of these (MMAP, 2008).
Romania has implemented several afforestation programs, such as the "National Afforestation Program", which encourages the rehabilitation of degraded lands, including sandy soils in the south of the country. These projects are carried out in collaboration with local authorities and environmental organizations and aim to protect soils and improve ecosystems.
MMAP (2017) emitted a National Forest Strategy for 2018-2027 was published, putting an emphasis on sustainable management of the national forest fund.
Generally, funding is a problem of afforestation in Romania. Along time, afforestation projects were supported mainly through different funding mechanisms: Special Accession Program for Agriculture and Rural Development (SAPARD) (Law no. 316/2001), the Environmental Fund (Law no. 73/2000, completed by Government Emergency Ordinance no. 196/2005 and the European Union funding instruments implemented through the National Program for Rural Development (PNDR) actions (Government Decision no. 1.284/2008 for 2007-2013 and no. 226/2015 for 2014-2020) (PNDR, 2017) (Palaghianu & Dutca, 2017).
Afforestation projects implementation is hindered by the lack of cadastre and funds. Also, to the population and the landowners it must be explained the importance of forest protection belts for the improvement of environment and living conditions, for the gradual diminishing of drought effects and for the enhancement of agricultural production (Achim et al., 2012).
PNDR, 2014-2020, through Measure 8.1 for afforestation by the concept of transferable carbon credits could potentially contribute to increasing forest area in Romania and carbon sequestration projects such as PCF, could represent viable opportunities for future afforestation (Palaghianu & Dutca, 2017).
123 Measure "Increasing the added value of agricultural and forestry products" has as general objectives to increase the competitiveness of agrifood and forestry processing enterprises by improving the general performance of enterprises in the processing and marketing sector of agricultural and forestry products, through better use of human resources and other factors of production (Vladu et al., 2018).
A large part of the budget for afforestation funds from the National Plan for Recovery and Resilience (PNRR) is being allocated to the south of the country, where it is most needed. 70 hectares of sand from the Oltenia Sahara were afforested with acacia, elm and mulberry.

Another 2500 hectares of sandy land will be afforested to protect localities and crops.
In 2023, Romania added 3,159 hectares of new forests, bringing the total forested area to 6.45 million hectares. This increase is largely due to reforestation efforts on pastures, afforestation of degraded lands, and inclusion of new areas in the national forest fund.
Key contributors to this growth include:
- Government and EU-funded initiatives focusing on afforestation and reforestation.
- NGOs and private projects, such as the Tomorrow's Forest Foundation and Mossy Earth, which restore forests and combat illegal deforestation. Their projects in Dolj County, for instance, aim to restore ecosystems and support local communities. There were also some reforestation initiatives made by students, teachers and volunteers' communities in order to contribute to climate change mitigation efforts.
Afforestation efforts are increasing, but deforestation still poses challenges, especially in areas affected by illegal logging or land-use changes. Sustainable forest management remains a key priority. The afforestation of degraded sandy soils is seen as a valuable opportunity to expand the national forest fund, providing ecological benefits and supporting local communities.

CONCLUSIONS

Oltenia is a region with significant agricultural potential due to the diversity of its soils. However, the challenges related to desertification require innovative solutions to maintain the viability of agriculture in this area. Adapting agricultural techniques to local conditions will be essential for the future of the region.
Afforestation of sandy soils helps stabilize them, but also contributes to improving the quality of the environment, having a positive impact on biodiversity. Also, can be a viable solution for ecological restoration and sustainable land management. By carefully selecting appropriate species, employing effective planting techniques, and managing resources wisely, it is possible to transform degraded sandy landscapes into productive ecosystems that benefit both the environment and local communities.
For the afforestation of sandy soils, species capable of stabilizing the soil, reducing erosion and contributing to improving environmental quality are recommended.

Abstract

Research on climate change has become a cornerstone of the global scientific and political response to one of the most pressing environmental crises. This paper provides an overview of major climate research directions, with a focus on international, European, and national institutional frameworks. Based on the analysis of strategic documents and institutional sources, the paper identifies key trends, structural gaps, and opportunities for advancing national climate research in Romania. It highlights the need for interdisciplinary approaches and stronger links between science and public policy as critical components of effective climate action.

Key words**:** *adaptation, climate change, climate research, mitigation, science-policy interface.*

INTRODUCTION

Climate change has evolved from an environmental concern to an emerging issue on global political, economic, and scientific agendas. The manifestations of climate instability, ranging from extreme weather events to shifts in precipitation patterns and rising sea levels, pose direct risks to biodiversity, public health, water availability, and infrastructure.

What distinguishes current climate dynamics from previous geological or meteorological shifts is the speed, scale, and underlying anthropogenic influence. A growing body of evidence confirms that human activities, particularly fossil fuel combustion, deforestation, and industrial agriculture, have drastically altered atmospheric composition, leading to global warming and associated feedback effects (IPCC, 2021; IPCC, 2022).

Since the late 20th century, climate science has matured as an interdisciplinary field, integrating atmospheric physics, oceanography, ecology, geography, and socio-economic analysis.

The European Union (EU) has played a significant role in coordinating climate research and funding programmes, which will be further detailed in subsequent sections.

Over the past two decades, scientific research has emerged as both a diagnostic and a prescriptive tool in addressing climate change. It not only deepens our understanding of physical and ecological systems but also informs the design of mitigation and adaptation strategies. As the climate crisis intersects with challenges such as urbanisation, food security, and energy transition, there is an increasing demand for interdisciplinary and problem-oriented approaches to climate research (Bai et al., 2016). This article contributes to the scientific dialogue by reviewing the current state of climate change research. It identifies dominant research directions, maps institutional ecosystems at global and European levels, and reflects on Romania's position within this broader context.

MATERIALS AND METHODS

This study adopts a qualitative research approach, based on documentary analysis and thematic synthesis. Primary sources include official reports from international organisations such as the Intergovernmental Panel on Climate Change (IPCC) (IPCC, 2021), the World Meteorological Organization (WMO) (WMO, 2023), the European Environment Agency (EEA) (EEA, 2025), and the European Commission (EC) (European Commission, 2020). These sources were selected based on four key criteria: (i) credibility and institutional authority, (ii) thematic relevance to climate science and policy, (iii) recency (2015–2024),

and (iv) open-access availability to ensure transparency and replicability.

To structure the analysis, a thematic framework was applied, comprising the following four axes:

1. institutional structure and governance – this axis explore the key actors involved in climate change research at the international, European, and national levels, as well as their mandates, coordination mechanisms, and roles in policy support;
2. major scientific trends and innovations – here, the focus is on the evolving directions of climate research, including technological innovation, modelling capacities, and interdisciplinary shifts;
3. science–policy integration – this axis investigates how scientific knowledge is used to inform climate legislation, adaptation planning, and multilevel governance;
4. regional and national disparities – the final axis assesses asymmetries in research infrastructure, funding availability, institutional capacities, and participation in transnational programmes.

The Romanian research context was examined through national policy strategies, websites of public research institutes, and academic literature (National Meteorological Administration; The Ministry of Research, Innovation and Digitalisation) and recent integrative approaches on local governance in climate strategy (Drăghici et al., 2024). Particular emphasis was placed on identifying structural gaps in funding, digital infrastructure, scientific collaboration, and stakeholder engagement. The data analysis process was descriptive-interpretive, aimed at identifying systemic patterns and practical recommendations.

While qualitative documentary analysis is an effective tool for mapping institutional and thematic trends, its limitations must also be acknowledged. The method does not allow for empirical testing of hypotheses or for generalisation of findings across all EU member states. Furthermore, the reliance on official publications may overlook grey literature or localised research initiatives not captured in mainstream data repositories. However, the method is justified by the study's exploratory and comparative objectives, and by the need to establish a foundational understanding of systemic structures in climate research.

RESULTS AND DISCUSSIONS

International climate change research is coordinated through established institutions with distinct but complementary mandates. The IPCC synthesises scientific literature and provides assessment reports that inform global climate policy (IPCC, 2021). The WMO ensures access to harmonised meteorological datasets, which are essential for modelling and forecasting (WMO, 2023). The UNEP facilitates knowledge transfer, particularly for low- and middle-income countries (UNEP, 2023). These organisations increasingly collaborate to align climate science with policy and capacity-building efforts, contributing to a more integrated global research ecosystem.

At the European level, climate research is supported through a combination of strategic frameworks, legislative instruments, and dedicated funding programmes aimed at fostering innovation, scientific collaboration, and evidence-based policymaking. The European Commission's Joint Research Centre and EEA produce decision-support tools, vulnerability indices, and thematic maps used by national authorities (European Commission, 2020; EEA, 2025).

Table 1 presents a selection of key international and European institutions involved in climate change research, highlighting their primary areas of focus and the roles they play in supporting scientific advancement, policy development, and global coordination efforts.

Thematic evolution in climate research reveals a broadening scope that transcends disciplinary boundaries. Early scientific efforts focused on climatology and atmospheric chemistry, but the current landscape includes socio-economic vulnerability, policy innovation, technological transitions, and public engagement. One area is impact assessment, which quantifies climate effects on agriculture, infrastructure, public health, and water security. The development of mitigation strategies, including renewable energy, and sustainable transport, is equally prominent. Research into adaptation measures has gained ground, especially regarding nature-based solutions, climate-resilient infrastructure, and community-based planning (IPBES and IPCC, 2021; Raymond et al., 2017).

Table 1. Key Climate Research Institutions

Institution	Main Focus	Role
Intergovernmental Panel on Climate Change	Assessment of climate science and policy recommendations	Provides scientific basis for international climate negotiations
World Meteorological Organization	Meteorological observations and climate monitoring	Coordinates global weather and climate data systems
United Nations Environment Programme	Environmental policy and sustainable development	Supports climate initiatives and policy in developing countries
European Environment Agency	Environmental indicators and data for EU policy	Publishes key reports on EU environmental status
Joint Research Centre	Scientific support for EU policies	Develops tools and models for EU policy design

Despite these advances, significant asymmetries persist across regions. Romania illustrates some of the structural challenges facing Eastern European countries in aligning with EU and global research frameworks. Although institutions like the National Meteorological Administration (ANM), the National Institute for Earth Physics (INCDFP), and several universities contribute to climate research, their efforts are often isolated and underfunded. Participation in European projects remains low, and the country lacks integrated databases and interdisciplinary networks. Scientific findings are seldom used in policymaking, and there is little institutional capacity to bridge the gap between research and decision-making (Sarkki et al., 2015).

Key challenges include weak coordination between ministries and research bodies, insufficient digital tools, lack of long-term funding, and limited incentives for interdisciplinary collaboration. Yet, Romania's integration into European research frameworks presents a significant opportunity for capacity building, especially if local research agendas are aligned with EU priorities.

To consolidate these observations, a SWOT analysis was developed to outline the key strengths, weaknesses, opportunities, and threats influencing Romania's climate research system. This strategic overview (Figure 1) highlights internal capabilities and limitations, as well as external drivers that may either support or constrain future development.

In order to synthesise the structural challenges and strategic potential of Romania's climate research system, a SWOT analysis was conducted (Figure 1). This structured approach highlights internal and external factors influencing the national research environment and supports the identification of priority areas for capacity development.

Among the strengths, Romania benefits from an increasing academic interest in climate-related themes, with several universities and research institutes such as ANM actively engaged in monitoring and scientific studies.

However, the analysis also identifies significant weaknesses. The national research landscape remains fragmented and underfunded, with minimal strategic coordination between relevant ministries, academic bodies, and public authorities. The lack of open-access, interoperable data infrastructures, such as climate risk maps or national research repositories, limits both the visibility and the applicability of scientific work in national decision-making.

On the opportunity side, Romania has the potential to improve its position by leveraging available European funding mechanisms, responding to growing political and societal awareness of climate risks, and investing in interdisciplinary collaboration and innovation (OECD, 2021). The ongoing push for green transition policies, resilience planning, and sustainable development can serve as entry points for strengthening institutional research frameworks.

Nevertheless, several threats persist. These include continued underinvestment in research and development, the emigration of qualified researchers, administrative complexity in accessing funding, and the limited use of scientific evidence in policymaking processes. If left unaddressed, these factors could deepen existing gaps between Romania and more research-intensive EU Member States.

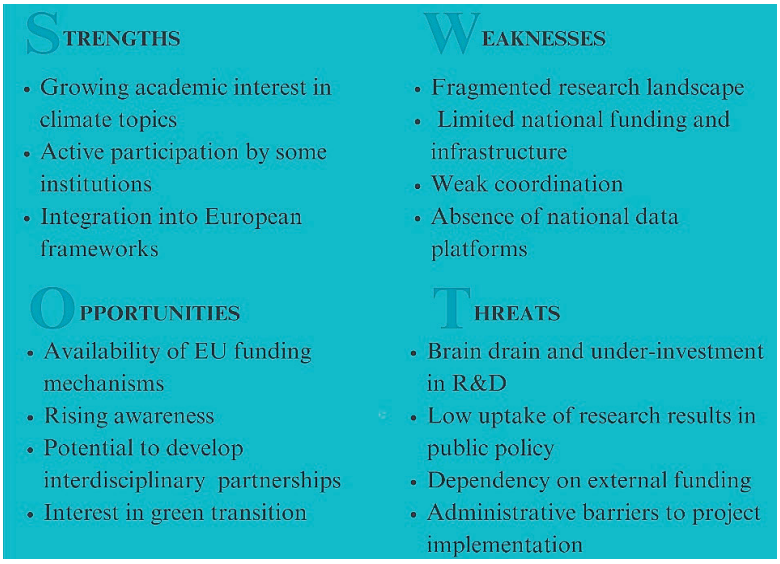

Figure 1. National-level capacity: SWOT Perspective on Romania's climate research landscape

This SWOT analysis reinforces the need for a national strategic vision that bridges science, policy, and practice, while supporting long-term investment in knowledge systems capable of responding to complex climate challenges.

Moreover, aligning Romania's research directions with foresight-based strategic planning is essential to strengthen institutional resilience and adaptive governance mechanisms. As highlighted by the European Commission's Strategic Foresight Report (European Commission, 2023), placing sustainability and wellbeing at the centre of strategic autonomy can help bridge the divide between knowledge production and societal needs. This implies not only more inclusive research agendas but also the mobilisation of innovation ecosystems around climate adaptation, mitigation, and environmental equity.

Recent studies underscore the importance of iterative, reflexive science-policy interfaces to support climate action in complex governance systems.

Sarkki et al. (2015) propose a dynamic framework that integrates credibility, relevance, legitimacy, and "iterativity" as dimensions that influence the effectiveness of science-based decision-making. Such frameworks could inspire improvements in Romania's institutional settings, particularly in strengthening the integration of scientific knowledge in local and national planning processes.

Additionally, climate science in Romania would benefit from adopting anticipatory and transdisciplinary methodologies. As Bai et al. (2016) argue, envisioning plausible and desirable futures in the Anthropocene requires transformative research agendas that go beyond problem identification and focus on systems innovation. This involves deeper collaboration between public authorities, academic institutions, and civil society, as already piloted in some local contexts.

Ultimately, strengthening Romania's position in the global climate research landscape requires both institutional transformation and alignment with forward-looking EU policy priorities.

Integrating foresight, innovation, and co-designed research can help Romania better generate and apply climate knowledge in support of public needs.

CONCLUSIONS

This article has outlined the evolving landscape of climate change research, with a particular focus on institutional structures, thematic directions, and regional disparities. Globally, the institutional architecture supporting climate science has matured through well-established organisations, as discussed earlier in the paper.

In Europe, the combination of policy instruments, dedicated research programmes, and technological platforms has fostered a dynamic research environment with increasingly integrated outputs.

Romania, however, continues to face structural challenges in aligning with this evolving framework.

As evidenced by the SWOT analysis, the national climate research ecosystem suffers from weak institutional coordination, inadequate funding, and a lack of digital infrastructure. Although several public research institutes have longstanding expertise, their efforts remain disconnected from policy processes and broader European initiatives.

Despite these weaknesses, Romania has the potential to strengthen its position through targeted reforms and strategic investments.

Opportunities include aligning national priorities with European foresight frameworks. Romania could also strengthen its participation in international research consortia and foster closer ties between academia, public institutions, and civil society. Lessons from countries with successful integration into EU research ecosystems could offer useful models for institutional reform.

Overall, strengthening climate resilience and adaptation capacities requires more than scientific output, it calls for coherent strategies that link research, governance, and innovation.

The insights presented here serve as a stepping stone for continued doctoral research and contribute to the broader understanding of how science can inform robust climate action, especially in structurally underrepresented regions like Romania.

Moreover, as climate research increasingly intersects with areas such as urban resilience, health, biodiversity, and digital innovation, the capacity to develop integrated, cross-sectoral responses becomes essential. Romania's future progress will depend not only on scientific excellence but also on the ability to embed research findings into operational decision-making, local planning, and national policy frameworks.

Finally, the institutional landscape must be supported by a long-term vision that promotes continuity, transparency, and collaboration. Establishing dedicated national programmes for climate knowledge co-production, incentivising open data sharing, and creating platforms for public-private partnerships can serve as catalysts for systemic change.

As climate risks intensify, the need for responsive, inclusive, and adaptive research systems will grow. This calls for a cultural shift in how research is prioritised, communicated, and leveraged, transforming climate science from an academic pursuit into a cornerstone of societal transformation.

Abstract

In the context of several solutions that can be used to improve the performance of asphalt mixtures during their service life, the paper presents a case study in which asphalt mixtures are manufactured using some recycled materials such as glass, plastic and rubber. The level of performance will be quantified both by the rheological properties measured by conventional tests (viscosity, permanent deformation etc.), but also by some tests that take into account the change in response over time and that lead to variation curves for the stiffness modulus, yielding and fatigue resistance etc. Asphalt mixtures with different percentages of recycled materials will be studied and the results obtained from dynamic and rheological tests before and after the aging process will be compared and interpreted. Determining the degree of influence of recycled materials on the aging resistance of modified asphalt mixtures and characterizing the dynamic and rheological properties can lead to optimizing the percentages of additions and choosing the most advantageous solution based on multi-criteria analyses in different climatic and stress conditions.

Key words*: asphalt mixtures, performances, recycled materials, service life.*

INTRODUCTION

In the context of reducing the irrational use of resources and reducing the level of pollution, the use of waste or secondary materials instead of natural materials can have great benefits, of an economic and environmental nature, with a relatively low energy consumption (Gheorghe et al., 2008; Croitoru, 2016; Dobrescu et al., 2016; Radu et al., 2017; Dobrescu & Calarasu, 2019; Petcu & Racanel, 2024; Saca et al., 2023; 2024).

The choice of materials used for asphalt mixtures depends on the traffic and climate conditions for which the respective asphalt mixture is designed. When designing the asphalt mixture recipe, it is important to consider the ways in which the raw material can affect the performance of asphalt mixtures during the exploitation period, as well as how it will affect the performance of the mixture and the service life of the road structure.

In order to obtain durable, cheap, high-quality asphalt mixtures, with physical-mechanical and dynamic characteristics comparable to those of existing asphalt mixtures, consideration will be given to improving the qualities of bitumen, as well as the use of recyclable materials (glass, recycled mixture, slag aggregates, recycled plastic, recycled rubber, industrial waste, oils), which will replace part of the quantity of aggregates and fillers.

The following research directions outline the development of solutions and formulations incorporating specific dosages of recycled materials.

Use of industrial waste powders in asphalt mixtures

By using power plant ash in asphalt mixtures, the Marshall stability determined for temperatures higher than the test temperature by 10°C, respectively 20°C, due to the higher conductivity and specific heat for the asphalt mixture containing a significant percentage of ash in the mixture (7.5%, 10%), decreases by approximately 5% compared to 30% for the mixture containing limestone filler in the mixture (Paul Marc, 2011).

Use of bio-oil as a substitute for bituminous binder in asphalt mixtures

Replacing 25% bitumen with bio-oil, at the current production price of the asphalt mixture, will result in a production saving of 5%. If the reduction of mixing and compaction temperature are taken into account, the economic opportunity in using this technology is greater (Perlata, 2013).

Use of bituminous binders modified with industrial waste and bio-oil in asphalt mixtures

Regarding the fatigue behavior of asphalt mixtures with polymer-modified bitumen, the fatigue resistance of the studied asphalt mixtures highlights the fact that the working temperature in the laboratory must be correlated with the *in situ* atmospheric temperature. An increase in temperature by 10°C corresponds to an increase in specific deformation by almost 280% (Burlacu & Răcănel, 2014).

Use of crushed glass in asphalt mixtures

In the study on the performance of asphalt mixtures (paving asphalt), in which a finely divided aggregate is replaced by crushed glass, it was found that the performance of the aggregate is not affected for crushed glass percentages of up to 30% of the aggregate mass, a combination of 3% rubber polymer plus 2% glass powder can considerably improve the mechanical properties of the asphalt mixture and that asphalt mixture layers containing 10-15% ground glass in surface mixtures performed satisfactorily (Issa, 2016).

Use of recycled construction aggregates in asphalt mixtures

Asphalt mixtures containing recycled construction aggregates (roads, concrete) have the problem of high bitumen absorption. The effects of glass on bitumen absorption and volumetric properties of asphalt mixtures containing 25% and 50% recycled aggregates are demonstrated through laboratory investigations. Three glass contents of 0%, 10% and 20% in terms of the total weight of fine aggregates are used in the mix design to prepare 100 mm diameter samples containing 0%, 25% and 50% recycled aggregates, under 120 rotation cycles. The results indicate that waste glass can be a viable material for improving the problem of high bitumen absorption of asphalt mixtures containing recycled aggregates (Tahmoorian et al., 2018).

The use of compounds obtained by processing industrial waste in ecological asphalt mixtures

The partial replacement of quarry mineral aggregates with steel mill slag considerably influences the physical-mechanical characteristics of the asphalt mixture. The addition of certain materials derived from industrial waste can bring benefits to the quality of the asphalt mixture, e.g. the behavior of adding power plant ash as a substitute for the usual limestone filler that leads to the stiffening of the asphalt mixture, giving it properties that can be compared to the use of polymers/elastomers in the composition of the bituminous mixture (Lixandru et al., 2018).

Use of aggregates from recycled asphalt mixtures

These mixtures were prepared with two filler additives, steel mill slag and silica fume, at four different percentages of the aggregate weight. A total of 234 mixtures were tested. The laboratory results indicated the effectiveness of using such additives as fillers. Marshall stability showed an improvement for mixtures prepared with steel slag ranging from 11.73 to 32.73 kN as the dosage of recovered asphalt aggregates increased; high stability was recorded for a dosage of 75% recovered asphalt pavement aggregates with a mixture of 50% steel slag. On the other hand, silica fume showed variations in its strength, however the maximum load value of 31.02 kN was for a dosage of 75% recovered asphalt aggregates with 100% silica fume (Naser et al., 2023).

Finite element modelling of asphalt mixture

An advanced area of research and testing aims to assess deformations and stress distributions under specific static and dynamic loading conditions for asphalt mixtures, both homogeneous and inhomogeneous. This approach incorporates the use of recyclable materials and employs modelling through the finite element method within a multidisciplinary framework that includes

chemistry, engineering, and finite element analysis (Ionescu et al., 2024).

MATERIALS AND METHODS

Testing the physical and mechanical properties according to normative standards

Given the importance of asphalt mixtures' performances, this paper highlights the behavior of classic asphalt mixtures, as well as those modified by introducing a recycled material, used in the base, binding and wear layers.

The physical-mechanical characteristics of the asphalt mixtures were determined on Marshall specimens made from the asphalt mixture prepared in the laboratory to establish the optimal dosages of materials: aggregates, filler, bitumen and fiber (according to the requirements of Normative AND 605).

To prepare the asphalt mixtures in the laboratory, all materials were heated to a temperature of 180°C in an oven. After that, they were mixed for homogenization for 5 minutes in the laboratory mixer. Marshall samples were compacted at 170-180°C using an impact hammer stand (Marshall press), by applying a compaction effort on each side of the specimen 50 blows or 75 blows (for SMA).

The following physical and mechanical characteristics were determined on the specimens made with the Marshall press:

- apparent density, according to SR EN 12697-6;
- Marshall stability, at 60°C, according to SR EN 12697-34;
- flow index, at 60°C, according to SR EN 12697-34;
- void volume, according to SR EN 12697-8;
- water sensitivity, according to SR EN 12697-12;
- water absorption, Normative AND 605:2016;

After obtaining the optimal bitumen dosage, the following tests were performed:

- on specimens made with a rotary press;
- modulus of rigidity, SR EN 12697-26;
- fatigue resistance, SR EN 12 697-24;
- resistance to permanent deformations by cyclic compression (dynamic creep), SR EN 12 697-25;
- resistance to permanent deformations (tracking), SR EN 12697- 22.

RESULTS AND DISCUSSIONS

Experimental data analysis for different classic asphalt mixtures

To highlight the behavior of mixtures with different percentages of bitumen (behavior of interest in the case of the action of external agents such as traffic, or atmospheric phenomena), some representations will be presented based on the results of the tests carried out (Figures 1, 2 and 3), for the following types of asphalt mixtures:

- wear layer:
  - asphalt mixture with high mastic content using modified bitumen with a maximum grain size of 16 mm - SMA 16 (bitumen PmB 45/80-80);
  - asphalt mixture with high mastic content using simple bitumen type 50/70 with a maximum grain size of 16 mm - SMA 16 (bitumen 50/70);
  - asphalt concrete with crushed gravel with a maximum grain size of 16 mm - BAPC 16 (Bitumen 50/70);
  - asphalt concrete with a maximum grain size of 11.2 mm - BA 11.2;
  - asphalt concrete with crushed gravel with a maximum grain size of 8 mm - BAPC 8;
  - asphalt concrete with a maximum grain size of 8 mm - BA 8;
  - asphalt concrete with crushed gravel with a maximum grain size of 31.5 mm - BAPC 31.5.
- binder layer:
  - asphalt concrete with modified bitumen and a maximum grain size of 22.4 - BAD 22.4 (Bitumen PmB45/80-65)
- base layer:
  - bituminous asphalt with a maximum grain size of 31.5 mm - AB 31.5;
  - bituminous asphalt with a maximum grain size of 22.4 mm - AB 22.4.

Bitumen is part of an asphalt mixture in a proportion of 5-7% of its mass and the optimal dosage must be chosen depending on the physical and mechanical characteristics considered.

High stability for approx. 5.3 % percentage of bitumen is shown in Figure 1.
An inverse dependence, i.e. bitumen content increases, water absorption decreases, is observed in Figure 2.
In Figure 3, density is mainly influenced by the source of aggregates (i.e. their density).
The characterization of asphalt mixtures through dynamic laboratory tests is presented in Figures 4, 5 and 6.

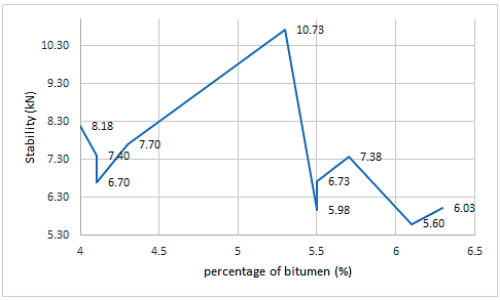

Figure 1. Graphical representation of Stability - the percentage of bitumen

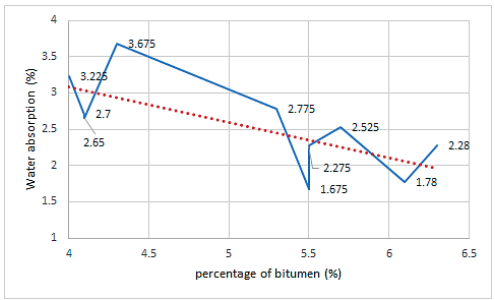

Figure 2. Graphical representation of water absorption - percentage of bitumen

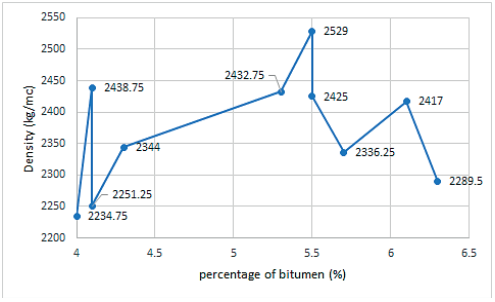

Figure 3. Graphical representation of Density-percentage of bitumen

The modulus of rigidity is higher for asphalt mixtures used in base layers (Figure 4).

The lower the dynamic creep, the more resistant the mixture is under traffic (Figure 5). It is important that the tracking resistance is below 5 min. cycles to cracking at 15°C to avoid undulations under traffic (Figure 6).

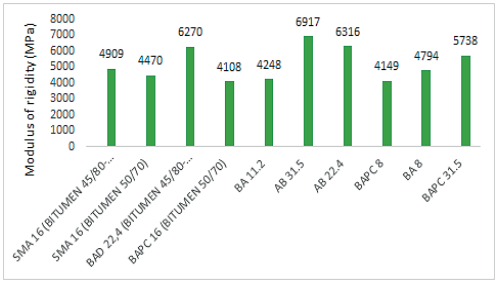

Figure 4. Graphical representation of the modulus of rigidity

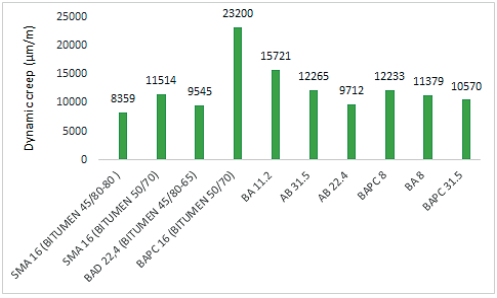

Figure 5. Graphical representation of the resistance to permanent deformations – dynamic creep - deformation at 50°C, 300 kPa and 10000 impulses

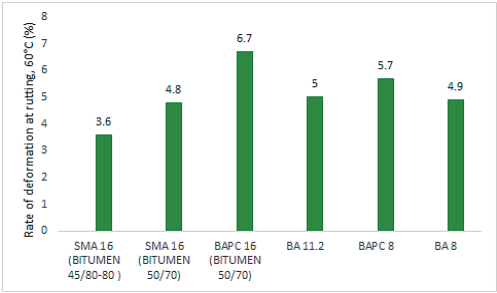

Figure 6. Graphical representation of the rate of deformation at tracking at 60°C

Description of different types of asphalt mixtures, including those with recycled materials

As a case study, the asphalt mixture type SMA 16 is presented, prepared in two variants in which different conventional raw materials and recycled materials were used:

- asphalt mixture prepared with quarry aggregates, filler, fibre and road bitumen type 50/70 modified with 15% recycled rubber (MA1);
- asphalt mixture prepared with recycled asphalt mixture, quarry aggregates, filler, fibre and bitumen PmB45/80-50 (MA2).

The two asphalt mixtures were designed in accordance with the requirements of the documents: Normative AND 605:2016 and SR EN 13108-5:2016.

Bitumen modified with a polymer (in our case recycled rubber) and which consists of two distinct phases, can be considered in three situations (Brule, 1993; Dony, 2014):

• The polymer content is low (below 4%), the bitumen constitutes the continuous phase of the system in which the polymer phase is dispersed (Figure 7a). The dispersed polymer phase improves the properties at high service temperature and at low temperatures.

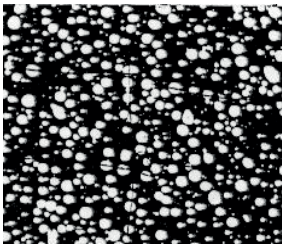

Figure 7a. The polymer phase is dispersed (Dony, 2014)

• The polymer content is high (above 7%), the polymer phase constitutes the matrix of the system (Figure 7b). In this case the polymer is plasticized by the oils in the bitumen in which the heavy fractions of the initial binder are dispersed. The properties of this system are fundamentally different from those of a bitumen and depend largely on the properties of the polymer.

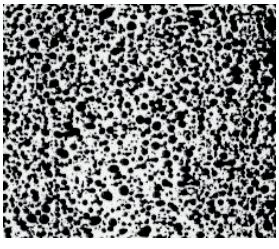

Figure 7b. The polymer is plasticized by the oils in the bitumen (Dony, 2014)

• The polymer content is around 5%, microstructures are obtained in which the two phases are continuous and interpenetrated (Figure 7c). However, this system presents stability problems, being difficult to control.

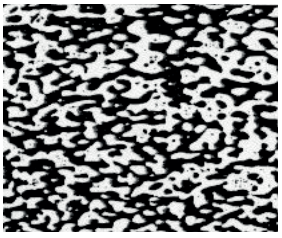

Figure 7c. Microstructures are obtained in which the two phases are continuous and interpenetrated (Dony, 2014)

The rheological properties of modified bitumen are strongly influenced by the polymer content (Tudose, 1982). For a low polymer content (3%) the behavior of modified bitumen remains close to that of plain bitumen, and for modified bitumen with a high polymer content (e.g. higher than 6%) the rheological behavior changes fundamentally. These rheological properties are highlighted in (Background of SUPERPAVE asphalt binder test methods, 1994), which selects the measurement of the bitumen's contribution to improving the resistance to permanent deformation. This methodology demonstrates that the bitumen must have both a high complex modulus and high elasticity at the maximum temperature that the asphalt pavement can withstand.

Dynamic shear and bending tests on plain and modified bitumen have revealed the dynamic shear modulus (G, Pa), and the phase angle (δ, deg). For a given complex shear modulus, low values of the phase angle are found, so better resistance to permanent deformations and better fatigue resistance (Tudose, 1982). There is an influence of the styrene-butadiene-styrene type polymer (rubber) on the complex modulus and the phase shift angle (Tudose, 1982), a decrease in the phase shift with the increase in the values of the complex shear modulus.

The graphical representation of Complex shear modulus-temperature shows a plateau with a high modulus that varies little with temperature (low temperature susceptibility), resulting in good resistance to permanent deformation (Tudose, 1982).

In Figure 8, two asphalt mixtures used for thewear layer are presented in comparison: MA1-asphalt mixture (prepared with bitumen type 50/70 modified with 15% rubber powder) and MA2-asphalt mixture (prepared with modified bitumen type PmB45/80-50). The results for the tracking test by monitoring are the deformation rate at 50°C, 300 kPa and 10000 pulses (mm/10000 cycles) and the rut depth % of the initial thickness of the sample.
Bitumen modified with rubber powder is obtained in bitumen modification installation or laboratory, by introducing a recycled material into the bitumen mass, in this case recycled rubber.

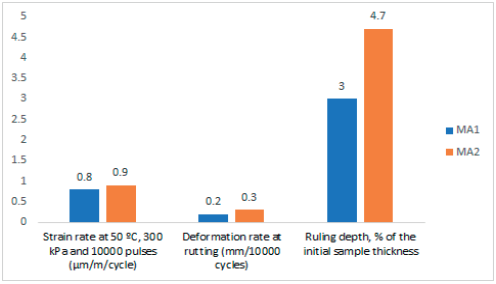

Figure 8. Comparative representation of MA1 and MA2

The performance of the two asphalt mixtures MA1 and MA2 in operation was also monitored, by performing *in situ* tests on two road sections, 6 months after laying (Table 1).

Table 1. Results of *in situ* tests

Determined characteristics	Values			Test method
	Obtained		Imposed by Normative AND 605	
	MA1	MA2		
Roughness (with SRT pendulum), SRT units at 1 m from axis at 3 m from axis	90 87	83 81	min. 80	SR EN 13036-4
Roughness (volumetric method), mm at 1 m from the axis at 3 m from the axis	1.6 1.5	1.3 1.2	min. 1.2	SR EN 13036-1
Resistance to permanent deformation at 60°C (tracking) determined on cores taken from the road: -rut depth, mm/% of the initial sample thickness -tracking deformation rate, mm/10000 cycles	3.56 0.23	4.87 0.35	max. 5 max. 0.5	SR EN 12697-22 +A1

The behavior of the two mixtures in terms of roughness and deformations can be compared using Figures 9 and 10. The asphalt mixture with recycled rubber shows greater roughness but also a high resistance to permanent deformation at 60°C, as illustrated in Figure 10.

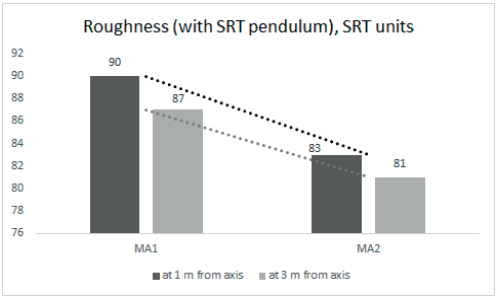

Figure 9. Variation of roughness between asphalt mixtures (MA1 and MA2)

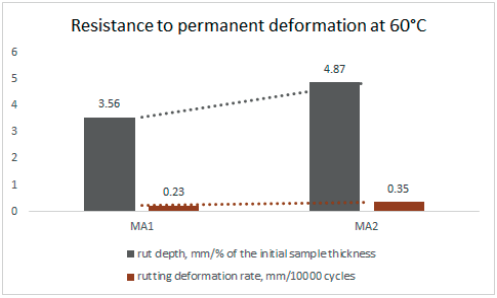

Figure 10. Variation of resistance to deformations between asphalt mixtures (MA1 and MA2)

CONCLUSIONS

The service life of road structures is very important, starting from the date of execution and commissioning until the decision to rehabilitate or reconstruct is made.
From the presented study it can be concluded that recycled materials used in the preparation of asphalt mixtures can have better performance compared to classic asphalt mixtures, important for the road‘s service life. To carry out durable and high-performance works, it is important to test the physical-mechanical and dynamic characteristics of the resulting asphalt mixture. It is also important to declare the performance of asphalt mixtures under the requirements of Regulation (EU) No. 305/2011 and the harmonized European standards (often referred to as "CE marking").

The trend of studying the potential of some additions of animal waste and agro-industrial by-products for use in the construction field should be sustained at the level of exploratory research also in the direction of additions in asphalt mixtures (only for temporary roads, no heavy traffic) (Popa et al., 2021; 2023).

Abstract

The restoration of sites contaminated by the petroleum industry aims to mitigate negative effects on the environment, and human health, and facilitate the reuse of significant land areas. In addition to reducing soil contaminant concentrations, another objective of restoration is the rehabilitation of the vegetation layer. The use of sewage sludge in decontamination processes can provide nutrients and microorganisms, potentially forming the basis for vegetation layer regeneration. However, the application of sewage sludge can also have negative environmental impacts due to high concentrations of heavy metals and the presence of various pathogenic microbiota. This study presents an experimental investigation into the potential use of sewage sludge for remediating petroleum-contaminated sites and regenerating the vegetation layer. Lawn grass was sown in the remediated soil treated with sewage sludge to study its development. Using combined SEM-EDX and electrochemical methods, we analysed the plant microstructure and the distribution of chemical elements to evaluate turf growth. The results obtained are promising and open new research perspectives for the use of sewage sludge in the remediation of sites contaminated by the oil industry.

Key words*: bioremediation, environment, petroleum, pollution, sewage sludge.*

INTRODUCTION

Contaminated sites from the petroleum industry represent a mosaic in the world's geographical landscape, occupying large areas of land. Restoring the natural environment with the aim of reusing land has become a global concern of humanity, but with the optimization of restoration activities and minimizing costs. A current approach to the remediation of contaminated sites is based on the assessment of associated risks, so that the return to the natural cycle does not pose risks to the environment and human health.

The present study is a continuation of the research on the restoration of contaminated sites from the petroleum industry using sewage sludge. Previous studies have shown the bioremediation potential of sewage sludge for lands polluted with petroleum hydrocarbons. In addition to the nutrient and microorganism content of sewage sludge that helps in the bioremediation process, it also comes with a contribution of mineral matter that, when mixed with the soil it has bioremediated, can to a certain extent complete the need for filling material in excavated areas, thus minimizing the use of natural resources. By using sewage sludge in the bioremediation processes of soils contaminated with petroleum hydrocarbons, it was found that there is a double recovery of two materials with harmful effects on the environment: sewage sludge and contaminated soil from the petroleum industry, thus reducing the disposal of hazardous waste (Iorga et al., 2025). Previous research has shown that petroleum hydrocarbons contaminated soil and bioremediated with sewage sludge can be the basis for the development of a fertile layer for plant growth (Iorga et al., 2024). Both the high content of heterotrophic bacteria and filamentous fungi identified by microbiological analyses the soil microstructure and the distribution of chemical elements with a role in

plant growth were identified in petroleum hydrocarbon contaminated soils and bioremediated with sewage sludge.

In the present study, the microstructure and elemental analysis of the soil-sewage sludge/ plant systems were studied using a scanning electron microscope coupled with an energy dispersive X-ray analyzer (SEM-EDX) method. The morphological and elemental characteristics of the control soil were presented before (Iorga et al., 2024). Therefore, the results of these two research papers will be correlated to validate them.

Nitrite monitoring in soil is essential as these compounds have a significant impact on agriculture and human health. Nitrite is part of the nitrogen cycle and eutrophication, and its accumulation in soil can lead to high toxic effects on plants and animals. Furthermore, nitrites and nitrates are used as additives in food processing and as inhibitors of the growth of microorganisms, and their overexpression in the body can affect the transport of oxygen in the blood and generate methemoglobinemia, which is known to cause death (Beeckman et al., 2018; Zdolec et al., 2022). In this regard, electrochemical detection methods were used because they have high sensitivity and rapidity in detection. Electrochemical sensors based on carbon nanomaterials were developed for the sensitive and rapid determination of nitrite from soil solution samples extracted with low-volume suction lysimeters. The techniques used in this study were cyclic voltammetry (CV) and amperometry.

MATERIALS AND METHODS

The analyzed samples come from three mixtures made from soil contaminated with petroleum products bioremedied with sewage sludge (S: N v/v), in three different proportions S2:N1 (2:1 v/v), S1:N1 (1:1 v/v), and S1:N2 (1:2 v/v). The soil mixtures were introduced separately into pots and sown with turf. The analysis of the samples was carried out both from each bioremedied soil mixture and from each pot, two months after the development of the plants. The turf was sown on the last day of January 2024, during a period of the year when seed germination cannot occur under natural conditions. The pots were kept in the free atmosphere of the laboratory, at a temperature of approximately 22-24°C (Iorga et al., 2024).

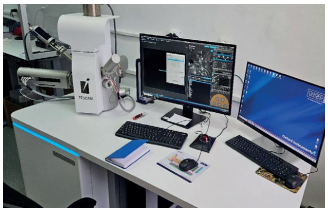
SEM images were captured using TESCAN VEGA microscope (Brno, Czech Republic), from CC-ITI laboratory "Dunărea de Jos" University of Galati. Prior to imagistic evaluation, the organic samples were thin metal layered by means of pulverization method (SPI Supplies, West Chester, USA) (Iorga et al., 2024). The powdered and grass samples were dried, then fixed onto aluminium stub using double adhesive carbon tape, as described by Caprita et al. (2021). The low-vacuum pressure (60 Pa) and electron accelerating voltage of 10 kV allowed to identify many chemical elements as possible, at two different magnifications (260X and 1400X). SEM-EDX results were obtained on randomly selected areas from the surface, for major and trace elements quantification and spatially mapping. Electrochemical measurements were performed with a portable Potentiostat/Galvanostat from Metrohm Dropsens, and data recording was performed using the DropView8400 software. The sensors used in this study were commercial, screen-printed, carbon paste electrochemical sensors DRP-110 (SPE) from Metrohm Dropsense, which consisted of three electrodes, the working electrode made of carbon paste, the reference electrode made of Ag, and the auxiliary electrode made of graphite. Cyclic voltammetry measurements were performed in stationary solution, by sweeping the potential between -0.2 and 1.0 V, with a scan rate of 0.05 V/sec. Amperometric measurements were performed in stirred solution, all working potentials being referenced to the reference electrode made of Ag/AgCl. Amperometric detection of NO_2^- concentration in soil solutions was performed with the portable bipotentiostat, at different applied potentials, depending on the pH of the soil solution (Gurban et al., 2023).

Preparation of nanomaterial-modified sensors

To determine the NO_2^- concentration, the sensors were functionalized by depositing on the active surface of the SPE electrodes a volume ranging from 5 to 20 µL of the multi-walledcarbon nanotubes (MWCNTs) suspension made in a 0.5% low molecular weight Chitosan solution (CS, molecular weight =

50-190 kDa) in 2% acetic acid. The sensors obtained and labelled with MC/SPE were stored at room temperature, protected from light.

Measurements on real soil samples



Small volume suction lysimeters from Hanna Instruments, 30 cm, were used to collect the soil solutions that were analyzed. Nitrite concentrations were determined by amperometric measurements using the nanomaterial-modified screen-printed sensors.

Electrochemical characterization of the sensors

Cyclic Voltammetry (CV) Studies were performed using the sensors obtained by MC/SPE (MWCNT-CS nanomaterial-based sensors) in a stationary solution of phosphate buffer electrolyte (PBS) 0.1 M, pH=7, in the absence and presence of 5 mM $NaNO_2$ (Figure 1). The potential was swept in a range between -0.2 V and 1.0 V vs. Ag/AgCl, with a scan rate of 0.05 V/sec, for a single scan cycle.

Data recording

Figure 1. Soil sample analysis steps

The voltammograms were recorded using the MC/SPE sensor, and it was observed that the shape of the cyclic voltammograms for both the simple electrolyte and the 5 mM nitrite solution underwent changes (Figure 2).

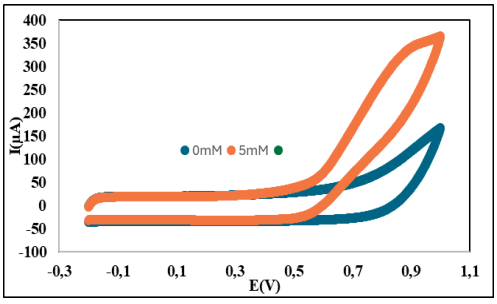

Figure 2. Influence of nitrite concentration on the oxidizing character

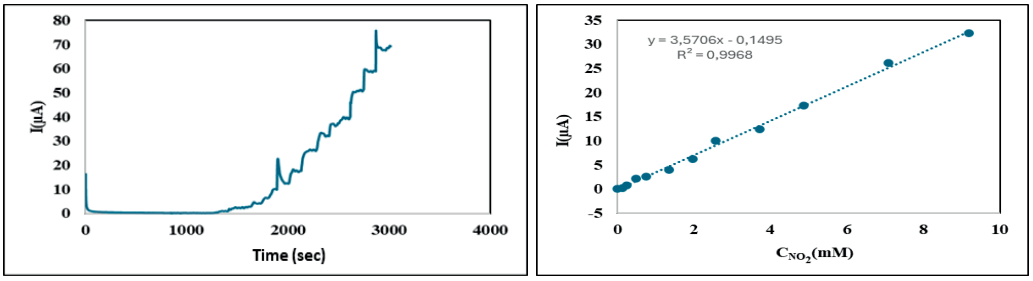
Cyclic voltammograms recorded at the surface of the sensor modified with MWCNTs, MC/SPE (PBS, 0.1 M, pH = 7): in the absence and in the presence of the analyte at different nitrite concentrations.

In the case of voltammograms recorded using the MC/SPE sensor, an increase in the intensity of the anodic current peak can be observed with the increase in nitrite concentration from 1 to 5 mM (Table 1).

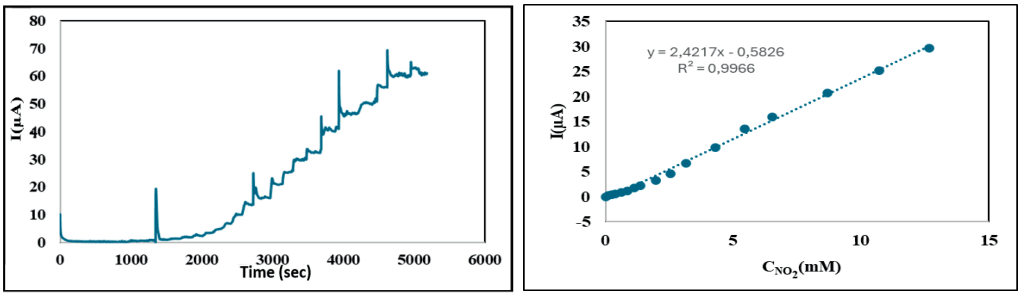
Table 1. Influence of nitrite concentration on oxidation current and potential



$[NO_2^-]$ (mM)	I (μA)	E (V)
0	-	-
1	145.682	0.832
2	198.581	0.904
5	292.962	0.890

The increase in the intensity of the anodic peak current with increasing nitrite concentration demonstrates the synergistic effect of multi-walled carbon nanotubes and chitosan. The

sensors based on MWCNTs-CS showed high electrocatalytic behavior for nitrite oxidation, the stability of the nanomaterial on the sensor surface being considerably improved by using the chitosan solution.
The potential value of 0.65 V was selected for performing amperometric studies of nitrite detection in order to ensure increased sensitivity and selectivity.



Amperometric determination of nitrite using MC/SPE-based sensors. Considering the previous CV studies, the working conditions for amperometric detection of nitrite were optimized by using MWCNT-CS/SPE sensors at an applied potential of 0.65 V, using PBS (pH of 7-7.5) (Figure 3A and Figure 4A). Sensor calibration was performed at room temperature in stirred 0.1 M phosphate buffer saline (PBS) electrolyte solution, pH 7 (Figure 3A) and pH 7.5 (Figure 4A), respectively, by applying a potential of 0.65 V vs Ag/AgCl and successively injecting increasing volumes of 0.1 M nitrite standard solution.

The analytical performances of the MWCNTs-CS sensors at different pH values were obtained from the calibration curves using linear regressions shown in Figure 3B (pH 7) and Figure 4B (pH 7.5), respectively. Table 2 shows the analytical parameters obtained from the calibration curves for nitrite detection.
After the development and electrochemical characterization of the sensors modified with MWCNTs, using the analytical parameters obtained from the calibration curves, they were further used to determine the nitrite content in solutions of bioremedied soils.
To collect the soil solutions, lysimeters were used that were introduced into the bioremedied soil before and after turf cultivation. The sensors were introduced into the soil solution in these lysimeters. The determination of the nitrite content was performed for each sample volume by interpolating the values of the currents recorded on the calibration curves for the used sensors, using the provided portable potentiostat

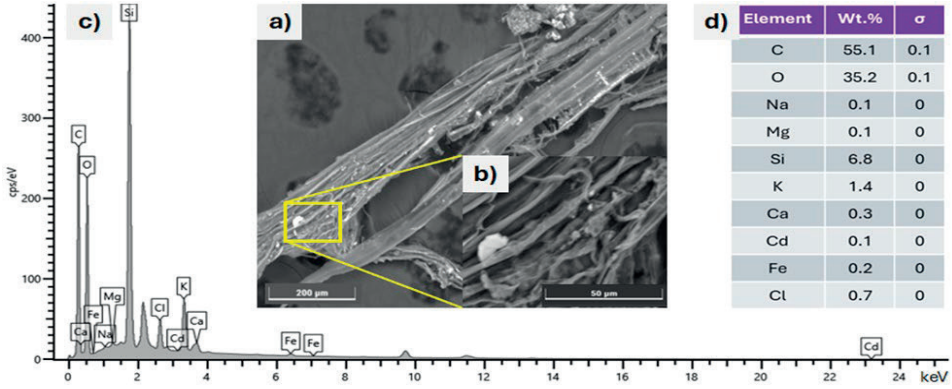
RESULTS AND DISCUSSIONS

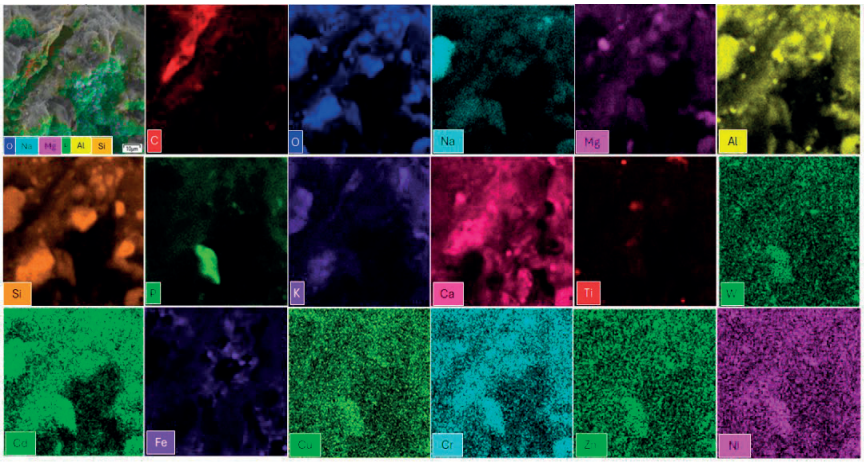
Morphological and chemical characterization



Microstructure, variability and distribution of chemical elements in plants which are developed under un-treated and treated soil systems were investigated by means of SEM-EDX combined method (Figures 5-7).

Morphological and elemental characteristics of control soil were presented by (Iorga, et al.2024). Therefore, the results from these two research papers will be corelated to validate them. The microstructure of root's lawn grass grew up from uncontaminated soil was imagistic explored at two scale bars – 200 μm (total view) and 50 μm (detail) (Figure 5a-b). Mineral compounds can be distinguished by varied shapes and gray shades, attached on the plant cellular tissue. The presence of natural elements was marked out by semi-quantitative and qualitative X-ray analysis (Figure 5c-d). Higher carbon content (55.1 wt.%) has a component derived from carbon tape, as fixation tool. The macro / micro-elements and nutrients identified from roots have very low concentrations compared to that from soil, as presented by Iorga et al. in 2024. This could be explained by the soil fertilization deficiency during these experiments, which can slow down the vegetal growing process and affect root evolution (the case of phosphorous). Figure 6a shows the mapping of macro / micro and trace of elements in the sewage sludge powder.

It is known that sewage sludge has high content in organic compounds and lower in nutrients. Usually, 2.39 wt.% of carbon in soil is comparable with the European average for the soil upper horizon (2.48 wt.%) (Salminen et al., 2005). However, higher C value of 11.03 wt.% in sludge is due to the presence of carbonates. Heavy metals were identified as minor elements in sludge, around 1 wt.%. The bioremediation effect of sewage sludge on vegetal layer is here discussed in terms of macro and micro-elements, and nutrients, respectively. SEM micrographs of underside plants developed in three soil-sludge systems are shown in Figure 7 a-c. After experimental soil remediation, a lot of necessary elements were identified in roots, with increasing concentration. So, we can remark the stimulating effect of sewage sludge, attributed to large amounts of nutrients (Mg, P, S, Na, Ca), as showed (Kominko et al., 2022). For example, P content increased from 0 wt.% (S1:N1 v/v) to 1.7 wt.% (S2:N1 v/v); Ca varied from 5.5 wt.% (S1:N1 v/v) to 9.9 wt.% (S2:N1 v/v); Fe is almost constant (2.16 wt.%). At the same time, some heavy elements (Al, Ni, Mn, Cu, Zr, Cr, Cd) from sludge (Figure 7b) are accumulated in roots. Aluminium is one of the toxic elements which has been found decreasing from 2.6 wt.% (S1:N1 v/v) to 1.9 wt.% (S2:N1 v/v) and the others are trace of element (< 0.5 wt.%). Thus, we can conclude that S2:N1 v/v mixture of soil and sewage sludge could be a promising solution for natural fertilizer of contaminated sites.



Amperometric detection of nitrite in real soil samples using MWCNTs/SPE sensors

MWCNTs/SPE sensors were used to detect nitrite content in different soil samples. Using lysimeters, a sufficient amount of soil solutions was extracted and transferred to new containers. The electrode was placed in a horizontal position and for amperometric detection, 200 μL of sample was taken and injected directly onto the sensor surface. The actual detection took place and the nitrite amounts in the samples were determined by interpolating the values of the currents recorded on the calibration curves obtained for the pH values 7, respectively 7.5 corresponding to the soil samples. Table 3 shows the results obtained from amperometric studies on soil samples. From the soil samples without plants analyzed, it is observed that at pH 7 in the S2:N1(v/v) mixture, the lowest nitrite concentration value was recorded (0.023 g/L).

Element	Wt.%	σ

Figure 7. Imagistic and chemical composition results of root's lawn grass tested in three soil-sewage sludge/plant systems: a) S1:N1; b) S1:N2; c) S2:N1

Table 3. Nitrite concentration determined from soil samples

Sample	pH	Soil without plants		pH	Soil with plants	
		mM	g/L		mM	g/L
S2-N1	7	0.491	0.023	7.5	0.471	0.022
S1-N1	7.5	0.532	0.024	7.5	0.491	0.023
S1-N2	7.5	0.880	0.040	7.5	0.749	0.034

In the mixtures where a slight increase in pH 7.5 was observed, an increase in nitrite concentration values was also observed as the amount of sludge increased from 0.024 g/L in S1:N1 (v/v) to 0.040 g/L in S1:N2 (v/v). At the time of determination, from the analysis of the results of the soil samples with plants, it is observed that at pH 7.5 of the S2:N1 mixture, the determined nitrite concentration is lower than in the initial S2:N1 mixture. For the other mixtures, the pH values did not change, remaining at 7.5, but the nitrite concentration values decreased from 0.024 g/L in S1:N1 without plants to 0.023 g/L in the S1:N1 sample with plants, respectively from 0.040 g/L (S1:N2 without plants) to 0.034 g/L (S1:N2 with plants). The results are predictable, as it is known that some nitrites are absorbed by plant roots. Considering the pH variation in the analyzed samples, a determination over time was carried out on samples of mixtures cultivated with turf, for a period of 32 days, the results being presented in the following Table 4. Sample S1-N1 had a relatively constant pH of 7.5, except for a decrease to pH 7 after 7 days. Sample S1-N2 showed a small decrease in pH from 7.5 to 7 after one week and then increased to 7.5 after 19 days, remained at 7.5 after 29 days and increased slightly to pH 8 on day 32. Sample S2-N1 showed pH variations between 7 and 7.5 over the course of 29 days, then increased to pH 8 after 32 days. Electrochemical determinations were performed as a function of pH.

Table 4. pH values recorded over time for the analysed soil samples

Time period between tests (days)	pH		
	S1-N1	S1-N2	S2-N1
0	7.5	7.5	7
7	7	7	7.5
19	7.5	7.5	7
29	7.5	7.5	7.5
32	7.5	8	8

CONCLUSIONS

The use of sewage sludge for remediating petroleum-contaminated sites and regeneration of vegetation was studied. The stimulating effect of the sewage sludge on plant growth is attributed to the presence of a large amounts of nutrients in the sludge which is confirmed by SEM-EDX analysis. Electrochemical sensors modified with MWCNTs-CS nanomaterials were used for the amperometric detection of nitrite in real soil samples collected using lysimeters, showing a decrease of nitrite concentrations due to plant growth and thus, a bioremediation effect.

ACKNOWLEDGEMENTS

The support was provided by the Ministry of Research, Innovation, and Digitization through Core Program PN 23.06.01.01.

Abstract

This study aimed to analyze the concentrations of iron (Fe), copper (Cu), and zinc (Zn) in pontic shad (Alosa immaculata) and assess the influence of factors such as capture year, length, and weight on these concentrations. Fish samples were collected during the 2023 and 2024 fishing seasons. After recording the length and weight of each specimen, the muscle underwent acidic digestion. The concentrations of Fe, Cu, and Zn were then determined using a Total Reflection X-ray Fluorescence (TXRF) spectrometer. The results revealed an overall increase in chemical elements concentrations from 2023 to 2024. While Cu levels showed no correlation with length or weight, Fe and Zn exhibited strong correlations with these parameters.

Key words*: Alosa immaculata, chemical elements, correlation, Total Reflection X-ray Fluorescence (TXRF).*

INTRODUCTION

Fish size may influence the concentration of some important metals in its tissues. But does this association apply to all chemical elements? Copper (Cu), zinc (Zn) and iron (Fe) are chemical elements that are vital to all living species, including fish, and play important roles in cellular metabolic processes. However, high concentrations of these substances may produce more harm than benefits (Simionov et al., 2023; Dinu (Iacob) et al., 2024). For instance, redox activity of Cu and Fe can produce harmful free radicals that can react with biomolecules including lipids, proteins, and DNA. The oxidation of these compounds can cause cellular damage, damage normal biological functioning, and contribute to the development of a variety of disorders (Bury, 2003; Kozlowski et al., 2009; Wang et al., 2024). In fish, these compounds can enter the body in two main ways: through the intestines from food or through the gills from the water (Bury, 2003). According to Kumar et al. (2024), many factors impact the concentrations of Fe, Cu, and Zn in fish, including age, size, sex, swimming behavior, the environment, and eating behaviors. Since larger fish generally have more body mass and muscle tissue, they tend to have higher concentrations of certain chemical elements compared to smaller fish, although the concentration per unit of muscle may be lower than in smaller fish. Additionally, larger fish are often older and may have accumulated more chemical elements due to longer exposure to their environment, particularly if those metals are present in the water, sediment, or food (Jezierska & Witeska, 2006; Łuczyńska & Tonska, 2006; Has-Schön et al., 2015; Balzani et al., 2022).

Alosa immaculata (Bennett, 1835), commonly referred to as the pontic shad, is a marine teleost fish native to the Black Sea. It belongs to the *Clupeidae* family, along with the herrings, sardines and sprats. As an anadromous

migratory species, it inhabits the sea but migrates to coastal lakes and lower sections of rivers (such as the Danube, Dniester, and Prut) to spawn in the springtime. It is predominantly a predator and a secondary macrophage that feeds solely in saltwater habitats, consuming small fish and crustaceans. It does not feed in freshwater (https://fish-commercial-names.ec.europa.eu/; https://fishbase.se/).

In Romania, the Pontic shad is an economically valuable fish species, with its population in decline (Milea et al., 2023). For this reason, the Pontic shad has been added to the IUCN Red List of Threatened Species (Lazăr et al., 2024).

In the scientific literature there are several studies on the presence of heavy metals in the transition zone of the Pontic shad, the presence of these heavy metals being characteristic of the Lower Danube area (Burada et al., 2015).

Considering that the Pontic shad is not a fish species as extensively studied as others, yet it holds significant importance for Romanian traditions, customs, gastronomy, and economy, the aim of this study was:

- The use of the TXRF method for precise determination of the Fe, Cu, and Zn.
- The analysis of Fe, Cu, and Zn content in *Alosa immaculata* captured in 2023 and 2024.
- The preliminary investigation of the correlations between fish length, weight, and the concentrations of these metals.

MATERIALS AND METHODS

Chemicals and reagents

The following reagents were used: Gallium (Ga) standard solution purchased from SCP Science (Canada); polyvinyl alcohol (PVA), Suprapur nitric acid 65% (HNO_3), and perhydrol 30% (H_2O_2) purchased from Sigma-Aldrich (Germany), and silicone solution in isopropanol purchased from Serva Electrophoresis GmbH (Germany).

Sample preparation

Three Pontic shad specimens were collected during each fishing season (April-May) in 2023 and 2024, utilizing traditional methods associated with commercial fishing in the Lower Danube Basin. Following capture, they were transported to the REXDAN Research Infrastructure, at the "Dunărea de Jos" University of Galați, Romania. After having measured the total length and weight, the fish were washed with ultrapure water, dissected, and muscle tissue samples were taken for analysis. Each muscle sample was subsequently digested using a microwave digestion procedure, as described by Simionov et al. (2023), with a mixture of 65% HNO_3 and 30% H_2O_2 in a 9:1 ratio. Following digestion, the samples were diluted to 50 mL with ultrapure type I water and stored in Falcon tubes for further analysis using TXRF (Figure 1).

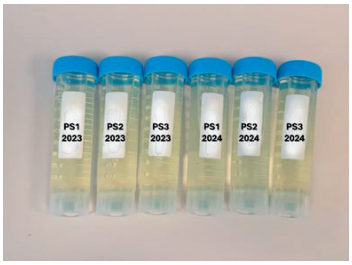

Figure 1. Digested samples of pontic shad

TXRF analysis

The sample preparation process included mixing the digested samples with a 0.3 g/L PVA solution at a 10:1 ratio and incorporating an internal standard. In our study, gallium (Ga) was used as the internal standard at concentrations ranging from 50 to 100 µg/L, depending on the sample matrix. Subsequently, 10 µL of each prepared sample was transferred onto a siliconized quartz carrier and dried on a hot plate at 50°C for 5 min. Measurements were conducted in triplicate for 1000 sec per sample, using a Bruker S4 T-Star spectrometer (Bruker AXS Microanalysis GmbH, Billerica, MA, USA) illustrated in Figure 2. The results were reported as the mean ± standard deviation of the triplicates. The elemental concentrations in the samples were calculated using the following equation:

$$Ci = CIS \cdot Ni \cdot SIS/NIS \cdot Si$$

where:

- Ci represents the element concentration;
- CIS is the Ga concentration;
- Ni is the element net count rate;
- NIS is the Ga net count rate,
- Si is the element sensitivity factor;
- SIS is the Ga sensitivity factor.

Before measurements, the equipment was calibrated as described by Lazăr et al. (2025).

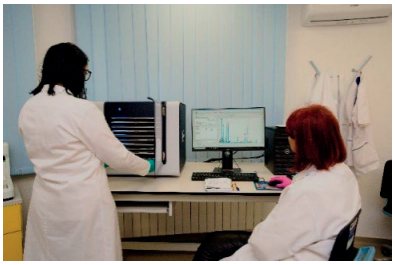

Figure 2. Sample analyzis using Bruker S4 T-Star spectrometer at REXDAN Research Infrastructure

Statistical Analysis

The data were analyzed using descriptive statistics (mean and standard deviation), inferential statistics (ANOVA), and exploratory and relational analysis (correlation matrices), employing Minitab 17 software and Microsoft Excel.

RESULTS AND DISCUSSIONS

Understanding fish weight, length, and metals' concentrations offers essential information for managing fish populations, protecting human health, and ensuring environmental sustainability. These factors contribute to the responsible use of fishery resources while protecting aquatic ecosystems and public health. Table 1 shows the length and weight ranges of the pontic shad specimens captured and analysed in our study. The lengths of the fish from 2023 ranged between 26.70 cm and 32.40 cm, while for those of 2024 varied between 27.90 cm and 31.60 cm. The weight of the fish captured in 2023 varied from 144.10 g to 206.17 g, while for the specimens from 2024 varied between 200.58 g and 273.21 g, with a mean weight of 226.76 ± 40.33 g. Stroe et al. (2024) reported a mean weight of 223.5 ± 44.95 g and a mean length of 29.53 ± 1.79 cm for the Pontic shad specimens captured during March-June 2023 between 169-197 river km along the Danube.

In our study, it can be noted that the Pontic shad specimens captured in 2024 were larger in terms of weight compared to the specimens captured in 2023, which may suggest a possible greater food availability or favorable environmental factors.

Table 1. Biometric data of the analyzed pontic shad specimens

Fish specimen	Length (cm)	Weight (g)
PS 1 (2023)	29.30	206.17
PS 2 (2023)	32.40	179.42
PS 3 (2023)	26.70	144.10
PS 1 (2024)	27.90	206.50
PS 2 (2024)	28.70	200.58
PS 3 (2024)	31.60	273.21

Figure 3 illustrates the average metal concentrations in the muscle tissue of pontic shad, along with their standard deviations. The highest Fe concentration was observed in PS1 captured in 2024. The highest Cu concentrations were identified in PS2 from 2024. The highest Zn concentration was observed in PS3 from 2024.

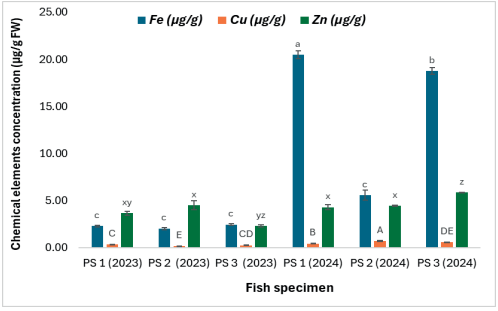

Figure 3. Concentration of Fe, Cu, and Zn in pontic shad. Statistical differences in Fe concentrations are indicated by lowercase letters (a-c), in Cu by uppercase letters (A-E), and in Zn concentrations by lowercase letters (x-z). Values that share the same letter are not significantly different ($p > 0.05$)

Numerous studies have analyzed heavy metal concentrations in fish from the Danube River, yet few have focused on the pontic shad. Stancheva et al. (2014) reported Fe concentrations of 9.00 ± 1.00 µg/g wet weight in pontic shad from the Bulgarian coast of the Black Sea, captured in 2010. Jitar et al. (2015) documented Cu concentrations ranging from 0.73 to 2.10 µg/g wet weight and Zn concentrations between 2.22 and 4.12 µg/g wet weight in specimens collected along the Romanian coastline of the Black Sea, between 2011 and 2012. Makedonski et al. (2017) identified Cu concentrations of 0.45 ± 0.03 µg/g wet weight and Zn concentrations of 9.00 ± 1.00 µg/g wet weight in Pontic shad from the Bulgarian coast, also from 2010. Bat et al.

(2018) reported a Cu concentration of 2.25 ± 0.81 µg/g wet weight in the muscle tissue of Pontic shad fished from Turkish waters of the Black Sea in 2016. More recently, Simionov et al. (2021) reported Cu concentrations of 0.40 ± 0.10 µg/g wet weight in Pontic shad from both the Black Sea and the Danube River. They also recorded Zn concentrations of 4.00 ± 0.40 µg/g wet weight in specimens from the Black Sea and 3.60 ± 0.30 µg/g wet weight from the Danube River. Additionally, Fe concentrations were reported at 10.50 ± 1.60 µg/g wet weight in Pontic shad from the Black Sea, and 6.00 ± 1.00 µg/g wet weight from the Danube River.

Comparing our results with previous studies on metals' accumulation in pontic shad highlights both similarities and differences across various geographic areas and years, providing insight into potential environmental and ecological influences.

Furthermore, beyond concentration levels, it is also crucial to explore how these metals relate to the biometric characteristics of the specimens. Figures 4 and 5 present the correlation between the concentrations of metals identified in the muscle of the pontic shad fished in 2023 and 2024, and their biometric data. In the case of the specimens from 2023, both negative and positive correlations can be observed. For instance, between Fe and Zn, a strong negative correlation can be observed with a value of -0.96. Fe also showed a strong negative correlation with a value of -0.99 with the length, and a moderate negative correlation with the weight of the fish. Zn has a strong positive correlation with the length (0.98) and moderate positive correlation with the weight (0.67). Cu has a moderate positive correlation with Fe (0.69), suggesting that these metals may be regulated similarly in the body. Cu also showed a negative correlation with length (-0.62), indicating a possible dilution of copper in larger fish. Weight and length are somewhat positively correlated, with a value of 0.52, suggesting allometric growth (not necessarily proportional between length and weight).

In the case of the pontic shad caught in 2024, a strong negative correlation between Fe and Cu (-0.85) was also observed. Fe showed a low correlation with the length and Zn concentration, but a high correlation with weight.

Figure 5. Correlation matrix of Fe, Cu, Zn, and biometric data of the pontic shad from 2024. Green color - highest value; yellow color - average value; red color - lowest value

Zn had very strong correlations with the length (0.99) and weight (0.99). In addition, the length (L) and weight (G) had a very strong correlation (0.96). This fact confirms that as fish grow in length, they also increase in weight, but not necessarily in a linear manner (possible allometric growth as already stated by other authors).

In our study, Fe and Cu had an antagonistic relationship in both data sets, with strong negative correlations. This suggests a biological competition between the two metals, either at the level of absorption or in the tissue distribution of the fish. On the other hand, Zn was strongly correlated with length and weight in both cases indicating that Zn is an essential element for fish growth, as it is involved in the metabolic and structural processes of the fish. In correlation with weight and length, fish growth does not seem to be directly proportional to the accumulation of Fe, Zn, Cu. In a similar study, a positive correlation between Zn content and biometric data of pike and negative correlation between Zn and weight and length of perch was reported (Łuczyńska & Tonska, 2006). Positive correlations between the Cu and Zn concentrations and the length of fish were reported in various species of fish from Yangtze River in China (Yi & Zhangm, 2012). Contrary to our study, other authors observed a negative correlation between Cu concentrations and fish length and weight (Balzani et al., 2022; Kaçar, 2022). Furthermore, a positive correlation

between Fe and the length of *S. glaris* captured in Arno river in Italy was reported (Balzani et al., 2022).

To address the initial question raised at the beginning of the manuscript, fish size and weight can affect the bioaccumulation of certain elements, while having no impact on others. As previously stated, the concentration of metals in fish is influenced by multiple factors, such as age, size, sex, swimming behaviour, the environment, and feeding habits. Therefore, a more in-depth study is necessary to fully understand the process of bioaccumulation in fish.

CONCLUSIONS

Our research highlighted variations in Fe, Cu, and Zn concentrations among Pontic shad specimens. Zn was positively associated with fish growth, while Fe and Cu showed an inverse relationship, suggesting that the metal metabolism and absorption in fish are complex and primarily influenced by interactions between metals rather than by size. These findings contribute to sustainable fisheries management, ensuring both environmental protection and public health. However, further research is needed to fully understand bioaccumulation mechanisms and their potential effects on fish health and human consumption. Studies on biota can be associated with studies on the quality of surface aquatic ecosystems that include the determination of the presence of heavy metals, studies that use statistical methods of integration of major pollutants with an impact on biodiversity (Popa et al., 2018).

For future research, we aim to address Lower Danube areas located in the cross-border area of Romania, Ukraine and the Republic of Moldova, where, due to various anthropogenic factors, the presence of certain pollutants in surface waters has an important impact on the ichthyofauna (Iticescu et al., 2016).

Abstract

Geopolymers can be regarded as a type of sustainable and green building material, with the potential to significantly reduce carbon emissions when compared with conventional alternatives. The present study analyses the performance of geopolymeric binder-based composites that have been obtained by means of alkaline activation of fly ash, which is an abundant industrial waste. The present research is centred upon the evaluation of mechanical properties, such as compressive strength and flexural strength, as main characteristics of their durability. A further objective of the project was to investigate the influences of various factors on the final properties of the material. The experimental findings suggest that the optimised mixture displays enhanced performance with regard to durability and sustainability. This suggests that the material has considerable potential for use in a variety of construction applications. The study provides detailed insight into the potential of this innovative material, which contributes to the development of environmentally friendly construction technologies.

Key words*: alkaline activator, Circular Economy, fly ash, geopolymer binder.*

INTRODUCTION

The increasing environmental concerns surrounding the excessive use of Portland cement (PC) in construction have led researchers to explore alternative, sustainable binders with lower carbon footprints (Provis & Bernal, 2014; Davidovits, 2015). The utilisation of geopolymer binders as a substitute for conventional materials has been identified as a potential solution for mitigating climate change, with their capacity to incorporate industrial by-products such as fly ash, blast furnace slag and metakaolin, leading to a substantial reduction in carbon dioxide (CO_2) emissions (Duxson et al., 2007; Zhang et al., 2009). Of particular interest are fly ash-based geopolymers, which have proven to be a subject of considerable interest due to their widespread availability and favourable mechanical and durability characteristics (Temuujin et al., 2009; Heah et al., 2011). It is estimated that Protland cement production is responsible for approximately 8% of global CO_2 emissions. This is primarily attributable to the limestone calcination process and the significant amount of energy consumption inherent in manufacturing processes (Gartner & Hirao, 2015; Andrew, 2018). In contrast, the synthesis of geopolymeric binders entails the alkaline activation of aluminosilicate-rich precursors, resulting in the formation of a three-dimensional amorphous network, which exhibits enhanced mechanical and chemical properties (Xu & van Deventer, 2000; Chindaprasirt et al., 2007). The use of fly ash, a by-product of coal combustion, further enhances sustainability by diverting waste materials from landfills while reducing the demand for virgin resources (Van Riessen et al., 2013; Abhishek et al., 2020).

Geopolymerization is a chemical process involving the dissolution of aluminosilicate precursors in an alkaline medium, followed by the formation of oligomers that subsequently condense into a rigid network (Phair & van Deventer, 2001; Fernández-Jiménez et al., 2005). The reaction kinetics and final properties of geopolymer composites are influenced by factors such as the precursor composition, activator type and concentration, curing temperature, and water-to-solid ratio

(Provis & van Deventer, 2009; Zhang et al., 2009). The amorphous to semi-crystalline nature of geopolymer binders provides excellent mechanical strength, chemical resistance, and long-term durability (Kumar et al., 2010; Fernández-Jiménez et al., 2019). Fly ash-based geopolymer composites exhibit high compressive strength, reaching up to 80 MPa depending on the synthesis conditions (Sathonsaowaphak et al., 2009; Ryu et al., 2013). Their mechanical performance is attributed to the compact microstructure and strong bonding within the aluminosilicate gel matrix (Lloyd & Rangan, 2010; Sukmak et al., 2013). In addition, geopolymer composites demonstrate enhanced flexural and tensile strength compared to PC-based counterparts due to their dense microstructure and reduced porosity (Lee & van Deventer, 2004; Deb et al., 2014).

Durability is a critical parameter for assessing the long-term performance of construction materials. Fly ash-based geopolymers exhibit superior resistance to sulfate attack, acid corrosion, and freeze-thaw cycles compared to conventional cementitious materials (Bakharev, 2005; Olivia & van Riessen, 2011). The low calcium content and dense matrix of geopolymers hinder the formation of expansive ettringite, thus mitigating degradation due to sulfate exposure (Lloyd et al., 2012; Ismail et al., 2013). Additionally, their reduced permeability and high resistance to chloride penetration make them suitable for marine and aggressive environments (Pan et al., 2012; Pasupathy et al., 2021).

The integration of geopolymer binders into the circular economy framework is crucial for achieving sustainable construction practices. Circular economy principles emphasize the reduction, reuse, and recycling of materials to minimize environmental impact and resource depletion (Ghisellini et al., 2016; Kirchherr et al., 2017). Fly ash-based geopolymers align with this concept by utilizing industrial waste as raw materials, thereby reducing landfill disposal and promoting the valorization of secondary resources (Pacheco-Torgal et al., 2012). Moreover, the long service life and recyclability of geopolymer composites contribute to a closed-loop material flow, further enhancing sustainability (Rahman & Rasul, 2020). By adopting circular economy strategies, the construction industry can significantly decrease its reliance on virgin materials while improving environmental and economic performance. Despite the notable strides made in the field of developing fly ash-based geopolymer binders, challenges persist in the optimisation of their formulation, the assessment of their long-term performance, and the expansion of their production capacities for large-scale implementation (Bernal et al., 2011; Provis, 2018). The present article aims to provide a comprehensive analysis of the mechanical and durability characteristics of fly ash-based geopolymer composites, utilising various types of aggregates. The article places particular emphasis on recent advancements in synthesis techniques, performance evaluation, and factors that influence the mechanical properties of the material. The discussion will contribute to the ongoing efforts to promote geopolymer technology as a sustainable alternative to traditional cement-based materials using Romanian local raw materials.

MATERIALS AND METHODS

The raw materials used in this study were sourced from local Romanian industries to promote sustainability and regional resource utilization. The primary aluminosilicate precursor, fly ash (FA), was obtained from a Romanian coal-fired power plant. The chemical composition of the fly ash was analyzed using X-ray fluorescence (XRF) (Table 1).

Table 1. Fly ash sample chemical composition

Oxides	Percentage (%)
SiO_2	46.94
Al_2O_3	23.83
Fe_2O_3	10.08
CaO	10.72
MgO	2.625
SO_3	0.45
Na_2O	0.62
K_2O	1.645
P_2O_5	0.25
TiO_2	0.92
Cr_2O_3	0.02
Mn_2O_3	0.06
ZnO	0.02
SrO	0.03
L.O.I.	2.105

The cumulative distribution of fly ash particles from a Romanian thermal power plant was determined using a HELOS RODOS/L, R5 instrument (Sympatec, Germany) in order to analyse the particle size of the material utilised in the development of alkali-activated geopolymers. The physical characteristics of the fly ash are presented in Figure 1 (Particle size distribution) and Figure 2 (Distribution density of the particles), offering a better visualisation representation.

In order to obtain the alkaline activator (AA) solution, a commercially purchased sodium silicate (Na_2SiO_3) solution was combined with a sodium hydroxide (NaOH) solution (purity ≥ 98%) of 6M, 8M, and 10M molar concentrations in various mass ratios at room temperature. Following the completion of the preparatory stage, the alkaline activator solution was stored under laboratory conditions (23°C) in a closed container for a period of 24 hours in order to allow maturation. In this study, two types of fine aggregates were utilised in the preparation of geopolymer samples: polygranular sand and recycled glass aggregates with a diameter of 0/4 mm (Figure 3). Each aggregate was used independently to evaluate its influence on the material's performance. The selected aggregates were thoroughly mixed with the binder to ensure uniform distribution and proper interaction within the geopolymer matrix. The use of recycled glass aimed to enhance sustainability while maintaining the structural integrity of the material. The activation process and curing conditions were optimized to promote effective geopolymerization and achieve a stable hardened structure.

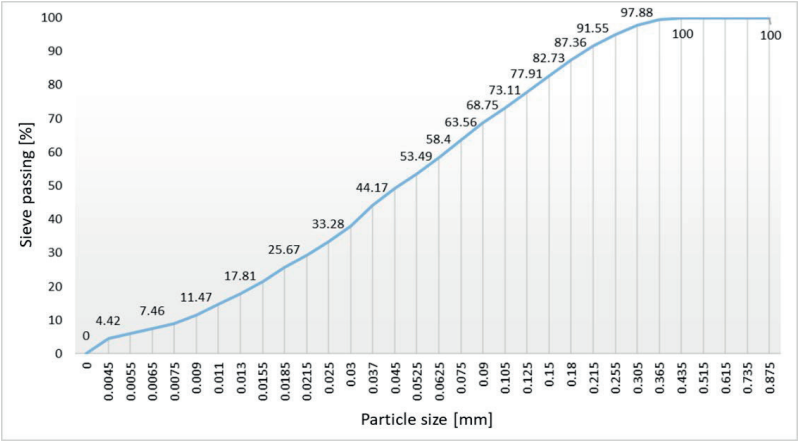

Figure 1. Fly ash particle size distribution

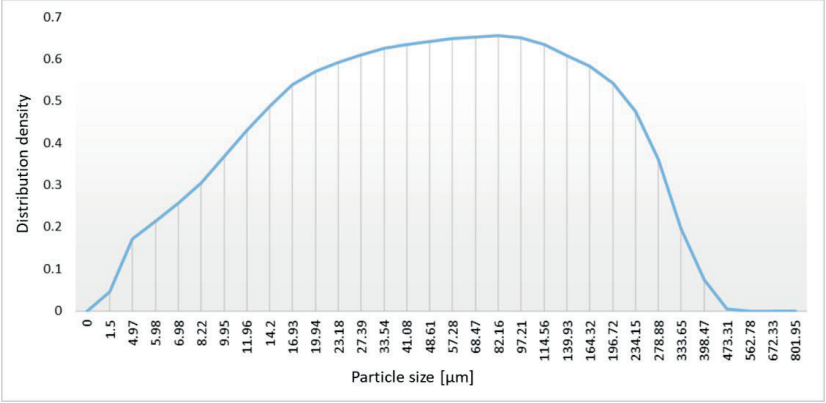

Figure 2. Fly ash distribution density of the particles

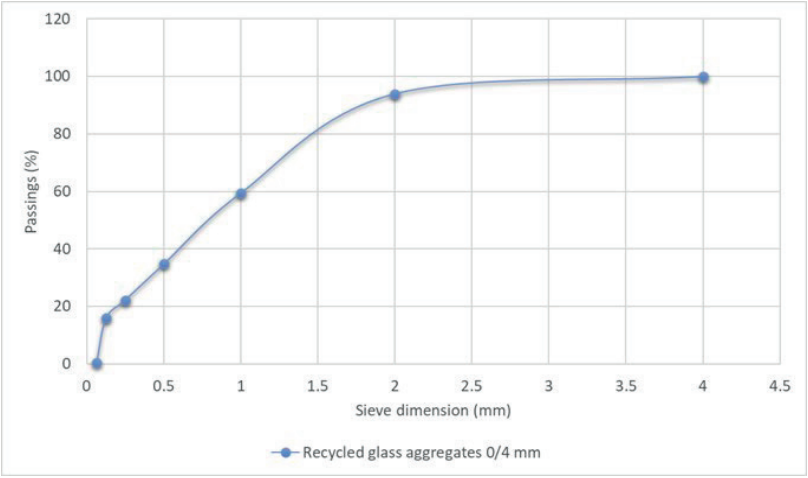

Figure 3. Particle size analysis of the recycled glass aggregates (granular class 0/4 mm)

The geopolymer samples were formulated using two different binder-to-aggregate ratios of 1:1 and 1.25:1 to assess their influence on the material's properties. In the alkaline activation system, sodium silicate (Na_2SiO_3) was dissolved in a solution of sodium hydroxide (NaOH), at a ratio of 2:1 and 1:2, respectively.

To evaluate the influence of alkalinity on the geopolymerisation process, the NaOH solution was prepared in a range of molar concentrations: 6M, 8M, and 10M. The fly ash-to-alkaline activator ratio was fixed at 0.9 to ensure a consistent binder composition. The prepared mixtures were homogenized to achieve a uniform consistency before being cast into molds and subjected to curing under controlled conditions (70°C for 24 hours).

The specimens were demolded after 24 hours and cured at elevated temperatures to study the impact of thermal curing on strength development. Based on preliminay research, curing conditions were optimized to achieve maximum compressive strength and durability resistance (Lăzărescu et al., 2020).

The mix design ratios of the geopolymer samples are presented in Table 2 (samples produced using polygranular standardized sand - PS and samples produced using recycled glass agreggates - GA). For each mixture, a color coding was considered. Each result was obtained from the combination of a minimum of three independently tested samples.

All tests were conducted at the age of 7 days, primarily because geopolymer samples typically gain most of their strength and resistance during this period, particularly due to the heat treatment applied. Research indicates that heat curing accelerates the polymerization process, allowing geopolymers to reach their maximum strength within the first week (Lăzărescu et al., 2024). This time frame was critical for evaluating the material's early-stage properties, as the heat treatment enhances the formation of the geopolymer matrix and strengthens the material. Compressive strength was selected as the main parameter for evaluation due to its direct correlation with the material's structural integrity.

RESULTS AND DISCUSSIONS

The results are presented in graphical form, with each graph, with specific colour code representing different mixtures. The colour coding facilitated the identification of variations in the mixture. Throughout the analysis, the molar concentration of the NaOH solution remained constant, ensuring that the observed differences in the results are solely attributable to the variations in the other components of the mixture (Figures 4-6).

Table 2. Mix design ratio of the alkali-activated geopolymer samples

Type of aggregate	Code	Code colour	NaOH solution concentration	Binder:Aggregate ratio	Na_2SiO_3 / NaOH ratio
Polygranular standardized sand (PS)	P1(PS)		10M	1:1	1:2
	P2(PS)				2:1
	P3(PS)			1.25:1	1:2
	P4(PS)				2:1
	P5(PS)		8M	1:1	1:2
	P6(PS)				2:1
	P7(PS)			1.25:1	1:2
	P8(PS)				2:1
	P9(PS)		6M	1:1	1:2
	P10(PS)				2:1
	P11(PS)			1.25:1	1:2
	P12(PS)				2:1
Recycled glass Granular class 0/4 mm (RG)	P1(RG)		10M	1:1	1:2
	P2(RG)				2:1
	P3(RG)			1.25:1	1:2
	P4(RG)				2:1
	P5(RG)		8M	1:1	1:2
	P6(RG)				2:1
	P7(RG)			1.25:1	1:2
	P8(RG)				2:1
	P9(RG)		6M	1:1	1:2
	P10(RG)				2:1
	P11(RG)			1.25:1	1:2
	P12(RG)				2:1

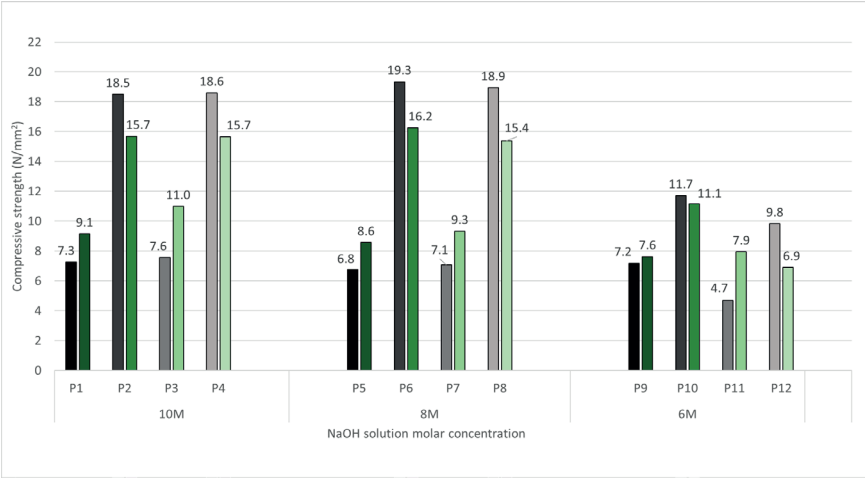

Figure 4. Graphical representation of the compressive strength variation in alkali-activated geopolymer samples (10M, 8M, and 6M)

The performance of the geopolymer samples, particularly in terms of compressive strength, was found to be significantly affected by the incorporation of polygranular sand, as indicated by the results of mechanical tests (Figure 4). Samples with Na_2SiO_3/NaOH ratio of 2:1 (P2(PS), P4(PS) -10M, P6(PS), P8(PS) – 8M and P10(PS), P12(PS) – 6M) exhibited higher values of compressive strength than those with a ratio of 1: 2, suggesting that a higher content of sodium silicate contributes to a better consolidated and denser geopolymer matrix. Regarding the influence of the molar concentration of the NaOH solution, a significant increase in compressive strength between 6M and 8M can be observed, but above this threshold, samples produced with 10M NaOH solution do not show an improvement in compressive strength, which indicates reaching a saturation level in the alkaline activation process.

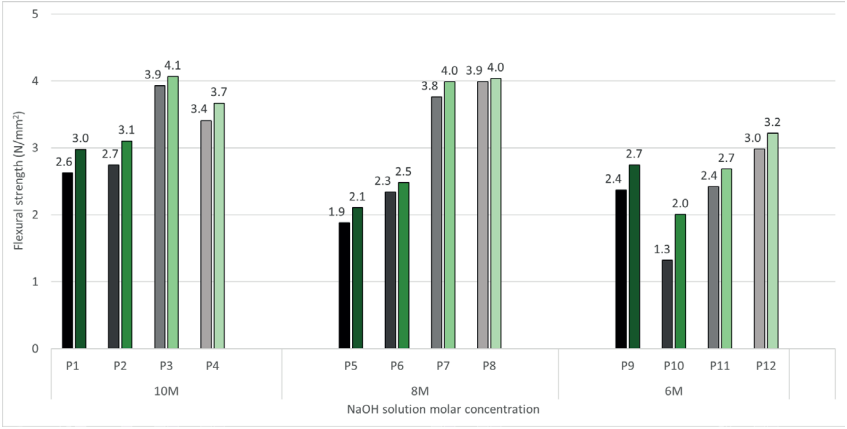

Figure 5. Graphical representation of the flexural strength variation in the alkali-activated geopolymer samples (10M, 8M, and 6M)

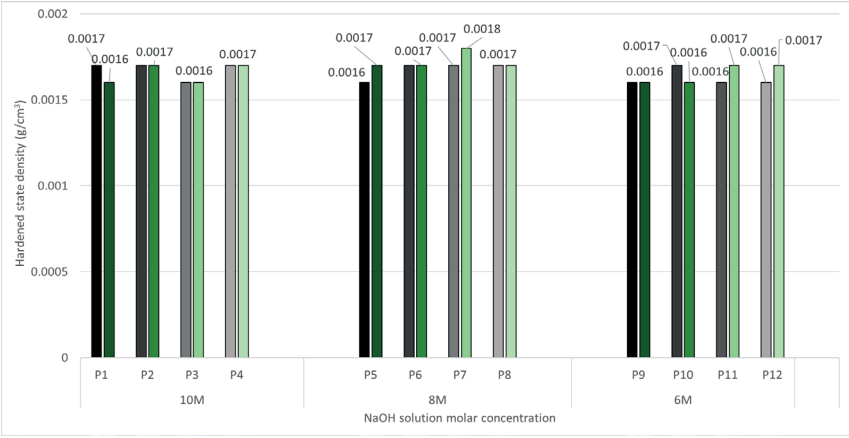

Figure 6. Graphical representation of the hardened state density variation in the alkali-activated geopolymer samples (10M, 8M, and 6M)

However, the flexural strength test results did not follow the same trend (Figure 5). Although the samples with an activator ratio of 2:1 had better compressive strength, the values obtained for flexural strength did not show a direct correlation with this ratio. This difference suggests that although a denser geopolymer matrix favors compressive behavior, the mechanisms of cracking and crack propagation under tensile stress are influenced by additional factors such as pore distribution, microstructure of the gel formed, and interfacial adhesion between component phases.

The mechanical performance of the samples exhibited variation depending on the type of aggregate utilised. Recycled glass aggregates demonstrated distinct behaviour in both compressive and flexural strength when compared to polygranular sand. For the 1:2 activator ratio, samples incorporating recycled glass (P1(RG), P3(RG) – 10M, P5(RG), P7(RG) – 8M, and P9(RG), P11(RG) – 6M) demonstrated higher compressive strength values. The enhancement in strength is attributed to the improved compaction of the geopolymer matrix, a consequence of the morphology of the glass particles, and the potential contribution of an additional pozzolanic reaction involving the glass particles. However, the general trend was maintained, and the samples with 2:1 activator ratio continued to show the best compressive performance regardless of the type of aggregate used.

In terms of the influence of the molar concentration of NaOH, the same significant increase was observed between 6M and 8M, with no significant improvements when using 10M NaOH solution.

However, the tensile behavior was different from that observed in compression. In contrast to the samples with polygranular sand, those with recycled glass aggregates exhibited higher values of tensile strength, for all the mixtures (P1-P12(RG)).

This result suggests that glass aggregates may contribute to improve the ability of the geopolymer to respond to tensile stresses, possibly through a more favorable stress distribution in the matrix and a more efficient interface between the binder and the aggregates. Despite the smooth surface of the glass particles, which could reduce interfacial adhesion, it is possible that this effect could be compensated by a better interaction at the microstructural level, limiting crack initiation and propagation under tensile stress.

Moreover, optimising the molar concentration of NaOH within the 6M to 8M range, where mechanical performance improvements become negligible beyond this threshold, may have significant sustainability implications. This optimisation enables a reduction in the quantity of alkaline substances required for geopolymer activation, thereby minimising both the consumption of chemical resources and the environmental impact associated with their production and handling. Within the framework of the circular economy, geopolymers emerge as a viable and environmentally friendly alternative to conventional building materials, as their mechanical properties benefit from the incorporation of recycled aggregates. This approach not only enhances material performance but also contributes to effective glass waste management.

A key aspect highlighted by this study is that, although the mechanical performance of the samples differs depending on the type of aggregates used and the activator ratios, the density in the hardened state remains relatively constant for all samples (Figure 6). This result is extremely important, as it suggests that the improvement in mechanical properties observed in some samples is not due to a simple variation in density, but to a complex interaction between the geopolymer matrix and the aggregates. Thus, optimization of material performance is achieved by changing the chemical composition and type of aggregates without significantly affecting the final density. This observation further supports the potential of using recycled aggregates in the development of sustainable geopolymers. Should the density remain consistent, irrespective of the type of aggregate utilised, it can be deduced that recycled glass has the potential to serve as a substitute for conventional aggregates without altering the material's fundamental characteristics. Additionally, the observation that recycled glass samples exhibited higher tensile strength values suggests that these aggregates contribute to a more uniform stress distribution and reduce premature cracking. These phenomena, if substantiated, may enhance the durability of constructed structures.

Furthermore, the consistency in sample density suggests that incorporating additional functionalization, such as the integration of TiO_2 nanoparticles, is unlikely to alter the material's density but rather enhance its functional properties. Thus, the utilisation of geopolymer materials as a medium for the creation of intelligent and environmentally sustainable solutions has been demonstrated to result in a dual effect, with a reduction in ecological impact through the reutilisation of discarded materials and an improvement in the functionality of these solutions, including self-cleaning properties and antibacterial protection. It is clear that the constant density of these materials offers a significant technological advantage. Indeed, these materials can be manufactured in a manner that does not demand substantial adjustments to existing processes. Consequently, the shift towards sustainable and intelligent geopolymers becomes a viable and readily implementable solution. This transformation has the potential to redefine the building materials industry by promoting structures that are more sustainable, efficient and environmentally friendly.

CONCLUSIONS

This study emphasises the considerable influence of aggregate type and activator ratios on the mechanical performance and durability of geopolymers, thereby validating their potential as a sustainable substitute for conventional building materials. Previous studies have shown that geopolymer concrete has higher initial costs due to the price of alkali activators and specialized production processes. However, due to its superior durability, low maintenance costs and significantly lower environmental impact, it is becoming a sustainable and cost-effective alternative to traditional concrete in the long term. A specific cost assessment can only be made on a case-by-case basis, considering both initial costs and long-term benefits. Furthermore, studies have shown that, when compared to ordinary Portland cement with similar mechanical properties, geopolymer concrete reduces CO_2 equivalent (CO_2eq) emissions by up to 50-60%, due to the use of industrial waste and the elimination of the Portland cement production process (Lăzărescu et al., 2024). Thus, in the long term, geopolymer concrete not only offers the benefits of durability and low maintenance but also contributes significantly to the goals of sustainability and reduced environmental impact.

This study has shown that, the use of recycled glass aggregates was found to be beneficial, improving the tensile strength and, in the case of an activator ratio of 1:2, even the compressive strength compared to polygranular sand. These results highlight that the right choice of aggregates can lead to optimized performance of geopolymeric materials, thus facilitating the transition towards more sustainable and environmentally friendly solutions. Furthermore, the recovery of waste glass contributes directly to reducing the impact on natural resources, promoting a circular economy model.

The study also demonstrated that the ratio of activators to NaOH molar concentration plays a crucial role in the formation of a stable and efficient geopolymer network. The significance of sodium silicate in establishing a compact structure is substantiated by the attainment of optimal mechanical strengths at an activator ratio of 2:1. An analysis of molar concentration of NaOH revealed a significant increase between 6M and 8M, with no such improvement observed at 10M, thus indicating the attaining of a saturation point in the activation process. This finding carries significant implications for sustainability as it facilitates optimisation of chemical consumption, leading to a reduction in costs and a diminished environmental impact within the manufacturing process.

It is anticipated that future research on geopolymer materials will concentrate on mechanical properties and sustainability. In addition, however, there is a growing recognition of the importance of exploring the development of smart, eco-innovative materials that can provide enhanced benefits to meet evolving efficiency and performance demands. The integration of titanium dioxide (TiO_2) nanoparticles has been identified as a potentially significant solution in this regard. This integration has the capacity to impart self-cleaning, antibacterial, and antimicrobial properties to geopolymers, thereby enhancing their applicability in environments subject to contamination or within urban infrastructure. The incorporation of TiO_2 into geopolymer materials has been shown to yield a photocatalytic property, enabling the degradation of organic pollutants when exposed to light. This property has the potential to mitigate the environmental impact of buildings, positioning geopolymers as a promising alternative to conventional materials. The functionalization of geopolymers with TiO_2 could lead to their advancement as smart materials that actively contribute to environmental protection and safety.

In this context, geopolymers are evolving beyond their traditional role as a sustainable alternative to conventional cement. They are increasingly recognised as a pivotal component in the development of innovative materials characterised by advanced, adaptable and environmentally friendly properties. The integration of the principles of the circular economy, utilising recycled aggregates, with cutting-edge nanomaterials-based technologies is pivotal in shaping a genuine transition towards smart, eco-innovative materials. These

materials have the potential to redefine standards in the domains of construction and infrastructure. This will not only reduce environmental impact, but also increase the durability, functionality, and safety of built structures, thus contributing to a more sustainable and smarter future.

Abstract

The thermal properties of loess soil are essential for the distribution of heat generated by electrical cables in wind turbines. In these systems, where high-intensity electrical flow induces conductor heating through the Joule effect, the ability of the soil to facilitate heat transfer has a direct impact on the energy efficiency, operational safety and the durability of the electrical infrastructure, as inefficient thermal diffusion can lead to conductor overheating, affecting electrical resistance, degrading insulation and reducing cable lifespan. This study investigates the effects of density and moisture content on the thermal conductivity of silty soils at different compaction levels. Experimental tests were conducted on loessial soil samples compacted to 85-90% of the maximum dry density determined by the modified Proctor test. All measurements included the determination of dry-out curves to observe the variations of thermal conductivity with a gradual decrease in moisture content. The results indicate an increase in thermal conductivity with higher degree of compaction due to reduced porosity and improved particle contact.

Key words*: dry-out curve, loess, thermal conductivity.*

INTRODUCTION

Wind power is considered as one of the most efficient and sustainable forms of renewable electricity, contributing significantly to the reduction of greenhouse gas emissions and global dependence on fossil fuels. As global energy consumption continues to rise, the integration of renewable energy sources such as wind power is becoming a strategic necessity to long-term environmental and energy security challenges. Wind energy systems are clean, widely available and can be implemented on a large scale.

The rapid development of renewable energy technologies has led to a significant expansion of wind energy infrastructure across different terrains and climates. In this evolving energy landscape, the reliability and durability of underground electrical systems, particularly those associated with wind turbines are critical to maintaining overall system performance and longevity. These systems play a vital role in the safe and efficient transmission of electrical power from turbines to substations and the main power grid.

One of the technical challenges associated with underground power cable systems is the thermal management of conductors that carry high-intensity currents and generate heat through the Joule effect. This heat must be effectively dissipated into the surrounding ground to prevent overheating. The ability of the ground to transfer this thermal energy - determined primarily by its thermal conductivity - is a key factor in preventing excessive temperatures, minimising energy losses and extending the operational life of electrical components such as insulation materials and cable sheaths (Wang et al., 2024). Loess is thought to be derived mainly from glacial or periglacial material transported by wind after glaciers have retreated. However, loess can also be formed from other sources, resulting from the accumulation of eroded material in dry continental conditions, either cold or warm, which has subsequently been transported and deposited by the wind. Volcanic ash carried by the wind over long distances from its source can also be a significant contributor.

In many areas, loess is eroded by precipitation and runoff and then redeposited in accumulations similar to the original, but losing

its aeolian character through sedimentation (Dragomir, 2002).

Loess a wind-deposited, fine-grained soil is common in many regions with large-scale wind energy projects. It forms extensive sedimentary layers that often underlie wind turbine foundations and cable routes. Its physical properties, such as porosity, moisture retention capacity, and mineral composition, vary significantly with compaction and environmental conditions, affecting its thermal behaviour. The inherent variability in the structure and composition of loess presents a challenge to the design of consistent and safe cable installations. Inadequate thermal conductivity in such soils can lead to conductor overheating, insulation degradation and a reduction in the reliability of the underground cable system (Sangprasat et al., 2024). For this reason, a thorough investigation of the thermal conductivity of loess is essential.

In this study, soil samples were collected from a construction site near Medgidia, Constanța County, at a depth between 1 to 2 meters. The site was selected based of its typical loessial profile, which is common in south-eastern Romania and representative of the conditions encountered in wind farm development. The testing was conducted at the Geotechnical Laboratory of the Technical University of Civil Engineering Bucharest. The soil was identified as loessial, characterised by fine texture, high capillarity and moderate to high water retention, making it suitable for detailed thermal analysis.

The aim of this work is to provide insight into the optimisation of underground electrical design in wind energy applications by highlighting the influence of soil properties, in particular moisture content and maximum dry density on thermal conductivity. This approach is in line with the wider aims of improving renewable energy infrastructure through innovations in materials science and geotechnical engineering.

MATERIALS AND METHODS

Methods for thermal conductivity measurements

The most relevant thermal parameter of the earth is the thermal conductivity λ, as it directly influences the heat transfer processes in underground applications. For the preliminary design of complex energy foundations, the detailed sizing of standard geothermal systems and the engineering layout of underground electrical cables in wind energy infrastructure, thermal conductivity can be reasonably estimated using empirical diagrams that correlate with water content, saturation density and soil texture. This approach provides a practical and sufficiently accurate basis for early-stage thermal analysis in geotechnical and energy systems applications (Brandl, 2006).

In the laboratory, the experimental procedure was carefully designed to avoid any disturbance of the internal structure of the loess soil samples or alterations to the local thermal environment. Ensuring minimal disturbance is essential to preserve the native properties of the soil, which directly affect the accuracy of the thermal conductivity measurements. To achieve this, no pushing or mechanical insertion forces were applied to the thermal needle during installation (ASTM D5334-14 STM, 2014) (Figure 1).

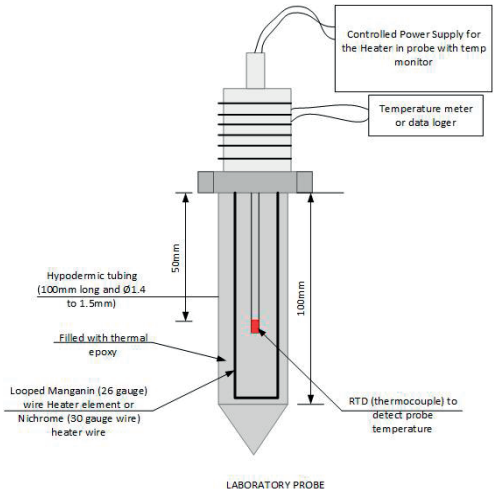

Figure 1. Thermal needle apparatus (IEEE Std 442™, 2017)

Instead, a precise pre-drilling method was used to create an access path within the sample, see Figure 2, allowing the thermal needle to be placed in direct contact with the soil along its entire length without causing deformation or compaction. This technique ensures uniform thermal contact between the probe and the surrounding material, which is essential to

replicate in-situ conditions and avoid artificial thermal gradients. Pre-drilling also helped to eliminate potential sources of mechanical heat that could interfere with the temperature readings during the test.

Figure 2. Pre-drilled soil sample

To further minimise errors, special attention was given to thermal stabilisation prior to measurement. The sample and instrumentation were allowed sufficient time to reach thermal equilibrium with the laboratory environment. This stabilisation period ranged from a few minutes to over an hour, depending on initial temperature differences and environmental factors such as air flow or sample moisture content levels. The thermal conductivity measurement cycles were not initiated until a stable temperature had been reached and maintained.

The entire test protocol strictly followed the methodology outlined in IEEE Std 442™, (2017) – "IEEE Guide for Thermal Resistivity Measurements of Soils and Backfill Materials". This standard prescribes installation procedures, measurement timing, calibration requirements and data interpretation techniques necessary to ensure reliable and repeatable results in assessing soil thermal resistivity. Adherence to this guide will ensure consistency in the evaluation of loess soil behaviour under thermal stress conditions typically encountered in energy infrastructure projects.

Methods for laboratory measurements

The thermal needle probe is primarily used to determine the effects of variations in density and moisture content on the thermal resistivity of the soil. This method is widely recognised in geotechnical and electrical engineering for its accuracy and adaptability to various soil types. It operates by applying a controlled and localised heat pulse and measuring the resulting temperature change over time, allowing the determination of soil thermal properties through analytical modelling.

The probe can be used to both undisturbed and reconstituted soil samples compacted using the Modified Proctor test. Undisturbed samples preserve the natural structure and stratification of the soil, while reconstituted soil samples allow controlled variations in compaction and moisture for comparative studies. The ASTM D1557-12 (2021) standard was used to determine the maximum dry density and optimum moisture content required for soil compaction. This standard is particularly relevant for the evaluation of soils used in civil engineering applications, such as backfill around buried utilities.

For this study, test samples were compacted to 85% and 90% of the Modified Proctor maximum dry density. These values represent realistic field conditions encountered after backfilling and compaction of soil in cable trenches. Compaction was carried out in five uniform layers using mechanical energy equivalent to 2700 kNm/m³, ensuring homogeneous sample preparation and consistent test conditions. The layered approach helps to minimise void heterogeneity and improve the reproducibility of thermal measurements.

After compaction, the soil samples were allowed to equilibrate with the laboratory temperature for a period to eliminate transient thermal effects. This step is essential to ensure that the initial thermal state of the sample does not bias the results, particularly given the sensitivity of thermal resistance to moisture migration and temperature gradients.

In practical field applications, particularly in wind energy infrastructure, foundation soils are compacted after cable installation to achieve densities ranging between 85% and 90% of the Modified Proctor maximum along the entire underground cable route. Ensuring consistent soil compaction is not only vital for mechanical stability but also has a significant impact on the thermal performance of the buried cables. Poorly compacted soil can retain air voids which act as thermal insulators, reducing the ability of

soil to dissipate heat effectively and creating a risk of conductor overheating. Therefore, replicating these field conditions in the laboratory provides an accurate representation of operational scenarios and helps in the design of optimised cable burial systems.

Analysis of thermal conductivity test results

The analytical model for calculating thermal resistance has been developed based on the assumption of an infinite linear heat source dissipating heat in an infinite homogeneous medium. Under these idealised conditions, the thermal resistivity (ρ) (IEEE Std 442™, 2017) can be calculated using the following equation:

$$\rho = \frac{4\pi(T_2 - T_1)}{q \ln\left(\frac{t_2}{t_1}\right)} \quad (1)$$

where:

r is thermal resistivity (K·m/W);

T_1 - temperature measured at some arbitrary elapsed time (K);

T_2 - temperature measured at another arbitrary elapsed time (K);

q - dissipated per unit length (W/m);

t_1 - elapsed time at which temperature T1 is recorded (min);

t_2 - elapsed time at which temperature T2 is recorded (min).

Initial thermal transients occur due to the finite diameter of the thermal probe and are not representative of the ideal line source model. Similarly, boundary effects can occur due to the finite size of the soil sample container, leading to distortions in the measured thermal profile at later times. To ensure accurate calculations, the measured data must be carefully filtered to exclude these non-linear periods.

A standard approach is to plot the recorded temperature against the logarithm of time. The linear portion of this semi-log plot is identified as the valid interval for analysis. Data points within this region reflect stable thermal diffusion unaffected by the probe transients or edge boundary conditions.

Deviations at the beginning or end of the curve indicate either insufficient thermal stabilisation or the onset of confounding factors such as heat reflection from sample boundaries or moisture redistribution.

To simplify the calculation process and increase reliability an alternative form of the equation is often used. If the temperature change (ΔT) is measured over a complete logarithmic cycle, the resistivity can be approximated as (IEEE Std 442™, 2017):

$$\rho = \frac{4\pi}{2.303q}\Delta T \quad (2)$$

This formulation allows a simpler interpretation of the linear segment and is endorsed by the IEEE Std 442™ (2017) for thermal resistivity assessments. The use of these analytical techniques provides a robust framework for comparing thermal behaviour under varying moisture and compaction conditions. Three determinations were made for each sample (Figure 3).

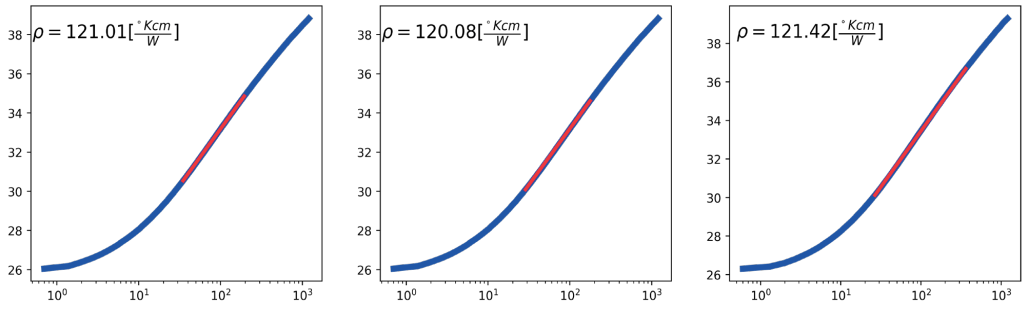

Figure 3. Thermal Resistivity Curves

Analysis of the geotechnical parameters of the soil

In order to characterise the investigated soil, a comprehensive programme of geotechnical laboratory tests was conducted to determine the physico-mechanical properties of the material. These tests were designed to provide essential data to evaluate the behaviour of the soil under different conditions, particularly for applications involving thermal performance, degree of compaction and load-bearing capacity. An understanding of these parameters is essential for the integration of thermal conductivity knowledge into practical design. Granulometric (particle-size) analysis indicated that the soil samples tested fell within the classification range of silty clay to clayey silt, as shown in Figure 4.

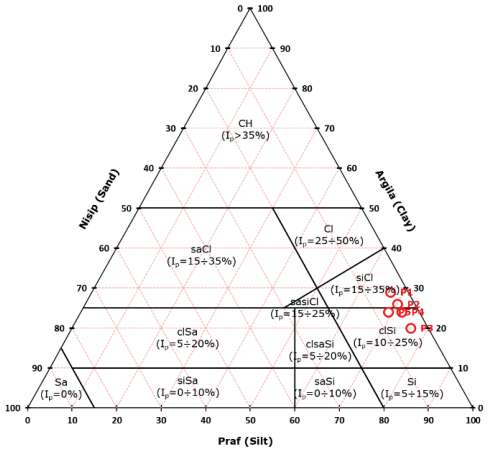

Figure 4. Ternary diagram of the soils

This classification suggests a fine-grained soil composition, which is typically associated with moderate permeability and relatively high-water retention capacity. Such properties have a direct influence on the thermal conductivity of the soil, as finer particles and higher moisture content levels can either promote or inhibit heat flow depending on their spatial arrangement and degree of saturation ration.

The Atterberg limits were determined to evaluate the soil's plasticity characteristics. The measured liquid and plastic limits indicate a medium plasticity index, indicating that the soil has a moderate deformation potential under variable moisture conditions (Figure 5). This plasticity range is important in determining how the soil content to seasonal changes in moisture, affecting both its thermal and mechanical stability. Soils with medium to high plasticity tend to be workable in the field, but their sensitivity to moisture variations requires careful consideration in the design of earthworks.

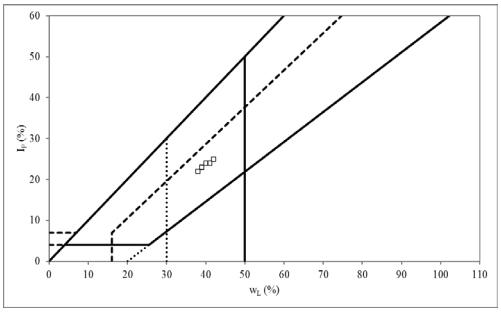

Figure 5. Soil plasticity

To further assess the quality and potential performance of the soil, the organic matter content was also determined. Laboratory results indicate that the organic content is between 2% and 3%. Although this level is not excessively high, it may still influence the soil's compaction behaviour, strength, and long-term stability. Organic materials tend to reduce dry density and increase water retention, which can alter thermal conductivity and pose risks in load-bearing applications, especially when the soil is used as backfill material.

To determine the optimum compaction parameters, Modified Proctor tests were performed on all tested samples in accordance with ASTM D1557. The test results helped identify the optimum moisture content and the corresponding maximum dry density necessary for achieving maximum density under in-situ conditions. The Modified Proctor curve (Figure 6) shows a clear peak, indicating the optimum moisture content at which soil particles are in the denseness state, minimising air voids and maximising thermal conduction potential.

In addition, California Bearing Ratio (CBR) tests were carried out in accordance with ASTM D1883 (2021) to assess the strength and bearing capacity of the soil. The CBR test results (Figure 7) provide critical information for assessing the mechanical performance of the soil, particularly the suitability of the subgrade material.

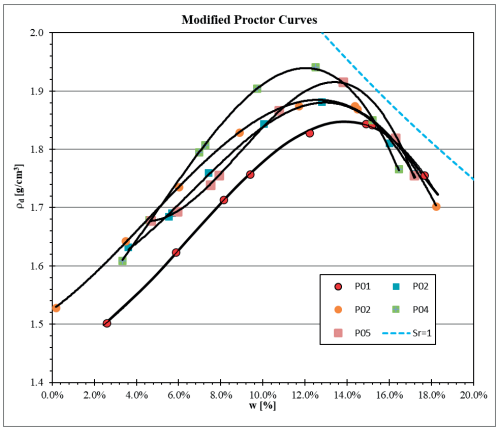

Figure 6. Modified Proctor Curves

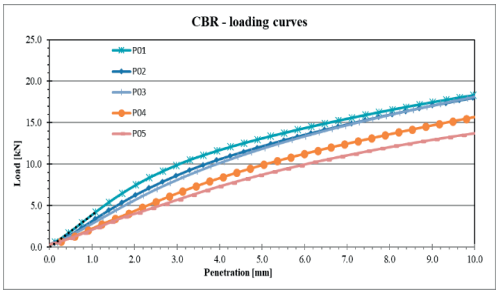

Figure 7. CBR Curves

Table 1 shows the compiled optimum compaction parameters, including the optimum water content (w_{opt}), the maximum dry density ($\gamma_{d,max}$) and CBR values for each of the conditions tested.

Table 1. Optimal compaction parameters

w_{opt}	$\gamma_{d,max}$	CBR	
		1	2
[%]	[g/cm^3]	[%]	
13.9	1.85	66.53	65.59
13.0	1.88	57.24	60.96
12.6	1.88	52.94	59.41
12.0	1.94	41.48	49.5
13.4	1.92	36.62	43.62

RESULTS AND DISCUSSIONS

The testing programme involved preparing samples at different Modified Proctor compaction levels, specifically 85% and 90%, to replicate field conditions typically encountered during the backfilling process (Olinic & Olinic, 2016) at underground cable installations. Each soil sample was meticulously prepared under controlled laboratory conditions to ensure repeatability and reliability of results. Compaction was carried out in successive layers to maintain a uniform density distribution throughout the soil sample volume.

All samples were pre-drilled along the vertical axis to accommodate the thermal needle probe, ensuring optimum thermal contact and minimising disturbance to the compacted matrix. This pre-drilling procedure is critical for accurate thermal conductivity measurements as it prevents deformation around the probe and eliminates artificial voids that could distort temperature readings.

Three independent resistivity tests were carried out on each sample at different moisture contents, allowing conductivity trends to be observed as a function of moisture content. The range of moisture contents tested ranged from near optimum compaction values to air-dried conditions. This enabled a detailed drying curve to be constructed, characterising how thermal resistivity evolves with progressive moisture loss.

Three independent resistivity tests were carried out on each sample at different moisture contents, allowing conductivity trends to be observed as a function of moisture content. The range of moisture contents tested ranged from near optimum compaction values to air-dried conditions. This enabled a detailed drying curve to be constructed, characterising how thermal resistivity evolves with progressive moisture loss

Figure 8 shows the variation in thermal conductivity over the range of moisture contents for both 85% and 90% compacted samples.

A comparative analysis of the curves highlights the significant effect of the degree of compaction level on thermal performance.

This observed behaviour confirms the critical role of both moisture content and dry density in optimising heat dissipation around underground conductors. The results reinforce the importance of proper site preparation and moisture control to ensure efficient thermal management in wind energy infrastructure.

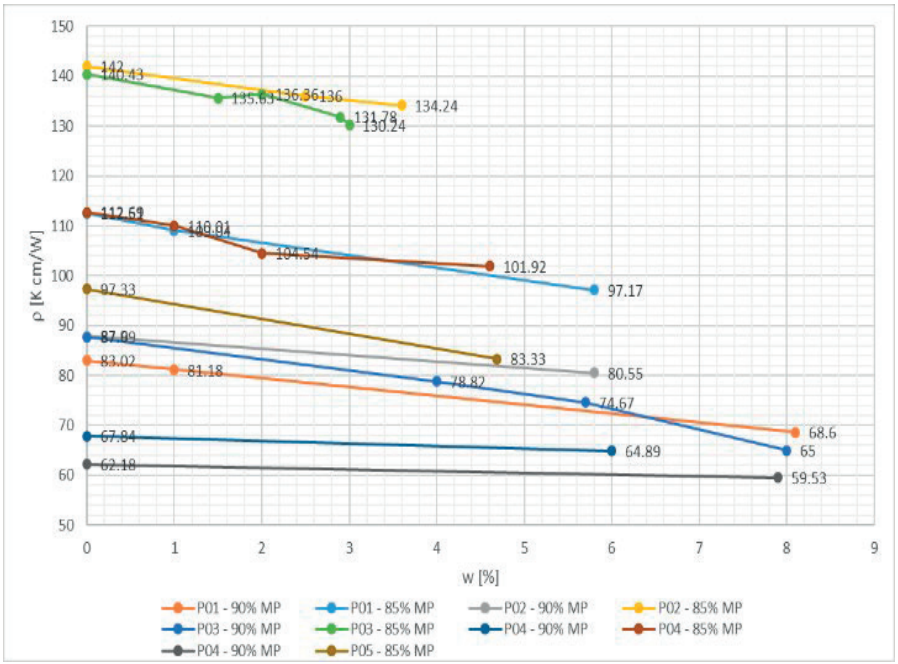

Figure 8. Thermal conductivity of tested soil

CONCLUSIONS

The experimental results clearly demonstrate that moisture content is a primary factor controlling the thermal conductivity of loess soils. The relationship between water content and heat transfer efficiency is non-linear and subject to threshold behaviour, influenced by soil microstructure and particle interactions (Nikiforova et al., 2013).

Three main regimes were identified:

- Dry state (low moisture content): In the absence of sufficient moisture, loess has very low thermal conductivity. This is mainly due to the dominance of air-filled pores which act as thermal insulators and significantly reduce the rate of heat transfer through the soil matrix.
- Moderate saturation (10–20%): As water content increases, capillary bridges begin to form between particles, allowing more efficient heat transfer. This is the optimum range for thermal conductivity where the combined effects of the higher thermal conductivity of water and increased interparticle contact significantly reduce the resistivity.
- High saturation (>40%): Surprisingly, thermal conductivity does not continue to increase indefinitely with moisture content. At high saturation levels, water tends to occupy voids in a discrete manner, forming capillary barriers. These restrict heat flow and can reduce conductivity by disrupting of continuous solid-liquid pathways.

The generation of drying curves proved to be an essential tool for understanding how progressive moisture loss affects thermal performance. These curves provide a dynamic perspective on how loess soils behave under real environmental conditions, particularly after compaction which is typical of wind farm installations.

In particular, below 8% moisture content, the thermal conductivity of remoulded loess samples prepared using the modified Proctor test showed inconsistent or subdued responses. Only when a stable temperature was achieved and maintained, the thermal conductivity measurement cycles were initiated. This variation is likely to be related to irregularities in void ratio and uneven moisture distribution within the soil matrix at very low water contents. Additionally, the degree of compaction level plays an important role in determining thermal

conductivity. At densities above 85–90% of the maximum dry density (according to Modified Proctor), the reduction in pore air volume significantly improves heat transfer through the soil. The denser particle arrangement creates more efficient conductive pathways, which is critical in preventing overheating of buried electrical systems (Mostafa et al., 2018).

In conclusion, the synergy between moisture content and dry density must be carefully considered in the thermal design of underground electrical installations. Loess soils, although generally suitable due to their fine structure and moisture retention properties, require site-specific assessment and control of compaction and drainage conditions to ensure reliable performance.

To improve thermal properties (Martinez et al. 2019), a mixture was proposed that exchanged heat more effectively than soil particle contact points, and a linear relationship was obtained between $CaCO_3$ content and thermal conductivity. The thermal conductivity increased by 50% when the $CaCO_3$ content exceeded 8%.

Further research is recommended to investigate long-term thermal behaviour under cyclic moisture conditions and to quantify the influence of soil anisotropy and mineralogical variability on thermal conductivity.

ACKNOWLEDGEMENTS

This paper was made possible through the contribution of the research grant, “Evaluation of the Thermal Conductivity of Soil and Injection Material in Geothermal Boreholes” (GeoThermo) awarded to the authors by the Technical University of Civil Engineering from Bucharest under the ARUST2024 research program.

Abstract

The Danube Basin collects water from nineteen countries and is exposed to significant amounts of pollutants. Heavy metals such as lead (Pb), cadmium (Cd), mercury (Hg), arsenic (As), chromium (Cr), nickel (Ni), zinc (Zn), copper (Cu), aluminum (Al) are considered critical contaminants of aquatic ecosystems, given their high predilection to enter and accumulate in food chains. The primary sources of heavy metal pollution consist of discharges from agricultural waste, industrial and urban wastewater into the aquatic environment, as well as mining activities. Given their persistence in the environment, it is required to conduct studies on heavy metal concentrations to understand their implications for aquatic life and to assess biomagnification through food chains. For this purpose, various pollution indices are utilised to evaluate the chemical speciation of metals within the environmental system. Shortly, it is essential to prioritize the development of technologies that can facilitate the recovery of harmful heavy metals, while mitigating potential risks to the environment.

Key words*: bioaccumulation, Danube River, heavy metals.*

INTRODUCTION

The Danube River is one of the most essential in Europe, covering around 2.860 kilometres and crossing ten countries: Germany, Austria, Slovakia, Hungary, Croatia, Serbia, Romania, Bulgaria, Moldova, and Ukraine. It is an important river for the economy, transportation, drinking water, agriculture, and biodiversity (Popa et al., 2018).

The Danube Delta Biosphere Reserve (UNESCO protected area) forms at the mouth of the Danube into the Black Sea, making it one of the world's largest deltas and the second largest in Europe. It is also one of Europe's largest wetlands and a refuge for numerous bird, fish, and plant species. This area is ecologically, economically and geographically important, having a significant impact on the environment and economy of the riparian regions since it is an important place for fishing and tourism (Mîndrescu et al., 2022).

The Danube has numerous important tributaries coming from different regions of Central, Eastern and South-Eastern Europe, such as Inn, Morava, Drava, Sava, Tisa, Iskar, Olt, Siret, Prut and Velika Morava, which play an important role in supplying the river with water, but also with pollutants, significantly influencing water quality and disrupting the ecological equilibrium (Culicov et al., 2022). Sources of pollution with these metals can be natural or anthropogenic. The natural sources can include volcanic eruptions, weathering, wildfires, while anthropological sources can be mining, chemical and metallurgical industries, industrial waste discharges, agriculture (using pesticides and fertilizers), and through transportation or construction activities (Benhadji et al., 2025). Human activity in river basins and deltas causes pollutants to be released into the air, soil and water. The principal pollutants found in aquatic systems include volatile organic compounds, pharmaceutical compounds, plant nutrients, suspended solids, microbial pathogens, and parasites (Paul, 2017). Among these pollutants are also heavy metals (HMs), which are chemical elements with a high density that can

pose serious risks to both human health and the ecosystem, such as lead (Pb), cadmium (Cd), mercury (Hg), arsenic (As), chromium (Cr), nickel (Ni), zinc (Zn), copper (Cu), aluminium (Al) (Zaynab et al., 2022). Because of their widespread distribution, toxicity, persistence in the environment and capacity for bioaccumulation, heavy metals represent a critical contaminant of aquatic ecosystems (Jarić et al., 2011). In the past years, monitoring heavy metals in the aquatic environment has become a priority for authorities. The presence of heavy metals can be examined by inductively coupled plasma optical emission spectroscopy (ICP-OES) (Mikala Okouyi et al., 2024), inductively coupled plasma mass spectrometry (ICP-MS) (Calmuc et al., 2021), atomic absorption spectrometry (Lazarević et al. 2022), atomic fluorescence spectrometry (AFS), X-ray absorption spectroscopy (XAS) and X-ray fluorescence spectrometry (XRF) (He et al., 2024).
This study assesses the heavy metal concentration of the surface water, sediment, and biota of the Danube River, as well as the environmental impact.

MATERIALS AND METHODS

Sources of heavy metals

Aluminum (Al) is one of the most abundant metallic elements in the Earth's crust and occurs naturally only in the +3-oxidation state (Al^{3+}), typically in combination with elements such as oxygen, silicon, and fluorine. Al^{3+} is a key component of various minerals, including mica, feldspars, and clays. Aluminum enters the environment through natural processes such as rock weathering and volcanic activity, as well as anthropogenic activities, including aluminum production, coal combustion, mining, waste incineration, motor vehicle emissions, fireworks, packaging, toothpaste, vaccines, antiperspirants, and certain pharmaceuticals such as buffered aspirin and antacids (Alasfar & Isaifan, n.d.; Briffa et al., 2020; Closset et al., 2022).
Arsenic (As) is a crystalline metalloid that occurs naturally in the environment. It originates from both natural processes - such as wildfires, pedogenesis, dust storms, volcanic and geothermal activity - and anthropogenic sources including electroplating, smelting, fossil fuel combustion, production of glass, pharmaceuticals, insecticides, pesticides, fertilizers, electronics, mining, and wood preservation (Briffa et al., 2020; Byeon et al., 2021; Liu et al., 2022; Zhang et al., 2022; Wang et al., 2023; Sevak & Pushkar, 2024). In aquatic systems, the dominant and most toxic inorganic forms are arsenate (As^{5+}) and arsenite (As^{3+}) (Jeong et al., 2023).
Cadmium (Cd) is a highly toxic heavy metal found abundant in Earth's crust, usually in combination with ores of copper, zinc and lead. Natural cadmium emissions arise from rock weathering, volcanic eruptions, dust transport, marine aerosols, forest fires, and soil erosion (Khan et al., 2022; Jeong et al., 2023; Oladimeji et al., 2024). Anthropogenic sources include electroplating, metal coatings, mining, plastics stabilization, cement manufacturing, paint pigments, battery production, fossil fuel combustion, pesticide and fertilizer use, as well as incineration of municipal and sewage sludge (Briffa et al., 2020; Khan et al., 2022; Jeong et al., 2023; Oladimeji et al., 2024).
Chromium (Cr) particularly in the Cr^{+3} and Cr^{+6} oxidation states, is one of the most toxic heavy metals naturally present in water and soil due to geological processes like weathering. Anthropogenic contributions include metal processing, chromate production, leather tanning, stainless steel welding, electroplating, cement and pigment manufacturing, textile dyeing, mining, coal and oil combustion, fertilizer application, thermal power generation, and the paper industry (Briffa et al., 2020; He et al., 2020; Tumolo et al., 2020; Ayele & Godeto, 2021; Kolarova & Napiórkowski, 2021; Prasad et al., 2021; Jeong et al., 2023).
Copper (Co) is naturally present in the form of sulphide and oxide ores, salt minerals, and native copper deposits. It is released into the environment via volcanic activity, geological deposits, and the weathering and erosion of rocks and soils (Rehman et al., 2019). Copper contamination of water can occur through corrosion of pipes and plumbing fixtures (Alkhanjaf et al., 2024). Human-induced sources include mining, smelting, metal and electronics manufacturing, discharge of industrial wastewater, wood preservatives, antifouling paints, fossil fuel combustion, urban runoff, fertilizers, fungicides, and pesticides

(Rehman et al., 2019; Briffa et al., 2020; Izydorczyk et al., 2021; Jeong et al., 2023).

Lead (Pb) is a trace metal found naturally in reduced quantities in the environment, with unknown role in cells, but extremely toxic even at low concentrations, which can be bioaccumulated by aquatic organisms (Valová et al., 2010). It can be found in galena and can be generated by volcanic activities, weathering and erosion (Briffa et al., 2020; Jeong et al., 2023), but it is predominantly produced due to anthropogenic sources such as metal processing, battery production industry, lead-based paints, lead in gasoline, mining, smelting, automobiles production, metal plating, agricultural fertilizers, insecticides, pesticides, waste disposal (batteries and electronics), unsuitable industrial waste, ammunitions and projectiles, lead crystal glass, pipes, glass screens, cable covers (Briffa et al., 2020; Jeong et al., 2023; Raj & Das, 2023; Oladimeji et al., 2024).

Mercury (Hg) is a non-essential, persistent, and highly toxic metal that bioaccumulates and biomagnifies in aquatic ecosystems. Naturally, mercury is emitted from the Earth's crust, wildfires, erosion of mercury-containing rocks, volcanic activity, geothermal processes, weathering, and evaporation from surface water (Budnik & Casteleyn, 2019; de Almeida Rodrigues et al., 2019; Jeong et al., 2023; 2024) Anthropogenic sources include chlor-alkali and thermal power plants, manufacturing of batteries, thermometers, and fluorescent lamps, ore smelting, agriculture, fossil fuel combustion, sewage, industrial wastewater, and cultural practices such as fish-based diets (Budnik & Casteleyn, 2019; de Almeida Rodrigues et al., 2019; Briffa et al., 2020; Kolarova & Napiórkowski, 2021; Jeong et al., 2023; 2024). Mercury exists in elemental (Hg^0), inorganic (Hg^+, Hg^{2+}), and organic forms (e.g., methylmercury – $MeHg^+$) (Kumar et al., 2024; Tsui et al., 2025).

Nickel (Ni) is a potentially toxic element commonly present in soil and aquatic systems. Natural inputs include rock weathering, wildfires, and volcanic activity (Gauthier et al., 2021), while anthropogenic sources include alloy manufacturing, pigment production, tannery wastewater, fossil fuel combustion, stainless steel manufacturing, battery production, electroplating, automobile and refinery emissions (Briffa et al., 2020; Wang et al., 2020; El-Naggar et al., 2021).

Zinc (Zn) is an abundant trace element in the Earth's crust, primarily found in sulphide minerals like sphalerite (Zn, Fe) S. Anthropogenic sources of zinc include metal processing, mining, municipal wastewater discharges, galvanization, smelting, electroplating, cosmetics, sunblock, deodorants, and vitamin supplements (Seto et al., 2013; Briffa et al., 2020; Jeong et al., 2023).

These pollutants mainly come from metallurgical, chemical, mining industries and urban wastewater, having a major impact on water quality and aquatic ecosystems (Simionov et al., 2021a). Identifying the sources of contamination is essential for developing effective monitoring, control and remediation strategies.

In ***Austria***, the city of Linz serves as a major industrial centre where metallurgical and chemical processes are potential sources of contamination (Winkler et al., 2018). This is further compounded by the Inn River, which traverses Switzerland, Austria, and Germany, and receives industrial runoff from regions such as Bavaria, where lead (Pb), zinc (Zn), and copper (Cu) have been detected in elevated concentrations (Saeed et al., 2023). In ***Slovakia***, the industrial area near the capital Bratislava includes oil refineries and chemical facilities that may release hazardous substances into nearby watercourses (Culicov et al., 2022), with additional input from the Morava River, which transports agro-industrial pollutants and legacy contaminants from former industrial facilities in Slovakia (Vesković et al., 2024). In ***Hungary***, the accumulation of industrial residues from bauxite processing, particularly in the form of "red mud", poses a major environmental threat, owing to elevated concentrations of aluminium (Al), iron (Fe), and cadmium (Cd), with implications for both ecosystem integrity and public health (Winkler et al., 2018). The capital Budapest hosts active industrial and port areas, contributing to the metal load of the Danube, mainly through metallurgical and chemical activities (Culicov et al., 2022). The Drava River, which flows through Hungary as well as Italy, Austria, Slovenia, and Croatia, adds further contamination originating from mining, agriculture, and industry (Šorša et al., 2022). In

Serbia, heavy industrial activity along the Danube in Belgrade is a key source of contaminants, with metal processing facilities discharging trace elements such as lead and zinc directly into the river (Subotić et al., 2013). The Sava River, Serbia's most significant tributary, passes through major industrial cities like Zagreb and Belgrade, transporting both metallic and organic pollutants (Vuković et al., 2012; Jovanović et al., 2017). Further inland, the Velika Morava River carries industrial effluents from central Serbia's densely populated areas (Culicov et al., 2022). In ***Romania***, the city of Galați, with one of the country's largest steel producers, is a major source of industrial emissions (Ioniță et al., 2014; Iticescu et al., 2014; Georgescu et al., 2023). Although industrial activity in Turnu Măgurele has diminished, the persistence of contaminants from former chemical plants continues to raise ecological concerns. Similarly, Drobeta-Turnu Severin presents industrial activities, such as shipyard operations, that may continue to influence water quality (Georgescu et al., 2023). The Tisza, flowing through five countries including Romania, has been affected by pollution by mining-related accidents in Maramureș that released cyanide and metal contaminants downstream (Kraft et al., 2006). The Olt River has been affected by longstanding pollution from the chemical and mining sectors around Râmnicu Vâlcea (Iordache et al., 2022), while the Siret and Prut Rivers are influenced by both agriculture and urban development across Ukraine, Moldova, and Romania (Calmuc et al., 2021; Burdenyuk et al., 2023; Georgescu et al., 2023). In ***Bulgaria***, the industrial cities of Ruse and Vidin host chemical and metallurgical facilities whose discharges further burden the Danube's ecological balance (Culicov et al., 2022). Similarly, the Iskar River carries pollutants from industrial areas in Sofia and northern Bulgaria into the Danube (Angelova et al., 2020).

These tributaries highlight the complexity and scale of the challenges related to heavy metal pollution in the Danube basin.

Analytical Techniques for Heavy Metals Determination

Several analytical techniques are available for detecting and quantifying heavy metals in environmental samples, each with specific advantages and limitations depending on the matrix and target elements. ICP-OES and AAS are commonly used for water, sediment, and biota analysis, both providing detection limits around 0.1-10 ppb. ICP-OES enables simultaneous multi-element analysis, high throughput, and reduced matrix effects compared to AAS, though spectral interferences may occur in complex samples (Mikala Okouyi et al., 2024). AAS is a well-established method offering high precision for single-element determinations, though it is limited to sequential analysis and requires complete digestion of solid matrices (Lazarević et al., 2022). ICP-MS offers exceptional sensitivity (0.001-0.1 ppb), supporting ultra-trace analysis, wide dynamic range, and applications in isotopic and speciation studies, though it may be affected by polyatomic and isobaric interferences (Burada et al., 2015; Calmuc et al., 2021). AFS, with detection limits between 0.01 and 1 ppb, is highly sensitive for select elements such as Hg, As, and Se, offering good selectivity and low background noise, although its applicability is limited to a narrow range of elements and can be influenced by molecular and matrix interferences (Abdelmonem et al., 2025). For elemental speciation and oxidation state determination, XAS provides detailed structural information in solid, liquid, and biological samples. This non-destructive, element-specific technique requires advanced facilities and complex data interpretation (Hu et al., 2020). Lastly, XRF allows rapid, non-destructive analysis of solid matrices like sediments and dried biota, with detection limits of 1-10 ppm. While effective for screening and minimal sample preparation, it offers lower sensitivity for trace-level elements and is less suitable for light elements or complex organic matrices (Lu et al., 2023).

RESULTS AND DISCUSSIONS

Status of heavy metal in Danube River water, sediments and biota

Extensive studies have been carried out by several researchers on heavy metal pollution of river Danube (Table 1). A research group (Saeed et al., 2023) studied the concentrations of arsenic, chromium, copper, nickel, lead and zinc

in the water of the river Danube at Dunaföldvár, Baja and Hercegszántó (Hungary) between 2013 and 2019 and reported temporal and spatial variations in heavy metal distribution. Concentrations of Zn reached up to 19.39 $\mu g \cdot L^{-1}$, Cu up to 4.4 $\mu g \cdot L^{-1}$, and Ni exceeded 3 $\mu g \cdot L^{-1}$ in some sites. Other study presents (Popescu et al., 2022) the levels of As, Cd, Hg, Pb and Zn in several Romanian sites along the Danube during 2020. It was found that arsenic levels, though low (0.09-0.14 $\mu g \cdot L^{-1}$), were present throughout all sampling stations, while Pb concentrations ranged from 0.21 to 0.31 $\mu g \cdot L^{-1}$ and Zn levels were notably high, up to 21.1 $\mu g \cdot L^{-1}$. Simionov and his team (Simionov et al., 2021b) also conducted an important study on the concentrations of As, Cd, Cu, Ni, Pb and Zn in surface waters collected from Galați and Tulcea. The highest recorded values were for Zn (57 $\mu g \cdot L^{-1}$), Cu (6.7 $\mu g \cdot L^{-1}$), and Ni (8.2 $\mu g \cdot L^{-1}$) around Galați, while Pb reached up to 3.1 $\mu g \cdot L^{-1}$ and Cd 0.14 $\mu g \cdot L^{-1}$. These values significantly exceeded those reported in upstream areas and reflect strong anthropogenic influence, likely related to industrial and urban discharge. A seasonal assessment was performed in Croatia (Redžović et al., 2023) at Medsave and Jarun, where Al, Cd, Cr, Cu, Ni, Pb and Zn were monitored in water samples. Aluminum levels reached 3.94 $\mu g \cdot L^{-1}$, and Cd was found up to 0.030 $\mu g \cdot L^{-1}$.

This study emphasized seasonal fluctuations, with higher concentrations typically recorded during summer and autumn months. Heavy metal contamination in sediments is a critical indicator of long-term pollution in riverine ecosystems (Table 2).

A collaborative study (Simionov et al., 2021b) analysed sediment samples from Galați, Tulcea, Pietrei Pond, Barcaz Lake, and Soschi Lake in Romania, detecting As, Cd, Cr, Cu, Ni, Pb and Zn at varying levels. The maximum values reached 0.7 $\mu g \cdot g^{-1}$ for Cd, 40 $\mu g \cdot g^{-1}$ for Cu, and 150 $\mu g \cdot g^{-1}$ for Zn, while arsenic was found in concentrations up to 13 $\mu g \cdot g^{-1}$ in Soschi Lake. Recent findings in Serbia (Kašanin-Grubin et al., 2023) highlight significant contamination in sediments from the Danube, Sava, Tisa and Tamiš rivers. In the Danube, Cd reached 2.75 $\mu g \cdot g^{-1}$, Cu up to 98.79 $\mu g \cdot g^{-1}$, and Zn 353.91 $\mu g \cdot g^{-1}$. Lead (Pb) was also present at concerning levels, up to 91.45 $\mu g \cdot g^{-1}$, while Cr measured 14.24 $\mu g \cdot g^{-1}$, indicating severe industrial pollution. A Croatian study (Redžović et al., 2023) conducted a seasonal assessment at Medsave and Jarun. Aluminum concentrations ranged from 5310 to 9270 $\mu g \cdot g^{-1}$, and cadmium reached up to 0.088 $\mu g \cdot g^{-1}$. While heavy metal values were moderate compared to other regions, seasonal variation influenced levels of Cr, Ni, and Zn, with higher concentrations typically observed in spring and summer.

Calmuc et al., 2021 assessed sediment contamination between Braila and Tulcea, Romania. At Grindu, Zn reached up to 146.23 $\mu g \cdot g^{-1}$ and Cu 13.42 $\mu g \cdot g^{-1}$. At Luncavița and Somova, Cd exceeded 0.70 $\mu g \cdot g^{-1}$, and Cu surpassed 27.50 $\mu g \cdot g^{-1}$. Elevated levels of Ni, Pb, and Zn suggest strong anthropogenic input, especially near industrial zones and confluence areas. Heavy metals accumulation in fish provides valuable insight into bioavailability and potential human health risks (Table 3). The investigation performed (Simionov et al., 2021b) focused on several species sampled from Galați, Tulcea, Pietrei Pond, Barcaz Lake, Soschi Lake, Black Sea Sf. Gheorghe, Black Sea Perisor (Romania). They determined that liver tissues generally exhibited higher concentrations of metals than muscle. Notably, Cd reached 0.8 $\mu g \cdot g^{-1}$ in *Cyprinus carpio* liver, while Zn levels peaked at 157 $\mu g \cdot g^{-1}$, indicating significant bioaccumulation. In addition, Jovičić et al., 2024 assessed metal content in *Rutilus rutilus* and *Blicca bjoerkna* from Veliko Ratno Ostrvo and Višnjica (Serbia), identifying the presence of As, Cr, Cu, Hg, Ni, Pb and Zn. Zinc concentrations were the highest, up to 27.64 $\mu g \cdot g^{-1}$, while Cr and Ni also showed moderate levels.

Table 3. Concentrations of heavy metals in biota from Danube Basin

Effects of heavy metals

Heavy metals present significant ecotoxicological threats to aquatic ecosystems, exerting their toxicity through a variety of mechanisms, including oxidative stress, neurotoxicity, enzymatic inhibition, impaired reproduction, and disruption of metabolic homeostasis. ***Lead*** accumulates in tissues such as gills, muscles, gonads, and digestive glands, where it mimics essential metals like copper, zinc, and iron, disrupting physiological functions (Jeong et al., 2023). Its affinity for sulfhydryl groups leads to enzymatic inhibition, including suppression of heme synthesis and antioxidant defense, resulting in lipid peroxidation, protein degradation, and DNA damage (Raj & Das, 2023; Oladimeji et al., 2024). ***Cadmium***, although not subject to biomagnification, bioaccumulates extensively and replaces essential metals in enzymatic systems, impairing cell signalling and inducing oxidative stress, calcium imbalance, and DNA damage (Khan et al., 2022; Jeong et al., 2023). Its toxicity is evident even at low concentrations, causing growth reduction and neurotoxicity in species such as *Daphnia magna* and *Ostrea edulis* (Abd Elnabi et al., 2023). Moreover, cadmium persists in sediments and alters microbial activity and plant growth, destabilizing ecosystem processes (Kolarova & Napiórkowski, 2021; Oladimeji et al., 2024). ***Mercury***, particularly as methylmercury (MeHg), is one of the most dangerous aquatic pollutants due to its ability to bioaccumulate and biomagnifies along food chains (Jeong et al., 2023). MeHg, formed under anoxic or even oxic

conditions, is readily absorbed by phytoplankton, initiating trophic transfer and causing severe neurotoxicity and structural deformities in fish (Kumar et al., 2024; Tsui et al., 2025). It also crosses the blood-brain barrier, accumulating in organs and impairing immune responses (Briffa et al., 2020). ***Arsenic***, influenced by pH, redox conditions, and organic matter, accumulates in sediments via adsorption to iron and manganese oxides, from where it may be remobilized (Wang et al., 2023). The inorganic form, arsenite (As^{+3}), is particularly toxic and bioavailable, accumulating in the liver and gills and causing oxidative stress, growth inhibition, and apoptosis (Jeong et al., 2023; Sevak & Pushkar, 2024). Although bioreduction is common in food chains, certain arsenic forms, such as arsenobetaines, may undergo biomagnification (Zhang et al., 2022). ***Chromium***, especially as Cr^{+6}, is mutagenic and carcinogenic, affecting fish, invertebrates, and aquatic plants through oxidative stress, reproductive toxicity, and developmental inhibition (He et al., 2020; Ayele & Godeto, 2021). Cr^{+6} reduces photosynthesis in aquatic flora, while Cr^{+3} can cause more severe effects in fish (Prasad et al., 2021; Jeong et al., 2023;). ***Nickel***, although essential for some microorganisms, becomes toxic at high concentrations, accumulating in gills, liver, and kidneys, where it induces respiratory disturbances and ionic imbalance (Gauthier et al., 2021). Sensitivity varies by species, with gastropods and vascular plants being more susceptible than fish or algae (Blewett & Leonard, 2017; Wang et al., 2020). ***Zinc***, an essential trace element, becomes toxic in excess, disturbing calcium metabolism in freshwater fish, leading to hypocalcemia and mortality (Jeong et al., 2023). While phytoplankton may mitigate its toxicity by supporting microbial metabolism, invertebrates often suffer from reduced respiration and excretion, leading to restricted growth (Seto et al., 2013). ***Aluminum***, particularly soluble at low pH, accumulates in tissues such as the brain in species like *Oncorhynchus mykiss*, where it causes neurotoxicity, oxidative stress, inflammation, and acetylcholinesterase inhibition (Closset et al., 2022). Its toxicity is form-dependent, with monomeric inorganic species being most harmful. Finally, ***copper***, though an essential micronutrient, is highly toxic at elevated levels, even exceeding the toxicity of cadmium or lead in some cases (Jeong et al., 2023). Cu disrupts enzymatic activity, reproduction, and neurological function, and may become remobilized from sediments under climate-induced changes, amplifying ecological risks (Izydorczyk et al., 2021; Cui et al., 2024). Its impact is compounded by its widespread use in industry and agriculture and its influence on drinking water toxicity under varying pH and hardness conditions (Rehman et al., 2019).

CONCLUSIONS

Heavy metal pollution in the Danube basin is the result of industrial, urban and agricultural sources, both along the river and from its major tributaries. The use of modern analytical methods and the precise identification of critical areas is essential to understand the dynamics of pollution and to implement coherent monitoring and remediation measures.

Abstract

Pesticides have been classified as the most harmful substances in the world because of their extensive application, toxicity, and persistence. Hydrophobic chemicals, such as pesticides, have a considerable tendency to sorb to organic matter in sediment and soil. Measuring pesticides in sediment is crucial for monitoring their environmental fate and possible toxicity because they are typically found at higher concentrations in sediment. Since many hydrophobic substances do not break down easily, they remain in the environment for a very long time. This study aims to develop an integrated approach to extracting and quantifying pesticides from sediment samples using QuEChERS-gas chromatography techniques. The extraction of organochlorine and organophosphorus pesticides from the sediment sample was achieved by slightly modifying the QuEChERS method. The extracted compounds were identified and quantified by gas chromatography with a triple-quadrupole mass detector. Organochlorine pesticides or their degradation compounds provided the majority of the target substances. Monitoring pesticide content in sediments is essential for understanding bioaccumulation and long-term environmental effects, as well as for promoting sustainable agricultural practices.

Key words*: pesticides, sediments, chromatography, QuEChERS.*

INTRODUCTION

In present-day agriculture, pesticides are crucial for both ensuring global food security and protecting crops from pests (Khurshid et al., 2024). Even though these substances offer several advantages, using them might have major negative effects on the environment and human health. Pesticide residues in food and the environment cause chronic health hazards, such as cancer, endocrine disruption, and neurological diseases (Zhou et al., 2025). Their presence in water, accumulation in sediments and soils, and possible biomagnification in the food chain could harm non-target organisms due to their possible toxicity (Peris et al., 2022). Pesticides that are used carelessly find their way into bottom sediments, where sediment particles absorb them and might eventually constitute a major cause of contamination in aquatic environments (Shah & Parveen, 2023). According to their physicochemical characteristics, such as solubility and octanol-water partition coefficient, pesticides disperse throughout the several aquatic ecosystem compartments (water, suspended materials, and biota) after being released into the environment (Ijzerman et al., 2024). Additionally, entrapped contaminants can be released at any moment through resuspension by natural processes or human intervention (Peris et al., 2022). Some pesticides adsorb onto suspended particles and have stronger affinities for organic materials; these particles subsequently settle and

accumulate in the waterbed (Khurshid et al., 2024).

The presence of hydrophobic pollutants in a waterway may be effectively determined by analyzing contaminants in the sediment and aquatic biota. Hydrophobic compounds have limited solubility in water, but high solubility in lipids. They also tend to accumulate to organic material in soil and sediment and their resistance to degradation makes them very persistent (USGS Fact Sheet, 2000). Over the past 50 years, a large number of pesticides have been detected in sediments, most of them belonging to organochlorine insecticides and their breakdown products.

The most frequently detected pesticides in sediment were DDTs, dieldrin, and chlordane even though some of them had been banned since the 1970s and 1980s (Yang et al., 2015). Studies have shown that sediment pollution has been linked to negative impacts on aquatic life such as hepatic lesions or DNA adducts (Yang et al., 2015). Moreover, hazardous substances present in aquatic ecosystems can accumulate and pose toxic risks when transferred to humans through consumption (Bashir et al., 2020). Pesticide residues were first analyzed using acetonitrile and petroleum ether. Then, acetone was added to prevent partial loss of polar insecticides, whereas salt improved their recovery.

In order to achieve a lower limit of quantification, solid-phase extraction and many other methods (supercritical fluid extraction, accelerated solvent extraction, gel-permeation chromatography, or microwave-assisted extraction) were included (Afify et al., 2022). The introduction of the (QuEChERS) method (quick, easy, cheap, effective, rugged, and safe) was revolutionary, innovative, and applicable to most official analysis methods. The QuEChERS approach is faster, requires less solvents, and produces consistent results (Shendy et al., 2019). Moreover, the combination of gas chromatography and mass spectrometry has proven to be among the best methods for the examination of pesticides from different matrices (Tankiewicz & Berg, 2022). Therefore, the objective of this study is to provide an optimal approach for the simultaneous extraction, determination, and quantification of 27 pesticides from both organochlorine (OCP) and organophosphorus (OPP) categories in sediment samples.

MATERIALS AND METHODS

QuEChERS Extraction

Organochlorine and organophosphorus pesticides were extracted from all sediment samples using a modified QuEChERS (rapid, simple, cheap, effective, robust, and safe) approach. Therefore, the following protocol was carried out, after spiking with different concentrations of the standard mix and the addition of the internal standard mix: 5 g of the sample and 10 mL of ACN (acetic acid 1%) were well homogenized. To begin the extraction stage, 6 g of MgSO4 and 1.5 g NaOAc were added as QuEChERS salts. The final mixture was vigorously shaken for 5 minutes and then centrifuged. A volume of 5 mL from the supernatant was collected and cleaned with different one, or two units of clean-up consisting of 50 mg MgSO4, 25 mg PSA, 25 mg C18, and 5 mg GCB. After a second centrifugation, the liquid part was subjected to evaporation through a nitrogen system and reconstituted with 0.5 mL or 0.250 mL acetonitrile. Even though this extraction method has many advantages, sometimes certain steps need to be particularly optimized because there are also problematic pesticides. Such pesticides are sensitive to pH, which creates strong bonds with other substances, leading to their misquantification. For example, using PSA (Primary Secondary Amine) in the QuEChERS extraction method is not indicated in the case of acidic pesticides that can form acid-base interactions with the sorbent. This combination can lead to the loss of acidic pesticides during the clean-up phase (Musarurwa et al., 2019).

Instrument and Method Setup

A TSQ 9000 Triple quadrupole GC-MS/MS instrument coupled with a Thermo Scientific™ TRACE™ 1310 GC was used to analyze the samples (Figure 1). A Thermo Scientific™ TriPlus™ RSH autosampler was used to inject the sample, and a Thermo Scientific™ TraceGOLD TG-5MS 30 m × 0.25 mm I.D. × 0.25 µm film capillary column was used for chromatographic separation. The instrument

was operated in a splitless mode with a 2 µL injection volume. The GC oven program was set up as follows: initial temperature 80°C with a 0.5 min hold time, from 80°C to 190°C at a rate of 25°C/min, from 130°C to 300°C at a rate of 6°C/min, and the final step, 300°C with a hold time of 10 min. The total run time was about 33 minutes.

Three SRM transitions - two for further ion ratio confirmation and one for quantitation - were utilized to identify each targeted compound. The Chromeleon 7.3 software was used to process and report the data.

Analytical standards

- EPA 625/CLP Pest. Mix, 1x1 mL, 2000 µg/mL in hexane:toluene (50:50) containing Aldrin, α-BHC, β-BHC, Lindane, δ-BHC, 4,4′-DDT, Dieldrin, α-Endosulfan, β-Endosulfan, Endosulfan sulfate, Endrin, Endrin aldehyde, Heptachlor, Heptachlor exo-epoxide
- EPA 8270 Organophosphorus Pesticides Mix 2, 1x1 mL, 2000 µg/mL in dichloromethane containing Dimethoate, Disulfoton, Famphur, Parathion, Parathion-methyl, Phorate, Sulfotep, Thionazin, Triethyl thiophosphate. A mixture containing two internal standards (ε-HCH and PCB-143) was used for the calibration curve.

RESULTS AND DISCUSSIONS

Five different samples were prepared to provide an optimal method for the extraction and detection of the target analytes. The first sample (A) is represented by sediment with internal standards. Sample B was obtained by spiking sample A with a standard solution in a concentration of 20 ng/mL. Samples coded C, D, and E represented sediment spiked with 100 ng/mL standard solution, cleaned up and redissolved differently after the concentration step. In this context, the evaluation of specific extraction steps was conducted to achieve the most precise, rapid, and efficient quantification of the compounds, while confirming their presence through three distinct transitions (Table 1).

Table 1. Pesticides retention time and product ions

Compounds	Retention Time	Quant. Ion	Conf. Ion #1	Conf. Ion #2
	min	m/z	m/z	m/z
O, O, O-Triethylphosphoro thioate	3.86	65	93.1	65

4,4`-DDT	14.17	165.1	199.5	165

Figure 2 displays the peaks corresponding to each investigated compound. In Figure 3, the final amount of each tested experimental variant is exposed.

As expected, similar values for most of the

organochlorine pesticides were obtained when variants E, D, and C were applied. The common aspect among these three samples is the spiking level, which is 100 ng/mL. The difference lies in the final step of the extraction. However, it is important to mention that variant E was distinguished by better and easier quantification during data processing. Therefore, in addition to a slightly higher final concentration, the peak intensities corresponding to each compound - including the internal standard - were significantly higher than those calculated in the other variants. Even though organochlorine chemicals are banned, their traces can still be found in food and the environment as contaminants (Zohair, 2001).

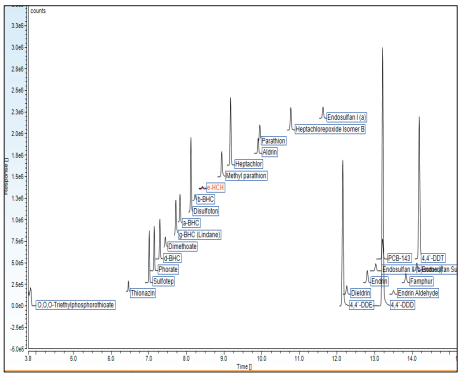

Figure 2. Standard solution (OCP and OPP) chromatogram in MS Quantitation

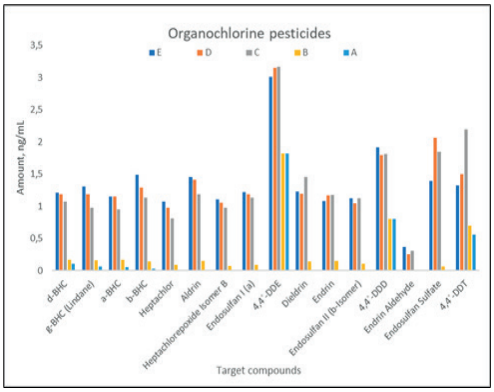

Figure 3. Organochlorine pesticides concentration in each experimental variant

A similar observation can be made for the organophosphorus pesticides in Figure 4. With a few exceptions, the best variant of the extraction is sample E. It seems that redissolving the final extract in a smaller volume of acetonitrile promotes the detection of the compounds. Of course, that in the case of sample B, where the spiking was made with a much lower concentration of pesticides, the final concentration is also much lower than the final amount detected in other samples.

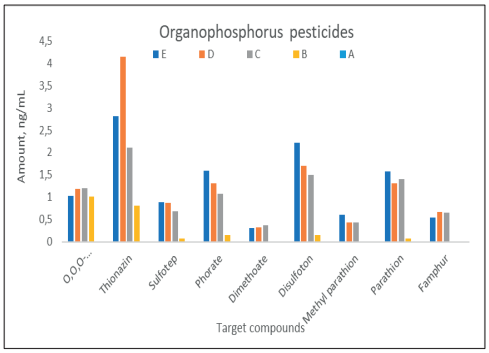

Figure 4. Organophosphorus pesticides concentration in each experimental variant

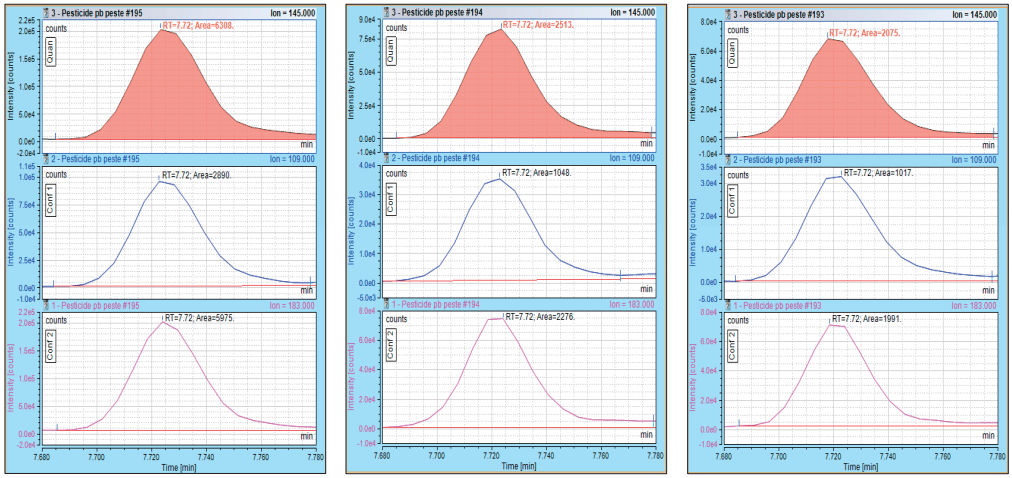
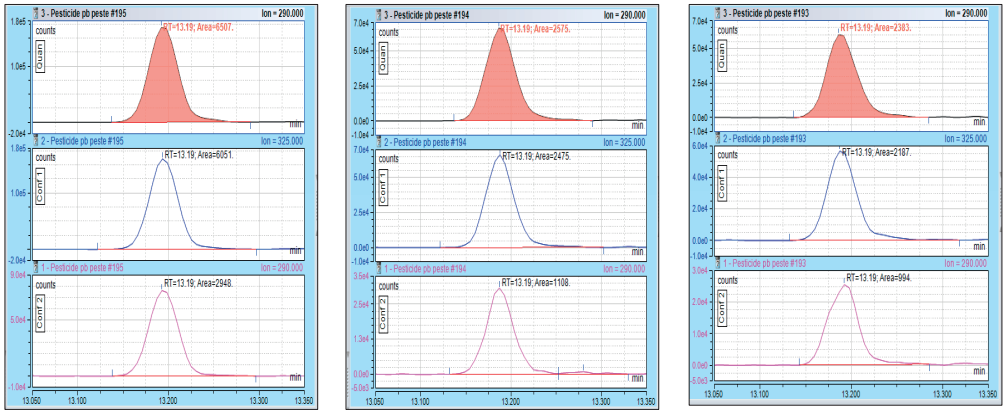


Compared to organochlorines, organophosphorus pesticides are more acutely hazardous, but they have the benefit of being quickly broken down in the environment (Zohair, 2001).

In a study conducted by Khurshid et al., 2024 on pesticide contamination in sediments of 38 water bodies, only one sample was 'pesticide-free' and 3 samples contained a single pesticide.

Figure 5 and Figure 6 confirm the abovementioned idea. As can be observed, an example of a well-known agricultural insecticide, γ-BHC is represented along with its representative ions (Figure 5). The higher intensity peak for this compound highlights variant E compared to Variants D and C. Moreover, an identical situation is valid for the internal standard PCB-143 represented in Figure 6. It is very important to improve the compounds' detection because in most cases they belong to complex matrices. Matrix effects are a major challenge for analyzing low levels of different contaminants using gas chromatography-triple quadrupole mass spectrometry. When examining complex matrices, a practical approach is required due to the complex nature of matrix effects, which can be influenced by various factors such as the



target analyte, sample preparation technique, composition, and instrument selection (Williams et al., 2023). Most often, salts and SPE sorbents are the key components in terms of removing water residues or other matrix interferences (QuEChERS Pesticides, 2011). However, PSA does not apply, for example, to non-polar pigments, and can be replaced or supplemented with GCB (graphitized carbon black). Florisil and low temperature can be used also when fatty matrices are analyzed (Musarurwa et al., 2019).

Moreover, studying residual pesticide compounds in sediments emphasizes the necessity of investigating the immediate and long-term impacts of pesticide use on aquatic systems and, eventually, the need for more ecologically friendly and sustainable farming methods (Khurshid et al., 2024).

a) Variant E b) Variant D c) Variant C

Figure 5. MS Components for g-BHC

a) Variant E b) Variant D c) Variant C

Figure 6. MS Components for PCB-143 (IS)

The screening of these contaminants in sediments is essential to understanding their dynamics and any possible hazards to aquatic life (Peris et al., 2022). Sediments may provide important details about the quality of water and vary considerably in composition, shape, and processes (Brondi et al., 2011).

CONCLUSIONS

The development of a method for determining pesticides in sediment is essential for many reasons, including pollution monitoring, ecosystem protection, identifying contamination sources, evaluating toxicity and bioaccumulation potential, establishing regulations in the field, and assessing the detrimental impact on human health.

QuEChERS approach' short operating time, ease of use, and affordability facilitate the simultaneous analysis of multiclass pesticide residues in sediment samples. Because the QuEChERS approach produces far less waste and requires less hazardous solvents and reagents, it is also consistent with green chemistry.

In the present study, the QuEChERS approach using the 1:5 ratio for the clean-up: liquid extract, as well as the re-dissolution after concentration in a smaller volume of solvent, resulted in better separation and identification of compounds.

There is an increasing demand for validated techniques capable of detecting pesticide residues in sediments, comparable to those used for water and vegetable samples. This is an area that is constantly evolving and demands ongoing research into better, more affordable, quicker, wider-ranging, and environmentally friendly methods.

Protecting and conserving aquatic ecosystems as well as achieving the European Union's goal of zero pollution in soil, air, and water by 2050 (European Commission. Directorate General for Environment. et al., 2021) depend on the understanding of the dynamics and effects of (mixtures of) pesticide residues.

Abstract

Nitrogen dioxide is found in the atmosphere as a key ingredient in the photochemical formation of smog and acid rain, nitrogen dioxide is a poisonous gas that is formed during combustion. Toxic at high concentrations, it reacts with moisture in the air to form nitric acid, which is highly corrosive and dangerous to plants and animals. In this study, we present a predictive model for nitrogen dioxide concentrations measured between 2017 and 2024 at ground level in a national network of monitoring stations. The model is based on a statistical approach to measurements from 152 automatic measurement points, with an hourly resolution. The analysis carried out allowed the construction of a mathematical model in order to make an effective prediction. The algorithms used were of the Recursive least squares filter type. The application used was made possible by running a dedicated software in PyCharm. It was found that the model for daytime concentrations depends linearly on a series of parameters monitored by the national network.

Key words*: NO_2, algorithm, RLS, statistical analysis.*

INTRODUCTION

Nitrogen dioxide (NO_2) pollution has emerged as a major environmental and public health concern globally (Moreda-Piñeiro et al., 2021), particularly following efforts to reduce $PM_{2.5}$ concentrations to below regulatory thresholds. There is widespread scientific and regulatory interest in understanding the dynamics of ground-level NO_2, a key atmospheric pollutant, due to its well-documented harmful effects on human health. Research has also highlighted the detrimental impacts of NO_2 on vegetation, contributing to reduced plant growth and crop yields (Pietrogrande et al., 2021). According to the World Health Organization (WHO), strong evidence from both epidemiological and toxicological studies shows that elevated NO_2 concentrations are a primary contributor to adverse respiratory outcomes (Varga-Balogh et al., 2021). These effects range from decreased lung function and aggravated asthma symptoms to increased mortality, particularly among sensitive population groups such as children, the elderly, and individuals with pre-existing respiratory conditions.

Ground-level ozone is a secondary pollutant that results predominantly from the photochemical chain reactions involving nitrogen oxides (NO_X = NO + NO_2), carbon monoxide (CO) and volatile organic compounds (VOCs) using the catalysis of sunlight in the troposphere (Vîrghileanu et al., 2020).

Over the past few decades, greenhouse gas concentrations have increased around the world. With the rapid development of car traffic and the car fleet in particular, air pollution has become increasingly in South-Eastern Europe (Constantin et al., 2017). Since 2017, several legislative actions have been carried out, including the elimination of the environmental tax on vehicle registration. This

fact led to the increase in the level of air pollution in the South-East of Europe.
In this paper, the nitrogen dioxide monitoring data in the South-East of Europe are presented, taking into account a system of 7 automatic air quality monitoring stations within the national network. The data were used to analyse the characteristics of variation and the main causes of the concentration of nitrogen dioxide - NO_2 in the South-East area of Europe in combination with the relationship between different pollutants and meteorological factors.

MATERIALS AND METHODS

Since 2010, a national air quality monitoring network (https://www.calitateaer.ro/) has been established in South-Eastern Europe, which now includes 158 national automatic stations. Data for NO_2 were sourced from seven automatic air quality monitoring stations that are part of Romania's national monitoring network. These stations provided hourly measurements of NO_2 and associated pollutants (e.g., NO, NO_x, O_3, CO, PM), along with meteorological variables such as solar radiation, wind speed, temperature, and humidity, covering the years 2017 to 2024. This high-resolution dataset enabled the examination of NO_2 variability across multiple temporal scales.
To investigate temporal trends, the researchers employed classical statistical techniques, notably one-way Analysis of Variance (ANOVA) and the Kruskal-Wallis test. These methods were applied to assess seasonal, weekly, and diurnal fluctuations in NO_2 concentrations. The statistical tests consistently yielded p-values below 0.001, confirming significant variation in NO_2 levels across different time periods. Seasonal changes likely reflected atmospheric chemistry and heating or traffic patterns, while weekly and hourly patterns pointed to anthropogenic influences such as workweek traffic cycles and photochemical processes during daylight hours.
The data recorded between 2017 and 2025 were used together for data processing in this paper. The equipment of the automatic air quality monitoring stations collects automatically air samples and generates data reports every 30 minutes; then automatically uploads this data to the national database from local environmental protection departments. Table 1 shows the details of the parameters taken into the statistical analysis from each sampling stations, and Table 2 presents the location of the air quality stations used in this study based on their coordinates.

Table 1. Monitored parameters in the network of monitoring points

RESULTS AND DISCUSSIONS

In this section, we will present the results of statistical analysis and the results of numerical simulations using digital fitre (Voipan, Voipan, & Barbu, 2025).

Statistical analysis of the temporal variation of nitrogen dioxide concentration.

Seasonal variation analyses were performed for the concentration of NO_2 in the South-East area of Romania. Figure 1 shows, for example, box plot charts (Afshar-Mohajer et al., 2018) of NO_2 concentration in relation to the season in

question for the set of monitoring stations for 2018.

Obviously, seasonal variation was analyzed using ANOVA methods (Koziel, Pietrenko-Dabrowska, Wójcikowski, & Pankiewicz, 2025). In Table 3 are presented the results obtained for the seasonal variation presented above. It is noted that there is certainly a significant difference between the seasons considered between 2017 and 2024 (Table 3).

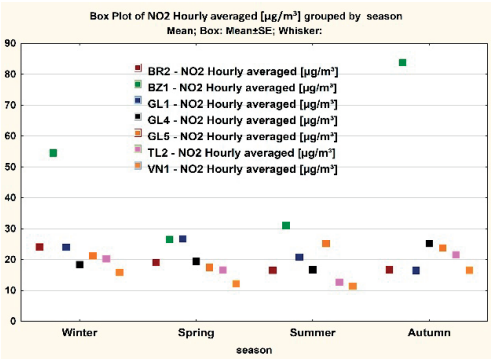

Figure 1. Seasonal variation of NO_2 during 2018

Thus, it is observed that in all cases submitted on NO_2 concentration, values of parameter p – confidence level, both for the analysis of using ANOVA methods one-way and for statistical analysis the Kruskal-Wallis test (KW) (Iticescu et al., 2019), are much smaller than 0.05 (Table 3).

Table 3. results obtained for the seasonal ANOVA method

Name	F value, p - value	H value, p- value
GL5	F(3.8751) = 223.6277, p = 0.0000	KW H(3.8755) = 861.4596, p = 0.0000
GL1	F(3.8751) = 1923.508, p = 0.0000	KW H(3.8755) = 2776.935, p = 0.0000
GL4	F(3.8751) = 186.0061, p = 0.0000	KW H(3.8755) = 995.1096, p = 0.0000
BR2	F(3.8751) = 72.9322, p = 0.0000	KW H(3.8755) = 179.6793, p = 0.0000
BZ1	F(3.8751) = 61.504, p = 0.0000	KW H(3.8755) = 173.5316, p = 0.0000
FP2	F(3.8751) = 133.792, p = 0.0000	KW H(3.8755) = 955.3999, p = 0.0000
VN1	F(3.8751) = 76.092, p = 0.0000	KW H(3.8755) = 424.889, p = 0.0000

Similarly, for all data sets, the weekly variation analysis for NO_2 concentration in the South-East area of Romania was performed.

Figure 2 shows, for example, the box plot graphs (NO_2 concentration in relation to the day of the week) for the set of monitoring stations for 2018 and Table 4 shows the values resulting from the ANOVA and Kruskal-Wallis test. Thus, it is observed that, in all cases, the values of the p parameter are much lower than 0.001, which means significant differences.

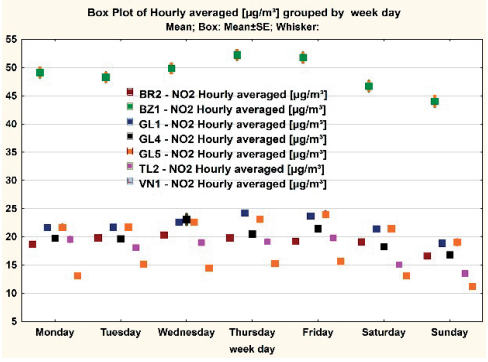

Figure 2. Weekdays variation of NO_2 during 2018

Table 4. Results obtained for weekly ANOVA (for a period of one week)

Name	F value, p – value	H value, p - value
GL5	F(6.8748) = 14.6618, p = 0.0000;	KW H(6.8755) = 118.6725, p = 0.0000
GL1	F(6.8748) = 7.906, p = 0.00000;	KW H(6.8755) = 133.5861, p = 0.0000
GL4	F(6.8748) = 16.3105, p = 0.0000;	KW H(6.8755) = 137.9648, p = 0.0000
BR2	F(6.8748) = 12.5073, p = 0.0000;	KW H(6.8755) = 162.6187, p = 0.0000
BZ1	F(6.8748) = 7.3831, p = 0.00000;	KW H(6.8755) = 239.9735, p = 0.0000
FP2	F(6.8748) = 27.9262, p = 0.0000;	KW H(6.8755) = 306.9294, p = 0.0000
VN1	F(6.8748) = 16.3649, p = 0.0000;	KW H(6.8755) = 138.5051, p = 0.0000

Lastly, we investigated the diurnal variability of NO_2 concentrations in the south-eastern region of Romania.

Figure 3 shows, for example, the box plot charts for the set of monitoring stations for 2018, and Table 5 shows the values for the ANOVA and Kruskal-Wallis test (NO_2 concentration in relation to the hour).

At this stage, the question arises whether a numerical model can be made that can integrate all these statistical data leading to the identification of some essential parameters - NO_x, NO, and solar radiation (Table 1).

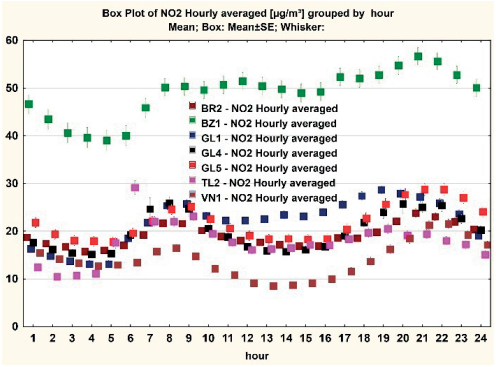

Figure 3. Diurnal variation of NO_2 during 2018

Table 5. Results obtained for daytime ANOVA

Name	F value, p - value	H value, p - value
GL5	F(23.8731) = 15.6522, p = 0.0000;	KW-H(23.8755) = 348.5298, p = 0.0000
GL1	F(23.8731) = 7.2156, p = 0.0000;	KW-H(23.8755) = 448.7269, p = 0.0000

In this regard, a multidimensional model was developed to identify the set of physical variables influencing ground-level NO_2 concentration. Table 6 presents the results obtained for the BR2 station in 2017. The statistical model employed a factorial analysis approach, using the parameters listed in Table 1, with the sum of squares (SS) as a key metric.
It is important to note that, for assessing NO_2 conformity, the key parameters comprise NO concentration, NO_x concentration, and ground-level solar radiation values - as indicated in Table 6 (Iticescu et al., 2019).
At this stage, the reliability and robustness of the developed statistical model can be evaluated. Table 7 presents the results for the BR-2 station based on the 2017 dataset, with respect to the model's approximation accuracy. For all other stations considered, the models achieved an R^2 coefficient exceeding 0.90, indicating a high degree of explanatory power.

Numerical simulation of the temporal variation of nitrogen dioxide concentration.
The specialized literature provides a variety of analysis and interpolation procedures, as well as algorithms, aimed at improving the accuracy of NO_2 estimation and prediction (Koziel et al., 2025). Several highly efficient algorithms implementing difference-based methods have been reported (Koziel et al., 2025). In the present study, we employed a filter with three input parameters and a single output parameter - NO_2 concentration (Figure 4) (Koziel et al., 2025). The algorithm follows the structure of a Recursive Least Squares (RLS) filter (Barbu, 2024). As a result of the iterative process, numerical simulations consistently converged in all cases, with the trace of the covariance matrix reaching its minimum value (Figure 5).

At the same time, the Nyquist diagram (Koziel et al., 2025) shows that the simulation process is stationary, being finally obtained closed trajectories in the right semiplane (Voipan et al., 2025). Finally, the response of the applied filter and the evolution of the estimation error exhibit a clear tendency toward convergence (Figure 6), indicating that the filter operates effectively.

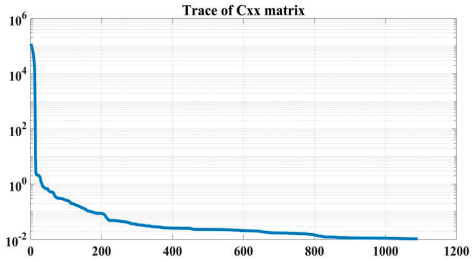

Figure 5. Digital filter covariance matrix trace and evolution towards convergence (matrix trace value versus simulation number)

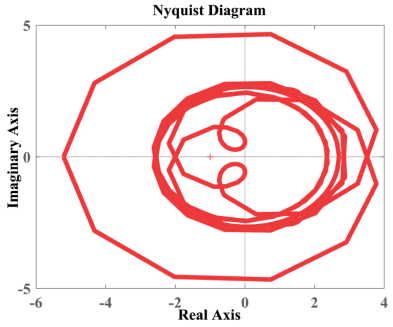

Figure 6. Nyquist filter response diagram

The final output of the filter is illustrated in Figure 7, where the amplification and refinement of the data following the filter's application are evident.

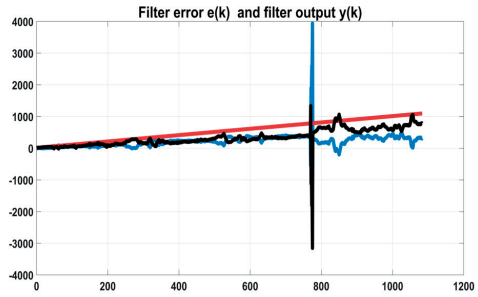

Figure 7. Digital filter response

CONCLUSIONS

Beyond exploratory statistics, the study advanced to multivariate modeling to identify key predictors influencing NO_2 concentrations. Using univariate tests of significance, our work determined that NO, NO_x, and solar radiation were the most impactful variables. These predictors were integrated into a factorial regression model, which showed exceptionally high accuracy, with R^2 values exceeding 0.99 for certain stations, such as BR2. This strong explanatory power highlighted the model's potential for accurate and localized air quality assessments.

The predictive component of the study was based on a Recursive Least Squares (RLS) filter, a numerical algorithm implemented in Python. This digital filter used the key predictors to estimate NO_2 concentrations in real-time, dynamically adjusting to new input data. The RLS model achieved convergence in all test cases, demonstrated by the minimization of the covariance matrix trace and stability confirmed through Nyquist diagram analysis. Model validation revealed high correlation with observed data and RMSE values under 3.5 $\mu g/m^3$, underscoring the model's effectiveness. These results indicate that the proposed approach not only enables reliable NO_2 prediction but also holds promise for cost-effective deployment in air quality monitoring and environmental management.

The corrective analysis and simulation process developed within the group exploited reference data and data provided by the national air quality monitoring network, collected in several locations, regarding the evaluation of the evolution and prediction of the NO_2 concentration. The rigorous verification indicates that the proposed correction technique achieves a very good accuracy of NO_2 monitoring, with a correlation coefficient exceeding 0.88, obtained for the reference data. Simultaneously, the RMSE error remains below 3.5 $\mu g/m^3$. Achieving such very high accuracy confirms the practicality and reliability of NO_2 detection using inexpensive detection devices. Further experiments involving alternative correction configurations emphasize the importance of the algorithmic tools developed in refining the correction scheme. Specifically, the inclusion of additional input variables, and the improvement of global data correlation together increase the accuracy of NO_2 detection.

Abstract

The phenomenon of global climate change, largely driven by human activities and associated with rising air temperatures, not only leads to intensified and longer-lasting droughts, but also increases the likelihood of extreme precipitation events that may trigger flooding concerns. The stress caused by soil waterlogging is intricate, leading to several concurrent challenges that disrupt normal plant functioning. A key challenge is the oxygen deficiency, which arises from the considerably reduced diffusion rates in floodwater relative to those in the atmosphere. The ability of plants to adapt to waterlogging stress is quite limited primarily because of the partial or complete absence of oxygen in the growth medium. However, certain plant species have evolved specific mechanisms through evolution that allow them to survive for a certain duration in hypoxic or anoxic environments. These mechanisms can be classified into two broad categories: plant morpho-anatomical adaptations to waterlogging stress and the biochemical and physiological responses of plants to such stress. These adaptations are interconnected rather than acting in isolation. Instead, they are intricately connected. This review explores: (i) the impact of soil waterlogging on plant development and function; (ii) current insights into the signal transduction pathways involved in stress recognition and response; and (iii) the key morpho-anatomical and physiological strategies plants use to cope with waterlogged conditions.

Key words*: waterlogging, plant stress, oxygen deficiency, ethylene, adventitious roots, aerenchyma, flooding adaptation.*

INTRODUCTION

Soil waterlogging is a severe abiotic stress that occurs when water saturates the spaces between soil particles, severely limiting oxygen availability to plant roots and leading to hypoxic or anoxic conditions (Walne & Reddy, 2021). Under these conditions, the oxygen diffusion rate is up to ten thousand times lower than in well-drained soils, significantly impairing root function (Manghwar et al., 2024).

When soil becomes waterlogged, oxygen supply to the roots drops sharply, which stunts their growth and reduces the plant's ability to absorb water and nutrients (Abuarab et al., 2019). Excess water also disrupts the metabolism of aerobic soil microorganisms (Siebielec et al., 2020). Without oxygen, these microbes either die off or shift to anaerobic metabolism, producing organic acids that lower soil pH (Abdul Rahman et al., 2021). This acidification encourages harmful microbial activity and accelerates nutrient leaching from the soil's adsorptive complex, further limiting root nutrient uptake (Husson, 2013).

The accumulation of excess water also alters the soil's hydraulic conductivity, reducing water movement and impeding root penetration. In saturated or nearly saturated conditions, the soil's capacity to transmit water is greatly diminished, hindering root penetration through the compacted layer of soil (Jitsuyama, 2017; Luo et al., 2024). Collectively, these effects slow plant metabolism and, if prolonged, may cause wilting.

Although drought stress is more common, waterlogging remains a significant threat - particularly to crops. Poor drainage and excessive rainfall can quickly create oxygen-deficient soil conditions that impair root function (Topali et al., 2024).

Moreover, global climate change - driven by human activities and marked by rising air temperatures - intensifies both droughts and heavy rainfall. Over the last few decades, scientists studying this topic have persistently raised awareness about the problems associated with global climate change (Furtak & Wolińska, 2023; Bolane et al., 2024). The growing frequency of alternating drought and flooding

events confirms their predictions and suggests that crops will face increasing vulnerability to both types of stress in the future.

EFFECTS OF WATERLOGGING STRESS ON PLANTS

Waterlogging stress occurs when oxygen is partially or completely absented from the growth medium, triggering several interconnected challenges that disrupt plant functioning. The primary concern is the impaired respiration, which consequently affects all metabolic processes in the plant that require energy, i.e., adenosine triphosphate (ATP) molecules (Aslam et al., 2023). The negative impact on the plant's metabolism due to low oxygen levels in the growth medium (soil) also leads to competition between the plant's roots and beneficial aerobic microflora. As a result, roots must compete with soil microflora for scarce oxygen, which weakens beneficial microbial nitrification and reduces nutrient uptake (Martínez-Arias et al., 2023). These circumstances pose significant challenges to all aspects of plant development, especially regarding the transition from the vegetative to the generative phase. Prolonged exposure of roots to anaerobic conditions caused by waterlogging prevents flowering, pollination, fertilization, and seed maturation (Insausti & Gorjón, 2013).

Roots are the first to encounter oxygen deprivation and are highly sensitive to it. Numerous studies show that root growth declines significantly when soil oxygen concentration drops below 20% (Tete et al., 2015; Fukao et al., 2019). As oxygen decreases, carbon dioxide (CO_2) concentrations rise, which further hinders root development. For instance, elevated CO_2 in the rhizosphere has been shown to suppress cell division in the root apical meristem (Ben-Noah and Friedman, 2018).

Greenway et al. (2006) have reported that increased soil CO_2 levels adversely affected the growth of the root apical meristem by restricting cell division. This finding agrees with He et al. (2019).

Above-ground symptoms of waterlogging resemble those caused by drought. Although it may seem counterintuitive, waterlogged plants often show signs of water stress. This happens because roots damaged by hypoxia cannot absorb water, prompting the plant to close its stomata to conserve internal moisture (Olorunwa et al., 2022). However, stomatal closure also restricts carbon dioxide uptake, reducing photosynthesis and leading to visible leaf chlorosis (Liu et al., 2022). This deficiency is visually evident through leaf chlorosis, which becomes more pronounced as the anaerobic conditions in the soil last longer.

If the closure of stomata is insufficient in effectively reducing transpiration, the plant may shed its lower leaves to reduce the surface area for transpiration, thereby limiting water loss. However, shedding leaves reduces the plant's ability to produce assimilates, which in turn lowers ATP levels and limits the synthesis of key stress-related metabolites (Chada et al., 2023).

The inability of plants to efficiently perform photosynthesis and respiration during anaerobic stress conditions results in a dysfunction in the mitochondrial electron transport chain and oxidative phosphorylation (Jethva et al., 2022). This, in turn, leads to an increased production of reactive oxygen species (ROS), resulting in oxidative stress. Oxidative stress is a common occurrence in all forms of stress, including waterlogging stress, and it poses a significant threat to plant organisms.

Overproduction of ROS causes severe damage to lipids, proteins and other biomolecules present in cells (Sachdev et al., 2021). Exposure to flooding stress can also lead to osmotic stress in plants, which disrupts all metabolic and physiological processes within plant cells (Li et al., 2025).

Due to the combined effects of oxygen deficiency, nutrient loss, oxidative damage, and metabolic disruption, most plants can only tolerate waterlogging for a limited time. Only those species with specific adaptive strategies can survive extended periods under hypoxic or anoxic conditions.

WATERLOGGING STRESS SIGNAL TRANSMISSION

Roots are the primary plant organs to encounter waterlogging stress, due to their direct exposure to the saturated soil environment. The precise mechanisms by which roots perceive anaerobic

stress and initiate signal transduction remain under active scientific investigation.

Some researchers propose that oxygen deficiency itself is the primary signal (Sasidharan et al., 2018), while others suggest that alterations in the physical or chemical properties of the soil under hypoxic conditions are responsible for triggering the stress response (Setter & Waters, 2003; Rupngam & Messiga, 2024).

Likewise, there is ongoing debate regarding the nature of the primary abiotic stress sensors that detect such signals within plant cells. One school of thought posits that plant cells contain specific oxygen-sensing molecules capable of detecting sharp declines in intracellular oxygen concentrations (Sewelam et al., 2016; León et al., 2021; Selinski et al., 2024). A notable example is Class-1 hemoglobin (Hb), a molecule with high oxygen affinity that allows it to bind oxygen even at extremely low intracellular concentrations (Cochrane et al., 2017).

Conversely, other researchers argue that no dedicated oxygen sensor exists. Instead, they propose that plant cells detect anaerobic stress through disturbances in cellular homeostasis resulting from oxygen deprivation (Schmidt et al., 2018; Kosová et al., 2018; Safavi-Rizi et al., 2020). These disturbances may manifest as changes in cytosolic pH, shifts from aerobic to anaerobic metabolism, fluctuations in the reduced-to-oxidized glutathione ratio, calcium ion (Ca^{2+}) fluxes, or broader disruptions in the cellular redox balance (Rathore et al., 2015).

When plant cells detect anaerobic stress - either directly or through disrupted homeostasis - they activate signaling pathways that produce second messengers, including ethylene, reactive oxygen species (ROS), calcium ions (Ca^{2+}), and nitric oxide (NO). These substances function as essential regulatory components of signaling pathways that transmit signals to transcription factors by activating a series of downstream cascades (Farnese et al., 2016). Ethylene or ROS trigger stress signaling cascades, primarily through MAPKs or calcium-dependent protein kinases. Ultimately, they stimulate the expression of specific defense genes, leading to a comprehensive defensive response (Jagodzik et al., 2018).

Under anaerobic conditions, ethylene serves as a key regulator of plant adaptation by activating ethylene response factors (ERFs). These transcription factors upregulate genes involved in several key adaptive responses, including:

1. the development of aerenchyma in roots,
2. the growth and development of adventitious roots,
3. stem elongation,
4. various morphological or physiological alterations that ultimately improve the plant's ability to adapt to anaerobic stress.

Figure 1 illustrates the general pathway by which plants detect flooding stress and initiate adaptive responses.

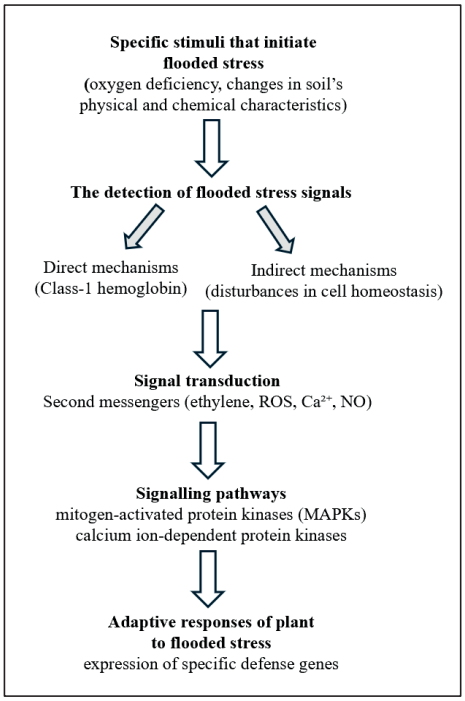

Figure 1. A simple diagram illustrating the pathway from recognizing flooded stress to the plant's response

PLANT MORPHO-ANATOMICAL AND PHYSIOLOGICAL ADAPTIONS TO WATERLOGGING STRESS

The ability of plants to adapt to anaerobic stress, caused by soil waterlogging, is quite limited because of the partial or complete absence of oxygen in the growth medium.

Nevertheless, certain plant species have evolved specific strategies that enable them to tolerate hypoxic or anoxic environments for limited periods. These strategies fall into two major categories: (1) morphological and anatomical adaptations, and (2) physiological modifications (Jia et al., 2021). These categories often operate in parallel; morpho-anatomical adaptations are typically accompanied by physiological changes, together forming an integrated response that enhances plant resilience under flooding stress.

Plant morpho-anatomical adaptations to waterlogging stress

Morphological and anatomical changes resulting from waterlogging primarily affect the root system, which is the first to detect anaerobic conditions in the soil (Lin et al., 2024). Common structural responses include: (1) the growth and development of adventitious roots, (2) the development of hypertrophic lenticels, (3) the formation of aerenchyma within the primary root cortex, and (4) the elongation of stem internodes (Leeggangers et al., 2023).

Growth and development of adventitious roots under soil waterlogging

In response to waterlogging, the plant activates a mechanism for the growth and development of adventitious roots, mainly occurring in the upper part of the root or in the lower part of the stem (Steffens & Rasmussen, 2016). These postembryonic roots are observed in several plant species, including rice, tomato and bittersweet (Sasidharan et al., 2018). When triggered by soil waterlogging, the formation of adventitious roots helps the plant escape hypoxic conditions in the root zone by improving oxygen uptake and increasing its chances of survival.

A plant's ability to promote the formation of adventitious roots is mainly based on the function of the hormone ethylene (Bai et al., 2020). Ethylene plays a significant role as a stress signal in plants affected by flooding, initiating various morphological and metabolic changes that facilitate their adaptation and survival in these challenging conditions. When plants face anaerobic stress, ethylene accumulates in plants underground parts at high levels because its diffusion and consequently its exit from the plant's roots are considerably hindered in these circumstances. During flooding, plant roots synthesize 1-aminocyclopropane-1-carboxylic acid (ACC), the direct precursor of ethylene. ACC is then transported to the stem—an aerobic region—where the enzyme ACC oxidase (ACO) converts it into ethylene, increasing ethylene concentrations in the stem. This rise in ethylene triggers adaptive responses in the submerged stem, initiating the plant's reaction to flooding stress (Khan et al., 2024). This response involves the activation of ethylene-responsive transcription factors (ERFs), which play a key role in regulating plant adaptation to flooding stress. Under anaerobic conditions, ethylene binds to membrane receptors, triggering a conformational change that releases ERFs into the cytosol. These transcription factors then move to the nucleus, where they activate stress-responsive genes essential for the plant's survival under hypoxic conditions (Wang et al., 2025) (Figure 2).

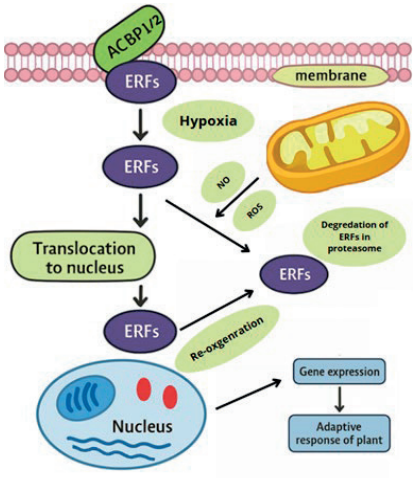

Figure 2. Diagram showing the ethylene-induced signaling pathway in plants facing waterlogging stress

In the context of adventitious root formation, ERF-activated genes are believed to encode enzymes that degrade cells adjacent to meristematic tissue in the root pericycle. This cell breakdown creates the necessary space for root meristem cells to divide and grow, ultimately leading to the emergence of adventitious roots (Roussos, 2023). While ethylene often promotes cell degradation or

death, in this case, the process is beneficial, enabling structural adaptation under stress.
Ethylene's role in enhancing plant adaptation to waterlogging becomes evident under low-oxygen conditions.
In well-aerated environments, ethylene-responsive transcription factors (ERFs) remain inactive. Under these normal conditions, cysteine oxidases - together with reactive oxygen species (ROS) and nitric oxide (NO) - oxidize ERFs, marking them for degradation via the proteasome pathway. ERF activation is therefore tightly regulated and occurs only under stress, with ethylene acting as the primary hormonal trigger (Giuntoli & Perata, 2018).

Formation of hypertrophic lenticels at the stem base

A significant adaptive mechanism that plants utilize to cope with waterlogging stress is the formation of hypertrophic lenticels at the stem base, situated slightly above the water surface (Shimamura et al., 2010). These lenticels function to improve oxygen intake while simultaneously allowing the release of ethanol, methane, and other toxic byproducts that arise from anaerobic metabolic activity. Many scientists note that the formation of hypertrophic lenticels occurs alongside the development of aerenchyma in roots (Thomas et al., 2005; Sou et al., 2021). This is quite reasonable, as it allows the plant to secure a constant influx of oxygen from the atmosphere to its roots.
Although the formation of large cracks (i.e., hypertrophic lenticels) at the stem base is not fully understood, it is generally accepted that the hypertrophy of secondary aerenchyma is responsible for their development. This aerenchyma is formed through successive divisions of the phellogen and is characterized by its white, porous (spongy) tissue. Being of secondary origin, it differs in both morphology and anatomy from the primary cortical aerenchyma (Jackson et al., 2009).

Aerenchyma formation in the root

The typical response of a plant to waterlogging is the development of aerenchyma in its roots. This formation, along with the connection to hypertrophied lenticels, creates a pathway for the roots to interact with the atmosphere. As a result, the plant can supply oxygen from the atmosphere to all root cells, despite being in anaerobic conditions (Evans, 2004). It is important to highlight that a certain amount of oxygen transported to the root aerenchyma is released into the rhizosphere, creating a distinct small zone of aerobic rhizosphere near the roots. This environment promotes the functioning of beneficial aerobic microflora, which greatly improves the roots' survival and, consequently, the plant's ability to withstand flooding (Björn et al., 2022).
Ethylene, a plant hormone, serves as the main mediator in the development of aerenchyma in the primary root cortex. The process through which ethylene promotes aerenchyma formation closely resembles its role in inducing the development of new adventitious roots when faced with anaerobic conditions. Essentially, a higher concentration of ethylene in the root, resulting from the roots' exposure to waterlogging stress, acts as a signal that activates a signaling pathway leading to the disintegration and programmed cell death of certain cells in the primary root cortex (Mergemann & Sauter, 2000). This leads to the formation of a specialized empty space in the primary root cortex i.e., aerenchyma, which serves to store and subsequently distribute oxygen throughout the root.
Recent studies have demonstrated that ethylene is not the only mediator in aerenchyma formation; nitric oxide (NO) and some other reactive oxygen species also fulfill this role (Wany & Gupta, 2018; Basu et al., 2020). The formation of aerenchyma in plant roots experiencing anaerobic stress is further influenced by the activity of certain enzymes that are responsible for the production and deposition of suberin in the cell walls of the root exodermis (Abiko et al., 2012).
Many agricultural species, including corn, tomato, soybean, wheat, and barley, have the ability to develop root aerenchyma under anaerobic stress conditions. Rice also has the capacity to form root cortical aerenchyma, but this process occurs independently of external environmental factors (Yamauchi et al., 2013).

Stem elongation

To cope with soil waterlogging, the plant initiates the development of adventitious roots, hypertrophied lenticels, and root aerenchyma,

while also facilitating the elongation of submerged stem internodes (Jing et al., 2024). The mediator of stem elongation is also ethylene; however, in this instance, its activity will not result in programmed cell death. Instead, it will promote the synthesis of gibberellins, resulting in the stem elongation (Sasidharan & Voesenek, 2015). Thus, the signaling pathways triggered by ethylene can vary significantly depending on the plant species, its demands, and the surrounding environments.

The ethylene-induced signaling pathway that results in the elongation of stem internodes, especially those underwater, consists of the following phases:

(1) ethylene, which accumulates highly in cells under anaerobic stress, binds to a membrane protein receptor associated with an ethylene-responsive factor that contains an APETALA2 (AP2) DNA-binding domain;

(2) the binding of ethylene to the receptor results in a conformational change in the receptor, leading to the release of ethylene-responsive factor, which subsequently initiates the expression of the SK1/SK2 genes in the nucleus;

(3) the expression of the SK1/SK2 gene leads to the production of an enzyme essential for gibberellin synthesis;

(4) the resulting gibberellins subsequently activate signaling pathways that ultimately lead to the elongation of cells, and consequently, the internodes of the submerged stem (Patil et al., 2019) (Figure 3).

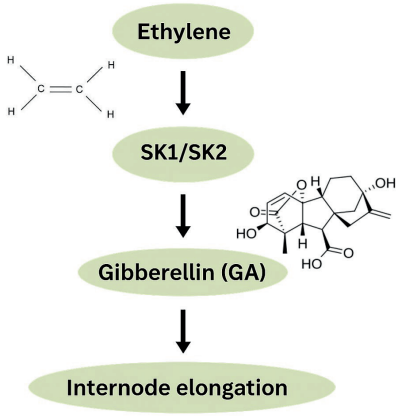

Figure 3. Diagram showing the ethylene-induced signaling pathway that results in the elongation of stem internodes

Plant physiological adaptations to waterlogging stress

In addition to mechanisms based on morpho-anatomical changes, plants strive to adapt to waterlogging stress by altering their metabolic processes. Key adaptations include shifts in respiration, adjustments in photosynthesis, and the synthesis of specific metabolites that enhance the plant's defense against flooding stress (Kato-Noguchi et al., 2003).

Plant respiration under oxygen deficiency

In the absence of oxygen, whether partially or fully, the capacity of plant cells to produce ATP in mitochondria through the Krebs cycle (aerobic metabolism) is limited, necessitating a switch to anaerobic metabolism, where ATP is generated via anaerobic respiration (Meng et al., 2020). From the standpoint of plant life, the greatest challenge of anaerobic respiration lies in its production of an extremely low amount of ATP. During anaerobic respiration, plant cells generate just two ATP molecules for every glucose molecule broken down, indicating that this process is much less efficient than aerobic respiration (2 ATP in glycolysis compared with 36 ATP in the Krebs cycle from one glucose molecule). For these reasons, the plant aims to enhance anaerobic metabolism by intensively producing the enzymes pyruvate decarboxylase and alcohol dehydrogenase within its cells.

The increased activity of these enzymes accelerates anaerobic metabolism, specifically the breakdown of pyruvate generated from glycolysis, leading to a faster production of ATP (Tougou et al., 2012).

Under oxygen deficiency, plant cells switch to anaerobic metabolism via two main pathways. The first pathway is characterized by the activity of the lactate dehydrogenase enzyme (LDH) which catalyzes the conversion of pyruvate into lactate, accompanied by the transformation of NADH into NAD^+. This pathway is referred to as lactic fermentation, enabling plant cells to transform one glucose molecule into two lactate molecules and produce two ATP molecules. Nonetheless, a negative aspect of lactic fermentation is the acidification of the cytoplasm, which adversely influences the metabolic reactions occurring in the cell (Peetermans et al., 2021). The second pathway is marked by the action of the pyruvate

decarboxylase enzyme (PDC), which transforms pyruvate into acetaldehyde. This acetaldehyde is then converted into ethanol by the alcohol dehydrogenase enzyme (ADH). This anaerobic fermentation process, known as alcoholic fermentation, also results in the generation of two ATP molecules.
A visual representation of anaerobic metabolism in plant cells is shown in Figure 4.

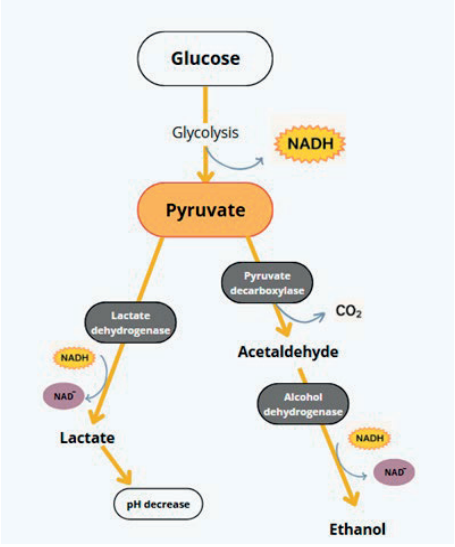

Figure 4. Diagram showing the process of anaerobic respiration in plant cell

Although ATP produced via anaerobic metabolism can offer temporary energy essential for a plant's existence, it is crucial to recognize that this process also generates toxic byproducts like lactate (lactic acid), ethanol, and aldehydes, which can severely disrupt cellular metabolism (Jain et al., 2020). Through anaerobic respiration, the plant cell can temporarily survive without oxygen; however, it cannot serve as a permanent alternative to aerobic metabolism. This means that a plant cell cannot survive for an extended time without oxygen.

Dynamics of photosynthesis under oxygen deficiency

In waterlogging stress conditions, plants cannot take up water through their root systems. Therefore, to maintain their existing water reserves, they must initiate mechanisms that result in stomatal closure. By closing their stomata, plants reduce transpiration but also limit CO_2 intake, which is essential for photosynthesis (Else et al., 2009). Waterlogging stress also negatively affects photosynthesis by limiting the distribution of nutrients, particularly nitrogen, throughout the plant (Zayed et al., 2023). This limitation obstructs chlorophyll synthesis, consequently threatening the plant's ability to absorb photosynthetically active light required for photosynthesis. Waterlogging stress adversely impacts the function of enzymes essential for photosynthesis and disrupts leaf development. This clearly demonstrates that performing photosynthesis under waterlogging stress is highly difficult (Zheng et al., 2009; Muhammad et al., 2021).
To overcome or at least reduce the negative effects of waterlogging stress on photosynthesis, plant cells in the early stages of flooding stress synthesize enzymes essential for converting starch into sucrose, which is then transported to other parts of the plant, particularly to the roots. By relocating assimilates to the roots, the plant aims to enhance root growth, helping it to escape the anaerobic zone of the growth medium and regain its ability to absorb the water and nutrients necessary for photosynthesis (Gangana Gowdra et al., 2025). Nevertheless, prolonged exposure to waterlogging stress can greatly diminish a plant's capacity to generate and transport assimilates to its roots, thereby restricting root growth. Under these conditions, the plant's chances of survival are considerably decreased.

Anaerobic stress-induced metabolites

Multiple studies have shown that plant cells subjected to waterlogging stress tend to either activate or produce significant quantities of specific metabolites, including non-symbiotic hemoglobin (Class-1 Hb) and nitric oxide (NO) (Igamberdiev et al., 2005; Zhao et al., 2008).
A key characteristic of Class-1 Hb is its strong affinity for oxygen, enabling it to effectively bind oxygen in conditions where its concentration in the cell is very low (Singh & Bhatla, 2019). The role of Class-1 Hb in plant cells subjected to anaerobic stress is highly significant: (1) it acts as a signaling molecule that transmits stress signals to target points, i.e., transcription factors; (2) it binds oxygen

necessary for cellular aerobic respiration, thus slowing down the transition of plant cells from aerobic to anaerobic metabolism; and (3) it helps maintain glycolysis in cells facing oxygen deficiency (Riquelme & Hinrichsen, 2015). The research by Hebelstrup et al. (2007) indicates that the synthesis of Class-1 hemoglobin happens whenever the respiratory chain is inhibited, regardless of the oxygen concentration within the cell. This implies that the signal for increased Class-1 Hb production is not solely due to oxygen deficiency in plant cells but also encompasses any situation that results in a significant decrease in ATP synthesis.

Nitric oxide (NO) serves as a vital signaling molecule that regulates plant growth and development under stress conditions such as flooding. It plays a crucial role in enhancing plant resistance to flooding stress through several mechanisms: (1) it interacts with reactive oxygen species (ROS) to control their levels, thereby reducing the harmful effects of oxidative stress on plants; (2) it serves as the mediator in the development of aerenchyma in the primary root cortex; (3) it enhances plant immunity and stress tolerance through the post-translational modification of proteins; (4) it interacts with various plant hormones, playing a significant role in the regulation of plant growth and development under stress conditions (Khan et al., 2023).

It is important to highlight that these two metabolites, Class-1 Hb and NO, work together to alleviate the negative effects of anaerobic stress. In this regard, these metabolites assist in regenerating the enzymatic cofactor NAD^+ from NADH during hypoxia, which is crucial for maintaining glycolysis in plant cells under anaerobic conditions. This synergistic relationship between Class-1 Hb and NO is recognized in scientific literature as the Hb/NO cycle (Dordas et al., 2003) (Figure 5).

Hb/NO cycle initiates with activity of nitrate reductase (NR), which catalyzes the reduction of nitrate (NO_3^-) into nitrite (NO_2^-). Subsequently, NO_2^- is oxidized to nitric oxide (NO) through the activity of nitrite-NO reductase (NiNOR). NO is than reduced to NO3- by oxyhemoglobin ($Hb(Fe^{2+})O_2$), which transforms into methemoglobin ($HbFe^{3+}$), consuming NAD(P)H in the process. In essence, hemoglobin in plant cells helps reduce nitric oxide (NO) levels generated from nitrate during hypoxia. Through the Hb/NO cycle, the plant oxidizes approximately 2.5 moles of NADH for every mole of nitrate (NO_3^-) recycled in the reaction. This cycle is crucial for sustaining redox and energy equilibrium during hypoxia, which in turn reduces the production of ethanol and lactic acid (van Veen et al., 2024).

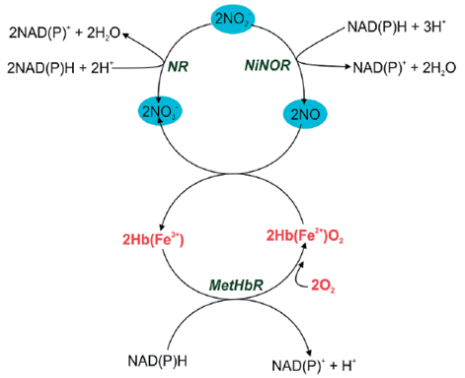

Figure 5. A simple diagram outlining the Hb/NO cycle

In addition to Class-1 Hb and NO, plant cells produce several additional metabolites that serve to strengthen the plant's ability to withstand the negative impacts of this stress. For instance, in response to osmotic stress caused by an excess of water in the growth medium, the plant cells intensively synthesize small organic metabolites (collectively called compatible solutes or osmolytes). Due to their small molecular weight and non-toxic nature, even at elevated concentrations, osmolytes are widely used by plants to alleviate osmotic stress. Among the most prevalent osmolytes in plant cells are amino acids like proline, sugars including mannitol, trehalose, and sorbitol, along with polyamines. This accumulation is beneficial as it enhances tolerance to osmotic stress without disrupting cellular processes. Plant species exhibit varying degrees of tolerance to osmotic stress, which depends on the type and level of osmolyte accumulation during osmotic stress caused by flooding or other stress factors (Chen et al., 2022).

To protect themselves from oxidative damage caused by flooding, plant cells strive to maintain a balance between the production of reactive oxygen species (ROS) and their neutralization.

An imbalance between ROS production and elimination can degrade essential structural and functional biomolecules, ultimately threatening the plant's overall integrity. To counteract these effects, plants deploy a broad array of enzymatic and non-enzymatic antioxidants that play a vital role in neutralizing excess ROS. Among the most prevalent non-enzymatic antioxidants in plant cells are ascorbic acid, tocopherol, glutathione, isoprenoids, carotenoids, flavonoids, ubiquinone and plastoquinone (Rudenko et al., 2023). These antioxidants typically serve as a secondary defense mechanism for plants, protecting them from the harmful effects of reactive oxygen species (ROS). While the mechanisms of action differ among these compounds, they generally function by providing an electron to free radicals, thereby neutralizing their harmful effects (Zandi & Schnug, 2022).

CONCLUSIONS

To address the escalating challenges posed by climate change, it is essential to deepen our understanding of how plants respond to waterlogging stress. This review highlights the complex physiological, morphological, and biochemical responses that plants employ to survive hypoxic conditions caused by soil saturation. Oxygen deprivation disrupts respiration, nutrient uptake, and photosynthesis, severely limiting plant productivity. However, certain species have evolved adaptive traits - such as adventitious root formation, aerenchyma development, and metabolic reprogramming - that enhance their survival under such conditions.

Recognizing these adaptive mechanisms holds significant value for improving agricultural resilience. As climate models predict more frequent and intense rainfall events, crop species will increasingly face alternating periods of drought and flooding. Integrating waterlogging-tolerant traits into breeding programs, particularly for staple crops, can help stabilize yields in flood-prone areas. Moreover, understanding root-zone adaptations can guide the design of land reclamation strategies on poorly drained or flood-affected soils.

In addition, these insights support the development of sustainable land and water management practices, which encompass improving drainage systems, altering planting schedules, and selecting or engineering robust crop varieties.

Ultimately, translating this knowledge into applied practices can help secure food production and maintain soil health in the face of accelerating climate variability.

Abstract

The consumption of vegetables and fruits is a major pathway for human exposure to heavy metals, especially when these elements accumulate in edible plant parts. This study assessed the accumulation of nickel (Ni), chromium (Cr), zinc (Zn), iron (Fe), and manganese (Mn) in soils and food crops cultivated near a former metallurgical plant in Elbasan, Albania. The analyzed crops included onion, salad, potato, pepper, and strawberry. Bioconcentration factors (BCFs) were calculated to evaluate the capacity of each crop to uptake heavy metals from soil. Available metal concentrations in soil were determined using the Mehlich-1 extraction method and quantified by atomic absorption spectrometry. The results indicated that Mn, Zn, Fe, and Cr concentrations in potatoes, and Fe levels in pepper, were within WHO safety limits. However, Fe levels in onion, salad, and strawberry, Ni in all edible crops, and Cr in onion, salad, strawberry, and pepper exceeded recommended thresholds. The calculated BCFs confirmed notable metal accumulation, particularly for Ni and Cr. These findings highlight the need for regular monitoring of heavy metal levels in both soil and crops to safeguard food safety and public health.

Key words*: accumulation; available metals; bioaccumulation factor plants (BFP*); *food crops; heavy metals.*

INTRODUCTION

Heavy metals are naturally occurring elements with a density greater than 5 g/cm³ and are integral components of the Earth's crust. Their concentration in soil varies depending on the geochemical and mineralogical characteristics of the soil, as well as the extent of anthropogenic pollution. Soil contamination with heavy metals can result from numerous human activities, including mining, metallurgical and smelting processes, the application of organic and inorganic fertilizers, the use of pesticides and insecticides containing metal compounds, emissions from transportation, discharges from chemical plants, runoff, and waste from landfills (Hu et al., 2013; Osmani et al., 2015; Gjoka et al., 2022).

In recent years, the widespread use of heavy metals in industrial applications, and in the production of agrochemicals, has heightened the risk of environmental contamination and their subsequent entry into the food chain (Bradl, 2002). Fruits and vegetables are essential components of the human diet, valued for their rich content of micronutrients, carbohydrates, vitamins, and fiber, all of which contribute positively to human health (Hu et al., 2013). However, elevated concentrations of heavy metals in edible plant parts pose significant health risks. Numerous studies have demonstrated that heavy metals can be absorbed by plant roots and transported to aerial parts, leading to accumulation in edible tissues, even when soil concentrations are relatively low (Jolly et al., 2013; Sharma et al., 2018; Zwolak et al., 2019).

Vegetables grown in agricultural soils located near industrial sites or in regions with naturally elevated metal content are particularly susceptible to contamination.

The metallurgical complex in Elbasan, central Albania, has long been identified as a major source of heavy metal pollution. Spanning an area of 155 hectares, this complex historically processed approximately 800,000 tons of ultramafic minerals (Fe-Ni), releasing an estimated 44.8 tons of toxic dust. Following

significant political and technological changes in the 1990s, many of the complex factories were shut down, and the surrounding area was repurposed for residential and agricultural use. Today, a variety of crops - including vegetables, fruits, and cereals - are cultivated on this land.

As a result of the long-term processing and smelting of Fe-Ni-rich minerals, the soils surrounding the former industrial site are heavily contaminated with several heavy metals, including Fe, Mn, Ni, Zn, and Cr (Shallari et al., 1998; Sallaku et al., 1999; Osmani et al., 2015; Osmani et al., 2018). Despite this known contamination, limited research has been conducted on the accumulation of heavy metals in food crops grown in this area, or on the potential for selecting crop species or cultivars with low metal uptake.

Therefore, the present study aims to fill this gap by (1) investigating the concentration and bioavailability of selected heavy metals in the soils of the study area, and (2) assessing the accumulation of these metals in the edible parts of selected vegetables and fruit cultivated in this industrial region of Elbasan, Albania.

MATERIALS AND METHODS

Study area

This study was conducted in 2024 on contaminated farmland located in the Elbasan region of central Albania. The site, situated near the former metallurgical plant (41°09’18.12"N, 20°04’34.17"E), lies to the west of Elbasan city and is characterized by flat topography (Figure 1). The area where the samples were collected is located about 500 meters from the former Ferro-nickel factory, which has not been operational for years. The local climate is typically Mediterranean, with an average annual temperature ranging between 15 and 16°C.

Sampling of Soil and Vegetables

Samples were collected from farmland adjacent to the metallurgical complex during the spring and summer of 2024. Three subsamples were taken for each of the four vegetable species and one fruit species cultivated in the area. Both soil and edible plant parts were collected.

The plant types and species included in the study are presented in Table 1.

Table 1. Vegetables type and species used in study

Vegetable Type	Vegetable Species
Bulb vegetable	*Allium cepa* (Onion)
Leafy vegetable	*Lactuca sativa* (Salad)
Tuber	*Solanum tuberosum* (Potato)
Fruits	*Fragaria vesca* (Strawberry)
Solanaceous	*Capsicum annuum* (Pepper)

Soil samples were taken from the rhizosphere (root zone) of each plant type, with three repetitions per crop. All samples were placed in clean polyethylene bags, clearly labeled by type, and transported to the Laboratory of the Department of Environment and Natural Resources at the Agricultural University of Tirana (AUT) for analysis.

Soil and Plant sample preparation and analysis

Plant samples were washed thoroughly with distilled water to remove the adhering dust. Soil samples were air-dried at room temperature to a constant weight and then finely ground using a mortar and pestle. The edible plant parts were chopped into small pieces using a pre-cleaned stainless-steel knife and oven-dried at 75°C for three days. Dried samples were then pulverized into a fine powder and stored in clean polyethylene (PE) bags for analysis.

Soil and plant analyses were performed at the Agricultural University of Tirana (AUT) and the University of Pristina in Kosovo. Soil pH was measured using a 0.01 M $CaCl_2$ solution at a 1:2.5 soil-to-solution ratio. Cation exchange capacity (CEC) was determined using the ammonium acetate method.

The Mehlich-1 extractant was used to determine the available concentrations of nickel (Ni) in soil, which were then analyzed using atomic absorption spectrometry (AAS). For total concentrations of macronutrients (P, K, Ca, Mg) and micronutrients (Fe, Mn, Zn, Ni, Cr, Co), 0.5 g of soil was digested in aqua regia (a 1:3 mixture of 65% HNO_3 and 37% HCl) at 200°C for 40 minutes, followed by analysis via AAS. To determine heavy metal concentrations in plant tissues, 0.2 g of dried plant material (edible parts and roots) was digested in a 4:1 mixture of 65% HNO_3 and 30% H_2O_2 using microwave digestion at 200°C for 25 minutes.

Digest solutions were analyzed using Atomic Absorption Spectrophotometry (AAS) with the Analytik Jena AAS 400 instrument. The elements analyzed included iron (Fe), magnesium (Mg), manganese (Mn), nickel (Ni), chromium (Cr), zinc (Zn), and cobalt (Co). The limit of detection (LOD) for each element was defined as three times the standard deviation of the blank signal. We used the slope of the curve (absorbance per mg/L) to convert absorbance units in mg/L. The LOD values (in mg/L) for Fe, Mg, Mn, Zn, Ni, Cr, and Co were 0.009, 0.03, 0.0018, 0.012, 0.015, 0.012, and 0.02, respectively. The calibration ranges used in this study (in mg/L) were as follows: Fe: 0-10, Mg: 0-5, Mn: 0-5, Zn: 0-5, Ni: 0-5, Cr: 0-5, Co: 0-5. Dilution was applied to samples containing element concentrations above the upper limit of the calibration range. Quality control was ensured through the use of blanks and certified reference materials (CRMs), with recovery rates maintained within ±10% of the target values.

Bioconcentration factor (BCF)

The Bioconcentration Factor (BCF) quantifies a plant's ability to accumulate metals from soil. It is calculated as the ratio of the metal concentration in the plant's edible part to its total concentration in the corresponding rhizospheric soil:

$$BCF = C_{plant} / C_{soil}$$

A BCF value below 1 indicates limited metal transfer from soil to plant, while a BCF greater than 1 suggests substantial uptake (Sharma et al., 2018; Ba et al., 2024).

Statistical analysis

Differences in the BCFs of heavy metals (Mn, Zn, Ni, and Cr) among the edible parts of the five crop species were evaluated using one-way ANOVA. A significance level of $p < 0.05$ was used to determine statistical relevance.

RESULTS AND DISCUSSIONS

Soil characteristics

Phosphorus (P) levels in the study soils were within the typical range, between 0.5 and 0.6 g/kg of dry soil. The total potassium (K) content in the upper 0.2 meters of agricultural soil generally ranges from 10 to 20 g/kg (Mandloi et al., 2022); however, in this study, values ranged from 6 to 9.8 g/kg, which is slightly below the expected range.

Calcium (Ca) and Magnesium (Mg), though considered secondary nutrients, are essential for plant growth. In the study soils, Ca concentrations were consistently higher than Mg concentrations. This pattern suggests that the soils do not have a natural ultramafic origin, as ultramafic soils typically show higher Mg levels relative to Ca. Instead, the elevated presence of elements commonly associated with ultramafic rocks - such as Fe, Mg, Ni, Cr, and Co - can likely be attributed to anthropogenic contamination from the long-term processing of ultramafic minerals at the nearby metallurgical complex (Table 2A).

Iron (Fe) concentrations in the soil ranged from 18 to 26 g/kg, aligning with typical background levels reported for agricultural soils (Bodek et al., 1988).

The soils in the study area were found to be contaminated with several heavy metals, including manganese (Mn), zinc (Zn), nickel (Ni), chromium (Cr), and cobalt (Co), as detailed in Tables 2A and 2B. Nickel concentrations in rhizospheric soils ranged from 400 to 610 mg/kg, exceeding both the background level for Albanian agricultural soils (287.15 mg/kg) (Gjoka et al., 2022) and the intervention threshold of 210 mg/kg set by Denneman and Robberse (1990) and the Netherlands Ministry of Housing (1994).

Cobalt concentrations varied between 85 and 111 mg/kg across different sampling sites, also exceeding the background value of 83.10 mg/kg. Chromium levels ranged from 310 to 380 mg/kg, far above the target value of 100 mg/kg and the background level of 131.63 mg/kg reported for Albanian agricultural soils.

These elevated concentrations of Ni, Cr, and Co are consistent with long-term emissions from metallurgical operations that processed ultramafic ores rich in these elements. Zinc concentrations ranged from 75 to 132 mg/kg. While these values are above the background concentration for Zn in Albanian soils (81.80 mg/kg) in the cases of soils under potato, strawberry, and pepper crops, they remain below the intervention threshold of 150-300 mg/kg established by the Council of the European Communities (1986).

As shown in Table 2, soils associated with all sampled crops exhibited elevated concentrations of Ni, Cr, and Co compared to both background levels and intervention thresholds.

Nickel and cobalt exceeded the permissible limits in all plots, with the highest Ni level recorded in strawberry soil (610 mg/kg), nearly three times the intervention threshold. Similarly, chromium levels in onion and strawberry soil surpassed the 360 mg/kg intervention value.

Zinc levels were highest in soils associated with strawberry and pepper but remained below the intervention limit of 300 mg/kg. Manganese concentrations were well below critical thresholds in all plots, though consistently elevated.

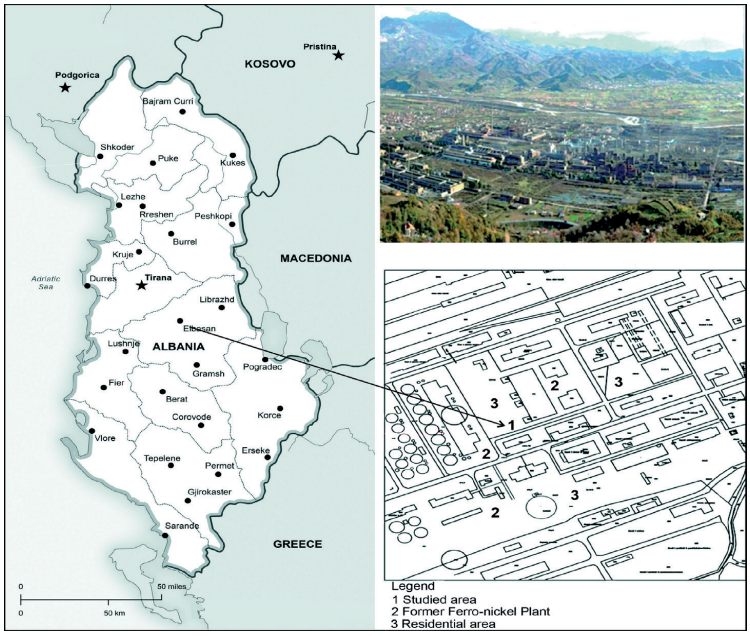

Figure 1. Map of Albania with the location of former Ferro-nickel plant and the study area.

Table 2. Total macronutrients and micronutrients (mean ± SD) in soils of different sampling sites

A) Macronutrients (g/kg dry soil)

Soil of Vegetable	P	K	Ca	Mg	Fe
Onion	0.5 ± 0.04	8.1 ± 1.0	31 ± 2	14 ± 2	26 ± 6
Salad	0.7 ± 0.01	7.2 ± 0.5	29 ± 5	13 ± 3	18 ± 1
Potato	0.6 ± 0.01	9.8 ± 0.5	30 ± 4	14 ± 5	19 ± 5
Strawberry	0.6 ± 0.02	6.0 ± 1.0	41 ± 8	15 ± 4	19 ± 2
Pepper	0.6 ± 0.02	8.1 ± 0.5	30 ± 5	14 ± 4	18 ± 1

B) Micronutrients (mg/kg dry soil)

Soil of Vegetable	Mn	Zn	Ni	Cr	Co
Onion	576 ± 40	75 ± 5	410 ± 7	380 ± 16	75 ± 9
Salad	538 ± 60	90 ± 14	440 ± 13	310 ± 52	74 ± 4
Potato	557 ± 15	122 ± 12	405 ± 10	315 ± 68	74 ± 8
Strawberry	547 ± 30	132 ± 16	610 ± 11	370 ± 62	111 ± 6
Pepper	565 ± 23	123 ± 8	400 ± 20	360 ± 19	85 ± 5

*Intervention Threshold Values (mg/kg): Mn - 1500, Zn - 300, Ni - 210, Cr - 360, Co – 50

Macronutrient data showed moderate variability across sites, with phosphorus ranging from 0.5 to 0.7 g/kg and potassium from 6.0 to 9.8 g/kg. Notably, the strawberry plot had the highest calcium concentration (41 g/kg), suggesting potential input differences or localized soil characteristics.

A soil pH between 6.0 and 7.2 is considered optimal for the growth of most garden crops, although many vegetable and fruit species can tolerate pH values between 7.0 and 8.0 (extension.usu.edu). The pH values in the rhizosphere of crops collected from the contaminated area in Elbasan (Table 3) fall within this acceptable range, suggesting that pH is not a limiting factor for plant growth in these soils.

Cation exchange capacity (CEC) in the studied soils ranged from 15 to 26 cmol/kg, with an average of 20.6 cmol/kg. These values reflect a moderate-to-high nutrient-holding capacity, which is typical of fertile agricultural soils.

While total metal concentrations are useful for identifying long-term contamination and possible sources, they do not accurately represent the portion of metals available for plant uptake. To evaluate bioavailability, the Mehlich-1 extraction method was used to assess the potentially available fractions of Fe, Mn, Zn, Ni, Cr, and Co.

The results indicate that available Fe concentrations ranged from 16 to 58 mg/kg, Mn from 4 to 15 mg/kg, and Ni from 2.4 to 4.5 mg/kg. Notably, Co and Cr showed very low extractable concentrations across all sampled soils, a finding consistent with their limited uptake by plants in this study.

Table 3. Soil pH, CEC, and available metal concentrations (mean values)

Soil of vegetable	pH	CEC (cmol/kg)	Fe (mg/kg)	Mn (mg/kg)	Zn (mg/kg)	Ni (mg/kg)	Cr (mg/kg)	Co (mg/kg)
Onion	7.5	15	38	4	3.8	3.6	0.1	0.2
Salad	8.0	17	57	5	3.0	4.0	0.1	0.2
Potato	7.7	14	16	3	3.7	3.6	0.1	0.2
Strawberry	7.5	16	58	12	2.9	4.5	0.1	0.2
Pepper	7.5	26	28	15	3.9	2.4	0.1	0.2

Nickel concentrations in edible plants and roots of food crops

The mean concentrations of iron (Fe), manganese (Mn), zinc (Zn), nickel (Ni), and chromium (Cr) in the edible parts of the sampled food crops ranged as follows: Fe (99-765 mg/kg), Mn (6.2-90 mg/kg), Zn (3.6-12 mg/kg), Ni (10-26 mg/kg), Cr (0.5-19 mg/kg) (Table 4).

Among these, the Mn, Zn, Fe, and Cr concentrations in potatoes, and Fe in peppers, remained below the permissible limits set by the World Health Organization (WHO). However, Fe levels in onion, salad, and strawberry, Ni concentrations in all edible samples, and Cr concentrations in onion, salad, strawberry, and pepper exceeded the WHO safety thresholds.

Table 4. Heavy Metal concentrations in edible parts of crops (mean ± SD)

Vegetable	Fe (mg/kg)	Mn (mg/kg)	Zn (mg/kg)	Ni (mg/kg)	Cr (mg/kg)
Onion	200 ± 4	6.4 ± 2	8 ± 2	12 ± 2	2.0 ± 0.1
Salad	646 ± 41	25 ± 3	3.6 ± 0.2	16 ± 1	5.0 ± 0.7
Potato	59.5 ± 9	6.2 ± 1	10.0 ± 0.7	10 ± 0.5	0.5 ± 0.3
Strawberry	765 ± 59	90 ± 2	7 ± 0.1	26 ± 3	19.0 ± 3.0
Pepper	99 ± 3	21 ± 4	12 ± 2	15 ± 1	4.0 ± 0.6
WHO Limits	270	300	300	10	1.3

These findings indicate a significant health concern, particularly regarding Ni and Cr accumulation. The order of Ni accumulation in edible parts of the crops was as follows: Strawberry (fruit) > Salad (leafy vegetable) > Pepper (solanaceous) > Onion (bulb) > Potato (tuber). The metal concentrations in the roots of these food crops were significantly higher than in the edible parts, ranging as follows: Fe (1899-2658 mg/kg), Mn (25-97 mg/kg), Zn (6-28 mg/kg), Ni (16-56 mg/kg), Cr (4.2-24 mg/kg) (Table 5).

Table 5. Heavy Metal concentrations in roots of crops from contaminated soil (mean ± SD)

Vegetable	Fe (mg/kg)	Mn (mg/kg)	Zn (mg/kg)	Ni (mg/kg)	Cr (mg/kg)
Onion	2658 ± 4	97 ± 2	26 ± 0.06	56 ± 0.4	21.0 ± 0.1
Salad	2494 ± 41	25 ± 3	6 ± 0.2	16 ± 0.8	23.0 ± 0.7
Potato	2239	87 ± 0.7	20.0 ± 0.7	42 ± 0.5	24.0 ± 0.3
Strawberry	2487 ± 59	70 ± 0.7	11 ± 0.1	27 ± 2.6	12.0 ± 3.0
Pepper	1899 ± 3	41 ± 4	28 ± 2	25 ± 1.2	4.2 ± 0.6

This pattern reflects the bioaccumulation of metals in root tissues and is consistent with the elevated levels of available metals in the rhizospheric soils. In all cases, root concentrations of Fe, Mn, Zn, Ni, and Cr exceeded WHO safety thresholds (FAO/WHO, 2001).

Bioconcentration Factor (BCF)

Bioconcentration Factors (BCFs) are used to evaluate the capacity of food crops to accumulate heavy metals in their edible tissues. The transfer of metals from soil to plants, and specifically into the edible parts, represents the principal route through which potentially toxic elements enter the human food chain. This process is influenced by several factors, including the type and concentration of the metal, plant species, soil physicochemical properties, and environmental conditions (Gebeyehu & Bayissa, 2020).

Figure 2 presents the BCF values calculated for Fe, Mn, Zn, Ni, and Cr in the edible parts of the crops analyzed in this study. Notably, the BCFs for Mn, Ni, and Cr were significantly higher in the fruit crop (strawberry) compared to the four vegetable types, indicating a greater potential for metal accumulation in fruit tissues under similar soil contamination conditions.

In all tested vegetables and fruits, BCF values were below 1.0 when calculated using the total metal concentrations in rhizospheric soil, suggesting that while metals were taken up, the transfer efficiency was relatively low. However, values close to or approaching 1 may still indicate concern when paired with high soil concentrations.

The relative order of metal transfer based on BCFs differed across plant types: Onion (Zn > Ni > Mn > Cr), Salad (Mn > Zn > Ni > Cr), Potato (Zn > Ni > Mn > Cr), Pepper (Zn > Ni > Mn > Cr). These differences highlight species-specific metal uptake mechanisms and the importance of crop selection when cultivating in contaminated areas.

Statistical analysis using one-way ANOVA revealed significant differences ($p < 0.05$) in the BCFs of Mn, Zn, Ni, and Cr among the five food crop types analyzed, as shown in Table 6.

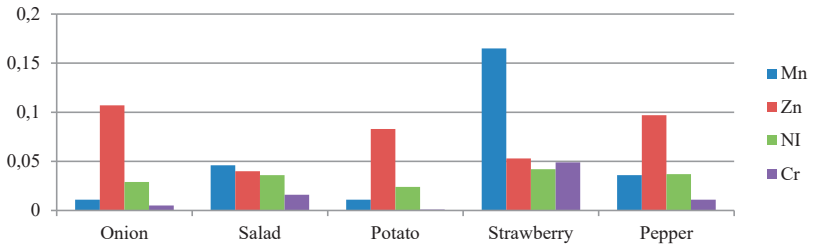

Figure 2. Bioconcentration Factor (BCF) in food plants

Table 6. ANOVA results: Significant differences in BCFs of Heavy Metals among edible parts of five food crops

Metal	Degrees of Freedom (df)	F-value	P-value	Critical F-value
Mn	4	208	0.000	3.47805
Zn	4	16.7	0.0002	3.47805
Ni	4	11.2	0.001	3.47805
Cr	4	153	0.000	3.47805

CONCLUSIONS

This study investigated the accumulation of heavy metals in four vegetable species and one fruit species cultivated on farmland contaminated with iron (Fe), manganese (Mn), zinc (Zn), and nickel (Ni) in Elbasan, Albania. The concentrations of these metals in the soil exceeded the typical background levels reported for Albanian agricultural soils.

Among the edible parts of the analyzed crops, metal concentrations decreased in the following order: Fruit (Strawberry) > Leafy vegetable (Salad) *(except for Zn)*> Solanaceous (Pepper) > Bulb (Onion) > Tuber (Potato). This gradient indicates that certain crop types, particularly fruits and leafy vegetables, are more prone to accumulating heavy metals and may therefore pose greater health risks when grown in contaminated environments.

These findings support the selection of low-accumulator plant species - such as onions and potatoes - for cultivation in areas with known soil contamination. Conversely, high-accumulator species should be avoided or managed carefully to reduce human exposure to toxic metals through the food chain.
Future research should focus on identifying the chemical forms and mineral phases of metals - especially Ni, soil to better understand their bioavailability, environmental mobility, and potential risks. This knowledge will be crucial for developing effective mitigation strategies and improving food safety in contaminated regions.

ACKNOWLEDGEMENTS

The authors extend their sincere thanks to the technical staff of the Laboratory of the Department of Environment and Natural Resources at the Agricultural University of Tirana (AUT), as well as the Laboratory of the University of Pristina in Kosovo, for them invaluable assistance with the analytical work presented in this study.

Abstract

Saline environments, characterized by extreme conditions, are unique habitats that harbor diverse microorganism communities capable of synthesizing biomolecules, such as extracellular hydrolytic enzymes and carotenoid pigments with significant industrial potential. These biomolecules are important in microorganisms' survival and adaptation to harsh environments. The present study aimed to isolate several new biomolecule-producing microorganisms from two salt wells (Curmătura and Băicoi, Prahova County, Romania). The strains NC18, NC21, NC28, and SB1 were isolated using a selective agar medium supplemented with 3.4 M sodium chloride (NaCl). Specifically, NC18, NC21, and NC28 were obtained from Curmătura, while SB1 was isolated from Băicoi. As a result of their ability to grow on agar medium with 1–5 M NaCl, all the new isolates were included in the extreme halophilic organisms. Based on their phenotypic and molecular characteristics, all these strains were included in the domain Archaea. The four isolates NC18, NC21, NC28, and SB1 were further assessed for their ability to produce extracellular hydrolytic enzymes, including lipase, protease, amylase, cellulase, xylanase, and pectinase, as well as carotenoid pigments. Due to their ability to produce a range of bioactive compounds, the halophilic isolates present promising opportunities for diverse biotechnological applications, such as industrial enzyme production, and the development of bio-based products.

Key words: *carotenoids, exoenzymes, halophiles, saline environment.*

INTRODUCTION

Halophilic Archaea, primarily belonging to the family *Halobacteriaceae*, are extremophiles that thrive in hypersaline environments, where high salt concentrations inhibit the growth of most other organisms. Extreme halophiles typically require NaCl concentrations exceeding 1.5 M for optimal development. They are ubiquitous and are widely distributed in habitats classified as salt lakes, hypersaline soils or sediments, salterns, and salt mines (Oren, 2002). To survive under osmotic stress, these organisms have evolved unique biochemical and physiological mechanisms. Their primary adaptation is the 'salt-in' strategy, maintaining high intracellular K^+ and Cl^- levels. They also possess specialized membrane lipids, an S-layer, and numerous acidic proteins that require high salt concentrations to maintain their native structure (Galinski, 1993; Oren, 1999). These adaptations make them a valuable source of biologically active compounds. Among the most significant compounds produced by halophiles are salt-resistant extracellular enzymes, pigments, and biosurfactants. These biomolecules have broad industrial and environmental applications due to their stability under extreme conditions (Antón et al., 2002; Mnif et al., 2009; Subramanian & Gurunathan, 2020).

Halophilic archaea are known for their ability to produce extracellular hydrolytic enzymes, such as amylases, proteases, and lipases (Qiu et al., 2021; Moopantakath et al., 2022; Song et al., 2023). Due to their remarkable stability and optimal activity under extreme environmental conditions, including high salinity and temperature, these exoenzymes are of both theoretical and practical interest. Their unique properties grant them significant value in industrial applications, such as detergent formulation, biofuel production, and pharmaceutical synthesis (Kasirajan et al., 2020; Schreck et al., 2021). For example, halophilic proteases have been employed in food processing and leather industries due to their catalytic efficiency at high salt concentrations (Antón et al., 2002).

Halophiles frequently produce carotenoid pigments, with bacterioruberin (C50 carotenoid) being the most characteristic in

extremely halophilic archaea. These microorganisms form colonies in shades of pink, orange, or red due to the high accumulation of bacterioruberin and related pigments. Such compounds absorb solar radiation and also protect the cells from photooxidative damage, shielding them against oxidative stress caused by UV exposure and high salinity. Beyond their protective role, C50 carotenoids exhibit strong antioxidant, antimicrobial, and anticancer properties, highlighting their relevance in pharmaceutical and cosmetic applications. Their stability and intense coloration enhance their potential as natural colorants (Antón et al., 2002; Subramanian & Gurunathan, 2020; Bouhamed et al., 2024).

The present study aimed to isolate several new halophilic microorganisms capable of producing biomolecules, including extracellular enzymes and carotenoid pigments, from different saline habitats, with a key role in their survival under extreme conditions.

MATERIALS AND METHODS

The samples used in this study were collected from two salt wells in Curmătura (Latitude: 45°09′25.307″ N, Longitude: 26°09′06.006″ E, Altitude: 213 m) and Băicoi (Latitude: 45°2′34.553″ N, Longitude: 25°53′18.667″ E, Altitude: 265 m), both located in Prahova County, Romania**.** We gathered and examined mud from Curmătura, and soil from the Băicoi salt well.

Isolation and characterization of biomolecule-producing halophiles

For the isolation and cultivation of halophilic microorganisms, we used JCM 168 medium (Rasooli et al., 2016), which contained the following components (g/L): NaCl (200), KCl (2), $MgSO_4 \cdot 7H_2O$ (20), $FeCl_2 \cdot 4H_2O$ (0.036), $MnCl_2 \cdot 4H_2O$ (0.00036), casamino acids (5), yeast extract (5), sodium glutamate (1), trisodium citrate (3), and agar (20)**,** with a final pH of 7.0. Decimal dilutions (10^{-1}-10^{-3}) of the samples were prepared in 3.4 M NaCl solution and inoculated by the pour-plate method (Sanders, 2012) in JCM 168 agar. The Petri plates were incubated at 37 °C up to 20 days. The number of viable microorganisms in samples was expressed as colony-forming units (CFU/g). The newly isolated strains were purified by multiple subculturing on JCM 168 agar medium and stored in glycerol at -80°C for long-term preservation. The new four isolates were further characterized by their phenotypic characteristics, including colony color, growth temperature, salt tolerance (0–5 M NaCl), production of extracellular hydrolytic enzymes, and molecular characteristics, specifically the 16S rRNA gene. Genomic DNA was extracted from isolates using the Pure Link genomic DNA kit (Invitrogen, Carlsbad, CA, USA). The 16S rRNA gene was amplified via polymerase chain reaction (PCR) using extracted genomic DNA, universal primers 27f/1492r (Marchesi et al., 1998) and 20f/1492r (Orphan et al., 2001), alongside GoTaq G2 Hot Start Polymerase (Promega, Madison, WI, USA), as previously described (Stancu, 2020; 2023; 2025). The thermal cycling conditions were carried out on an Eppendorf Mastercycler Pro S thermocycler (Hamburg, Germany) and included an initial denaturation at 94°C for 10 min, followed by 35 cycles of 94°C for 1 min, 55°C for 30 s, and 72°C for 2 min, with a final extension at 72°C for 10 min. The PCR products were visualized onto 1.5% (w/v) agarose gels stained with SYBR Safe (Invitrogen) (Stancu, 2020; 2023; 2025).

The four isolates were screened to produce extracellular hydrolases, including lipase, protease, amylase, cellulase, xylanase, and pectinase, using the plate assay method (Rohban et al., 2008). The composition of the JCM 168 medium was modified by removing casamino acids, and reducing yeast extract to 1 g/L, and supplementing with 1 g/L of specific substrates such as Tween-80, casein, starch, carboxymethylcellulose, xylan, and pectin. Cultures were spot-inoculated onto the surface of the medium and incubated at 37°C for 10 to 20 days. Enzymatic activity was determined based on halo formation around the cultures.

The four isolates were further screened to produce carotenoid pigments. After reaching the stationary phase, the cultures were centrifuged, and the biomass was resuspended in acetone to extract pigments. Carotenoid extracts analysis was conducted using UV-visible spectroscopy, with absorbance measured from 200 to 800 nm (SPECORD 200

UV-Vis spectrophotometer, Analytik Jena, Jena, Germany). Total carotenoid content was determined at 494 nm using an absorption coefficient of 2500 (Hiyama et al., 1969). High-Performance Thin-Layer Chromatography (HPTLC) analysis was further performed using a CAMAG system, with samples applied to silica gel plates and developed in a chloroform-methanol (90:10, v/v) mobile phase (Stancu, 2020). The TLC plates were scanned under UV light (366 nm) for pigments examination. Antimicrobial activity of carotenoid extracts was evaluated using the agar diffusion techniques (Gómez-Villegas et al., 2020). The reference strains tested were *Escherichia coli* ATCC 25922, *Pseudomonas aeruginosa* ATCC 15442, *Staphylococcus aureus* ATCC 25923, and *Candida albicans* ATCC 10231. Tryptic Soy Agar (TSA) plates were inoculated with 0.5 McFarland standard suspension of each pathogen. After drying, pigment extracts (10 µL), were spotted onto the medium. Acetone toxicity was ruled out before testing. Gentamicin (10 µg) and Fluconazole (25 µg) were used as positive controls. Petri Plates were incubated at 37°C for 24 hours.

RESULTS AND DISCUSSIONS

Romania has over 300 salt deposits, located either inside or outside the Carpathian Arc, formed through the evaporation of seawater and later shaped by tectonic processes, leading to the formation of salt massifs, saline springs, and hypersaline lakes (Cavruc & Chiricescu, 2006). Due to their high purity and accessibility, these deposits have been exploited over time for industrial purposes, balneotherapy, and human consumption. To make use of these resources, people have built salt wells, using their water for various food preservation, such as pickles and cheeses. Similar saline wells have been identified in Prahova County, specifically on the outskirts of Curmătura village and Băicoi town. These two saline wells, characterized by distinct physicochemical properties, including salinity exceeding 280 g/L, served as sources for the halophilic microorganisms' isolation (Figure 1.a).

Isolation and characterization of biomolecule-producing halophiles

From Curmătura mud and Băicoi soil we identified a microbial density of 10^4 CFU/g for both samples. Among the 27 isolates obtained in pure culture, four colonies with distinct morphological traits (Table 1) were chosen for further analysis. These colonies were designated as NC18, NC21, and NC28, all isolated from Curmătura mud, while SB1 was obtained from the Băicoi soil sample. Sensitivity tests to chloramphenicol (a broad-spectrum antibiotic) and sodium deoxycholate (a bile salt detergent), showed that all strains were resistant to chloramphenicol. This response differentiates them from typical bacteria and is consistent with established archaeal traits. Unlike bacteria, haloarchaea often exhibit antibiotic resistance patterns, including ampicillin, tetracycline, erythromycin, and chloramphenicol which generally target peptidoglycan synthesis and/or bacterial ribosomal structures (Thombre et al., 2016). Our results showed that all isolates were sensitive to sodium deoxycholate (Table 1), consistent with literature indicating that most non-coccoid halophilic archaea are more susceptible to bile salts than many bacteria. This sensitivity is likely due to structural variations in the membrane and S-layer, which differ among archaeal genera and species (Elevi & Oren, 2008). The four isolates exhibit remarkable salt tolerance, thriving in 1-5 M NaCl. Thus, NC18 grew from 1 up to 4 M salt, while NC21 and NC28 tolerated 1-5 M, and SB1 grew only in 2-5 M NaCl. Such high salt requirements are characteristic of halophilic Archaea. Extreme halophiles typically require over 1.5 M NaCl to develop, with optimal proliferation often at 3.4-5.2 M NaCl (Oren, 2002). Their growth temperature of 37 °C is within the mesophilic range common for many haloarchaeal species which generally grow well at 30-45 °C, with some able to exceed 50°C (Bowers et al, 2011).

Focusing on the amplification of the 16S rRNA gene, PCR-based molecular techniques were employed for the genetic characterization of the four isolates. All strains were successfully amplified using archaeal-specific primers (20f/1492r), confirming their classification within the Archaea domain, with the

characteristic 1472 bp amplicon obtained through PCR (Table 1, Figure 1c). No amplification was observed with bacterial-specific primers (27f/1492r) in any strain except NC28, suggesting the general absence of bacterial DNA. However, the amplification observed in NC28 could be due to horizontal gene transfer, which may have introduced the 16S rRNA gene of bacteria into the archaeal genome.

Positive reaction (+), negative reaction (–).

As confirmed by genetic and physiological characterization, the isolates belonging to the haloarchaea were further examined for their biotechnological potential by testing their ability to produce extracellular enzymes and carotenoid pigments.

Extremophilic enzymes, particularly extracellular ones, have a lot of promise for industrial applications due to their stability in high-salt environments and their ability to function in unconventional conditions (Moopantakath et al., 2022). In this study, the synthesis of six extracellular hydrolytic enzymes by haloarchaea isolates was assayed qualitatively (Table 1, Figure 1b). Several strains exhibited combined enzymatic activities, with NC21 and NC28 isolates capable of synthesizing amylase, lipase, and cellulase, while SB1 isolate synthesized lipase, cellulase, and xylanase. In contrast, NC18 displayed only amylase activity. No strains were capable of producing protease or pectinase. The findings are consistent with existing literature that indicates haloarchaea commonly produce amylase and lipase, which have applications in starch hydrolysis, biofuel production, and biocatalysis (Menasria et al., 2018). Extracellular enzymes, such as cellulase and xylanase, are less commonly found in halophilic Archaea (Zhang et al., 2011). Thus, their presence in certain strains is noteworthy. Our findings highlight the metabolic diversity of the haloarchaea isolates, their capability to produce multiple extracellular enzymes, and their consequent potential for diverse biotechnological applications.

One of the most prominent and conserved phenotypes observed in haloarchaea in their respective natural environments is the ability to produce carotenoids. UV-Vis spectra (in the domain 200-800 nm) of the carotenoid pigments extracted from the strains isolated in this study showed differences in their composition (Figure 2b). The absorbance spectrum of the red pigment extract from the NC18 showed a profile with maxima at 440, 500, and 530 nm. The peaks recorded at 500 and 536 nm are comparable to those documented for bacterioruberin (495 and 530 nm) (Bouhamed et al., 2024), the predominant C_{50} carotenoid in haloarchaea, indicating the potential presence of at least one variant of bacterioruberin.

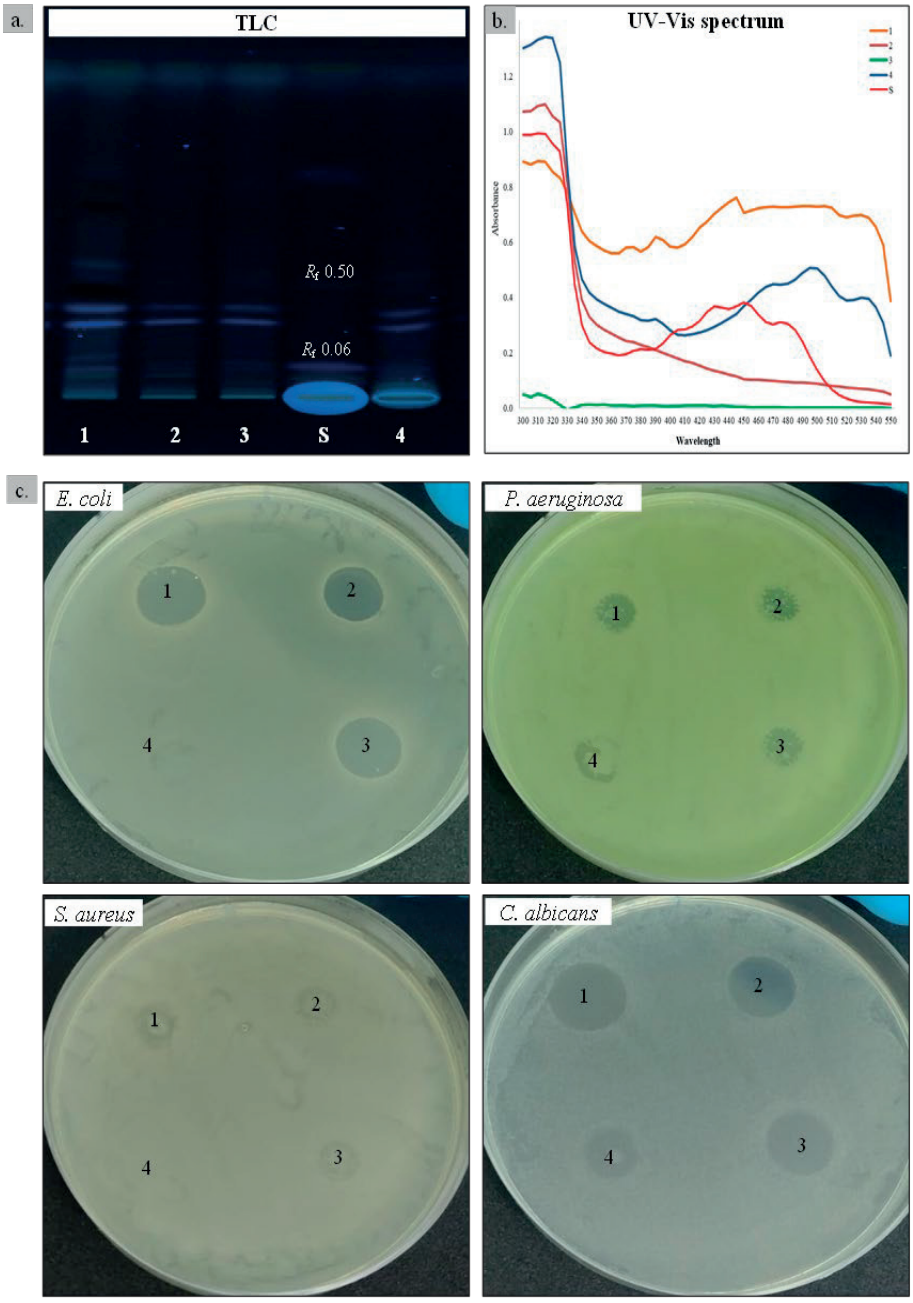

Figure 2. Carotenoid pigments production by halophiles: a. TLC of carotenoids extracted from strains NC18 (1), NC21 (2), NC28 (3), SB1 (4) grown in JCM168 medium with 3.4 M NaCl; retardation factor (Rf), carotenoid standards (S); b. UV-Vis spectrum of carotenoids (300-550 nm); c. antimicrobial activity of carotenoids extracted from strains NC18 (1), NC21 (2), NC28 (3), SB1 (4) on references pathogenic microorganisms

Given its known roles in photoprotection, membrane stability, and oxidative stress resistance, bacterioruberin presence may contribute to the survival and adaptation of these archaea in extreme environments. Additionally, its industrial potential in

biotechnology and pharmaceuticals further underscores the relevance of these results. The orange pigment extract from the SB1 also displayed three distinct absorption peaks at 470, 495, and 530 nm. This aligns with the findings of Kesbiç et al. (2023), who reported bacterioruberin absorption maxima at 467, 494, and 527 nm, values closely matching those observed in SB1. In contrast, the NC21 and NC28 did not exhibit peaks at these wavelengths (440-530 nm). However, all strains showed a peak at ~310 nm, likely corresponding to carotenoid precursors present in the cells, such as phytoene or phytofluene. Although no absorption peak in the visible range was identified for extracts from NC21 and NC28, HPTLC analysis revealed several visible bands in all the halophiles extracts, confirming the presence of carotenoid pigments with distinct R_f values ranging from 0.07 and 0.69 (Table 1, Figure 2a). The superior sensitivity of TLC, which may separate trace pigments undetectable by UV-Vis spectroscopy, may be responsible for this discrepancy. For better understanding of carotenoid production, the total carotenoid concentrations were further determined. NC18 and SB1 were the highest carotenoid producers, yielding 585.2 µg/mL and 406.2 µg/mL, respectively, while NC21 (84.2 µg/mL) and NC28 (52.0 µg/mL) produced significantly lower amounts, consistent with our previous results.

The antimicrobial activity of the carotenoid pigment extracts was assessed against the pathogenic reference strains *E. coli*, *S. aureus*, *P. aeruginosa,* and *C. albicans*. Our results revealed that the carotenoid extracts from NC18, NC21, and NC28 exhibited inhibitory effects against *E. coli* and *C. albicans*, but not against *P. aeruginosa* or *S. aureus* (Figure 2c). Interestingly, the SB1 pigment extract had no antimicrobial activity against any of the pathogens tested, despite the high carotenoid concentration. According to our results, stability, bioavailability, and composition of pigments are important factors in antibacterial activity. These results indicate that pigment stability, bioavailability, and composition are key to antimicrobial efficacy. The specific chemical structures of the pigments from NC18, NC21, and NC28 might interact more effectively with the membranes or metabolic pathways of *E. coli* and *C. albicans,* while the inherent resistance mechanisms in *P. aeruginosa* and *S. aureus* could inhibit these interactions. Moreover, the lack of activity in the SB1 extract shows that a high carotenoid concentration alone is not sufficient for antimicrobial action.

This underscores the necessity for an in-depth investigation of haloarchaeal carotenoids, particularly their structural and functional properties, to explore their potential in biotechnological applications. Halophilic microorganisms present sustainable solutions to industrial and environmental challenges, while their distinctive metabolic pathways offer valuable insights into extremophile adaptations, facilitating the development of innovative biotechnological applications (Antón et al., 2002; Subramanian & Gurunathan, 2020; Bouhamed et al., 2024).

CONCLUSIONS

Based on the phenotypic and molecular characteristics, the four newly isolated strains, designed as NC18, NC21, NC28, and SB1, were included in the Archaea domain. Our results highlight the remarkable ability of the halophilic isolates to thrive in extreme environments, making them promising candidates for industrial processes that require stability under harsh conditions. Their capability to synthesize biomolecules, including extracellular hydrolytic enzymes and carotenoid pigments under extreme environmental conditions (NaCl 3.4 M, pH 7.0, and 37 °C) minimizes the dependency on synthetic chemicals, thereby supporting the principles of green technology.

Abstract

The paper presents an assessment of the status of the sustainability of Dâmbovița County with special attention to the energy and environment interactions. A society seeking sustainable development ideally must utilize only energy resources that cause low or no environmental impact meaning no emissions released to the environment. In this matter, several indicators were analyzed and discussed such as increasing the share of renewable energy sources and low-carbon fuels in the transport sector (electric vehicles), including alternative fuels, and environmental issues in terms of energy conservation and renewable energy technologies, together with limitations on increased energy efficiency, and the relations between energy and sustainable development, and between the environment and sustainable development. To complete this complex approach, the role of innovation and technology transfer from universities actively involved in regional development was briefly discussed.

Key words*: critical analysis, energy efficiency, energy-environment interaction, low emissions, sustainable development goals.*

INTRODUCTION

The 2030 Agenda for Sustainable Development, adopted by all United Nations Member States in 2015, outlines a global vision for peace and prosperity for people and the planet. At the core of this agenda are 17 Sustainable Development Goals (SDGs) and 169 targets, addressing critical issues such as poverty, health, education, clean energy, and climate action (European Commission, 2015).
The European Union (EU) and its member states are fully committed to the 2030 Agenda, implementing it through comprehensive strategies including the 2030 Climate and Energy Framework and the Territorial Agenda 2030 (European Commission, 2020). (https://www.iea.org/policies/1494-2030-climate-and-energy-framework) particularly to These frameworks contribute significantly to SDG 13 (Climate Action) and SDG 7 (Affordable and Clean Energy), with targets to:

- Reduce greenhouse gas emissions by at least 55% by 2030 (compared to 1990 levels);
- Increase the share of renewable energy in gross final energy consumption to at least 42.5%, aiming for 45%;
- Improve energy efficiency by reducing final energy consumption by at least 11.7%.

The EU is implementing various policies and legislation to achieve these targets, aiming to become the first climate-neutral continent by 2050. The Territorial Agenda 2030 focuses on the territorial dimensions of sustainable development across Europe. It aims for an inclusive and sustainable future for all places and people in Europe and emphasizes the importance of strategic spatial planning and strengthening the territorial dimension of sector policies at all levels of governance.
Romania, as an EU member state, has aligned its national policies with the 2030 Agenda through the National Sustainable Development Strategy 2030. This strategy focuses on

economic, social, and environmental dimensions and emphasizes innovation, resilience, and citizen-centered development (FAO, 2018)

Romania's commitment includes:

- *National Sustainable Development Strategy 2030*, which is a central guiding document outlining Romania's framework for implementing the 2030 Agenda and achieving the 17 Sustainable Development Goals (SDGs), focusing on the three dimensions of sustainable development: economic, social, and environmental. The strategy follows a citizen-centered approach, innovation, employment, resilience, and environmental protection.
- *Aligning with the EU Green Deal.* Romania actively participated in the development of the 2030 Agenda and is committed to its implementation at the national level. The National Strategy 2030 directly addresses all 17 SDGs.
- *EU Green Deal Alignment*. As a member of the European Union, Romania is also committed to the EU's Green Deal, which aims to make Europe the first climate-neutral continent by 2050. Romania's national strategies and policies are increasingly aligned with the EU's ambitious climate and environmental targets.
- *Climate Action Commitments*. Romania has ratified key international agreements such as the United Nations Framework Convention on Climate Change (UNFCCC), the Kyoto Protocol, and the Paris Agreement, integrating them into national legislation. The country is working towards the EU's goal of reducing greenhouse gas emissions by at least 55% by 2030 compared to 1990 levels.
- *Renewable Energy and Energy Efficiency*. Romania has made progress in increasing the share of renewable energy in its energy production and is committed to further expanding this sector. Energy efficiency improvements are also a key focus.
- *The Romanian Sustainability Code* aims to promote sustainability and transparency within the Romanian business environment by increasing the number of entities reporting sustainability information, improving the transparency of these reports, and ensuring their comparability.
- *Green Financing Initiatives*: The National Bank of Romania (NBR) has established a working group to stimulate green financing and raise awareness about the importance of sustainability within the financial sector. Measures to incentivize private investment in sustainable projects, such as reduced VAT rates, have also been introduced.
- *Focus on Environmental Protection*: Romania recognizes the importance of environmental protection and is addressing challenges such as waste management, air quality, biodiversity protection, and sustainable forest management. Initiatives like the national afforestation program demonstrate a commitment to a cleaner environment.
- *Urban Sustainable Development*. Strategies are being developed at the urban level to address environmental issues and promote sustainable development in cities.

While Romania has established a strong framework and demonstrated commitment, progress towards achieving all SDGs is ongoing. Some areas where further effort is needed include waste management and recycling by improving recycling rates and waste management systems (it still remains a significant challenge), reducing inequalities (disparities between urban and rural areas need to be addressed to ensure inclusive and equitable growth), policy coherence and implementation (the principles of sustainable development should be reflected throughout the policy framework and effectively implemented at all levels), and data collection and monitoring (strengthening regular reporting mechanisms and data collection for the SDGs for tracking progress) (GR, 2023). Overall, Romania has made significant progress in committing to sustainability and has established a comprehensive framework to guide its efforts towards achieving the goals of the 2030 Agenda (GR, 2023). Continued dedication and effective implementation of policies will be key to realizing a sustainable future for the country.

A strong link between energy, environment, and sustainable development is well-documented (Dincer & Rosen, 1999). At the regional level, Dâmbovița County shows

progress in natural gas distribution and urban infrastructure but remains deficient in household drinking water supply (Davidescu et al., 2020).

From an energy perspective, Dâmbovița County's installed power capacity declined from 596.5 MW in 1989 to 133.2 MW in 2020. The county contributed just 0.7% to the national power system in 2020, with an average energy production of 285 GWh since 2018 (Badita, 2025). A major upcoming development is an 80 MWp solar project in Răscăeți village, led by the Swiss-based MET Group.

In this context, this paper explores key energy and environmental sustainability indicators relevant to Dâmbovița County. It also examines the role of universities, particularly Valahia University of Târgoviște, in supporting regional development through innovation and technology transfer.

MATERIALS AND METHODS

To evaluate the status of energy and environmental sustainability in Romania and Dâmbovița County, data were extracted from the Tempo Online database (http://statistici.insse.ro:8077/tempo-online/), focusing on time series spanning 2008 to 2020. The year 2020 represents the most recent period for which comprehensive data are available.

The assessment of objective achievement within each of the 17 Sustainable Development Goals (SDGs) necessitates measurable targets. Within Romania's SNDDR, 104 such targets have been defined for the 2030 horizon.

To effectively monitor the implementation of this strategy, the national sustainable development indicators - Horizon 2030 - were developed, encompassing 242 unique indicators, of which 99 are designated as core framework. This set received validation from the Sustainable Development Advisory Council on February 14, 2022, during a technical workshop facilitated by the Romanian National Institute of Statistics.

For this study, the analysis concentrated on three SDGs relevant to energy and environment:

- **SDG 7: Affordable and Clean Energy**
- **SDG 11: Sustainable Cities and Communities**
- **SDG 13: Climate Action**

Relevant indicators selected from the Tempo Online database include:

SDG 7: Affordable and Clean Energy

- ZBW0712 (Level 3 - Economic): Romania's foreign trade in electricity.
- ZBY0714 (Level 3 - Environment): Share of renewable energy in gross final energy consumption.
- ZBZ0715 (Level 3 - Environment): Share of electric vehicles in the total fleet.

SDG 11: Sustainable Cities and Communities (Natural Disasters and Climate Change)

- ZCV1111 (Level 3 - Environment): Expenditures for air and climate protection as a percentage of GDP.
- ZCW1112 (Level 3 - Environment): Investments in air and climate protection as a percentage of GDP.
- ZCX1111 (Level 4 - Environment): Production of environmental goods and services.
- ZCZ1113 (Level 4 - Environment): Deaths from respiratory and circulatory diseases.

SDG 13: Climate Action

Natural Disasters and Climate Change

- ZAB1311 (Level 1 - Environment): Greenhouse gas emissions by NACE Rev.2 economic activities.
- ZAG1312 (Level 1 - Environment): Average CO2 emissions per km from new passenger cars.

Education in Climate Change

- ZDP1321 (Level 2 - Environment): Yearly average temperatures in Romania.

Additionally, data reflecting the status of sustainable development in Dâmbovița County and, where unavailable, the South Muntenia Region, were selected to provide context-specific insights. These figures were primarily drawn from national social and economic statistics and include localized indicators on energy consumption, prosumer activity, and environmental health.

RESULTS AND DISCUSSIONS

At the national level, the foreign trade in electricity, corresponding to the ZBW0712,

was shifting towards a higher import in 2019 and 2020, with a corresponding negative trade balance. The average of the period between years 2008 and 2020 for export was 210.6 million euros, while the import was 117.2, and the trade balance was 93.4, respectively (Figure 1).

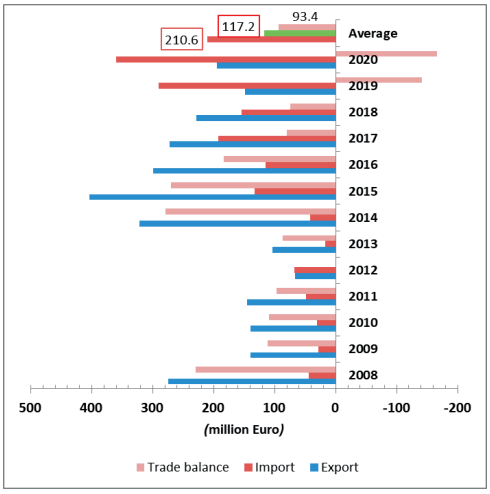

Figure 1. Romania's foreign trade in electricity, corresponding to the ZBW0712 (Data sources: National Institute of Statistics - Romania)

Figure 2 shows the expenditures for air and climate protection and investments for air and climate protection as a percentage of GDP, corresponding to the ZCV1111 and ZCW1112. A decrease in the percentage was observed for the investments starting from 2016 to 2020. The average of the 2008-2020 period was 0.1% of GDP for investments, while the expenditures reached 0.3.

Figure 3 highlights the percentage of renewable energy in gross final energy consumption (%), corresponding to the ZBY0714. A constant increase was observed from 2008 to 2020, with an average of the period of 23.5%. This can be related to the continuous development of new renewable installations.

The efforts of Romania to reduce the emissions from conventional vehicles were combined in a few initiatives, including the Rabla program. Despite the Rabla Program's efforts to promote electric and hybrid vehicle adoption in Romania's public transport and personal car sectors - evidenced by 2021 registrations of 6,903 electric and 38,531 hybrid vehicles, and a total of 26,277 electric vehicles registered in 2022 - the overall presence of these vehicles remains limited.

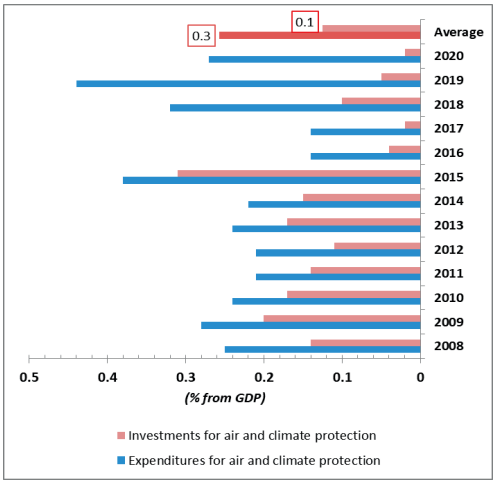

Figure 2. Expenditures for air and climate protection and Investments for air and climate protection as a percentage of GDP, corresponding to the ZCV1111 and ZCW1112, respectively (Data sources: National Institute of Statistics - Romania)

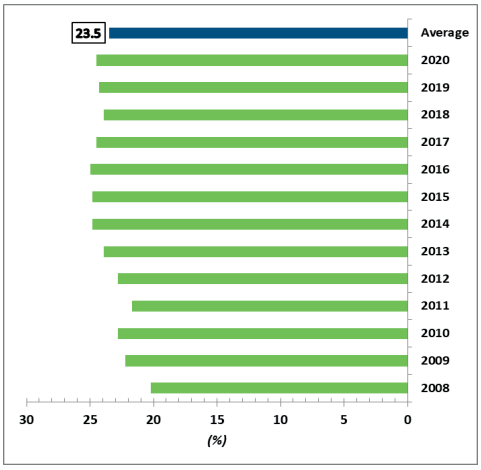

Figure 3. The percentage of renewable energy in gross final energy consumption (%), corresponding to the ZBY0714 (Data sources: Eurostat database - https://ec.europa.eu/)

As of the latest data, electric vehicles constitute a mere 0.07%, and hybrid vehicles 0.44% of the total vehicle count in Romania (GR, 2023). Figure 4 shows the evolution of the percentage of electric vehicles in the total fleet of vehicles from 2008 to 2020.

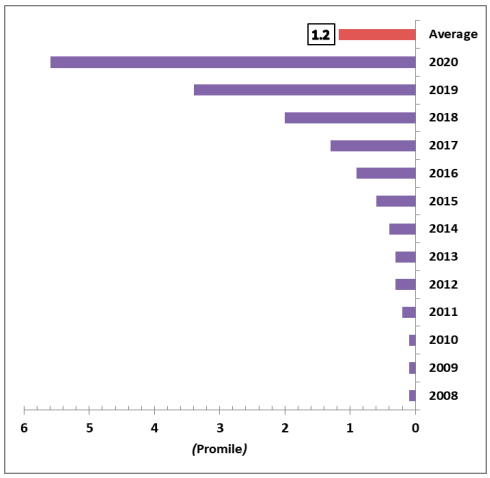

Figure 4. The percentage of electric vehicles in the total fleet of vehicles (promile), corresponding to the ZBZ0715 (Data sources: NIS Statistical survey on registered vehicles in circulation)

Figure 5 provides information regarding the production of environmental goods and services for the protection of the surrounding air and climate in millions of lei, showing a constant decrease and an average of the 2008-2020 period of 21635.1 million lei.

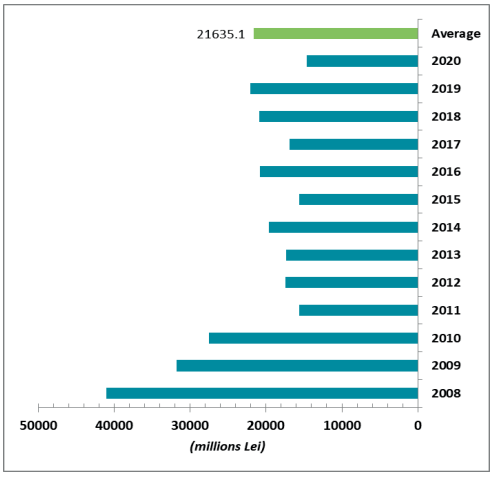

Figure 5. Production of environmental goods and services for the protection of the surrounding air and climate in millions of lei, corresponding to the ZCX1111 (Data sources: National Institute of Statistics - Romania)

Figure 6 shows the deaths from respiratory and circulatory diseases (number of persons), corresponding to the ZCZ1113. An increase in the deaths caused by diseases of the respiratory system occurred especially in 2020, being potentially correlated with air pollution in urban areas and other associated factors such as meteorology and topographical conditions (Dunea et al., 2015; Oprea et al., 2015).

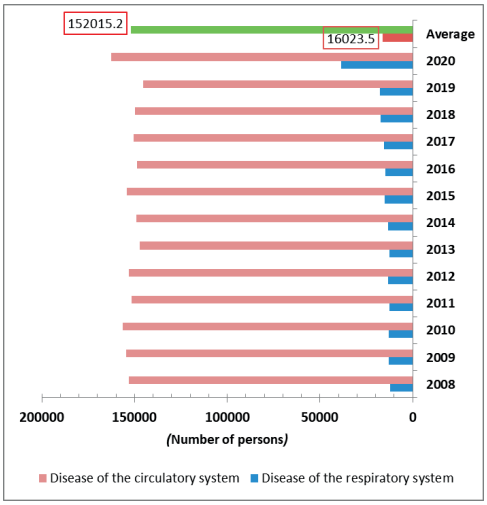

Figure 6. Deaths from respiratory and circulatory diseases (number of persons), corresponding to the ZCZ1113; causes of death are according to the WHO - ICD - 10th revision starting with 1994 (Data sources: National Institute of Statistics - Romania)

Regarding the greenhouse gas emissions by NACE Rev.2 economic activities, as sources of GHG emissions, corresponding to the ZAB1311, a decrease in the emissions can be observed. The average of the 2008-2020 period is 108,545.5 thousand tons of CO_2 equivalent (Figure 7).

On the other hand, the average CO_2 emissions per km from new passenger cars were 140.9 g CO_2/km from 2008 to 2020 (Figure 8).

Figure 9 shows the yearly average temperature recorded at Varfu Omu Meteorological station from the Bucegi Mountains located in the north of Dambovita County. An increase in the annual average temperature is evident compared to the 1901-2000 period, pointing out the effects of climate change (Venturi et al., 2025). This is related to the emissions effect and emphasizes the need for further exploration of the energy-transport-environment interaction in a complex approach and the fulfilment of the corresponding SDGs (Nakhle et al., 2024).

Dâmbovița County is one of the 41 counties of Romania, situated in the south-central part of

the country, within the historical region of Muntenia. Its capital city is Târgoviște, which holds significant historical importance as the former capital of Wallachia province. It covers an area of approximately 4,054 km^2, representing about 1.7% of Romania's total land. As of December 2021, the population of Dâmbovița County was approximately 479,404 inhabitants, making it one of the more densely populated counties in Romania. The county has 7 cities and towns (two of which are municipalities - Târgoviște and Moreni) and 82 communes with 361 villages (NIS, 2024). The county has been focusing on attracting EU funds for various development projects, including infrastructure improvements, tourism development, and environmental protection. The GDP per capita in 2023 was 11,439 euros per capita (NIS, 2024).

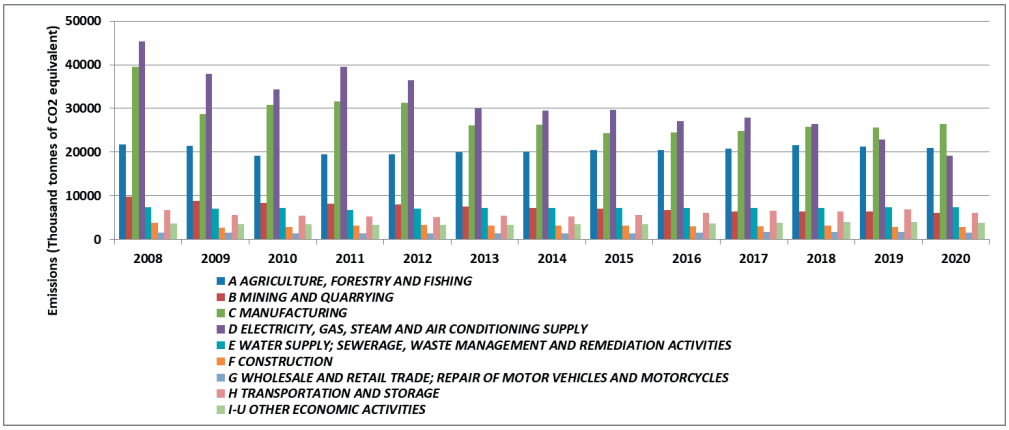

Figure 7. Greenhouse gas emissions by NACE Rev.2 economic activities, as sources of gas emissions, corresponding to the ZAB1311 (Data sources: National Institute of Statistics - Romania)

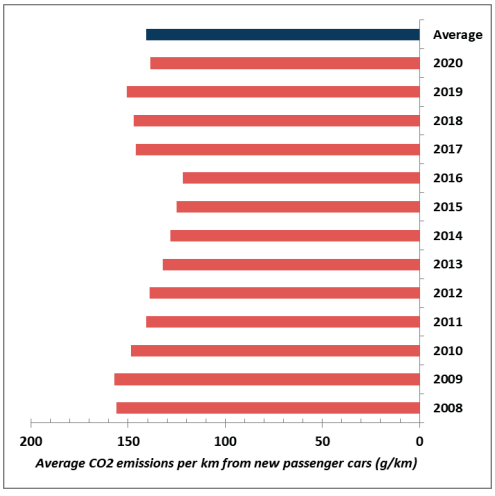

Figure 8. Average CO_2 emissions per km from new passenger cars, corresponding to the ZAG1312 (Data sources: National Institute of Statistics - Romania)

Table 1 shows some characteristics regarding the electricity and natural gas consumption in Dambovita County from 2021 and 2023. Both household and non-household consumption of electricity and natural gas have continuously decreased from one year to another.

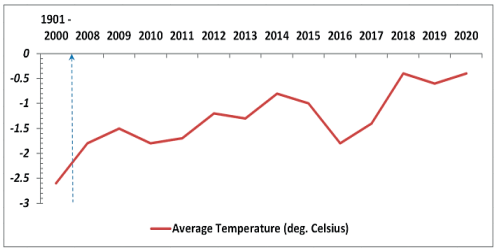

Figure 9. Yearly average temperature recorded at Vârfu Omu Meteorological station from the Bucegi Mountains located in the north of Dâmbovița County, corresponding to the ZDP1321 (Data sources: National Administration of Meteorology)

Furthermore, the number of prosumers increased considerably each year, contributing to the renewable energy production.

Another step for reducing the emissions and the environmental impact was the increase in the number of electric and hybrid vehicles

registered (Figure 10). Both directions contribute to the share of renewable energy and low-carbon fuel used in the transport sector (electric vehicles), including the use of alternative fuels. However, the monitoring of the air pollutants is not sufficient in Dambovita County to be able to quantify the benefits to the environment in urban areas.

Table 1. Details of electricity and natural gas consumption in Dâmboviţa county (Source: https://energymap.ro/en/)

Year	2021	2022	2023
Total Prosumers	200	586	2,258
Household consumption of electricity (MWh)	348,800	326,662	277,430
Non-household consumption of electricity (MWh)	1,062,355	958,503	901,012
Household consumption of natural gas (MWh)	1,026,064	975,523	971,525
Non-household consumption of natural gas (MWh)	1,160,538	1,115,428	936,177

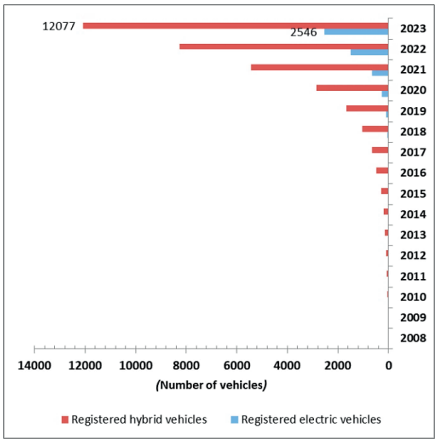

Figure 10. Target 4 - Environment - Number of electric and hybrid vehicles registered (Data sources: Ministry of home affairs - Direction of Driving-licenses Regime and Vehicles Registration)

There are only two urban background monitoring stations located in two towns, i.e., Târgovişte and Fieni. Unfortunately, the data reported from these stations did not meet the data capture criteria, and consequently, there were significant data gaps due to malfunction (Figure 11).

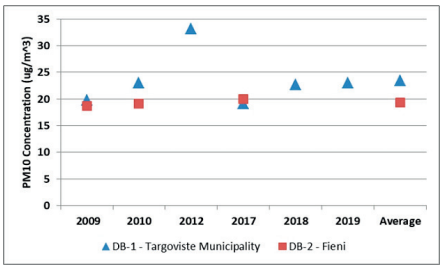

Figure 11. Target 7 - Environment - average annual levels of particulate matter PM10 at urban background monitoring stations, corresponding to the TMP1173 at the two monitoring stations located in Dâmboviţa County (Data sources: National Agency for Environmental Protection)

Furthermore, important pollutants that are responsible for serious adverse effects are not measured (e.g., PM1, PM2.5, PAH, etc.). Therefore, it is difficult to assess the exposure and the effects on human health. Figure 12 presents the number of deaths caused by respiratory and cardiovascular diseases (number of persons) in Dâmboviţa County. An increase in the number of persons affected by respiratory diseases was observed in 2020 and 2021, probably related to the COVID pandemic factors.

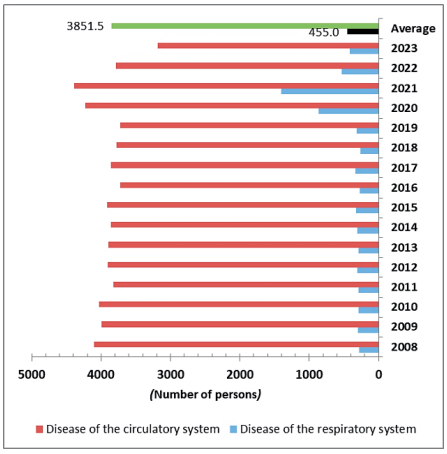

Figure 12. TMK1165 - Target 6 - Environment - number of deaths caused by respiratory and cardiovascular diseases (number of persons) in Dâmboviţa County, causes of death are according to the WHO - ICD - 10th revision starting with 1994 (Data sources: NIS - Statistical survey on mortality)

To establish the intrinsic aspects related to the energy-environment interactions, research

programs and entities should be sustained within a national and regional strategy. It is important to improve the number of employees from research-development activity (Figure 13) and the total expenditure from research-development activity (Figure 14).
Universities and research entities should be key vectors for sustainability, especially through the research results, including scientific articles, patents, and innovation items facilitating the transfer of technology to industry.

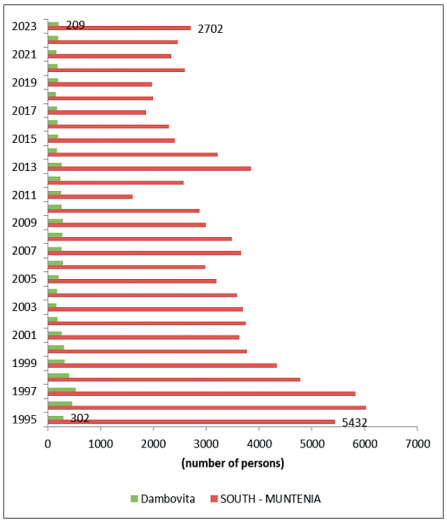

Figure 13. CDP103E - Employees from research - development activity (in full-time equivalent), by macroregions, development regions, and counties – Data for Dâmbovița County and South-Muntenia region (Data sources: National Institute of Statistics - Romania)

Valahia University is committed to contributing to sustainable development through the performed research. Figure 15 shows the research performed at Valahia University on the SDGs based on Scopus-indexed publications in the specific domains. From the 2,609 documents indexed in the Scopus database, 1064 are in Engineering, 200 in Environmental Sciences, and 196 in Energy. Important SDGs are related to SDG 12, SDG 8, SDG 9, SDG 11, SDG 6, and SDG 7. Valahia University is consistently promoting multi- and interdisciplinary research. This is reflected in the Institute of Multidisciplinary Research for Science and Technology, a research-dedicated facility with 36 laboratories with state-of-the-art equipment and spaces for scientific events, offering open access to all academic staff.

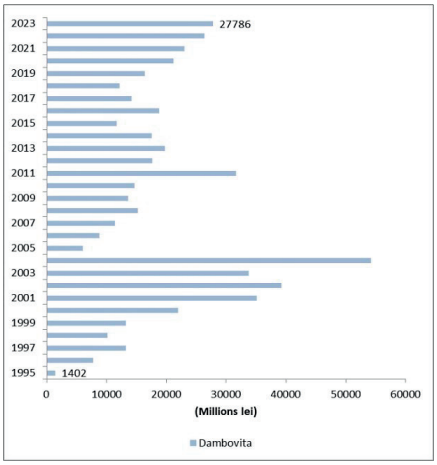

Figure 14. CDP104B - Total expenditure from research-development activity by macroregions, development regions and counties - current prices (millions of lei) – Data for Dâmbovița County (Data sources: National Institute of Statistics - Romania)

Valahia University of Târgoviște (VUT) cooperates with a key regional NGO (www.adrmuntenia.ro/) active in developing the Smart Specialization Strategy of South-Muntenia Region (2021-2027) and other policy documents related to SDGs, and the Management Authority for structural funds projects dedicated to regional development.
The university actively fosters cross-sectoral dialogue on SDGs, particularly through its engagement in projects focused on energy, environmental sustainability, and social inclusion. For instance, its contribution to the E-LAND project (https://elandh2020.eu/) is creating smarter energy systems using solar power and advanced building controls, actively involving energy businesses, regulatory bodies, and local communities. Furthermore, the university drives SDG progress through its research, educational projects, and scientific events centred on air quality, circular design, advanced materials, resource valorisation, food safety, and social inclusion.
This proactive, cross-sectoral approach enables the university to facilitate impactful discussions and contribute significantly to addressing current and future sustainability challenges.

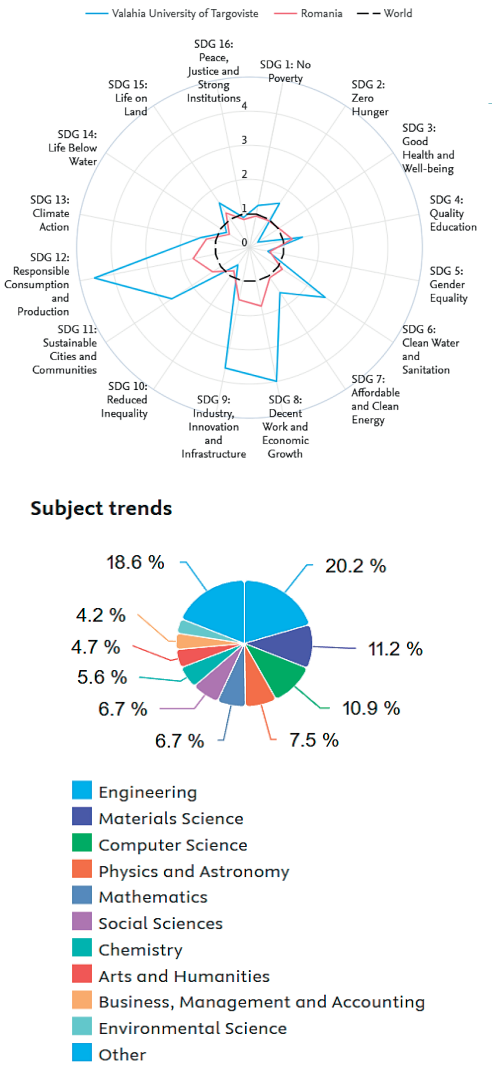

Figure 15. Contributions of the research performed at Valahia University to the SDGs based on Scopus indexed publications in the specific domains (Source: Scopus database)

Recognizing the importance of robust SDG data, VUT actively participates in international collaborations, including the development of the KreativEU university alliance. This alliance strives to be a catalyst for positive transformation at all levels by strategically linking cultural and ecological stewardship with a dedicated effort to gather and measure data relevant to achieving the SDGs.

CONCLUSIONS

In conclusion, the "European 2030 Agenda" is the main framework of the EU's commitment to the UN's 2030 Agenda for Sustainable Development, which includes ambitious climate and energy targets and a focus on territorial cohesion within Europe. Romania, as a member of the European Union, is committed to the Sustainable Development Goals outlined in the 2030 Agenda. The national Sustainable Development Strategy 2030 provides a framework for local and regional efforts. Projects in Dâmbovița County, particularly those funded by the EU, are likely aligned with these national and international sustainability objectives.

Dâmbovița County is engaged in various initiatives that contribute to sustainability, particularly in water management, renewable energy adoption, and the preservation of cultural heritage for sustainable development. These efforts reflect a commitment to both environmental protection and the well-being of its communities within the broader context of national and European sustainability goals. Romanian universities require advanced capacities in the field of interdisciplinary research and innovation for energy-environment interactions, ICT and bioeconomy to provide technology offers and transfer. VUT is actively involved in research and innovation, particularly in energy and sustainability. It has developed advanced Energy Management Systems (EMS) to support decarbonization and energy efficiency, aligning with EU strategies.

Additionally, research efforts have focused on initiatives that support sustainability, human health, and economic efficiency across the entire supply chain. With demonstrated engagement in European projects, VUT plays a vital role in advancing knowledge and innovation in key strategic areas at regional level.

ACKNOWLEDGEMENTS

The research leading to these results received support for publishing from the CNFIS-FDI-2025-F-0421 project financed by the Romanian Ministry of Education and implemented by Valahia University of Târgoviște.

Abstract

The main geotechnical parameter indicating the presence of active clays is the swelling pressure, which is globally determined using at least three different methods. In Romania, however, the swelling pressure is determined using only one method (through the compressibility test in oedometer on initially saturated samples). Regardless of the method used, the initial moisture content significantly influences the results. Two types of moisture content are typically considered: natural moisture content (according to STAS 1913/12-88) and the shrinkage limit (according to NP 126-2010). In current practice, the initial moisture content is usually the natural moisture content. However, by saturating the sample, only the swelling characteristics of the soil are identified, not the shrinkage characteristics. This article aims to synthesize the methods for determining the specific properties of active clays, based on international technical standards and norms.

Key words*: active clays, swelling pressure, technical norms, laboratory tests.*

INTRODUCTION

Expansive soils, characterized by their ability to undergo significant volume changes upon moisture variation (to shrink and/or swell), are found across many regions globally. They are particularly prevalent in semi-arid and arid climates, where the formation of smectite clay minerals (montmorillonite and illites) is geologically favoured (Diaz & Tomas, 2025). In Romania, expansive clays are frequently encountered, especially in the southern and eastern regions, where their geotechnical behavior is rigorously classified and evaluated under NP 126-2010, which sets the national standards for identifying and testing swelling pressure.

In geotechnical engineering, the determination of the swelling pressure (p_s, kPa) is critical for the design of shallow and deep foundations, retaining walls, underground structures, and linear infrastructure (Fredlund, 1996). This pressure quantifies the force exerted by a clayey soil when its volume is restrained during wetting (Chen & Ng, 2013).

The swelling pressure (p_s) is defined as the equilibrium pressure required to prevent volumetric expansion of an initially unsaturated clay soil when its moisture content increases to full saturation under constant volume conditions (Jones et al., 2020; BS 1377-5: 1990).

Various laboratory techniques such as: the one-dimensional oedometer (NP 126-2010; Feng et al, 1998), CBR and triaxial tests (Chen & Ng, 2013) are commonly employed to measure p_s directly.

Also, a wide array of empirical and semi-empirical correlations has been developed to estimate p_s from more readily available soil parameters. Extensive research has explored how p_s varies with clay fraction, dry unit weight, water content, liquid limit, and plasticity index (Mowafy & Bauer, 1985), affirming that such index properties can serve as reliable predictors under certain conditions.

The determination of the p_s is essential to reduce construction risks, limit post-construction deformations, and minimize maintenance costs, thereby enhancing the sustainability and safety of engineering projects (Jones et al., 2020).

MATERIALS AND METHODS

This study is based on an extensive review of the scientific literature, supported by a critical analysis of national and international standards and regulations relevant to the geotechnical characterization of expansive soils. Key references include normative documents such as NP 126-2010 (Romania), STAS 8942/1-89, as well as international standards like ASTM

D4546, BS 1377, and other globally recognized testing protocols.

The primary objective is to synthesize the most representative laboratory methods for determining swelling pressure (p_s), focusing particularly on one-dimensional oedometer tests (constant volume and free swell methods), triaxial testing procedures, and empirical correlations derived from index properties. The methodology involves a comparative and integrative analysis of procedures, test conditions, and parameters influencing p_s, as presented in both peer-reviewed scientific publications and engineering practice documents.

Wetting-after-loading tests on multiple specimens

The most complex method for determining the behaviour of active clays is the "wetting-after-loading tests on multiple specimens" or "Deformation versus Vertical Stress, Method A" from ASTM D4546. The tests are performed on several specimens from the same sample which, initially at natural moisture content, are loaded in the oedometer to different pressures and subsequently saturated. The final specific settlements of the sample at natural moisture content and, respectively, after saturation are recorded. Thus, compressibility curves are obtained for the material at natural moisture content (red dotted line from Figure 1) and in the hypothesis that, after being subjected to a certain compression stress (geological load or geological load to which the surcharge is added), it is saturated (blue dotted line from Figure 1). The swelling pressure is obtained at the intersection of the saturated soil compressibility curve with the zero-deformation line.

This method is a very complex one that identifies, in addition to the swelling pressure, the entire behaviour of the soil at natural moisture content, loaded at different pressures and subsequently saturated.

The method has two major disadvantages: (1) long duration or occupation of several oedometric devices and implicitly significant costs and (2) difficulties in taking quasi-identical samples to obtain accurate comparable results.

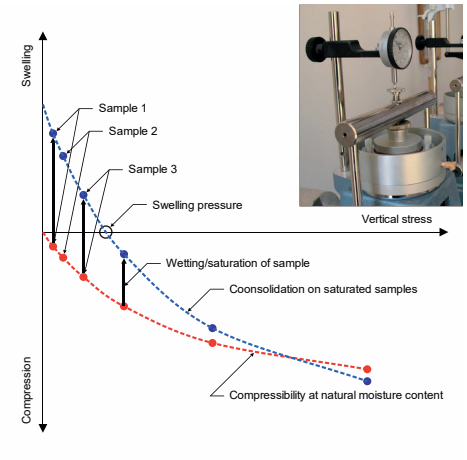

Figure 1. Wetting-after-loading tests on multiple specimens

Wetting-after-loading test on a single specimen

The "Wetting-after-loading test on a single specimen" or "Deformation versus Vertical Stress, Single-Point Test Method B" from ASTM D4546 is a method that only determines the swelling after the sample is loaded with a compression pressure (geological load or geological load to which the surcharge is added) (Figure 2).

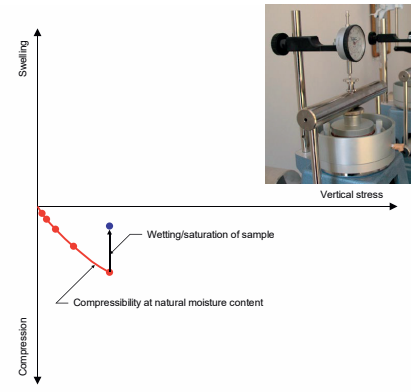

Figure 2. Wetting-after-loading test on a single specimen

This test determines the behaviour of a soil subjected to a certain compression stress and subsequently saturated. Through this test the swelling pressure is not determined.

Loading-wetting-loading test

The "Loading-wetting-loading test" or "Deformation versus Vertical Stress, Loading-after-Wetting Test Method C" from ASTM D4546 is a method in which a soil sample at natural moisture content is loaded to a certain pressure (geological load or geological load to which the surcharge is added) and then saturated and loaded further with different pressures. If the swelling is large enough to exceed the initial height of the sample, the swelling pressure can also be determined at the intersection of the saturated soil compressibility curve with the zero-deformation line (Figure 3).

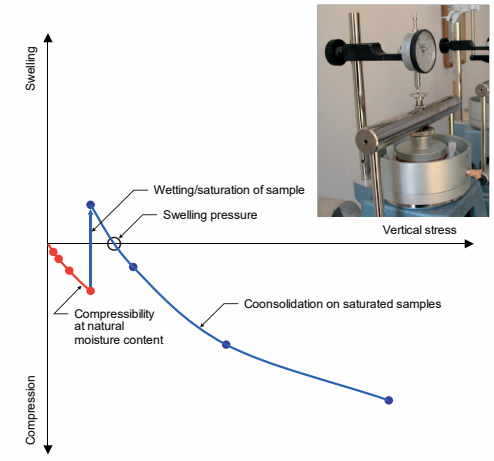

Figure 3. Loading-wetting-loading test

It is a method by which the behaviour of the soil is obtained after it, at natural humidity, is loaded with a certain pressure and subsequently saturated and the loading continues. Basically, it is described the behaviour of a soil loaded with the geological pressure, then saturated and subsequently the construction is built that comes with a certain surcharge.

Loading-after-wetting test

This method is imposed by STAS 1913/12-88 and NP 126-2010 and is almost identical to the "Deformation versus Vertical Stress, Loading-after-Wetting Test Method C" from ASTM D4546, with the difference that the sample is saturated after applying the first loading step, usually equal to 10...25 kPa (Figure 4).

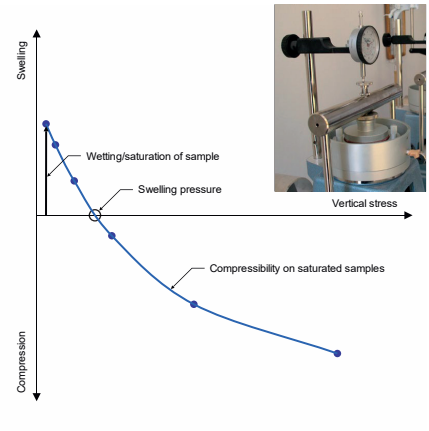

Figure 4. Loading-after-wetting test

According to STAS 1913/12-88 the initial moisture content is the equilibrium moisture content, which is very close to the natural moisture content, while according to NP 126-2010, the initial moisture content should be the shrinkage limit. This technical norm is the only one that refers to the shrinkage limit. In the specialized technical literature, tests are performed starting from the natural moisture content of the sample.

Most likely, the idea behind performing this test starting from the shrinkage limit is to identify the behaviour of the soil after it experiences significant drops in moisture content and subsequently becomes saturated. It is the worst-case scenario, but it does not consider the fact that shrinkage occur both vertically and horizontally (visible by cracks in the soil).

Performing the compressibility test in an oedometer on samples brought to the shrinkage limit involves major difficulties in soil sampling doe to its solid state.

Constant volume test

This method can be applied in two variants: (1) as described in "Deformation versus Vertical Stress, Loading-after-Wetting Test Method C" from ASTM D4546 in which small loading steps are applied to maintain the sample around zero deformations or (2) in a CBR type device through which the sample is kept at constant volume and by means of a dynamometric ring the force that the soil sample develops, following saturation, is measured (Figure 5).

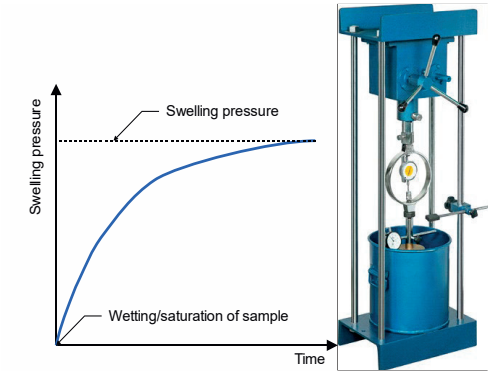

Figure 5. Constant volume

The swelling pressure is an indicator of whether a soil has swelling behaviour when saturated. The strict determination of the swelling pressure does not provide an image of the soil behaviour under different compression stresses which is necessary in order to estimate swelling/settlement.

RESULTS AND DISCUSSIONS

The swelling pressure (p_s) is the pressure required to prevent volumetric expansion of an initially unsaturated clayey soil when its moisture content increases to full saturation. In current practice, it is erroneously considered that if a foundation transmits a pressure greater than or equal to the swelling pressure to the foundation soil, then, in the event of saturation of the foundation soil, no swelling will occur.

In Figure 6 it is presented the scheme for the calculation of the foundation soil settlement, and it is the same scheme that should be applied for the estimation of swelling.

This scheme is taken from NP 125-2010 which is used to determine the additional specific settlement upon wetting of soils sensitive to wetting.

A soil element is initially subjected to a vertical stress equal to the geological stress (σ_{gn}) and, after a construction is built, the vertical stress due to surcharge is added (σ_z) resulting the total vertical stress equal to $p_n = \sigma_z + \sigma_{gn}$. If the foundation soil is saturated the geological stress (σ_{gi}) increases due to the unit weight of the soil increases to saturated unit weight and the total vertical stress becomes $p_i = \sigma_z + \sigma_{gi}$.

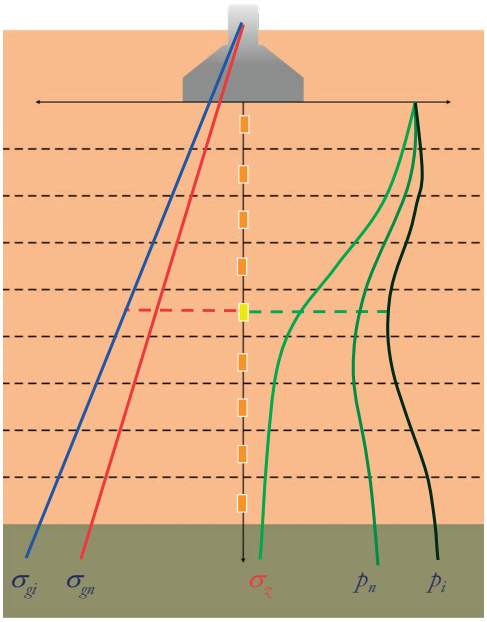

Figure 6. Calculation scheme for foundation soil settlement

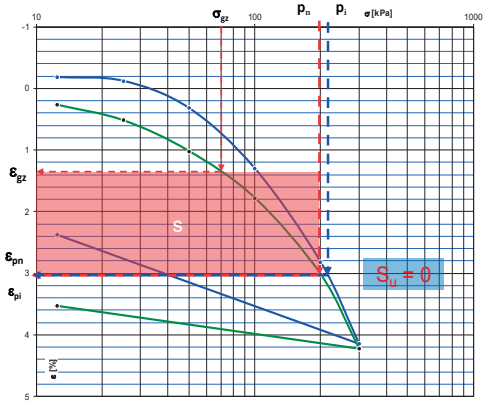
In Figure 7 a, b and c are presented different stress-strain curves of soil samples at natural moisture content and initially saturated obtained in different common laboratory tests (cases frequently encountered in current practice).

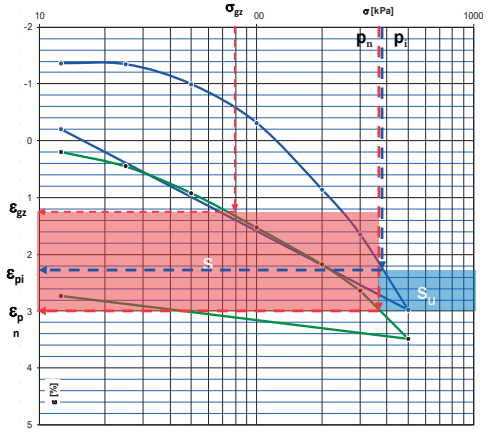
In Figure 7.a it is presented an example of a soil with a swelling pressure of about 35 kPa.

By estimating the geological load of the elementary layer “i” by intersecting with the stress-strain curve of the soil at natural moisture content, the specific settlement ε_{gz} is determined. This is the initial stress-strain state of the elementary layer “i”. After the execution of a construction, a vertical compression stress equal to p_n is transmitted to the same element and, by intersecting with the stress-strain curve of the sample at natural moisture content, the specific settlement (ε_{pn}) under this load is determined. The difference between ε_{pn} and ε_{gz} is the specific settlement of the elementary layer “i” at natural moisture content.



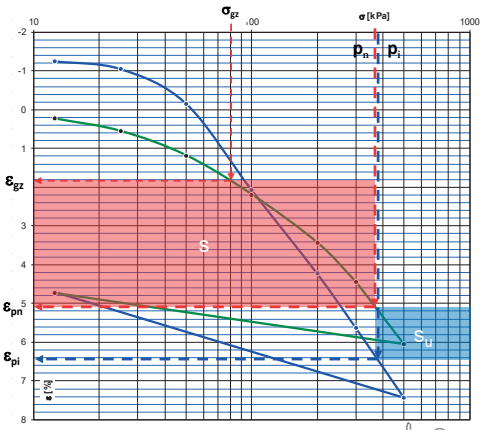
Considering that the foundation soil becomes saturated, at the level of elementary layer "i" the total vertical stress becomes p_i and by intersecting with the stress-strain curve of the initially saturated soil sample the specific settlement ε_{pi} is obtained. The difference

between ε_{pn} and ε_{pi} is the specific settlement or swelling of the elementary layer "i" when saturated.



In the case presented in Figure 7.a, it is found that, following the saturation of the foundation soil, neither settlement nor swelling is recorded at the level of the elementary layer "i".

Following the same principle described previously, by which the states of stress and deformation are evaluated from the initial moment, after the execution of the construction, respectively, in the hypothesis of saturation of the foundation soil, Figure 7.b presents a case in which the swelling pressure is equal to 120 kPa but, in the case of saturation of the foundation soil, even at pressures higher than the swelling pressure, a significant swelling of the elementary layer "i" is recorded.



In Figure 7.c, after saturation of the foundation soil, a settlement is recorded.

(a)

(b)

(c)

Figure 7. Stress-strain curves of soil samples at natural moisture content and initially saturated

CONCLUSIONS

The swelling pressure (p_s) is the pressure required to prevent volumetric expansion of an initially unsaturated clayey soil when its moisture content increases to full saturation and is just an indicator of whether a soil has high swelling when saturated.

As in accordance with NP 074-2022, double compressibility tests should be performed on soils with high swelling and shrinkage, on samples at natural moisture content and on samples initially saturated in order to obtain the behaviour of the soil under different vertical loads. The methodology imposed by the Romanian technical norms and standards is very close with the method A from ASTM D4546 but is performed only on two samples, not on minimum 4.

According to the calculation model of additional settlement upon wetting described in NP 125-2010, the stress-strain curves obtained from compressibility in oedometer tests (affected by correction coefficient M_0 used for the calculation of the deformation modulus $E=E_{oed} \cdot M_0$) allow the estimation of the settlement/swelling of the foundation soil.

THE SHEAR STRENGTH PARAMETERS OF SOIL-ROOT SYSTEMS

Tatiana OLINIC

University of Agronomic Sciences and Veterinary Medicine of Bucharest,

Corresponding author email: tatiana.olinic@fifim.ro

Abstract

The root systems of vegetation are fundamental in enhancing shallow slope stability, with the shear strength of soil-root systems serving as a critical parameter for its assessment. The role of roots in stabilizing shallow slopes has been extensively documented, and the use of vegetation for slope stabilization and soil erosion control is a well-established practice across many regions worldwide. This sustainable approach has even led to the emergence of new research disciplines focused on its development. This review article aims to synthesize and evaluate existing research on the shear strength parameters of soil-root systems across various plant species and soil types. Additionally, it examines how these parameters are affected when plant roots dry out due to hydric stress caused by recent climate change. The study provides insights into the impact of root desiccation on slope stability, highlighting the importance of understanding vegetation`s role in maintaining soil cohesion under changing conditions.

Key words*: shear strength, soil-roots, type of vegetation, age of vegetation.*

INTRODUCTION

Vegetation plays a crucial role in shallow slope stability and erosion control through both mechanical and hydrological mechanisms. Yen, as cited by Cazzuffi, classified root systems into five distinct categories based on their branching patterns: VH-type, H-type, V-type, R-type, and M-type. This classification, originally developed by Yen and later illustrated in Figure 1, highlights the varying effectiveness of root structures in stabilizing slopes (Cazzuffi et al., 2014). Among these, H-type and VH-type roots are particularly effective in combating soil erosion and enhancing slope stability. These root systems extend horizontally and vertically across the soil surface, creating a dense network that provides superior protection against the loss of topsoil. In contrast, R-type and M-type roots, while still beneficial, offer comparatively less resistance to erosion due to their less extensive branching patterns. Yen's analysis underscores the importance of selecting vegetation with H-type and VH-type root systems for optimal erosion control and slope stabilization.

Root networks contribute to hillslope stability through two key mechanisms: root pull-out resistance and enhanced soil cohesion (Wu, 2013; Fan et al., 2021). Key factors modulating this reinforcement include root architecture, soil moisture content, and vegetation type (Olinic et al., 2024). Under climate change, drought-induced root desiccation dynamically alters shear strength parameters, demanding context-specific assessments (Boldrin et al., 2018).

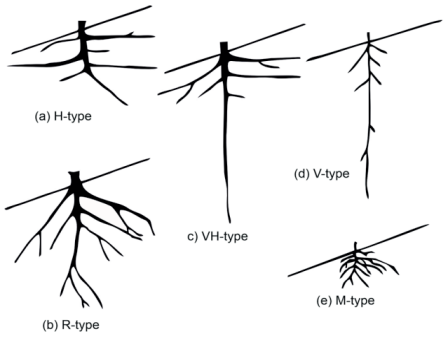

Figure 1. The root structure classified by Yen (recreated figure)

Optimal mitigation of land degradation requires detailed knowledge of site-specific soil materials, weather patterns, and terrain behaviour across diverse regions. Through laboratory testing and FEM simulations, Zhou et al. (2023) assessed how root-soil composite shear resistance varies across plant

developmental stages and influences slope reinforcement mechanisms.

This work aims to: synthesize practical insights on plant species selection for erosion control and slope stability; to evaluate species-specific efficacy in improving mechanical shear strength parameters, and to demonstrate that slope reinforcement by root systems is strongly governed by soil moisture dynamics.

MATERIALS AND METHODS

A systematic literature review was conducted from June 2022 to present, using Web of Science and Scopus databases, covering publications written in English. Primary search terms ('soil-roots system', 'soil erosion', 'shear strength' and 'shallow slope stability') identified candidate studies. Subsequent screening eliminated duplicates and prioritized research aligned with sustainable development principles. This process yielded 3 review articles addressing shear strength parameters of soil-roots applications for soil erosion control and shallow slope stability.

RESULTS AND DISCUSSIONS

Type of vegetation

Based on the critical role of vegetation type in determining erosion control efficacy and slope stabilization performance, key species analyzed in this review - including grasses (*Chrysopogon zizanioides, Elytrigia elongata, Panicum virgatum*) and threes/shrubs (alder - *Alnus* spp., paper Mulberry - *Broussonetia papyrifera*). They demonstrate how root biomechanics, soil adaptability, and hydrological resilience govern their suitability for geoenvironmental applications (Francis et al., 2005; Bischetti et al., 2005; Cazzuffi et al., 2006; Cazzuffi et al., 2014; Fan et al., 2021).

Table 1. The core strengths of various vegetation species, emphasizing their biomechanical properties, environmental adaptability, and erosion control performance (Francis et al., 2005; Bischetti et al., 2005; Cazzuffi et al., 2006; Cazzuffi et al., 2014; Fan et al., 2021)

Plant Species	Key strengths	Tensile strength (MPa)	Root depth	Environmental adaptability	Performance in erosion control
Chrysopogon zizanioides	Highest root density; deep vertical roots; tolerates pollutants/saline soils	25–60	4–5 m	pH 4–11; drought/flood/saline-tolerant	Very good: cohesion gain: ≤15 kPa; rapid stabilization
Cortaderia selloana	Drought-resistant; forms dense root mats; thrives in poor soils	15–23	3–4 m	Sandy/rocky substrates; full sun	Good: 90% survival in drought season; reduces surface erosion
Corylus avellana	Exceptional tensile strength; deep anchoring	≤60	>2 m	Temperate forests; well-drained soils	Good: superior slope reinforcement; high RAR in topsoil
Elytrigia elongata	Robust fibrous roots; high tensile strength per diameter	38–55	3–4 m	Dry, nutrient-poor soils; heat-tolerant	Medium: Good for arid slopes; moderate cohesion gain
Alnus alnobetula	Nitrogen-fixing; improves soil fertility; cold-adapted	~35	1–2 m	Alpine/subalpine zones; resists frost	Medium: enhances soil structure; moderate erosion reduction
Panicum virgatum	Evergreen; saline-tolerant; persistent ground cover	25–70	≤2 m	Coastal/arid regions; full sun	Medium: long-term resilience; slower initial growth
Broussonetia papyrifera	Pioneer species; fast-growing in disturbed soils	Depending on the diameter	≤1 m	Collapsed slopes; low-moisture soils	Low: limited use in saturated soils: strength drops to 64%

Shear strength

Depending on the soil types analysed and the plant species employed in stabilization techniques, an increase in shear strength parameters is consistently observed in root-reinforced soils compared to those without

vegetation. Most commonly, stabilization is applied to soils with inherently low cohesion - such as sandy or silty soils, where the contribution of roots to improved cohesion is particularly evident.

A study conducted by Zhou et al. (2023) confirms that the presence of plant roots substantially increases shear resistance. Direct shear tests on unrooted soil (bare soil) indicated a cohesion (c) of 33.2 kPa and an internal friction angle (φ) of 23.8°. In contrast, the soil-root composite with various plant types - namely *Cynodon dactylon* (Cd), *Magnolia multiflora* (Mm), and a grass-shrub mixture (Gs) recorded significantly higher values: cohesion ranged from 34.1-82.8 kPa (Cd), 49.5-72.9 kPa (Mm), and 36.8-99.8 kPa (Gs), while φ increased up to 39.1°. The maximum of 99.8 kPa (Gs, after 90 days) is three times higher than that of the bare soil, demonstrating the effective contribution of roots to the stabilization of the soil mass.

A study by Olinic & Olinic (2025) investigates the influence of plant roots on the shear strength parameters of sandy soils. Direct shear tests conducted on bare sand (BS) revealed a low cohesion value (c) of 1.24 kPa and an internal friction angle (φ) of 32.94°. They studied a root system composed of *Medicago sativa, Dactylis glomerata, Phleum pratense*, and *Trifolium* species which was growth in greenhouse conditions, cohesion increased to 23.43 kPa, representing a 1790% rise (because of the low value of unrooted soil), while the friction angle remained relatively stable at 32.35°, indicating a substantial reinforcement effect in sandy soils.

In the case of organic soil, a different behaviour was observed. Although the presence of roots reduced cohesion from 36.11 kPa (bare organic soil) to 29.72 kPa (approx. 18% decrease), the internal friction angle improved significantly, rising from 19.57° to 35.21°, an increase of nearly 80%. This pattern suggests that while roots may loosen compact soils, thereby reducing cohesion, they enhance internal friction through the mechanical interlocking effect of dense root networks.

The study further emphasizes that the reinforcement effect is most pronounced in the surface layer (0-5 cm), where root density is highest. For example, cohesion in sand drops to 10.65 kPa at 20-25 cm depth, indicating diminishing reinforcement with depth. These findings highlight the value of using dense-rooted vegetation as a sustainable and effective strategy for shallow slope stabilization and erosion control.

Growth period of vegetation

The type of vegetation and its temporal development dramatically influence reinforcement efficiency. In the study conducted by Zhou et al. (2023), the Gs mixture provided the best performance, owing to its complementary root structure: under a normal stress of 200 kPa, its shear strength was 15-30% higher than that of the other plant types. Furthermore, strength evolved nonlinearly over time, peaking at 90 days after germination (for both cohesion and shear resistance), followed by a slight decrease at 120 days. This pattern highlights the importance of species selection and optimal implementation timing. The effect depends on plant age and species: maximum performance is reached between 90-120 days, and Gs shows clear superiority over monoculture. These conclusions provide a scientific basis for designing ecological slope protection systems.

Also, stability analyses using the finite element method (FEM) validated the practical benefits of plant roots on the factor of safety (FS), resulting in an increase of 1.7-15.7% compared to slopes without vegetation (FS = 1.48).

Specifically, slopes planted with Gs had the highest value (FS = 1.72), followed by those with Mm (FS = 1.66), and those with Cd recorded the lowest value (FS = 1.60).

Hydric stress

Hydric stress (water deficiency or excess) influences plant physiology, root development, and ultimately, soil reinforcement capacity.

Roots improve slope stability via mechanical reinforcement (e.g., tensile strength, soil-root bond strength) and hydrological regulation (Wu et al., 2013; Fan et al., 2021).

Hydric stress significantly alters root architecture, directly impacting soil cohesion (c) and friction angle (ϕ). Under drought conditions, moderate water deficits can enhance deep-rooting in resilient species like *Salix elaeagnos*, increasing root tensile strength

and soil cohesion by up to 25% due to adaptive root elongation, as demonstrated in cyclic drying experiments (Ghestem et al., 2011). Conversely, severe drought triggers root shrinkage and mortality, reducing root density by 50% and diminishing shear strength by 18-22% due to weakened root-soil interlocking, elevating landslide risks (Ng et al., 2016).

Waterlogging equally compromises shear strength through root degradation. Prolonged saturation depletes soil oxygen, causing root rot in sensitive species like *Alnus incana*, which exhibits 35% biomass loss and 40% tensile strength reduction (Francis et al., 2005). Saturated conditions also induce fiber slippage and diminish root-soil friction, leading to 30-50% cohesion loss in root-soil systems, as quantified by Ghestem et al. (2011). These biomechanical failures critically undermine slope stability during extreme hydric events.

Recent studies demonstrate that soil moisture dramatically influences root-soil resistance. Fan et al. (2021) observed a 63.9% decrease in pullout resistance under high moisture conditions (w = 30.6%), compared to low moisture conditions (w = 6.5%). This decline is attributed to reduced soil cohesion and the formation of water films at the root-soil interface. Furthermore, a critical root diameter threshold (3 mm in dry soil vs. 7 mm in wet soil) was identified, determining the transition between failure by breaking versus pullout. Field tests, which account for the intertwining of root hairs with soil, yield values 3-15 times greater than laboratory tests, underscoring the necessity of in situ evaluations. This integration highlights the impact of water stress on slope stabilization mechanisms, providing an empirical basis for risk management recommenddations under extreme climatic conditions

Climate-induced hydric stress (drought/floods) compromises root functionality, escalating landslide risks (Boldrin et al., 2018; Francis et al., 2005).

The use of vegetation in sustainable soil stabilization and erosion control provides numerous benefits, but also presents certain challenges that require careful evaluation. As shown in Figure 2, root systems bind soil particles, increasing shear strength and reducing susceptibility to erosion (creating a natural reinforcement mechanism). As an eco-friendly and cost-effective solution is well known that vegetation-based methods are sustainable, require low maintenance once established, and are generally less expensive than hard engineering solutions (Stokes et al., 2014). Along with the other strengths, the use of vegetation in sustainable soil stabilization and erosion control enhances biodiversity, promotes carbon sequestration, improves soil structure, and regulates hydrological cycles.

The weaknesses of the use of vegetation in soil stabilization and erosion control depend on a required growth period needed for root systems to get mature and effectively stabilize the slope; effectiveness depends on local soil, climate and plant species and requires careful selection and site-specific planning. Also, drought of frost can weaken root systems, reducing stabilization capacity during critical periods (Lüscher et al., 2020).

The use of vegetation in soil stabilization and erosion control can be combined with bioengineering and nature-based solution making an opportunity in order to align with global and EU strategies on climate resilience, land reclamation and disaster risk reduction (Mickovski, 2021, Olinic & Olinic, 2025).

The threats are related to: climate change - increased frequency and intensity of rainfalls which may exceed root system capabilities, triggering shallow landslides (Noviandi et al., 2025), land-use conflicts - when the expansion of urban of agricultural land may limit vegetation-based slope interventions) and invasive species risk - non-native or poorly managed vegetation may disrupt local ecosystems or fail to provide stabilization (Sladonja and Poljuha, 2018).

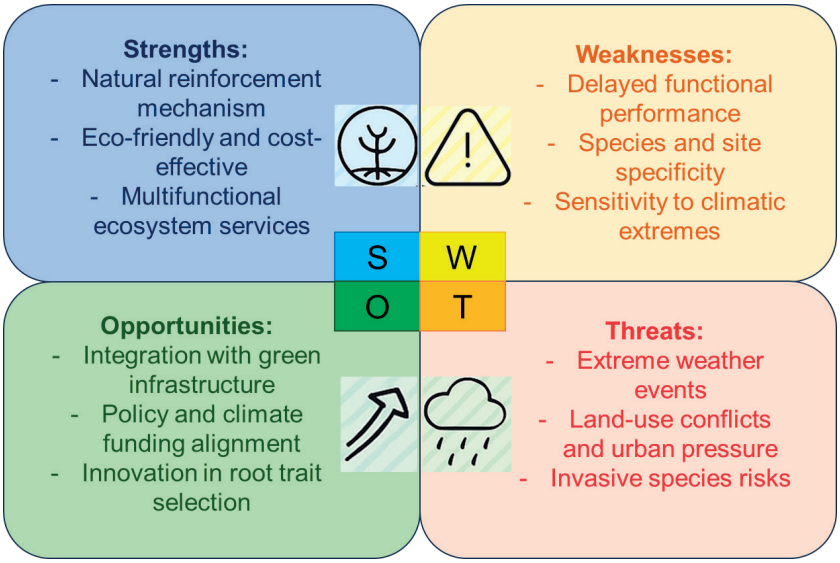

Figure 2. Vegetation for slope stabilization and surface erosion control

CONCLUSIONS

The shear strength parameters of soil-root systems are dynamic and highly sensitive to water stress. Effective slope stabilization strategies must incorporate (1) the selection of plant species based on their eco-physiological tolerance, and (2) the optimization of soil properties to mitigate the impacts of climate change.

Vegetation root systems significantly enhance slope stability through soil-root cohesion, with shear strength parameters serving as critical stability indicators. This review synthesizes global research on soil-root interactions across plant species and soil types, with emphasis on hydraulic stress impacts from climate change. Results demonstrate that root desiccation reduces shear strength by up to 64%, while interspecies variability in drought/flood tolerance dictates survival and reinforcement capacity. We argue that integrating root biomechanics with eco-physiological resilience is essential for sustainable slope management.

Plant roots, especially in the case of grass and shrub mixtures offer a sustainable solution for soil stabilization. Through the combined effect of deep roots (anchoring) and shallow roots (mechanical reinforcement), they reduce erosion and the risk of shallow landslides.

Vegetative root systems contribute to improving soil moisture regulation by facilitating water uptake and retention, thereby mitigating the likelihood of landslides triggered by slope saturation. In contrast to unsaturated, unvegetated slopes, analysing seepage and stability in vegetated terrains necessitates accounting for transpiration-induced variations in matric suction and the modified hydrological behaviour of soils influenced by plant activity.

Abstract

Studies on the influence of heavy metals are essential because they have a negative impact on human and animal health, the environment, and ecosystems. This work aims to assess the heavy metals content in soil and plant (Festuca rubra L.) samples collected from permanent grasslands in a heavily polluted area during 2023–2024. The total content and DTPA extractable forms of cadmium (Cd), lead (Pb), zinc (Zn), and copper (Cu) in soil and plant were analyzed. The mean value of total Cd content in soil was 5.50 mg/kg dry weight (DW), while the mean values for Pb, Zn and Cu were 201.1 mg/kg DW, 368.7 mg/kg DW and 46.9 mg/kg DW, respectively. In the plant the mean Cd content had the lowest value (0.47 mg/kg DW), the second lowest mean value was recorded for Pb, while the Zn content was the highest (47.6 mg/kg DW). The values of the correlation coefficients showed that heavy metals uptake by Festuca rubra varies according to the type of metal and its form in the soil. The results of this research showed that soils in the Copşa Mică area continue to have a high content of heavy metals, which may have a negative impact on the quality of human and animal life through their accumulation in the food chain.

Key words*: bioaccumulation, Festuca rubra L., heavy metals, meadows, pollution.*

INTRODUCTION

Mining, metal smelting, and agricultural practices are among the main anthropogenic activities that contribute to environmental contamination with heavy metals. Exposure to heavy metals, even in small quantities, through ingestion of contaminated food and water or inhalation of polluted air can lead to numerous health problems (Osman et al., 2019; Briffa et al., 2020; Budi et al., 2022).

Cd is a toxic heavy metal that is non-biodegradable, posing long-term risks to ecosystems and human health. Cd accumulation in plants causes oxidative stress and affects physiological processes (Suhani et al., 2021; Bouida et al., 2022).

Another microelement that can have negative effects in high amounts is Cu. Many studies have shown that Cu assimilation in high quantities can have numerous toxic effects on plants, such as growth inhibition observed through low seed germination rate, disruption of photosynthesis, oxidative stress, or nutrient imbalance (Adrees et al., 2015; Rehman et al., 2019; Mir et al., 2021).

Kuziemska et al. (2021) reported that the use of organic amendaments, especially cattle manure, reduces the bioavailability of Cu in soil. Also, the application of bacterial siderophores also promoted plant growth and improved phytoremediation by reducing metal toxicity (Grobelak et al., 2017).

Tan et al. (2020) reported that Zn plays an important role in plant metabolism.

However, Zn phytotoxicity can affect normal development, photosynthesis and nutrient uptake, but some plants are tolerant to high concentrations and have potential use in phytoremediation (Broadley et al., 2007; Kaur et al., 2021).

Festuca rubra L. is a perennial grass, widespread in various habitats around the world, used in the phytoremediation of contaminated soils due to its well-developed root system, large biomass and high capacity to grow in unfavorable environmental conditions (Gajić et al., 2020).

Phytoremediation is an ecological process of remediation of soils or water polluted with heavy metals. The phytoextraction process refers to the absorption and transfer of contaminants into the aerial parts of plants, while phytostabilization is the immobilization of contaminants in the roots of plants (Hrynkiewicz et al., 2018).

Pusz et al. (2021) analyzed the absorption capacity of heavy metals by red fescue (*Festuca rubra* L.) and reported that it accumulated higher amounts in roots compared to shoots.

Lago-Vila et al. (2015) demonstrated that red fescue can be grown on soils contaminated with heavy metals (Cd, Co, Ni) due to its high phytostabilization capacity.

Niesiobędzka (2023) demonstrated that the concentration of heavy metals in red fescue varies depending on the ecosystem, with the highest concentrations being found in plants grown in urban areas and along roads where the Pb content was above limits.

Red fescue is a species with high potential in phytoremediation of polluted soils, having the ability to retain high amounts of heavy metals in its roots (Gajić et al., 2016).

Mitrović et al. (2008) reported higher Zn concentrations in the roots of *Festuca rubra* compared to the aerial parts indicating a poor mobility of this metal in the plant. On the other hand, the phenomenon of wilting of young leaves was observed, being associated with Cu deficiency.

Wyszkowska et al. (2022) demonstrated that *Festuca rubra* exhibits higher resistance to Cd concentrations compared to Co, and the accumulation factor indicated that this plant has a high potential in the phytoremediation process for lands contaminated with these metals.

The study aims to assess the bioaccumulation of heavy metals (Cd, Pb, Zn, and Cu) by *Festuca rubra* plants from soil of permanent meadows affected by industrial pollution in the Copșa Mică area.

MATERIALS AND METHODS

This study was conducted in the most affected area by industrial pollution in Romania, Copșa Mică, during 2023-2024.

This area became known worldwide for its high pollution levels due to the two factories (Carbosin and Sometra) that operated in the past for approximately 60 years. Plant (aerial part) and soil samples were collected from the studied area to determine the content of heavy metals.

Festuca rubra plant samples harvested were oven dried then milled and treated with nitric acid in a microwave digestion system (Ethos Easy Microwave Dygestion System from Milestone).

Microwave digestion was performed using 10 mL mixture of HNO3 + H2O2 (9 mL HNO3 and 1 mL H2O2) at 210°C for 20 min, method developed in–house.

The measurement of heavy metals content was performed by atomic absorption spectrometry (Flame GBC 932AA to determine Zn and Cu content and Graphite furnace GBC SavanatAAZ to determine Cd and Pb content).

Soil samples were collected from the topsoil (0-20 cm). A soil sample was composed of 13 sub-samples, air-dried at room temperature, crushed, and sifted through a 0.2 mm to remove stones and plant waste.

For the determination of heavy metals content was used atomic absorption spectrometry, after the extraction by the aqua regia-microwave digestion method (Ethos Easy Microwave Dygestion System from Milestone).

Microwave digestion was performed using 10 mL of aqua regia (7.5 mL HCl and 2.5 mL HNO3) at 140°C for 30 min, method developed according to SR ISO 11466:1999.

(DTPA)–extractable heavy metals were extracted from soil (10 g) with 20 ml of extracting solution (0.05 M DTPA (dietilentriaminopentacetic acid), 0.01 M $CaCl_2$ and 0.1 M tetraethylammonium adjusted to pH 7.3), according to SR ISO 14870:2002.

Statistical data processing was performed using Microsoft Excel 2010.

RESULTS AND DISCUSSIONS

Based on the values of the statistical parameters that characterize the central tendency and variability of the total content of Cd, Pb, Zn and Cu in soil (Table 1), it was observed that the contents varied from 0.17 mg/kg DW to 17.74 mg/kg DW for Cd, between 13-692 mg/kg DW for Pb, while the content of Zn and Cu had values ranging between 42-993 mg/kg DW, respectively 12-161 mg/kg DW.

Regarding the median results, the highest value 223 mg/kg DW was recorded for Zn and the second highest in the case of the Pb content (118 mg/kg DW). Cu had a median value of 29 mg/kg DW, while the lowest value was observed for Cd (3.24 mg/kg).

Analyzing the values obtained for the geometric mean, they varied from 3.13 mg/kg DW for Cd to 255.9 mg/kg DW for Zn content. The geometric mean values for Pb and Cu contents were 126.5 mg/kg DW and 36.8 mg/kg DW, respectively.

Table 1. Values of statistical parameters that characterize the central tendency and the variability of the total cadmium, lead, zinc and copper contents in soil (n = 17)

Variable	Minimum	Maximum	Median	Geometric mean	Arithmetic mean	Standard deviation	Coefficient of variation
				mg/kg DW			
Cd_{soil}	0.17	17.74	3.24	3.13	5.50	5.50	100%
Pb_{soil}	13	692	118	126.5	201.1	188	93.5%
Zn_{soil}	42	993	223	255.9	368.7	297.8	80.8%
Cu_{soil}	12	161	29	36.8	46.9	38	81%

DW - dry weight

Regarding the arithmetic mean (Table 1), the heavy metals contents followed the order: Zn>Pb>Cu>Cd. The highest content was recorded by Zn at 368.7 mg/kg DW followed by the Pb content (201.1 mg/kg DW). Cu content had the third highest value (46.9 mg/kg DW) while the lowest content (5.50 mg/kg DW) was recorded for Cd.

According to the Order of the Ministry no. 756/1997 for the approval of the Regulation on the assessment of environmental pollution, the mean values for the Cd and Pb contents exceeded the alert threshold of 3 mg/kg, respectively 50 mg/kg and the intervention threshold of 5 mg/kg and 100 mg/kg for sensitive land use while, the mean values for the Zn and Cu contents remained within normal limits, below the alert thresholds of 300 mg/kg and, respectively, 200 mg/kg.

Muntean et al. (2010) obtained similar results regarding the Cd and Pb content in soil in Copșa Mică area.

Following the results for standard deviation, Cd had the lowest value (5.50 mg/kg DW), while Zn recorded the highest (297.8 mg/kg DW). The standard deviation for Pb was 188 mg/kg DW and for Cu, it was 38 mg/kg DW. A large standard deviation for Pb and Cd indicates that pollution is not evenly distributed.

Analyzing the values obtained for the coefficient of variation (Table 1), it is observed that Cd obtained the highest value (100%) followed by Pb which recorded the second highest result (93.5%). In comparison, the content of Cu and Zn recorded values of 81% and 80.8%, respectively.

The high values of the coefficients of variation indicate an uneven distribution of pollution in the 17 analyzed points suggesting non-uniform pollution.

The studied area is characterized both by a wide variability of soil types and the degree of heavy metal contamination.

Shabbir et al. (2020) reported that the main soil characteristics that influence the mobility and availability of Cu in the soil and uptake by plants are pH and organic matter.

Intrinsic soil factors and environmental variables such as pH, soil organic matter and topographic moisture index influence the spatial variation of heavy metals in soil (Wu et al., 2020).

Analyzing the values of statistical parameters that characterize the central tendency and variability of Cd, Pb, Zn and Cu content in soil – DTPA-extractable forms (Table 2), the order of heavy metals was as follows: Zn>Pb>Cu>Cd except for the values obtained for the coefficient of variation where the metals were ranked as: Pb>Cd>Zn>Cu.

Following the minimum and maximum values for the extractable forms, Cd content ranged from 0.08 mg/kg DW to 15.44 mg/kg DW, Pb varied between 2.7 mg/kg DW and 301 mg/kg

DW, Zn ranged from 2.6 mg/kg DW to 326.8 mg/kg DW, while Cu were between 1.13 mg/kg DW to 23.41 mg/kg DW.
Regarding the median values, Cd had the lowest value (2.28 mg/kg DW), while Zn had the highest (63.2 mg/kg DW). Pb had a median value of 58.8 mg/kg DW, whereas Cu obtained 4.83 mg/kg DW.

Table 2. Values of statistical parameters that characterize the central tendency and the variability of the cadmium, lead, zinc, copper contents in soil – DTPA-extractable forms (n = 17)

Variable	Minimum	Maximum	Median	Geometric mean	Arithmetic mean	Standard deviation	Coefficient of variation
			mg/kg DW				
Cd_{DTPA}	0.08	15.44	2.28	2.31	4.27	4.54	106.3%
Pb_{DTPA}	2.7	301	58.8	39	73	79.2	108.5%
Zn_{DTPA}	2.6	326.8	63.2	51.5	105.2	111.2	105.7%
Cu_{DTPA}	1.13	23.41	4.83	5.22	6.90	6.22	90.1%

DW–dry weight

Analyzing the results for the geometric mean, the highest value was obtained by Zn (51.5 mg/kg DW), Pb had the second highest value (39 mg/kg DW), while Cd and Cu obtained results of 2.31 mg/kg DW and 5.22 mg/kg DW, respectively.
Following the arithmetic mean values, they ranged between 4.27 mg/kg DW for Cd and 105.2 mg/kg DW Zn.
Pb had an arithmetic mean of 73 mg/kg DW, while Cu recorded 6.90 mg/kg DW.
Regarding the standard deviation, the lowest value was obtained for Cd (4.54 mg/kg DW), followed by Cu with a value of 6.22 mg/kg DW.
Pb had a standard deviation of 70.2 mg/kg DW, while Zn had the highest value (111.2 mg/kg DW).
Analyzing the coefficient of variation, the highest result was obtained by Pb (108.5%) and the lowest by Cu (90.1%). For the other metals, the values were 106.3% for Cd and 105.7% for Zn, respectively.
The high values obtained for the coefficient of variation and standard deviation indicate that pollution does not show a uniform distribution and that there are areas where the accumulation of heavy metals is significant. The median values are not influenced by extremes as is the case for the arithmetic mean. At the same time the geometric mean indicates a possibly asymmetric distribution of pollution.
Table 3 shows the statistical parameters that characterize the central tendency and variability of heavy metals content (Cd, Pb, Zn and Cu) in *Festuca rubra* plants.

Table 3. Values of statistical parameters that characterize the central tendency and the variability of the cadmium, lead, zinc, and copper contents in the red fescue (*Festuca rubra* L.) (n = 17)

Variable	Minimum	Maximum	Median	Geometric mean	Arithmetic mean	Standard deviation	Coefficient of variation
			mg/kg DW				
$Cd_{F.rubra}$	0.01	1.64	0.39	0.16	0.47	0.48	102.1%
$Pb_{F.rubra}$	0.09	1.92	0.35	0.36	0.62	0.61	98.4%
$Zn_{F.rubra}$	7.4	89.2	50.1	36.0	47.6	29.5	62%
$Cu_{F.rubra}$	1.19	7.53	3.35	3.44	3.84	1.79	46.6%

DW - dry weight

The ability of *Festuca rubra* to accumulate Cd, Pb, Zn and Cu indicates that it can be used in the phytoremediation of polluted soils (Gajić et al., 2020; Pusz et al., 2021).

Korzeniowska and Stanislawska-Glubiak (2023) demonstrated in a study regarding Zn accumulation in different grass species that *Festuca rubra* compared to *Deschampia caepitosa* is more suitable for phytostabilization than for phytoextraction because it has the ability to retain this element in the roots and limits the translocation to the leaves.

Gołda & Korzeniowska (2016) showed that *Festuca rubra* accumulates high amounts of Cd in the roots and translocates very small amounts to the aerial parts.

Fernández et al. (2017) reported that *Festuca rubra* is an efficient species for phytostabilization of heavy metals especially mercury and arsenic from contaminated areas.

Wyszkowska et al. (2022) investigated the potential use of *Festuca rubra* in phytostabilization of soils contaminated with heavy metals, including Zn and Cu and the results demonstrated that this species efficiently accumulates these metals, being suitable for phytostabilization in contaminated environments.

Based on the minimum and maximum heavy metals content in the plant, Cd levels ranged from 0.01 mg/kg DW to 1.64 mg/kg DW, while Pb varied between 0.09 mg/kg DW and 1.92 mg/kg DW, Zn content ranged from 7.4 mg/kg DW to 89.2 mg/kg DW, while Cu levels were between 1.19 mg/kg DW and 7.53 mg/kg DW.

Analyzing the median values, the highest concentration was obtained by Zn (50.1 mg/kg DW), while Pb had the lowest (0.35 mg/kg DW). The median values for Cd and Cu were 0.39 mg/kg DW and 3.35 mg/kg DW, respectively.

Analyzing the arithmetic mean values, Zn had the highest concentration (47.6 mg/kg DW), followed by Cu (3.84 mg/kg DW). The mean values for Cd and Pb were 0.47 mg/kg DW and 0.62 mg/kg DW respectively.

The arithmetic mean significantly higher than the median in the case of Pb and Cd (0.62 mg/kg DW vs. 0.35 mg/kg DW and 0.47 mg/kg DW vs. 0.39 mg/kg DW, respectively), suggests the presence of potential contamination hotspots while for Cu, the small difference between the mean and the median indicates a more uniform distribution.

Regarding the geometric mean, values ranged from 0.16 mg/kg DW for Cd to 36 mg/kg DW for Zn. The geometric mean values for Pb and Cu were 0.36 mg/kg DW and 3.44 mg/kg DW, respectively.

In a study conducted by Gómez et al. (2016) they showed that *Festuca rubra* tolerates high concentrations of Zn but is sensitive to Pb, especially in the mobile form (Pb-EDTA).

However, in a study by Begonia et al. (2005), the addition of EDTA and acetic acid was shown to enhance Pb uptake in tall fescue by increasing its translocation index, leading to higher Pb concentrations in shoots. This suggests that chelate amendments may improve the efficiency of tall fescue for phytoextraction.

In terms of standard deviation, Cd had the lowest value (0.48 mg/kg DW), the second lowest result was for Pb (0.61 mg/kg DW), followed by Cu with a value of 1.79 mg/kg DW, while Zn obtained the highest value (29.5 mg/kg DW).

Following the coefficient of variation, the highest value was obtained by Cd (102.1%) and the lowest value (46.6%) by Zn. Pb had a value of 98.4% while Cu obtained 62%.

The very high values of the coefficient of variation obtained for Cd and Pb (102.1% and 98.4%, respectively) suggest an extremely non-uniform accumulation of these metals in the plant indicating significant differences between harvesting points while the lower values obtained for Zn and Cu (62% and 46.6% respectively) suggest a more balanced accumulation in the sampled plants.

Following the high values obtained for standard deviation and coefficient of variation suggest that some areas are more affected than others.

Analyzing the log-log diagram for the power regression curves (Figure 1a), it can be observed that the correlation coefficient had distinctly significant value ($r = 0.697^{**}$) indicating a significant positive relationship between total Cd concentration in soil (mg/kg DW) and Cd concentration accumulated in the plant (*Festuca rubra*).

Similarly, the correlation coefficient value for soil Cd content DTPA-extractable form was also distinctly significant ($r = 0.659^{**}$) indicates a statistically significant correlation, but slightly weaker than for total Cd.

This relationship may signal a high mobility of Cd in soil and increased bioavailability, which

makes *Festuca rubra* an effective bioindicator of soil Cd contamination.

In a study conducted by Dong et al. (2019), they reported that tall fescue is effective in phytoremediation of Cd. They demonstrated that plants extract Cd from soil and can excrete it through leaves via hydathodes.

However, to reduce the risk of bioaccumulation it is necessary to add soil amendments that reduce Cd mobility, such as biochar, lime or zeolites.

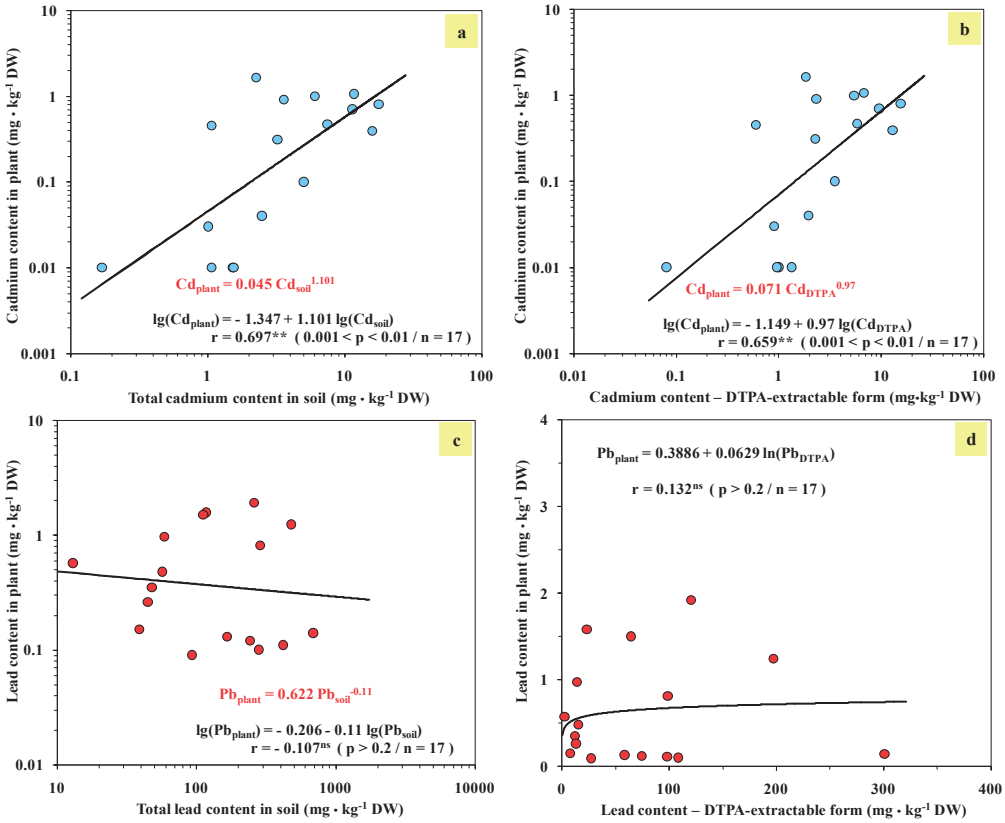

Figure 1. Log-log diagrams for power regression curves that estimate the stochastic dependency between total cadmium content in soil (a), soil cadmium content – DTPA-extractable form (b), total lead content in soil (c), soil lead content – DTPA-extractable form (d) and cadmium/lead contents in *Festuca rubra* plants

Figures 1c, 1d show the relationship between the total Pb and DTPA-extractable form contents in the soil and Pb accumulated in the plant. A very weak correlation is observed suggesting that these parameters are not suitable to assess the accumulation of Pb in aerial parts of *Festuca rubra* plants.

The absorption and toxicity of Pb depends on both time and concentration and affects plants by reducing the rate of seed germination and impairing the ability to absorb nutrients due to its interference with enzymatic activities (Zulfiqar et al., 2019).

According to log-log diagram (Figure 2a) which presents the power regression curves that estimate the stochastic dependence between the total Zn content in soil and Zn content in *Festuca rubra*, the correlation coefficient had a highly significant value (r = 0.826***) indicating a strong correlation.

A highly significant value (r = 0.885***) of the correlation coefficient is also observed for the Zn DTPA–extractable form indicating that bioavailable of this metal is a determining factor for accumulation in the plant.

Wołejko et al. (2013) investigated the impact

of sewage sludge on the accumulation of heavy metals in soil and grass mixtures (*Lolium perenne*, *Festuca rubra* and *Poa pratensis*). They demonstrated that the application of sewage sludge positively influenced the growth of the grass mixture, with Cd, Zn and Cu being more readily assimilated by plants than Pb and Ni.

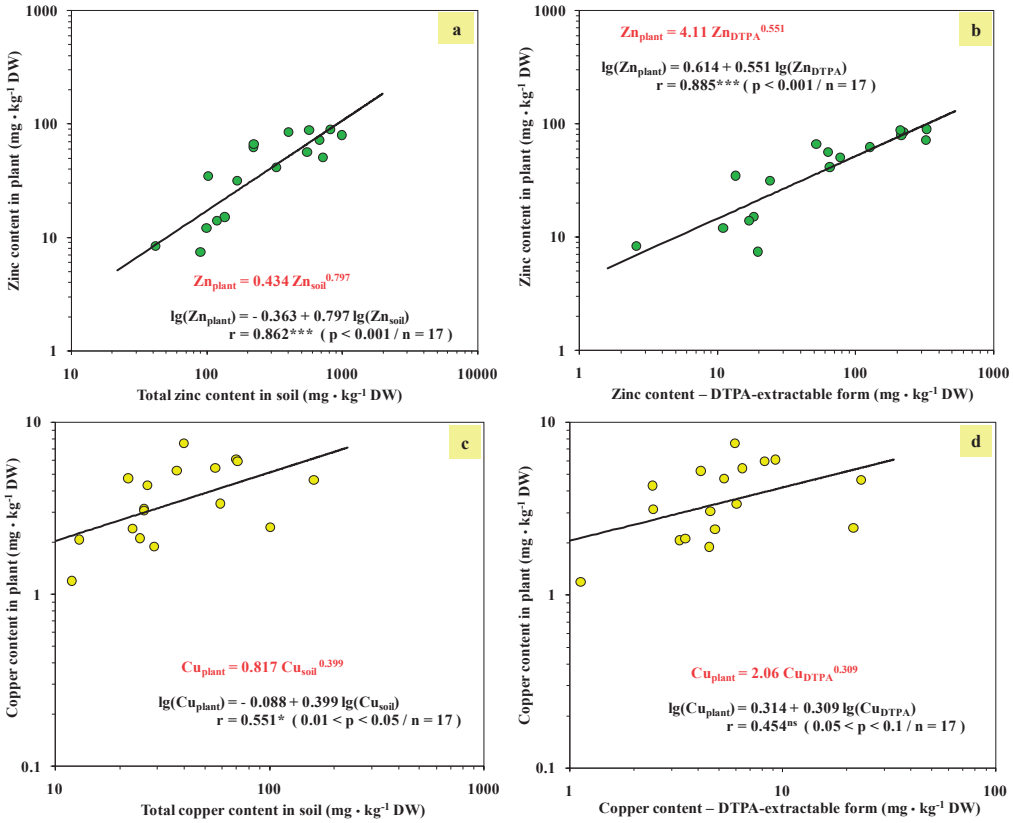

Figure 2. Log-log diagrams for power regression curves that estimate the stochastic dependency between total zinc content in soil (a), soil zinc content – DTPA–extractable form (b), total copper content in soil (c), soil copper content – DTPA–extractable form (d) and zinc/copper contents in *Festuca rubra* plants.

Analyzing the log-log diagram for the power regression curves that estimate the stochastic dependence between total Cu content in the soil and Cu content in plants (Figure 2c), it can be observed that the correlation coefficient value was significant (r = 0.551*). However, in the case of Cu content DTPA-extractable form (Figure 2d), it can be observed that the correlation coefficient value was insignificant (r = 0.454) suggesting a low accumulation rate of bioavailable Cu in the plant.

This could indicate either a higher Cu tolerance or an active uptake-regulating mechanism. Malagoli et al. (2014) reported that *Festuca rubra* accumulates more Cu in its roots than in its aerial parts.

Padmavathiamma and Li. (2009), demonstrated that *Festuca rubra* accumulated high amounts of Cu in the roots indicating that it is a plant that can be successfully used in the phytostabilization process.

CONCLUSIONS

Cd content in soil recorded the lowest mean value (5.50 mg/kg total content and 4.27 mg/kg DTPA-extractable form) while Zn had the highest mean value (368.7 mg/kg total

content and 105.2 mg/kg DTPA-extractable form).

The bioaccumulation of Cd and Zn in aerial parts of the plant (*Festuca rubra*) can be estimated using the total content and DTPA–extractable forms in soil. However, for Cu and Pb, due to their low mobility within the soil–plant system, the studied parameters are not suitable indicators of bioaccumulation.

The results of this research showed that soils in the Copșa Mică area continue to have a high content of heavy metals, which may have a negative impact on the quality of human and animal life through their accumulation in the food chain. Continuous monitoring of areas at risk of heavy metals contamination is needed to assess the dynamics of heavy metals accumulation in soil and plants. Such research is essential for tracking changes in contamination levels and determining the safety of using pastures for livestock farming or using land for crop growing.

Abstract

Research was conducted on the state of atmospheric air in the region of the village of Voyvodino, Maritsa municipality, and Plovdiv district, Bulgaria, influenced by industrial sources of impact. The indicators of main pollutants of the atmospheric air above populated areas were measured (PM10, SO2, CO, NO2, NO, O3, Benzene, Toluene, m-p-xylene, o-xylene). The research was carried out according to established standards. The chemical and ecological state is presented. The air quality index is analyzed. An ecological assessment of the state of atmospheric air was carried out. The risk to human health, the impact of pollution on living organisms, on protected species, habitats and territories was assessed. Measures to improve the ecological state of the air have been identified.

Key words*: air pollution, air quality index, chemical state, ecological assessment, industrial impact.*

INTRODUCTION

Clean air is a fundamental human right. Air pollution is identified as the biggest environmental threat to health and a leading cause of non-communicable diseases such as heart attack and stroke. According to World Health Organization (WHO), "there are no safe levels of air pollution". The organization identifies air pollution as one of the risk factors for early mortality worldwide (WHO, 2021; EEA, 2024). Article 6 of Directive 2016/2284/EU requires each EU Member State to submit a national air pollution control program (Directive (EU) 2016/2284 of The European Parliament and of the Council, 2016). Air pollution emissions have decreased significantly in recent decades. Nevertheless, problems with pollutant emissions from individual industries persist (Directive (EU) 2024/2881 of the European Parliament and of the Council, 2024; Nunez et al., 2024).

There are different systems for ambient air quality in individual countries and regions. Each system uses its own hazard index, pollution concentration, and time of measurement. This makes it difficult for the average consumer to navigate between the systems of different countries.

The United States Environmental Protection Agency (US-EPA) defines the Air Quality Index (AQI) – a number used to inform the public about the level of air pollution and to predict the expected level of pollution. The AQI is based on measurements of particulate matter emissions (PM2.5 and PM10), ozone, nitrogen dioxide, sulfur dioxide, and carbon monoxide. The AQI values indicate 6 levels of air pollution, each of which is color-coded and provides information on possible health effects (Table 1). The AQI provides the public with important information about the state of air pollution over the past five decades (Sheikh, 2019; Horn & Dasgupta, 2024).

The European Environment Agency is developing and implementing the European Air Quality Index (EAQI) for the countries of the European Union. The (EAQI) is based on the measurement of the following main pollutants in ambient air: PM10, PM2.5, ozone, nitrogen

dioxide and sulphur dioxide. The scale for each pollutant is different, and for PM10 it is presented in Table 2. The individual zones are based on the relative health risk, as defined by the World Health Organization, associated with short-term exposure to the pollutants. The Air Quality Index is not a tool for checking compliance with air quality standards but allows users to orient themselves on the quality of ambient air in populated areas or in places of travel and work.

These indices raise public awareness of the importance of clean air and help build broader support for air quality and emissions regulations. As regulatory constraints change, both indices change, keeping them relevant and alive (Sheikh, 2019; EAQI, 2024).

Table 1. Air Quality Index (AQI) values and corresponding condition color scale

Values	Condition color scale
0-50	good
51-100	moderate
101-150	unhealthy for sensitive individuals
151-200	unhealthy
201-300	very unhealthy
300+	dangerous

Table 2. European Air Quality Index (EAQI) values for PM10 and the corresponding condition color scale

EAQI, PM10, µg/m^3	Condition color scale
0-20	good
20-40	fair
40-50	moderate
50-100	poor
100-150	very poor
150-1200	extremely poor

There is growing interest in the contribution of fine particulate matter to air quality, climate and human health. The negative effects of these particles depend mainly on their chemical composition and physicochemical properties (Lei et al., 2024).

In aerosol science, heavy metal pollution is also a current problem, especially when it comes to road dust in densely populated cities. The main sources of heavy metals in road dust are industrial activities (32.05%), transport (34.90%), and a combination of transport, industrial, and construction activities (33.05%) (Ma et al., 2025).

The increase in public health incidents resulting from air quality, as well as environmental degradation, is prompting authorities and experts to improve and seek new ways to monitor air quality and "adequately" deploy air quality sensors (Chaudhuri & Roy, 2024).

Air pollution continues to have a negative impact on the health of Europeans. A significant part of Europe's population lives in cities where EU air quality standards to protect human health are often exceeded. These health impacts shorten lives, increase economic and medical costs and reduce work productivity. The pollutants with the most serious impact on human health are particulate matter, nitrogen dioxide and ground-level ozone. According to the latest EEA estimates, at least 239,000 deaths in the EU in 2022 were due to exposure to PM2.5 pollution above the WHO recommended limit 5 µg/m^3. 70,000 deaths were due to exposure to ozone pollution, and 48,000 deaths were due to exposure to nitrogen dioxide pollution. These deaths could have been avoided if WHO guidelines had been followed (EEA, 2024a).

For Bulgaria, deaths due to long-term exposure to fine particles decreased by 53% between 2005 and 2022. Yield losses due to ozone exposure at the national level in 2022 were estimated at 1.98% yield loss for wheat and 4.22% yield loss for potatoes. This represents an economic loss of approximately €26 million for wheat and €1.6 million for potatoes (EEA, 2024a).

Air pollution has a negative impact on both terrestrial and aquatic ecosystems, degrading the environment and reducing biodiversity. Different pollutants damage ecosystems in different ways. Ozone (secondary air pollutant) damages crops, forests and plants by reducing growth rates, lowering yields and affecting biodiversity. Reduced yields of wheat and potatoes demonstrate the negative impact of ozone layer, with losses expected to amount to €1.3 billion for wheat and €680 million for potatoes across Europe by 2022.

Nitrogen deposition on land and in water bodies is mainly caused by ammonia from agricultural activities and nitrogen oxides from combustion processes. In water bodies, increased nitrogen content contributes to eutrophication, characterized by algal blooms and less available oxygen due to excess nutrients. In sensitive terrestrial ecosystems, such as grasslands, exceeding critical loads for nitrogen deposition can lead to the loss of sensitive species. At the

same time, species requiring high levels of nitrogen may develop excessively, which can alter the structure and function of the ecosystem. Sulfur dioxide can also have a significant negative impact on ecosystems. Its deposition can lead to changes in the chemical composition of soil, lakes, rivers and seas. This can cause acidification, which disrupts ecosystems and leads to a loss of biodiversity. A major source of SO_2 is coal-based energy.

Heavy metals are toxic pollutants that travel long distances in the atmosphere and are deposited in ecosystems. They accumulate in soils and subsequently bioaccumulate and biomagnify in the food chain (i.e., concentrations of substances in animal tissues increase progressively through the food web). The main sources of heavy metals include the processing and mining industries, energy, and road transport.

Europe's waters continue to be affected by chemicals, mainly from atmospheric pollution from coal-fired power generation and diffuse pollution from agriculture. The main pollutants in surface waters are related to pollution from diffuse sources, such as atmospheric deposition (52%) (Impacts of air pollution on ecosystems in Europe, 2024)

The latest data confirms once again that Europeans remain exposed to concentrations of air pollutants well above the World Health Organization (WHO) recommended levels. Nearly three quarters of European ecosystems are exposed to harmful levels of air pollution (EEA, 2024).

The main indicators characterizing the quality of atmospheric air in the ground layer are suspended particles, fine dust particles, sulfur dioxide, nitrogen dioxide and/or nitrogen oxides, carbon monoxide, ozone, lead (aerosol), benzene, polycyclic aromatic hydrocarbons, heavy metals - cadmium, nickel and mercury, arsenic (RIAA, 2023; 2024).

The present research concerns the region of Plovdiv, Bulgaria. The territory of the city is urbanized, with high density of construction, intensive automobile traffic and industrial activity. The main factors of air pollution are combustion processes, transport, the condition of the road and adjacent infrastructure and finally the industrial sector. During the summer period, construction and repair-construction activities acquire significant importance for atmospheric air pollution.

Specific climatic conditions have a significant impact on the quality of atmospheric air. The Plovdiv Field is alluvial lowland formed by the Maritsa River and its tributaries. There is a so-called trough-shaped morphostructure, at the "bottom" of which the city is located. Plovdiv is located on six syenite hills. These natural features significantly contribute to the adverse meteorological conditions associated with temperature inversions, fogs along the Maritsa River, long periods of drought and a large number of days a year with calm weather, reflecting on the dispersion of locally emitted pollutants. (RIAA, 2023; 2024).

MATERIALS AND METHODS

The measurements were carried out hourly with a Mobile Automatic Station in 2023 in spring (13 days), summer (14 days) and autumn (16 days) (Figure 1). The following main indicators of atmospheric air quality were recorded – Particulate matter, Sulphur dioxide, Carbon monoxide, Nitrogen dioxide, Nitrogen monoxide, Ozone, Benzene, Toluene, m-p-xylene, o-xylene. The main characteristics of these indicators are presented in Table 3. The total number of samples taken is as follows – 3116 for spring, 3240 for summer and 2784 for autumn. The production activities carried out in the study area are in the field of metalworking, chemical and food industry.

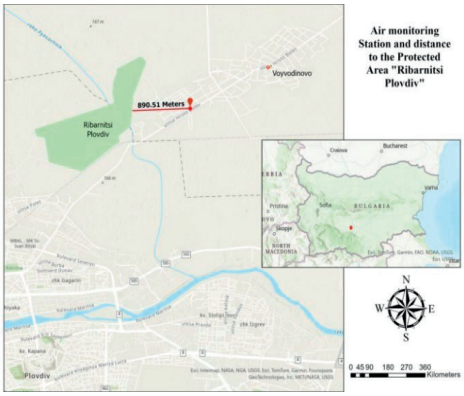

Figure 1. Location of the air monitoring station and the protected area "Ribarnitsi", Plovdiv

The dust emissions formed are of short-term local nature, with a low discharge height and high gravitational deposition velocity (RIAA, 2023; 2024).

Table 3. Main characteristics of the measured indicators

Indicator	Unit of measure	Analysis method	Uncertainty	Standard, μg/m³
Particulate matter	μg/m³	BDS EN 16450:2017	U=14.7%	ADN – 50 AAN – 40
Sulphur dioxide	μg/m³	BDS EN 14212:2012	U=3.70%	AHN – 325 AND – 125
Carbon monoxide	μg/m³	BDS EN 14626:2012	U=3.75%	HHPS – 10
Nitrogen dioxide and Nitrogen oxides	μg/m³	BDS EN 14211:2012	U=3.74%	AHN – 200 AAN – 40
Ozone	μg/m³	BDS EN 14625:2012	U=3.60%	HHPS – 120
Benzene	μg/m³	BDS EN 14662-3:2015	U=4.5%	AAN – 5

Legend: ADN – Average daily norm for the protection of human health; AAN – Average annual norm for the protection of human health; AHN – Average hourly norm for protecting human health; HHPS – Human health protection standard (maximum eight-hour average value within 24 hours); Regulation No. 12 (2010).

The norm for the PM10 indicator is average daily, that is, the registered hourly values during the day are averaged, which does not imply exceedances of the average daily values, due to the fact that the likely intensive transport traffic is in the period 08.00 – 17.00. Based on the results obtained in 2023, an assessment of the pollution levels in the studied area was carried out in accordance with the requirements of the currently current Regulation No. 12 of 2010 (Regulation No. 12, 2010).

RESULTS AND DISCUSSIONS

The measurements in 2023 were carried out with a Mobile Automatic Station in spring, summer and autumn, as indicated in the previous chapter. The choice of the location of the station is in accordance with the requirements of Regulation No. 12 of 2010 (Regulation No. 12, 2010). The monitoring station is a non-urban background station, located more than 5 km from the city of Plovdiv (Figure 1). Point sources of emissions from industrial sites are located more than 5 km from the station area. In the area studied there are both industrial enterprises and residential buildings.

Emission sources can be combustion processes; road transport; other mobile sources and machinery; natural processes - adverse weather conditions that contribute to the accumulation and hinder the dispersion of pollutants.

The results obtained as a range of values are presented in Table 4.

Table 4. Interval of measured daily average concentrations for the reported indicators by season

Indicator	Value range, μg/m³		
	spring	summer	autumn
Particulate matter	9 ÷ 48	15 ÷ 33	23 ÷ 73
Sulphur dioxide	8 ÷ 14	1 ÷ 10	7 ÷ 16
Carbon monoxide	0.1 ÷ 0.4	0.2 ÷ 0.4	0.2 ÷ 0.4
Nitrogen dioxide	7 ÷ 23	9 ÷ 15	10 ÷ 34
Nitrogen monoxide	1 ÷ 8	1 ÷ 2	1 ÷ 12
Ozone	30 ÷ 67	37 ÷ 66	17 ÷ 53
Benzene	0.20 ÷ 0.60	0.12 ÷ 0.25	0.27 ÷ 0.40
Toluene	0.17 ÷ 1.35	0.24 ÷ 0.70	0.39 ÷ 0.58
m-p-xylene	0.14 ÷ 0.67	0.27 ÷ 0.61	0.34 ÷ 2.10
o-xylene	0.06 ÷ 0.23	0.01 ÷ 0.17	0.09 ÷ 0.49

The only exceedances of the average daily concentrations were for PM10 during the autumn period – 56, 61, 70 and 73μg/m³ at a norm of 50μg/m³. All other measured average daily indicators have values in accordance with the regulatory requirements.

The hourly exceedances of the norm for the average daily concentration (50 μg/m³) are only for the PM10 values for the measurement intervals during the 3 seasons (Table 5). Of the total 1032 hourly PM10 values obtained for the measurements made during the spring, summer and autumn seasons, 10.17% (105 values) indicate poor air quality; 1.07% (11 values) indicate very poor air quality, and 0.48% (5 values) indicate extremely poor air quality (Table 5). The main PM10 assessment indicators for ambient air quality are summarized in Table 5.

The lower and upper assessment thresholds for the average daily and annual values are two exceedances of the upper threshold for spring, one for summer and 10 for autumn. The average annual norm of the upper threshold is exceeded based on the results obtained for the three seasons 31.30 μg/m³.

This exceedance is below the average daily norm for the protection of human health (50 μg/m³) and below the average annual norm for the protection of human health (40 μg/m³) from the legislation in Bulgaria (Regulation No. 12, 2010).

With increasing temperatures, PM10 values decrease, which is why lower maximum short-term (60 minutes) single values and average daily values are recorded during summer days.

Table 5. Summarized exceedances of PM10 according to the main assessment standards for ambient air quality

Criteria	Overshoots, µg/m³		
	spring	summer	autumn
Maximum hourly values measured, µg/m³	198 461	57 85 52 88	60 53 94 114 70 84 71 150 55 63 69 139 178 159
Number of hourly exceedances of the average daily norm (over **50** µg/m³)	10	5	107
Average daily norm for the protection of human health - **50** µg/m³ (exceeded no more than 35 times per calendar year)	-	-	56 61 70 73
Lower and upper assessment thresholds - norm **25 – 35** µg/m³ **average daily value** (exceeded no more than 35 times per calendar year)	43, 48	36	43, 47, 56, 47, 61, 40, 42, 49, 70, 73
Lower and upper assessment thresholds - norm **20-28** µg/m³ **average annual value**	**31.30 µg/m³ – upper assessment threshold exceeded for the period spring, summer and autumn**		
Average annual norm for the protection of human health - **40** µg/m³	–		

Legend: EAQI – poor, very poor, extremely poor; Regulation No. 12 (2010).

In calm weather (wind speed < 1.5 m/s) and fog, pollutants are retained and accumulated. The number of days and nights with calm weather during the periods of measurements taken is respectively: 7 in spring, 14 in summer and 15 in autumn. As humidity increases, the levels of pollutants in the air decrease. According to the PM10 indicator, maximum short-term values were not recorded only at 100% relative humidity. Such are only 5 days of the reporting periods. The hourly and daily average exceedances recorded during the autumn period from the measurements of the quality of the ambient air in the range of 20.00-07.00 hours of the day could be the result of the operation of wood and coal-fired heating appliances, although the night temperatures in October and the reporting period are not low, but also as a result of the certain meteorological conditions that hinder the dispersion of pollutants (calm, others). Overall, for the year - the unfavorable climatic conditions in the region - more than 50% days a year with calm weather and over 75% days a year with inversion processes, lead to the retention of the formed relatively high background concentrations of PM10.

The impact of the obtained values of the monitored air quality parameters on the health of the population was assessed on the basis of the Environmental Protection Act, the Clean Air Act, the Health Act, and Regulation No. 12 from 2010 on standards of harmful substances in the ambient air of populated areas. (AAPL, 1996; Law on environmental protection, 2002; Law of Health, 2005; Regulation No. 12, 2010).

The exceeded average daily values indicate acceptable ambient air quality, moderately dangerous for very sensitive people with respiratory diseases. The hourly standards exceed the average daily standard by 1.02 – 9.22 times. Of the total 1032 hourly values for PM10 obtained, 8.72% of the values (90 values) indicate a moderate state of ambient air quality, with a risk for very sensitive people with respiratory diseases; 0.39% (4 values) indicate an unhealthy state of ambient air quality for sensitive groups of the population; 0.1% or 1 value is dangerous for the entire population. Even though the relative share of the results for the most part indicates a good state of AQI (below 50 µg/m3; 90.60%, 937 values), the obtained exceedances are not to be ignored, especially those associated with risks to human health.

PM is not a single substance, but a mixture of pollutants with different chemical properties and varying physical properties such as size and surface area, which has a major impact on the distribution and deposition in the respiratory tract. A significant relationship has been found between high PM concentrations and mortality, hospital admissions for respiratory diseases, and person-days of bronchodilator use.

The resulting exceedances have a negative impact on the health of the population. The increase in PM levels is also expected to affect cultural, household, agricultural and other economic activities. All this requires immediate measures to be taken to eliminate the sources of pollution and provide permanent control by the control bodies, aimed at achieving good

ecological status for PM10 and the overall quality of air.

The protected area BG0002016 "Fisheries Plovdiv" is located near the assessed site (Figure 1; Natura 2000).

The objectives of declaring the protected area are related to the protection and maintenance of the habitats of the bird species specified in the Biodiversity Act to achieve their favorable conservation status, as well as the restoration of the habitats of those bird species for which it is necessary to improve their conservation status (Biodiversity Law, 2002).

Of the total 43 protected species, 39 bird species are concentrated in the protected area (c), 15 species are wintering (w, non-migratory species) and 3 species are breeding in the protected area (r). Two of the species are not sufficiently studied in the protected area but are represented (p; *Ardea cinerea* and *Tachybaptus ruficollis*). Overall, the quality of data on birds in the protected area is good (G), with minor exceptions (2 cases with insufficient study (DD) and one with moderate (M)). Of the 43 protected bird species, the International Red Data Book includes: 33 species with the category Least Concern (LC); 4 species with the category Vulnerable (VU); 5 species with the category Near Threatened (NT). 18 species are included in Appendix 2 of the Bern Convention; 16 species – in Appendix 3 and respectively 2, 23 and 1 species are included in Appendix 1, 2 and 3 of the Bonn Convention. In CITES – Appendices 1 and 2, 1 and 5 species are included respectively, and in the Birds Directive – 16 species in Annex 1 and 3 and in Annex 3. The Red Book of the Republic of Bulgaria includes 28 species with the following protection categories: vulnerable (VU) – 12 species; endangered (EN) – 8 species; critically endangered (CR) – 7 species; near threatened (NT) – 1 species. The Biodiversity Act protects: 16 species included in Annex 2; 26 species included in Annex 3 and 1 species included in Annex 4 (Biodiversity Law, 2002; Biserkov et al., 2015; Golemanski et al., 2015; Red List of Peev et al., 2015; RLTS, 2025;).

Increasing PM10 levels are expected to worsen the living conditions of these species and their ability to inhabit the protected area.

Air pollutants of various anthropogenic origins have an adverse effect on plant and animal life. These effects occur not only at high concentrations, but also at values close to or even below the maximum permissible concentrations. Phytotoxicity depends on many factors such as the type of plants, duration of exposure to pollutants, nature of pollutants, and others. As a result, a number of consequences are observed, such as disruption of normal metabolism, disruptions in the process of photosynthesis, and even death of plants and animals (Chuturkova, 2015).

CONCLUSIONS

The resulting exceedances have a negative impact on the health of the population. The increase in PM levels is expected to also affect the cultural, household, agricultural and other economic activities carried out. All this requires immediate measures to be taken to eliminate the sources of pollution and provide permanent control by the control bodies, aimed at achieving a good ecological status for PM10 and air quality in general.

The increase in PM10 levels is expected to worsen the living conditions of people, plants and animals (including those living in the vicinity of the protected area).

Particulate matter is a serious problem. To reduce the impact of this pollutant on atmospheric air, the following are necessary: modernization and quality maintenance of the road surface; control of construction activities; quality washing of road arteries; landscaping of open areas.

Abstract

The results of ecological monitoring studies of groundwater and soils in the region of the city of Plovdiv, East Aegean Basin, and Ecoregion 7 Eastern Balkans are presented. The studies were necessary as a result of the repair activities carried out on a damaged oil pipeline. The results obtained from the physicochemical monitoring of waters and soils are discussed (electrical conductivity, odour, turbidity, pH, colour, anthracene, aromatic hydrocarbons, acenaphthene, acenaphthylene, benzene, benz(a)pyrene, naphthalene, petroleum pyrene, polycyclic petroleum products, fluorene, fluoranthene, phenanthrene, chrysene), with the application of the existed standards. The exceedances of the monitored indicators of water quality for irrigation of crops, for the adjacent sources of surface water, and these oils are assessed. An ecological assessment of the studied groundwater and soils is presented. The health risks from using anthropogenically influenced groundwater and soils for plants, animals, and humans have been assessed. Measures to improve the ecological state have been identified.

Key words*: chemical state, ecological assessment, groundwater, health risk assessment, pollutions, soils.*

INTRODUCTION

Oil, or petroleum, is a mixture of gaseous, liquid and solid hydrocarbons of varying densities. Petroleum products are derived from crude oil (petroleum) (Walther & Otto, 2005). Oil spills result from the release of oil from tankers, oil platforms, drilling rigs and oil wells, as well as from refined petroleum products (gasoline, diesel) and their by-products (fuel oil). Spilled oil can affect animals and plants in two ways: directly through the oil spills and through the response to the clean-up process (Bautista & Rahman, 2016b; Sarbatly, 2016). There is no clear relationship between the amount of oil in the aquatic environment and the potential impact on biodiversity. A smaller spill in the wrong place or at the wrong season in a sensitive environment can be much more devastating than a larger spill at a different time of year, even in the same environment (Bautista & Rahman, 2016a). Animals can be poisoned or die from oil entering their lungs. Oil spills can degrade air quality (Middlebrook et al., 2011). The constituents of crude oil are mainly hydrocarbons, which contain toxic chemicals such as benzene, toluene, and polycyclic aromatic hydrocarbons (Tidwell et al., 2015). These chemicals have adverse effects when they enter the human body. They can be oxidized in the atmosphere and form fine particles (Li et al., 2013). Clean up and restoration also generates air pollutants, such as nitrogen oxides and ozone (Ehrenhauser et al., 2014; Nance et al., 2016). The impact of oil and oil products on aquatic systems can be expressed in the following directions: some substances dissolved in water are toxic, and their effect on organisms can be lethal; another part accumulates in the tissues and disrupts the physiological activity of organisms; leads to a change in the species composition of aquatic

communities because organisms adapt to oil pollution differently (Velev, 2015).

The study aims to present ecomonitoring results for contamination of anthracene, aromatic hydrocarbons, acenaphthene, acenaphthylene, benzene, benzo(α)pyrene, naphthalene, petroleum pyrene, polycyclic petroleum products, fluorene, fluoranthene, phenanthrene, chrysene, as well as the indicators electrical conductivity, odour, turbidity, pH, colour in groundwater and soil samples from the vicinity of the city of Plovdiv, Bulgaria, provoked by repair activities of a damaged oil pipeline.

MATERIALS AND METHODS

Twenty-three groundwater samples and four soil samples were tested near a damaged oil pipeline (Figure 1) during 2024. Groundwater samples were taken from a 9-10 m depth according to standard BSS ISO 5667-11:2011. Soil samples were taken from two depths: 0-10 cm and 10-20 cm, according to standard BSS ISO 18400-203:2020.

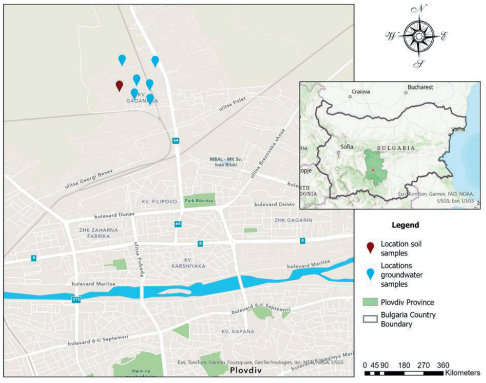

Figure 1. Spatial sampling locations

Chemical analyses were carried out in an accredited laboratory using approved standards: active reaction (pH) - BSS EN ISO 10523:2012; dissolved oxygen (mg/l) - BSS EN ISO 5814:2012; temperature (^{0}C) - BSS 17.1.4.01:1977; electrical conductivity (μS/cm) - BSS EN 27888:2000; petroleum products (μ/l) - BSS EN ISO 9377-2:2004; benzene (μ/l) - BSS EN ISO 15680:2004; benzo(α)pyrene, naphthalene, petroleum pyrene, polycyclic petroleum products, fluorene, fluoranthene, phenanthrene, chrysene - Internal laboratory methodology (ILM 1016/2010). Soil samples were tested for petroleum products according to BSS EN ISO 16703:2011. The results are statistically processed using MS Excel (Microsoft 2010).

RESULTS AND DISCUSSIONS

Chemical analyses were performed to determine the benzene, benzo(α)pyrene, petroleum products, anthracene, acenaphthene, acenaphthylene, naphthalene, pyrene, phenanthrene, fluoranthene, fluorene, chrysene content in the samples of groundwaters (Table 1).

Table 1. Contamination of the samples of groundwater

Pollutants	Mean ± SD (μg/l)
Benzene	79.17 ± 25.38
Benzo(α)pyrene	78.50 ± 6.36
Petroleum products	653.00 ± 386.35
Polycyclic aromatic hydrocarbons:	
Anthracene	0.22 ± 0.06
Acenaphthene	0.80 ± 0.44
Acenaphthylene	0.18 ± 0.07
Naphthalene	25.82 ± 22.24
Pyrene	0.19 ± 0.12
Phenanthrene	1.50 ± 1.73
Fluoranthene	0.17 ± 0.03
Fluorene	5.2 ± 1.19
Chrysene	0.11 ± 0.01

The ecological assessment of the impact of groundwater contaminated with oil and petroleum products on the health of humans, animals and plants is based on the provisions of the Water Directive (Directive 2000/60/EC), the Groundwater Directive (Directive 2006/118/EC), the Environmental Protection Act (EPA), the Water Law, the Health Law. The analysis of the results obtained from the study is based on specific standards regulated by Regulation No.1 of 10 October 2007 on the study, use and protection of groundwater; Regulation No.H-4 of 14 September 2012 on the characterization of surface waters; Regulation No.9 of 16 March 2001 on the quality of water intended for drinking and domestic purposes; Regulation No.8 of 27 May 2009 on the quality of waters for irrigation of crops; Regulation on environmental quality standards for priority substances and certain other pollutants (2010), etc.

Twenty-three groundwater samples were tested by Appendix No.1 of Regulation No.1 (2007)

for the study, use and protection of groundwater. The standards approved under the ordinance are: Benzene – 1.0 µg/l; Benzo(a)pyrene – 0.01 µg/l; Petroleum products – 50 µg/l; Polycyclic aromatic hydrocarbons – 0.10 µg/l.

According to Appendix No.1 to Regulation No.1 (2007) for the study, use and protection of groundwater, polycyclic hydrocarbons are defined as the sum of benzo(b) fluoranthene, benzo(k) fluoranthene, benzo(ghi)perylene and indeno(1,2,3-cd) pyrene, naphthalene, acenaphthene, fluorene, phenanthrene, acenaphthalene, anthracene, pyrene, fluoranthene, and chrysene are polycyclic aromatic hydrocarbons. Measurements on groundwater samples show contamination with petroleum products and related pollutants such as benzene and benzo(a)pyrene, representatives of polycyclic aromatic hydrocarbons.

The highest exceedances compared to the applicable standards were found for benzo(b)pyrene (7400-8300 times), followed by those for benzene (1.9-98 times) and petroleum products (1.7-19.9 times) (Table 2).

Table 2. Exceedance of standards under regulatory documents

Pollutants	Exceedances, Mean ± SD				
	1	2	3	4	5
Benzene	59.94 ± 41.56	55.35 ± 42.66	-	5.83 ± 10.65	1.78 ± 0.18
Benz(a)pyrene	7850 ± 636.39	7850 ± 636.39	-	289.21 ± 21.50	
Petroleum products	12.95 ± 7.63		1.12 - 3.32		
Polycyclic petroleum products				Anthracene 2.15 ± 0.64	

Legend: 1 - Regulation No.1(2007); 2 - Regulation No.9(2001); 3 - Regulation No.18(2009); 4 - Regulation (2010); 5 - Regulation H-4(2012).

The Health Law (2004) and Regulation No.9 (2001) on the quality of water intended for drinking and domestic purposes, promulgated to protect human health from the adverse effects of drinking water pollution, regulate requirements for the quality and safety of drinking water, as well as for improving access to water intended for drinking and domestic purposes. According to Regulation No.9, the maximum values for chemical water quality indicators for drinking and domestic water supply are (µg/l): benzene – 1.0; benzo(a)pyrene – 0.010; polycyclic aromatic hydrocarbons – 0.10 (as the sum of the concentrations of: benzo(b)fluoranthene; benzo(k)fluoranthene; benzo(ghi)perylene; indeno(1,2,3-cd)pyrene). Indicators with indicative significance are: pH ≥6.5≤9.5; Electrical conductivity – 2,000 µS.cm^{-1}; Odour – without significant fluctuations; Turbidity – without significant fluctuations; Colour – without significant fluctuations. The exceedances of the indicators from Regulation No. 9 are as follows: pH – 0.99 times; benzene – from 1.9 to 98 times; benzo(b)pyrene – from 7,400 to 97,400 times. A smell of petroleum products and a visible film were detected (Table 2). Based on these findings, the withdrawal of groundwater for drinking and domestic use is not permitted, regardless of whether wells are constructed for private or industrial purposes, as the studied groundwater poses a risk to human health if used for drinking or other domestic applications. At the same time, no pollutants were detected in the samples from the water supply network for drinking and domestic water supply.

Exceedances of the indicators in Regulation No.18 (2009) on the quality of water for irrigation of crops were established for petroleum products at the MPC of 0.3 mg/dm^3 (= 300 µg/l): from 1.12-3.32 times. Therefore, using water for irrigation of crops from the tested groundwater is unacceptable because it poses a risk to human health, cultivated crops, and animals. The Water Law carries out monitoring of irrigation water, Regulation No.5 (2007) on water monitoring, and Regulation No.18 (2009) on the quality of water for irrigation of crops.

The Regulation on Environmental Quality Standards for Priority Substances and Certain Other Pollutants establishes the environmental quality standards (EQS) for priority substances and certain other pollutants to achieve good chemical status of surface waters by the provisions and objectives of Chapter Ten, Section III of the Water Law (WL). According

to this regulation, the MPC (μg/l) in surface waters for some of the pollutants identified in groundwater from the studied sites are: benz(a)pyrene – 0.27; anthracene – 0.1; naphthalene – 130; fluoranthene – 0.12; benzene – 50. The tests carried out on groundwater samples showed excesses of benzene (from 1.5-30 times), benzo(α)pyrene (from 274-304.41 times), anthracene (from 1.7-2.6 times), and fluoranthene (1.42 times). Therefore, using tested groundwater is unacceptable because it poses a risk to humans, plants, and animals.

Regulation No.H-4 (2012) regulates the procedure and manner for the characterization, classification and presentation of the ecological status/potential of surface water bodies. According to this regulation, the SCC/MPC (μg/l) in surface waters, for comparison with some of the established pollutants in groundwater from the studied sites, are: acenaphthene – 3.8 SCC; 50 MAC; acenaphthylene – 0.64 SCC; fluorene – 3.1 SCC; phenanthrene – 1.3 SCC; pyrene – 0.012 SCC; chrysene – 0.02 SCC; benzene – 10 SCC; 50 MPC; Oil and oil products – without visible film on the surface and without odour. Exceedances of the standards set by Regulation H-4 were found in the tested groundwater samples for benzene (1.5-1.96 times), anthracene (1.7-2.6 times), and chrysene (5.5 times). The established exceedances and changes in the condition and quality of the analysed groundwater (smell of oil products; visible film) make the water abstraction and use of the tested groundwater inadmissible because they pose a risk to humans, animals and plants.

According to Regulation No.4 (2000) on the quality of waters for fish farming and shellfish breeding, the presence of oil products that form a film on the surface of the water or form deposits on the beds of river streams and lakes is not allowed, because they give a petroleum taste to fish and fish products and they have a harmful effect on fish. The deteriorated quality of groundwater affects the quality of surface waters when used to connect with surface waters. The tested soil samples did not show excesses in the oil products indicator. The reported amount is less than the detection limit according to the approved standard (below 15 $\mu g.kg^{-1}$ soil) and the requirements of Regulation No.3 (2008). Deterioration in the condition of terrestrial ecosystems is expected due to water abstraction and use of the studied groundwater, which is unacceptable because it poses a risk to the health of people, animals and plants.

The increase in oil production and its processing, its transportation through pipelines, accidental spills during its transportation, poor storage and manipulation lead to a number of environmental problems. Hydrocarbon pollution of the environment is a huge catastrophe for ecosystems because it leads to lethality and damage to flora and fauna for a long period. Oil and its derivatives penetrating the soil specifically impact the entire environment, the former communities and ecosystems. It has been established that the main reason for the delay in the development or death of plants is due to the deterioration of the water-physical properties of the soil, the blocking of nutrients (Crummer, 1964), the occurrence of oxygen starvation (Odu, 1972) and a complete disruption of biochemical processes (Gaydarova et al., 1990). The extracted groundwater contains oil and many salts (80-90%). Soil contamination occurs most often when corroded pipelines break, resulting oil and salt pollution. Drilling wells are located on vast areas, usually agricultural lands and pastures. The most intensive pollution is about 2.5 km from petrochemical and oil refining enterprises. With a distance of 6-10 km from the source, the content of pollutants decreases, but the range of soil pollution is not less than 20 km (Suleĭmanov et al., 1996).

Crop contamination occurs when groundwater containing petroleum products is used for irrigation. Soil contamination with petroleum products is not limited to the surface horizon. Infiltration is directly dependent on the current humidity. This rate decreases by 6 to 14 times at higher humidity compared to dry soil (Dimitrov et al., 1995). The properties of soils contaminated with petroleum and petroleum products change. Petroleum products are a permanent component of organic environmental pollution. Their presence in the soil significantly disrupts its water-physical, agrochemical and microbiological properties. The changes resulting from pollution with petroleum products are mainly associated with

the disruption of the water-air regime due to filling the pore spaces with petroleum products and the aggregation of soil particles. As a result, the oxidative conditions dominant before the contamination in the soil change to oxidative-reductive and reduction. The emergence of anaerobic conditions leads to the suppression of nitrification and the enhancement of ammonification. An accumulation of ammonia nitrogen of 20-40 $mg \cdot kg^{-1}$ occurs, and the content of nitrate nitrogen remains in traces. The amount of mobile phosphorus decreases (from 2 to 9 times), which is explained by the immobilization of inorganic phosphorus by microorganisms and phosphine formation. With very strong salinization, regardless of the pollution with petroleum products, the content of mobile phosphates can increase. Mineralization increases, and sulphate, chloride, calcium, magnesium, sodium, and potassium ions appear. The amount of trace elements increases - Mn (up to 4 times), Co, Mo, Cu, Zn, Pb, Ni (up to 2 times), the oxidation-reduction potential decreases (up to -340 mW) (Haziev et al., 1987; Gabbasova et al., 1997).

Oil and oil products have a toxic effect on soil microorganisms. Fungi are relatively resistant to pollution. Their resistance to higher concentrations of oil products and the increase in saprophytic fungi is related to the fact that the pH in some of the studied contaminated soils is in the acidic range, favouring fungi development. Fungi use the hydrocarbons as a source of "carbon" nutrition, and thanks to the high enzymatic activity, they decompose oil into low-molecular compounds quite quickly. Of the algae, the most resistant to oil pollution is blue-green algae. When components of oil pollutants penetrate the aquifer, specific microorganisms settle which are difficult to be purified. The number of one of the most important participants in soil-forming processes - the earthworm, decreases almost twice near the source of pollution (Molodova, 1978). Oil and petroleum products have a detrimental effect on the metabolism of plants, with some lighter fractions entering them directly (Markov, 2009).

CONCLUSIONS

The studied groundwater is significantly contaminated with petroleum products. Environmental monitoring studies show excess petroleum products and/or related indicators such as benzene, benzo(α)pyrene, and representatives of polycyclic aromatic hydrocarbons. According to environmental legislation, the excesses range from several times to tens and thousands of times as deviations from the standards. On this basis, water withdrawal and water use from the studied groundwater for personal or industrial purposes, drinking and domestic needs, water use for irrigation of crops and other needs is inadmissible because it poses a risk to people, plants and animals until their decontamination.

Abstract

Groundwater, a vital resource in Bulgaria, is increasingly at risk of contamination from anthropogenic activities. A study in the Stara Zagora district for a year, situated in an area with strong anthropogenic pressure (urbanization, 4 TPPs, open-pit mining of lignite coal, large military training ground, intensive agriculture) assessed the groundwater quality of 6 wells (Ws) and 6 springs (Ss), based on 48 samples, analyzing 11 physicochemical (colour, taste, odour, pH, EC, TH, Cl^-, SO_4^{2-}, NH_4^+, NO_3^-, and OM) and 3 bacteriological (AMO, E.coli and Enterococci) parameters. The groundwater partly meets the Bulgarian standards as a natural resource (W1, W2 - summer, autumn and winter, W3 - summer and winter, S1, S2, S5 - autumn, and S6) and as a source for drinking (W1 and S2 - except for spring, W2 - except for spring and autumn, S1 and S6 - except for summer, autumn and winter). The deviation from the norms of groundwater as a natural resource results from pollution with NH_4^+, NO_3 and OM, and for drinking purposes: with E. coli, enterococci, AMO, OM, NH_4^+ and NO_3. Agriculture and livestock waste were identified as major pollution sources. Many positive and negative Pearson correlations existed between controlled groundwater parameters. Immediate treatment of contaminated Ws and Ss, and regular monitoring and health risk assessments are essential to mitigate groundwater pollution and ensure safe water for consumption.

Key words*: environmental risk, groundwater, physico-chemical and bacteriological parameters, quality assessment.*

INTRODUCTION

Water equals life. No living thing on the planet can exist without water. Among all living organisms in the world, humans use the most water. That's why water is a critical resource for people's life as it is used for various purposes – human consumption, industrial processes, agriculture, and recreation (Saadatpour et al., 2021; Nadjai et al., 2024). In the last decades, the quality of water has been impacted by contamination with a wide range of pollutants (Adimalla & Qian, 2019; Taloor et al., 2024). In addition, water will become increasingly scarce as a result of population growth, urbani-zation, anthropogenic activities and climate change (Nawaz et al., 2023; Abdessamed et al., 2023). Water scarcity in many parts of the world is a serious problem. Groundwater seems to be the potential natural resource capable to reverse this situation (Taloor et al., 2020). Due to unavailability or inadequate quality of surface water, demand for groundwater resources has increased over the years and in present days constitutes about 20% of the world's supply (Barakat et al., 2018; Jyothilekshmi et al., 2019). In many countries, groundwater is a major source of water for drinking, irrigation and industry, and its quality is very important regarding its safe use for all these purposes (Sharma et al., 2017; Singh et al., 2022; Kumar et al., 2024). The poor quality of potable water is responsible for 80% of water-borne diseases in the world (Malik et al., 2012). Water quality illustrates the physical, chemical and biological condition of water bodies, aiming to identify and address concerns through a comprehensive approach tailored to specific uses (Giri, 2021). Numerous studies revealed different aspects of the groundwater quality used for drinking purposes: physicochemical and microbial status of spring/well water (Giao et al., 2023; Devolli et al., 2024); physicochemical characterization of ground-water in urban areas (Wakode et al.,

2018; Ali et al., 2022; Subba et al., 2024); water quality and pollution sources in areas with mining activities (Mohammadpour et al., 2024), etc.

According to data from the EEA within the European Union (EU), 65% of water for drinking purposes and 25% for agricultural needs is provided by groundwater. At the same time, groundwater pollution and extraction is a serious threat to this resource: 24% of the total groundwater bodies are in poor chemical status and 9% - in poor quantitative status (EEA, 2023). A study of Sentek et al. (2024) shows that groundwater in the EU-27 is under significant pressure from excessive irrigation, industrial overexploitation, and a cocktail of pollutants, so that the resulting water scarcity is serious enough to affect livelihoods and even entire sectors.

Bulgaria has significant groundwater reserves, with a flow rate of about 193 millions m^3/year. In 2023, groundwater was 10.2% of the total amount of the extracted fresh water in the country (5336.1 million m^3), of which 79.3% were used for drinking, 14.2% for industry, 3.5% for agriculture and 2.9% for other purposes (National Statistical Institute, 2024). In the period 2003-2022, a gradual improvement in groundwater quality was observed for most of the analyzed indicators. Despite this positive trend, the main pollutants of groundwater with exceedance of the quality standards were nitrate (at 25% of all Monitoring points /MPs/) and partly sulfate, total Fe, Na and Mg (at 3.6-5% of MPs) (ExEA, 2024).

In some areas of Bulgaria, mainly semi-urban and rural, groundwater are single sources for water supply, especially in private farmyards and animal farms (Kostadinova, 2014). Usually, those sources are outside the National Monitoring System (NMS) and the lack of reliable information about the groundwater quality is a major concern. All the above have motivated conducting this study, aiming to assess the groundwater quality as a natural resource and for drinking purposes by physico-chemical and microbiological parameters from wells and springs out of the NMS in Stara Zagora district, exposed to strong anthropogenic pressure – urbanization, energetics, industry, transport and intensive agriculture.

MATERIALS AND METHODS

Study area

The study was conducted during the period July 2023 - June 2024 in Stara Zagora district, situated in South-Central Bulgaria (5.151 km^2), divided into 11 municipalities with 11 towns and 195 villages and population of 307,140 inhabitants (86 people/km^2). About 72% of the population lives in the cities, of which about 80% lives in the two largest cities – Stara Zagora (142,000) and Kazanlak (64,000) (National Statistical Institute, 2025). The region is characterized by a moderately continental climate (average annual maximum/minimum temperature +17.9°C and +8.0°C, respectively, average annual rainfall 598 mm), diverse and fertile soils, relatively good water resources and flat, hilly and low mountainous relief. Stara Zagora district is under strong anthropogenic pressure: the industry - the largest energy complex in the country Maritsa-Iztok (4 coal-fired Thermal Power Plants, 3400 MW, and open-pit mining of lignite coal) operates here as well as many other enterprises; transport - the region is an important road and railway center, connecting the eastern and western, northern and southern parts of Bulgaria; agriculture, characterized by intensive crop (mainly grain) and animal (milk, eggs and meat) production; in addition a large military training ground is also situated here (District administration - Stara Zagora, 2025). The region is rich in groundwater sources, with a significant portion of the population relying on groundwater for their daily needs. The depth of the aquifers varies from 30 to 200 m. Boreholes wells are a cost-effective and sustainable solution for accessing groundwater resources. They provide a reliable source of water for domestic, agricultural and industrial use (ExEA, 2024).

Monitoring Points

For the purpose of the study, 12 monitoring points (MPs), outside the National Monitoring System, covering 12 groundwater sources used for drinking purposes were selected: six open wells (Ws) and six springs (Ss), situated on the territory of Stara Zagora district (Table 1, Figure 1).

6	S6	42.381	25.540	280

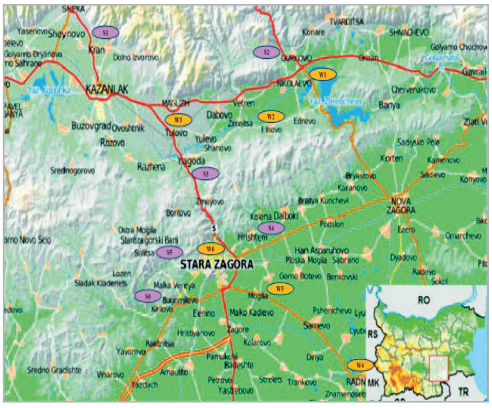

Figure 1. Map with monitoring points in Stara Zagora district, Bulgaria

Sampling and sample preparation

During the one-year monitoring period, groundwater samples were collected once in a season (March, June, September and December) from each MP, a total of 48 samples, including 24 samples from the wells and 24 samples from the springs. For water sampling and sample preparation for analyses, international references (ISO 5667-5, 11) were used. The samples for physicochemical analysis were collected in chemically clean polypropylene containers (1L) and for the microbiological analysis - in sterile glass containers (0.5L), transported in a cooler bag (2-5ºC), and processed for analysis within 2 hours after collection in the laboratories of the Environmental Center at Trakia University.

Physico-chemical parameters and analysis

All analyses were performed in triplicate. In the study, the following 11 physicochemical parameters were determined: colour, taste and odour (visual, organoleptic observation), pH and electrical conductivity (EC) - *in situ*, with portable Multi-340i/SET meter; the other parameters were analyzed in the laboratory: total hardness (TH) - titrimetrically, using standard EDTA, chloride (Cl^-) - by standard $AgNO_3$ titration (ISO 9297), sulfate (SO_4^{2-}) - by Bulgarian State Standard (BDS) 3588, ammonia (NH_4^+) - by BDS 3587 and nitrate (NO_3^-) - by BDS 3758, using UV-VIS Spectrophotometer JENWAY 6705, and oxidizability (organic matter, OM) - by titration method with $KMnO_4$.

Microbiological parameters and analysis

The bacteriological analyses included three microbiological parameters: total aerobic mesophilic bacteria (AMO) at 22°C - by ISO 6222, *Escherichia coli* - by ISO 9308-1 and enterococci - by ISO 7899-2. The total germs were counted after filtering the water using 0.45 µm pore size membranes, incorporated on selective chromogenic medium sheets (Rida® Count, R-Biopharm AG, Germany), and incubated at 22°C for 24 to 48 hours. The results are expressed in colony forming units (cfu/ml).

Assessment of groundwater quality

The assessment of groundwater quality from the monitored water bodies was conducted in two aspects:

a) the groundwater as a natural resource: the evaluation was based on eight physicochemical parameters (pH, EC, TH, Cl^-, SO_4^{2-}, NH_4^+, NO_3^-, and OM) as stipulated in Ordinance No. 1/2007. The chemical status of each groundwater body was classified as "good" if the parameter values were below the permissible limits, and "poor" if the values exceeded these limits. The overall ecological status of each water body was then determined by the lowest status recorded among the individual parameters assessed;

b) the groundwater as a source for drinking and domestic purposes by 14 parameters - 3 organoleptic (colour, taste and odour), 8 physicochemical (similar as in "a") and 3 microbiological (AMO, *E. coli* and Enterococci), according to Ordinance No. 9/2001.

Statistical analysis

All data ware analyzed by statistical software and data analysis tool XLSTAT, Version 2016.02, Addinsoft.

RESULTS AND DISCUSSIONS

Assessment of groundwater quality as a natural resource

The assessment was conducted using eight physicochemical parameters (Tables 2 and 3).

Among these, **pH**, which indicates the acidity or alkalinity of water, is a key parameter in groundwater quality assessment, as it influences the chemical and biological properties of groundwater. The pH values ranged between 6.89 and 8.22 and confirmed the results from previous studies that groundwater from wells/spring has natural or light alkalinity: 6.3-8.5 (Barakat et al., 2018, Ali et al., 2022, Abdessamed et al., 2023, Kumar et al., 2024). The coefficient of variation shows that pH is a conservative parameter with low variability - Cv = 2.41-3.47%. The same variation was reported by Nadjai et al. (2024), Cv = 2-5%.

Electrical Conductivity (EC) is an indicator of the total dissolved solids and salinity of the water. High salinity can affect the taste, sight, and smell of drinking water, and can worsen its quality. The EC values ranged between 382 and 5470 µS/cm for Ws, average 1487 µS/cm (Table 2), and within a much narrower range 298-910 µS/cm, average 627.4 µS/cm for Ss (Table 3). The coefficient of variation reflected those differences and demonstrated higher variability at Ws (Cv=88.8%) than at Ss (Cv=31.6%). The high EC values for Ws, except for W4 indicated high salinity and mineral content in groundwater with low runoff and high intensity of infiltration (Ravikumar & Somashekar, 2017).

*****Ordinance No. 9/16.03.2001 (for drinking water - includes all tested parameters) and Ordinance No. 1/10.10.2007 (for groundwater as natural resource - includes only physicochemical parameters).

The low values for Ss could be related to high-elevation topography, high runoff, low infiltration, and recharge water type with low salt enrichment (Rao et al., 2012).

Previous studies also reported significant variation of that parameter: 220-8250 µs/cm, Cv = 35-51% (Barakat et al., 2018; Abdessamed et al., 2023; Kumar et al., 2024; Nadjai et al., 2024). The results obtained classified the ecological status of all tested groundwater as "good"; the exemption was W4, whose water's ecological status was determined as "bad".

TH in groundwater is computed as the total sum of Ca and Mg ion concentrations. The range of TH values in our study was between 1.83 and 38.0 mg/l, average 8.20 mg/l, Cv = 101.0% for Ws (Table 2), and between 1.83 and 8.88 mg/l, average 4.43 mg/l, Cv = 37.9% for Ss (Table 3). All concentrations were under the permissible level (<12 mg/l) according to the standard and classified the ecological status groundwater as "good"; the only exception was the W4, where concentrations were over the norm and determined the "bad" ecological status of water. In comparison to our results, other authors found higher levels of TH in groundwater: 90-940 mg/l (Barakat et al., 2018, Ali et al., 2022, Kumar et al., 2024), which is logical as the conditions of the studies were different than those in our study. **Chloride** is found in almost all-natural groundwater resources due to its high stability. The main sources of Cl^- include anthro-pogenic activities as well as leaching and weathering of different minerals. The chloride content imparts a salty taste to groundwater (Nag, 2009). The chloride concentration ranged from 6.38 to 398.5 mg/l for Ws (Table 2) and from 3.97 to 76.7 mg/l for Ss (Table 3). The coefficient of variation revealed a high variability of that parameter - Cv = 62.0-167.0% and indicated its sensibility to environmental factors.

The results obtained determine groundwater of all monitored water bodies as water in "good" ecological status (<250 mg/l) with one exception - W4, where Cl^- exceeded the norm in spring, summer, autumn and winter. Data from

previous studies also reveal a large variation in the groundwater chloride concentration from differ-rent sources: 9-2400 mg/l, Cv = 63-74% (Ali et al., 2022, Kumar et al., 2024; Subba et al., 2024; Nadjai et al., 2024).

Sulfate ions are a natural component of groundwater, as they are the result of diverse processes - dissolution and precipitation of minerals, wastewater penetration from diffuse sources, deposition from the atmosphere (SO_2, H_2SO_4, and sulfate), others; the main source of SO_4^{2-} in groundwater are metallic sulfides (Tiwari et al., 2016). The indicator values varied from 5.25 to 394.2 mg/l, average 80.0 mg/l, Cv = 140.1% for Ws, and from 3.8 to 68.8 mg/l, average 32.6 mg/l, Cv = 64.4% for Ss. All SO_4^{2-} concentrations from Ss, and those from W1, W2, W3, W5, and W6 met the requirements of the standard for "good" ecological status, while the W4 groundwater was determined in "bad" ecological status. Some authors reported SO_4^{2-} concentrations in ranges close to ours: 7-421 mg/l, Cv = 76-81% (Ali et al., 2022; Panneerselvam et al., 2023; Kumar et al., 2024; Subba et al., 2024).

The **ammonium** is a common contaminant in groundwater, in many cases as result of human activities, mostly from the application of fertilizers, disposal of manure, discharge of sewage and leakage from landfills. That's why the traceability of ammonium in groundwater is of great importance (Liang et al., 2022; Liu et al., 2023). The range of NH_4^+ in groundwater of both water source types was 0.06 to 3.82 mg/l. Under the permissible level, determining "good" ecological status of the water body were the NH_4^+ concentrations for W1, W2 (summer, autumn and winter), W3 (summer and winter), S1, S2, S3 (summer, autumn and winter), S5 (autumn) and S6; in all other cases groundwater status was "bad". Devolli et al. (2024) found lower concentrations of NH_4^+ in spring and well water than in our study - 0.03-0.48 mg/l.

Nitrates are a major groundwater pollutant, especially in areas with high levels of industrialization, agricultural activities, and urbanization. Nitrate fertilizers, which are water-soluble (e.g., urea, ammonium sulfate), easily leach into the groundwater system, leading to serious NO_3^- pollution (Adimalla & Qian, 2019); septic tanks and leaks from wastewater pipes are other anthropogenic sources of nitrate in groundwater (Pawar & Shaikh, 1995). The NO_3^- concentration in the study area ranged from 11.3 to 511.8 mg/l, average 74.3 mg/l, Cv = 64.7% for Ws and from 5.52 to 49.9 mg/l, average 24.7 mg/l, Cv = 58.7% for Ss. The measured levels determine a "good" ecological status for groundwater from all monitored water bodies; the exceptions were W4 and W5 (summer) which fell in the "bad" ecological status category. Comparable to our results were data reported by Barakat et al. (2018), Panneerselvam et al. (2023), Subba et al. (2024), and Nadjai et al. (2024), (0.12-280 mg/l, Cv = 92-167%).

OM is an indicator characterizing the groundwater quality. Dissolved OM in groundwater is generally low compared to inland surface waters, but even traces of OM can lead to insipid taste of water and promote bacterial growth (Prasad et al., 2023). The ecological impact of OM inputs does not solely depend on its quantity but also by form of the constituents - dissolved or bound (Harjung et al., 2923). OM levels were between 0.81 and 23.1 mg/l and classified groundwater from all water bodies in the "good" ecological status category; exceptions were W4 and S3 (summer, autumn, winter), and S4 and S5 (summer) where the ecological status of groundwater was "bad".

Based on the assessments of the different physicochemical parameters, the final assessment determined W1, W2 (summer, autumn and winter), W3 (summer and winter), S1, S2, S5 (autumn) and S6 in "good" ecological status, meeting the Bulgarian standard quality requirements for a natural resource (Ordinance No. 1/2007). In all other cases, the water bodies were classified as the "bad" ecological status category. The status of W4 was particularly worrying, as throughout the entire monitoring period the levels of the analyzed physico-chemical parameters (except for pH) exceeded the permissible levels (Table 2). The poor state of the groundwater can be explained with the water body location, characterized with many anthropogenic activities: close vicinity to a TPP (908 MW), lignite coalmine and slag heap; in addition, intensive agriculture, involving fertilization and irrigation, is practiced in the area. Obviously, those activities influence the groundwater quality and determine the *bad* ecological status of that natural resource. It is

necessary to conduct systematic monitoring of groundwater resources in order to identify the sources of pollution with a view to taking measures to improve the groundwater quality in the region.

Assessment of groundwater quality as a source for drinking purposes

The assessment was made by 14 physico-chemical and microbiological parameters as follows (Tables 2 and 3):

Physico-chemical parameters: The first group of those parameters included 3 organoleptic parameters - colour, taste and odour. By those parameters, all groundwater samples collected (total 48) met the requirements of the standard (Ordinance No. 9/2001), as they were "acceptable for users and without significant fluctuations from the usual for the indicator". The second group covered 8 parameters (pH, EC, TH, Cl^-, SO_4^{2-}, NH_4^+, NO_3^-, and OM), with permissible levels equal for both standards - for drinking water (Ordinance No. 9/2001), and for groundwater as a natural resource (Ordinance No. 1/2007). That's why, the assessments of the Ws and Ss as natural resources are also valid as sources of drinking water. Therefore, the groundwater resources in good ecological status can be used for drinking and conversely, the groundwater from water bodies in poor ecological status are not suitable for potable purposes (Tables 2 and 3).

Microbiological parameters: Microbes influence and often control geochemical processes and hence, are important to the quality of the natural water, they determine when the wells' clogging is a problem, and often whether anthropogenic chemicals (contaminants) disappear or persist in groundwater or not (Ferris, 2021). The quality assessment of the tested groundwater, made by three groups sanitary indicator microorganisms - Aerobic mesophilic microorganisms (AMO), *E. coli* and Enterococci, showed that the counts of all bacterial groups ranged within large limits: AMO - <0.1-770 cfu/ml, Cv = 108.3% for Ws, and <0.1-109 cfu/ml, Cv = 113.6% for Ss; *E. coli* - <0.1-103 cfu/ml, Cv = 181.3% for Ws, and <0.1-61 cfu/ml, Cv = 97.7% for Ss; enterococci - <0.1-208 cfu/ml, Cv = 131.5% for Ws, and <0.1 - 218 cfu/ml, Cv = 218.2% for Ss (Tables 2 and 3). Colony counts at 22ºC or AMO, provide a general idea of how contaminated the water is. Their presence in natural water can raise concerns regarding water quality and safety. *E. coli* and Enterococci indicate a fecal contamination of groundwater and the possible presence of disease-causing bacteria, viruses, and protozoa (Ateba & Maribeng, 2011; Tropea et al., 2021; Naily et al., 2023). Barakat et al. (2018) reported higher upper borders for *E. coli* (1-650 cfu/100 ml) and Enterococci (0-750 cfu/100 ml) for water from 8 springs in Morocco, while much lower variation for *E. coli* was established by Nawaz et al. (2023), 0-5 cfu/100 ml in groundwater from 10 different sites of Panjab city, Pakistan, and Devolli et al. (2024), 0-3 cfu/100 ml in groundwater form 7 wells in Albania. The established bacterial counts meet the requirements of the standard as follows: for AMO at W1, W2, W3 (except for spring), W4 (except for summer, autumn and winter), W6, S1, S2, S3, S4, S5 (except for autumn and winter), and S6; for *E. coli* at W1 and S2 (except for spring), W2, W3, W5 and S5 (except for spring and summer), W4, S3 and S4 (except for summer), W6 (except for summer and winter), S1 and S6, and for Enterococci at W1, W2 (except for spring and autumn), W3 (except for spring and winter), W4 (except for summer), W6 and S6 (except for summer, autumn and winter), S1, S2 (except for spring), S3 and S4 (except for autumn); in the other cases the quality of ground-water deviated from the norms for drinking water.

Considering that the final assessment of groundwater of the relevant water body is made based on the lower quality assessment for the tested physicochemical and microbiological parameters, it can be concluded that only groundwaters from W1 and S2 (except for spring), W2 (except for spring and autumn), S1 and S6 (except for summer, autumn and winter) meet the standard. In all other cases the groundwaters were not suitable for drinking. The most aggravating factor is the presence of *E. coli* and Enterococci and partly of AMO, OM, NH_4^+ and NO_3^- above the permissible limits. All these pollutants contribute to organic sources of pollution, most likely with wastewater from settlements and livestock farms, including farmyards in the villages. It is necessary to continue monitoring groundwater sources used for drinking purposes, aiming to develop

measures to eliminate or reduce organic/microbial contamination within the limits set by the standard.

Correlation analysis

The correlation matrices, calculated using Pearson correlation coefficients, revealed strong and moderate relationships (both positive and negative) among the investigated parameters for both types of groundwater sources (Tables 4 and 5).

In **wells**, significant correlations were identified between EC and TH, Cl^-, SO_4^{2-}, NH_4^+, NO_3^-, *E. coli*, and Enterococci; between TH and Cl^-, SO_4^{2-}, NH_4^+, NO_3^-, *E. coli*, and Enterococci; and between Cl^- and SO_4^{2-}, NH_4^+, NO_3^-, and Enterococci. Additional correlations were observed between SO_4^{2-} and NH_4^+, NO_3^-, *E. coli*, and Enterococci; between NH_4^+ and NO_3^-, AMO, *E. coli*, and Enterococci; as well as between NO_3^- and *E. coli* and Enterococci, and between *E. coli* and Enterococci, with correlation coefficients ranging from r = 0.40 to 0.99.

In **springs**, notable correlations included those between season and TH (r = -0.58); EC and Cl^- and SO_4^{2-}; SO_4^{2-} and NH_4^+; NH_4^+ and *E. coli* and Enterococci; NO_3^- and AMO, *E. coli*, and Enterococci; OM and *E. coli* and Enterococci; AMO and Enterococci; and *E. coli* and Enterococci, with correlation coefficients ranging from r = 0.44 to 0.90.

There was overlap in certain correlations observed in both types of water bodies; for example, correlations were found between EC and Cl^- and SO_4^{2-}, as well as between NH_4^+ and NO_3^-, *E. coli*, and Enterococci, and between *E. coli* and Enterococci. However, notable differences were also identified. Some correlations observed in wells were not present in springs (e.g., TH with Cl^- and SO_4^{2-}; Cl^- with SO_4^{2-}; NH_4^+ with NO_3^-), while certain correlations present in springs were absent in wells (e.g., OM with *E. coli* and Enterococci; NO_3^- with AMO, *E. coli*, and Enterococci; AMO with Enterococci). Previous studies have also reported significant correlations among several monitored parameters, consistent with the findings of our study. For example, correlations between TH and NO_3^- and Cl^- have been reported by Ali et al. (2022); between EC and TH and SO_4^{2-}, and between TH and Cl^- and SO_4^{2-} by Abdessamed et al. (2023); and between EC and Cl^-, NH_4^+, and NO_3^-, as well as between

TH and Cl^-, NH_4^+, and NO_3^-, by Shrestha et al. (2023). Additionally, Giao et al. (2023) observed a correlation between NO_3^- and TH.

Several of the correlations identified in our study are logical and causally linked. For example, the correlations between EC and TH, Cl^-, and SO_4^{2-} can be attributed to the fact that higher EC reflects higher levels of dissolved salts in water, which correspond to increased concentrations of Ca^{2+}, Mg^{2+}, chloride, and sulfate (Schubert et al., 2024). Similarly, correlations between NH_4^+ and NO_3^- and AMO, *E. coli*, and Enterococci are expected, as nitrogen is an essential element for microbial growth, and higher nitrogen concentrations can support increased microbial populations (Mattoo & Suman, 2023). The correlation between NH_4^+ and NO_3^- is consistent with the nitrification process, in which ammonium is oxidized to nitrite and subsequently to nitrate, leading to higher NO_3^- concentrations in the presence of elevated NH_4^+ levels (Mattoo & Suman, 2023). Additionally, correlations between OM and *E. coli* and Enterococci are expected, as higher organic matter concentrations provide a substrate for microbial growth, resulting in increased microbial counts (Harjung et al., 2023). The correlation between *E. coli* and Enterococci is also logical, as both bacteria are indicators of fecal contamination, and their concentrations typically correspond in contaminated water sources (Wang et al., 2013). However, some observed correlations, such as those between TH and Cl^- and SO_4^{2-}, Cl^- and SO_4^{2-}, NH_4^+, NO_3^-, and Enterococci, EC and Cl^- and SO_4^{2-}, and SO_4^{2-} and NH_4^+, are more difficult to interpret. Further targeted research is needed to confirm or clarify the underlying mechanisms of these associations.

CONCLUSIONS

This study assessed the quality of groundwater from six wells (Ws) and six springs (Ss) in the Stara Zagora region, an area characterized by strong anthropogenic pressure, including high levels of urbanization, four thermal power plants (3400 MW), a large lignite coal mine, a military training ground, and intensive agriculture. The evaluation was conducted using 11 physicochemical parameters (colour, taste, odour, pH, EC, TH, Cl^-, SO_4^{2-}, NH_4^+, NO_3^-, and OM) and three microbiological parameters (AMO, *E. coli*, and Enterococci), considering groundwater both as a natural resource and as a source for drinking water.

The findings indicate that:

(i) Groundwater met the Bulgarian standards for ecological status (as a natural resource) based on pH, EC, TH, Cl^-, SO_4^{2-}, NH_4^+, NO_3^-, and OM in W1, W2 (summer, autumn, and winter), W3 (summer and winter), and in S1, S2, S5 (autumn), and S6. In all other cases, groundwater exhibited poor ecological status, with NH_4^+ identified as the main pollutant, followed by NO_3^- and OM.

(ii) Groundwater met the Bulgarian standards for drinking water for all tested parameters in W1 and S2 (except in spring), in W2 (except in spring and autumn), and in S1 and S6 (except in summer, autumn, and winter). Deviations from the standards in other cases were primarily due to contamination with *E. coli* and Enterococci, and to a lesser extent with AMO, OM, NH_4^+, and NO_3^-.

(iii) Numerous significant positive and negative Pearson correlations were identified among the monitored groundwater parameters, with 28 correlations observed in wells and 13 in springs.

Abstract

Polycyclic aromatic hydrocarbons (PAHs) are organic pollutants composed of two or more aromatic rings of carbon and hydrogen atoms. PAHs are characterized by low water solubility, low vapor pressure, high melting and boiling points. As the molecular mass increases, the lipophilic character increases, making them more persistent in the environment. Incomplete combustion is the main source of PAHs. This study evaluates PAHs contamination in soil samples collected from 30 locations in Bucharest, focusing on potential pollution sources such as industrial activities, vehicular emissions, and domestic sources. Industrial zones and high-traffic areas recorded the highest total PAH concentrations at 1.06 mg/kg and 1.01 mg/kg, respectively. Diagnostic ratios analysis suggests combustion as the predominant source of PAHs.

Key words*: diagnostic ratios, PAHs, soil pollution, urban contamination.*

INTRODUCTION

Polycyclic aromatic hydrocarbons (PAHs) are widespread environmental pollutants consisting of two or more benzene rings arranged in linear, clustered, or angular formations (Arey & Atkinson, 2003). They have low solubility in water, low vapor pressure, and high melting and boiling points. As their molecular weight increases, their lipophilic nature intensifies, making them more resistant to degradation (Lee & Vu, 2010).

PAHs are found in terrestrial, aquatic, and atmospheric environments (Adeniji et al., 2019). In soils and sediments, PAHs accumulate due to their lipophilic properties, binding strongly to soil particles, which serve as reservoirs for these compounds (Kuppusamy et al., 2017).

Many PAHs are mutagenic, carcinogenic, teratogenic, immunotoxic for living organisms, including microorganisms, mammals and humans (Bolden et al., 2017). Benzo(a)pyrene is considered one of the most carcinogenic PAHs and generally used as an exposure marker for risk assessments (Lee & Vu, 2010).

In 1983, the US Environmental Protection Agency (USEPA) designated 16 polycyclic aromatic hydrocarbons (PAHs) as priority pollutants, due to their high environmental concentrations, their recalcitrant nature and toxicity (Deziel et al., 2014). PAHs can be divided into two groups according to their properties and molecular weights: low molecular weight (LMW-PAHs) which have two or three aromatic rings and high molecular weight (HMW-PAHs) with four to six aromatic rings (Jia et al., 2021).

LMW-PAHs typically form during incomplete combustion of organic matter, such as in vehicle exhaust, industrial emissions, and biomass burning. Their appearance is linked to low temperatures.

HMW-PAHs tend to form in more complex combustion conditions, at high temperature as in coal or oil burning, and they are found in higher concentrations in soot (Wang et al., 2013).

Sources of PAHs are classified as either anthropogenic or natural. Some PAHs are produced by natural processes such as volcanic eruptions, vegetation fires or pyrolysis of organic matter in geological processes.

While natural sources contribute minimally to overall PAH emissions, anthropogenic sources dominate. So, anthropogenic sources are considered the main cause of pollution with these compounds and can be divided into

industrial, vehicular, domestic and agricultural activities (Ravindra et al., 2008).

The most common anthropogenic sources are:

- Industrial sources when incomplete combustion, the main source of PAHs pollution can appear:
  - waste incineration,
  - iron and steel production, aluminum production, cement production, tar, asphalt, rubber production;
  - coke oven emissions, and petroleum refining (Mojiri et al., 2019);
  - paint and pigment production;
  - insecticide and fungicide production;
  - energy production (Srogi, 2007).
- Vehicular sources represented by gases from aircraft, boats, trains, vehicles (Ravindra et al., 2008)
- Domestic sources: household activities such as burning waste, burning wood or coal for heating (Gupte et al., 2016).
- Agricultural sources: burning of plant residues left after harvesting (Ravindra et al., 2008).

The aim of this study is to assess PAHs contamination in Bucharest soils, identify major pollution sources, and analyse the impact of different environmental factors on PAH distribution.

MATERIALS AND METHODS

Soil sampling

A total of sixty topsoil samples were collected from depths of 0-10 cm and 10-20 cm across 30 locations in Bucharest and its surrounding areas, including Chitila, Jilava, and Popești-Leordeni. These sites were selected to target various pollution sources, such as industrial zones, high-traffic areas, and residential neighborhoods.

The industrial sites, represented by sampling points S1, S2, S10, S12-S19, S21, S23, S24, S26 and S27, cover a range of facilities including paint factories, concrete factories, incinerators, rubber manufacturing units, a power station, pharmaceutical plants, an emulsion station, as well as the IMGB and Faur-Laminorului industrial platforms.

High traffic areas are covered by sampling points S4, S5, S6, S8, S9, S11, S25 and S28, where vehicle emissions are a significant source of pollution. In addition, the Ruteni and Vidra landfill sites are designated as sampling points S3 and S22, respectively. Residential areas and urban green spaces were also considered, with sampling points S20 and S7 representing these environments.

All sampling sites were georeferenced using GPS for accurate spatial analysis (Figure 1).

Samples were collected in March when air temperatures averaged 15°C.

Each sample was a composite of five subsamples taken from the four corners and the centre of a 5 × 5 m² plot.

The samples were placed in glass containers, shielded from light, and stored under refrigeration until analysis. In proximity to potential pollution sources (e.g., the Green Global Chitila waste dump, S1), additional samples were taken at distances of 200 m and 400 m from the source.

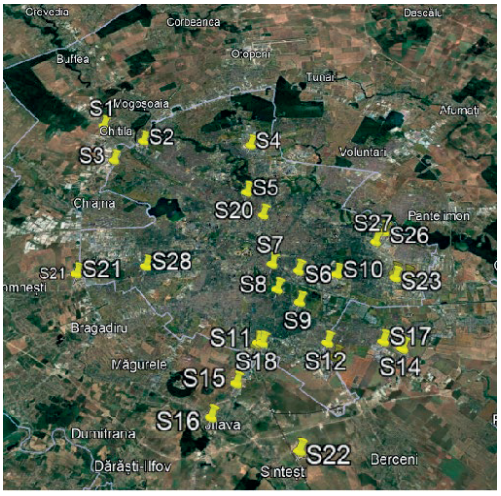

Figure 1. Map of the sampling points

Soil physicochemical properties

Soil properties were analysed using standard methods:

- pH: potentiometric method (SR-7184-13);
- Organic carbon (C, %): wet oxidation method (Walkley-Black, STAS 7184/21-82);
- Mobile Phosphorus (PAL, mg/kg): Egner-Riehm-Domingo method (STAS 7184/19-82);
- Electrical Conductivity (EC, µS/cm): aqueous extract and conductometric method (STAS 7184/7-87);

- Nitrate (N-NO_3, mg/kg): potentiometric method (ICPA methodology);
- Particle size distribution: wet/dry sieving and sedimentation (STAS 7184/7-87).

The soils studied are classified into the following textural classes: sand, sandy loam and loam (Table 1). The chemical properties of the studied soils are summarised in Table 2.

Table 1. Textural classes of the soil analysed in the study

Textural classes	Number of collection points
Sand	10
Sandy Loam	22
Loam	28

Table 2. Chemical properties of the analysed soil samples

Chemical properties of the analysed soil sample (N = 60)	Range
pH	4.98-8.56
C (%)	0.86-6.19
N (%)	0.09-0.499
EC (µS/cm)	23.3-1521
N-NO_3 (mg/kg)	2.68-65
P (mg/kg)	16.34-271.2

The analysed soils exhibit a broad spectrum of chemical properties, which is typical for urban soils (Preda et al., 2010). The pH varied from slightly acidic to alkaline, organic carbon levels ranged from extremely low to high, as did electrical conductivity (EC). Nitrate levels fluctuated between low and high, while phosphorus and nitrogen availability ranged from low to very high, respectively from low to high.

PAHs extraction from soil and analysis

PAHs are analysed from soil according to the standards set forth in the European Standards (SR EN 17503:2022). To extract these compounds from soil, an automated Soxhlet extractor and a mixture of hexane and acetone (in a 1:1 ratio) were employed. The extract is washed with water for chromatography to remove acetone and it is passed through anhydrous sodium sulphate. If necessary to remove the sulphur, copper powder can be used. The determination of PAHs was performed on a Knauer ultrahigh pressure liquid chromatograph (UHPLC) with UV-VIS detection, at 254 nm. The concentration for each compound were quantitatively determined by comparison the peak area of the standard with that of the samples.

In accordance with Order 756/1997, the following priority PAHs are to be quantified: anthracene, benzo(a)anthracene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[a]pyrene, benzo[ghi]perylene, chrysene, fluoranthene, indeno(1,2,3)pyrene, naphthalene, and phenanthrene, as well as pyrene. The pair consisting of benzo[*ghi*]perylene and indeno(1,2,3)pyrene cannot be determined with UV-VIS detector. The separation of the other compounds was performed with a C18 column (2.1 mm x 100 mm x 1.8 µm) operated at 40°C. The mobile phase is composed of water and acetonitrile and the gradient of this mobile phase is presented in Table 3.

Table 3. Flow and gradient of the mobile phase

Time (minute)	Flow (ml/min)	Acetonitrile (%)	Water (%)
0	0.4	50	50
1.6	0.4	55	45
2.9	0.4	60	40
3.7	0.4	70	30
8.5	0.4	85	15
13	0.4	50	50
13	0.4	50	50

Quality assurance/Quality control

To ensure the accuracy and reliability of the results, quality control and quality assurance procedures included duplicate samples, blank samples, and certified reference materials. The limit of quantification for PAHs ranged from 0.02 mg/kg to 0.05 mg/kg. Reagents are of chromatographic grade. To minimize the contamination, all the glassware is rinsed with hexane, acetonitrile and acetone.

RESULTS AND DISCUSSIONS

PAHs concentrations and patterns in the analysed soil samples

The total concentration of the PAH compounds in soil ranged between 0.047 mg/kg and 1.060 mg/kg, with an average value of 0.212 mg/kg (Figure 2). According to Order 756/1997, 33.3% from analysed soil samples have normal concentration (<0.1 mg/kg), 66.7% have concentrations ten times higher than normal

values. The highest PAHs concentrations were observed at S4 (Ficusului Blvd), a high-traffic area, and at S12 and S13 (IMGB), a well-known industrialized zone in Bucharest (Figure 2). Similar studies in other European cities have reported comparable PAHs concentrations, suggesting common urban pollution patterns. For example, the total PAHs content was reported to range from 0.148 mg/kg to 3.410 mg/kg in Torino, from 0.218 mg/kg to 4.490 mg/kg in Ljubljana (Morillo et al., 2007), and from 0.450 mg/kg to 5.650 mg/kg in the soil of the River Seine basin in Paris (Motelay-Massei et al., 2004). These results are significantly lower compared to those found in soils with specific pollution sources. For instance, near a tar works in the UK, the total concentration of PAHs ranged from 6.6 mg/kg to 872 mg/kg (Lorenzi et al., 2010). This suggests that the study data presented represents diffuse pollution sources.

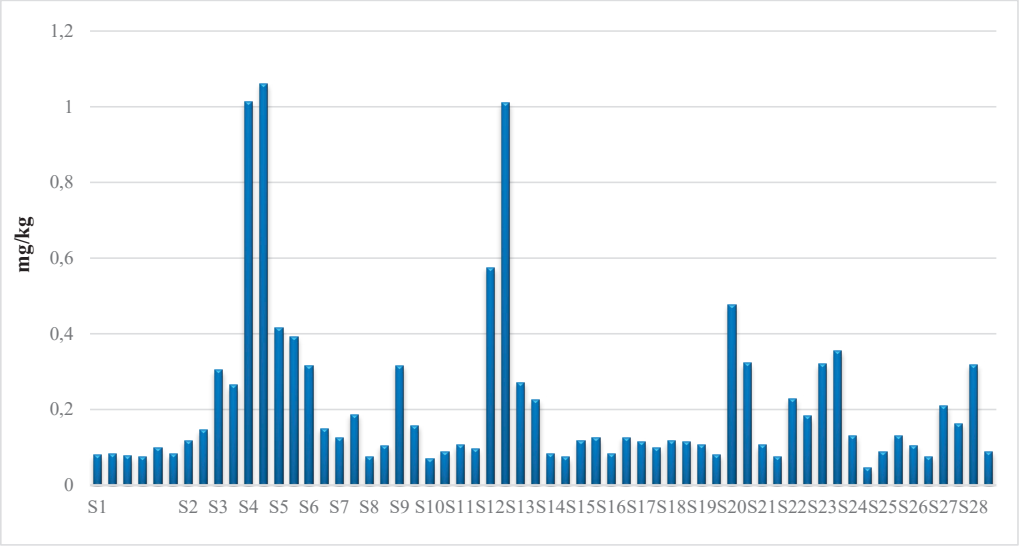

Figure 2. Total PAHs concentration in soil samples collected from Bucharest

The mean concentration of the individual PAH compounds increases in order: benzo(a)pyrene, benzo(k)fluoranthene, naphthalene, anthracene, phenanthrene, pyren, benzo(b)fluoranthen, benzo(a)anthracene, fluoranthen (Figure 3).

The highest concentrations were reported for fluoranthene, benzo(a)antracene and benzo(b)fluoranthene. Similar results were obtained by Wang (2013) in a study regarding the soil contamination with PAHs in Beijing.

The range of the concentration for the individual PAHs are presented in Table 4. The PAH distribution in Bucharest soils shows a minor contribution from LMW-PAHs (2-3 rings), such as naphthalene, phenanthrene, and anthracene. Instead, 4-ring polynuclear aromatic hydrocarbons (fluoranthene, pyrene, chrysene, and benzo(a)anthracene) are dominant (Figure 4). Among this group, fluoranthene and benzo(a)anthracene has the highest concentration.

Regarding 5-ring PAHs, benzo(b)fluoranthene has the highest contribution to the total PAH content.

Naphthalene is one of the most volatile PAHs, meaning it can evaporate relatively quickly from the soil surface. Naphthalene contaminates 46.7% from the analysed soil sample. The highest concentration was recorded in the soil sample collected from the S3 (Ruteni landfill). Naphthalene can be found in landfills due to its presence in various waste materials, including plastics, coal tar, petroleum products, and mothballs. Jia & Batterman (2010) also reported the presence of naphthalene in a landfill site.

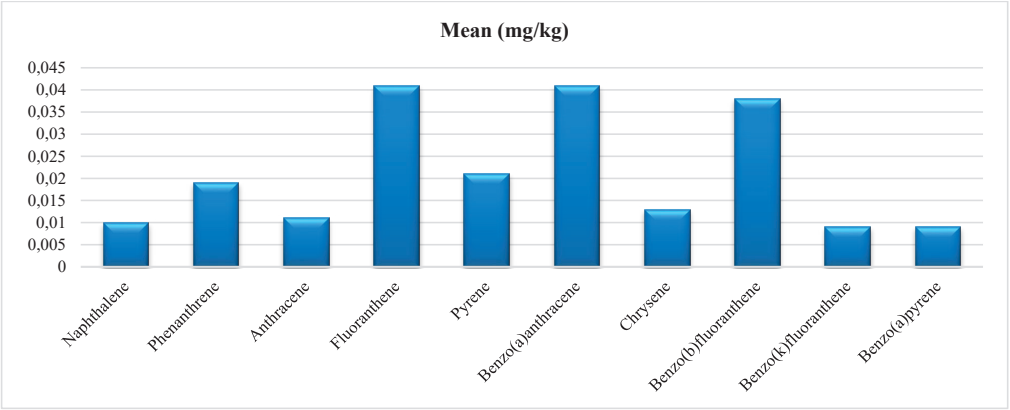

Figure 3. Concentration of the individual PAH compounds in the soil samples collected from Bucharest

Table 4. Range and mean value of concentration of the individual PAHs in studied soil samples

PAH compounds	Type of PAH	Range (mg/kg)		Mean (mg/kg)
		Min.	Max.	
Naphthalene	LMW	ND	0.104	0.010
Phenanthrene	LMW	0.004	0.072	0.019
Anthracene	LMW	ND	0.089	0.011
Fluoranthene	HMW	0.012	0.280	0.041
Pyren	HMW	ND	0.128	0.021
Benzo(a)anthracene	HMW	0.004	0.632	0.041
Chrysen	HMW	ND	0.054	0.013
Benzo(b)fluoranthene	HMW	ND	0.525	0.038
Benzo(k)fluoranthene	HMW	ND	0.054	0.009
Benzo(a)pyrene	HMW	ND	0.032	0.009

LMW = Low molecular weight
HMW = High molecular weight
ND = Not detection

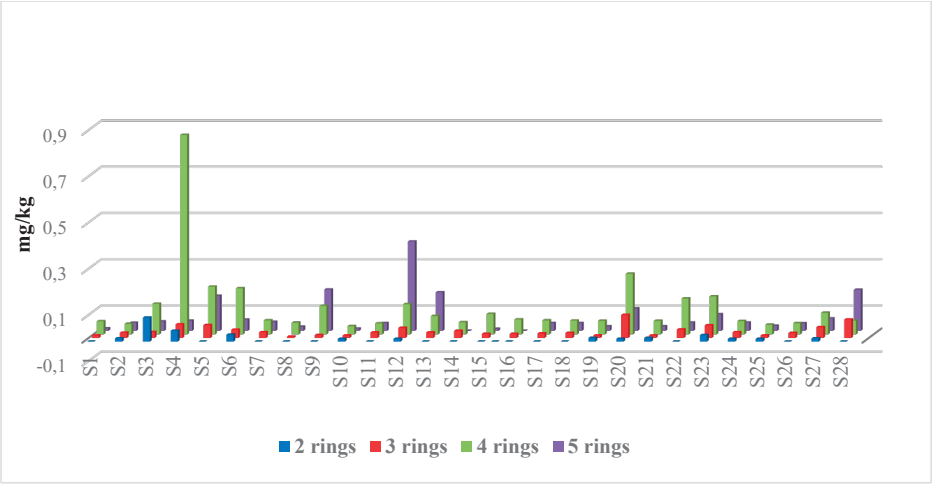

Figure 4. Profiles of the PAHs in the soil samples by number of rings

Phenanthrene is the most thermodynamically stable of the 3-ringed PAHs. This can be the reason it contaminates all the soil samples, even at small concentrations that slightly exceed the

upper limit of the normal threshold (<0.05 mg/kg). Similar results were reported by Vane et al. (2014). The highest concentrations were identified in a boulevard with heavy traffic congestion, S28 (Prelungirea Ghencea).

In contrast, there is a major presence of HMW-PAHs (4-5 rings), including fluoranthene, pyrene, benzo[a]anthracene, chrysene, and particularly benzo[b]fluoranthene (Figure 4). This suggests a dominance of HMW-PAHs, likely indicating sources such as combustion processes rather than petrogenic inputs (McCready et al., 2000).

Fluoranthene, a 4 rings PAH contaminates all the soil samples. 80% from collected samples have concentrations that exceed the upper threshold of normal values (<0.02 mg/kg). Fluoranthene is relatively stable in soil, it strongly binds to soil particles, especially in organic-rich soils (Abdel-Shafy & Mansour, 2016). The highest concentration of fluoranthene was recorded in S4, once again in an area with heavy car traffic.

70% from soil samples are contaminated with pyrene, another 4 rings PAH. The highest concentration (0.128 mg/kg), which is considered a normal value according to Order 756/1997 (<0.5 mg/kg), was recorded in the IMGB industrial area. Pyrene is not the most toxic PAH, but it can act as a precursor to more harmful compounds like benzo[a]pyrene, which is carcinogenic (Gabriele et al., 2021).

Chrysene contaminates almost all soil samples, with 60% of them having normal concentrations (<0.02 mg/kg). The highest concentration (0.054 mg/kg) was recorded in S5 (Kiseleff Boulevard).

Benzo(a)anthracene has also 4 aromatic rings in the molecule and it can persist in soil for long periods due to its low volatility and stability. It can adhere strongly to soil particles, making it resistant to degradation. It is considered a possible human carcinogen (Group 2B by the International Agency for Research on Cancer, IARC) (Abdel-Shafy & Mansour, 2016). Long-term exposure can increase the risk of cancers, especially if the compound enters the human body through ingestion or inhalation. 63% from the studied soil samples have concentrations that exceed the upper threshold of normal values (<0.02 mg/kg). The highest concentrations (0.632 mg/kg) were obtained in sample collected from S4 (Ficusului Boulevard). This value exceeds the normal upper threshold (<0.02 mg/kg) but remains below the alert threshold (2 mg/kg).

From the 5-ring PAHs, benzo(b)fluoranthene, benzo(k)fluoranthene and benzo(a)pyrene were evaluated. The compound with a major contribution to the total content of PAH is benzo(b)fluoranthene. It is relatively persistent in the environment. It does not readily degrade in the presence of sunlight, air, or water, and can remain in soil or sediments for a long time. The highest concentration (0.535 mg/kg) was obtained in the sample collected from the IMGB area. This value exceeds the normal upper threshold (<0.02 mg/kg) but remains below the alert threshold (2 mg/kg).

The highest concentrations of benzo(k)fluoranthene and benzo(a)pyrene (0.054 mg/kg, respectively 0.032 mg/kg) were recorded in S5 (Kiseleff Boulevard). These concentrations slightly exceed the normal value (<0.02 mg/kg) according with Order 756/1997.

Effect of soil properties on the total PAHs concentration

PAHs are hydrophobic and have a high affinity for organic matter. Soils rich in organic matter tend to adsorb and retain PAHs more effectively, reducing their mobility and bioavailability (Yang et al., 2010). Higher organic carbon content is often correlated with higher PAH concentrations due to stronger sorption (Du et al., 2022). No correlation found in this study between the total content of PAHs in soil and organic carbon. A lack of a correlation is not an uncommon finding for soils (Ribes et al., 2003; Bucheli et al., 2004; Heywood et al., 2006) and has been attributed to a state of non-equilibrium. Low molecular weight PAHs (2-3 rings) associated with soot tend to partition and equilibrate more easily between the vapor phase and the soil organic matter, whereas high molecular weight PAHs (4-6 rings) remain more strongly bound to particles (Bucheli et al., 2004).

The influence of pH on PAHs content in soil is indirect, as PAHs are nonpolar compounds and do not ionize in response to pH changes. However, pH affects PAHs behaviour by influencing microbial degradation and their interactions with metal ions or organic matter.

Pawar (2015) was observed that soil with pH 7.5 was most suitable for the degradation of phenanthrene, anthracene, fluoranthene, and pyrene. Thus, on Theodor Pallady Boulevard, the pH is 7.54, the phenanthrene content is 0.011 mg/kg, anthracene is below the limit of quantification, and fluoranthene has the lowest concentration: 0.012 mg/kg.

Soils with high EC can adsorb more PAHs due to electrostatic interactions with organic matter. Studies show a positive correlation between PAH content in soil and conductivity, instead nitrate, which acts as an electron acceptor, has played a significant role in the oxidation of PAHs (Du et al., 2022).

In soil samples collected from Bucharest, no correlation can be established between PAHs and EC or nitrate, likely because the total concentration of PAHs is more influenced by pollution sources, which are highly diverse in Bucharest.

Identifying PAHs sources using isomer ratios

Diagnostic ratios are used to distinguish between pyrogenic (fire-related) and petrogenic (oil or fossil fuel-related) sources of polycyclic aromatic hydrocarbons.

The key point mentioned is that while these diagnostic ratios are useful, their application can be limited because there may be overlap in the ratios from both pyrogenic and petrogenic sources.

This overlap can make it challenging to pinpoint specific types of pyrogenic or petrogenic sources using these ratios alone. (Stout et al., 2004; Galarneau, 2008). In the real world, PAHs often originate from multiple sources, making it difficult to pinpoint one specific source. For instance, both vehicular emissions and industrial activities might contribute to contamination in the same area. This mixing complicates the identification and assessment of specific sources. Despite this, ratios are widely used and applied in various environments for source apportionment estimations of PAHs (Dickhut et al., 2000; Yunker et al., 2002; Tobiszewski & Namieśnik, 2012).

The following diagnostic ratios were used to indicate possible sources (Davis et al., 2019):

- ∑LMW/∑HMW PAHs;
- Anthracene/ (Anthracene + Phenanthrene);
- Fluoranthene/ (Fluoranthene + Pyrene);
- Benzo[*a*]anthracene/(Benzo[*a*]anthracene + Chrysene).

The ratio of LMW to HMW PAHs aims to distinguish between petrogenic and pyrogenic sources. Values < 1 suggest pyrogenic sources, while a value > 1 suggests petrogenic sources (Zhang et al., 2008). In this study the ratio ranged from 0.03 to 0.91, suggesting the pyrogenic sources may be most impactful in soil collected (Figure 5).

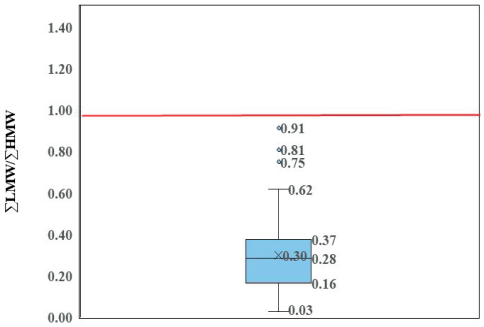

Figure 5. PAH diagnostic ratio plot of ∑LMW/∑HMW

The Anthracene/(Anthracene + Phenanthrene) ratio distinguishes between petrogenic and combustion sources, as values <0.1 indicate petrogenic and those > 0.1 indicate combustion (Yunker et al., 2002). Values obtained for this ratio ranged between 0.1 and 0.62. The value 0.1 is obtained in sample collected from S 28, Prelungirea Ghencea (Figure 6).

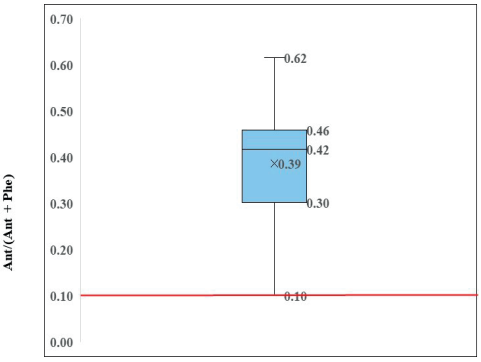

Figure 6. PAH diagnostic ratio plot of Ant/(Ant+Phe)

The Fluoranthene/(Fluoranthene + Pyrene) ratio provides valuable insight into distinguishing between petroleum sources, petroleum combustion, and other combustion processes. Ratio values < 0.4 indicate petrogenic sourcing, values between 0.4 and 0.5 are indicative of petroleum combustion, while values > 0.5 suggest wood, grass, and/or coal combustion (Yunker et al., 2002). This ratio is greater than 0.5 for all the soil samples collected from Bucharest (Figure 7).

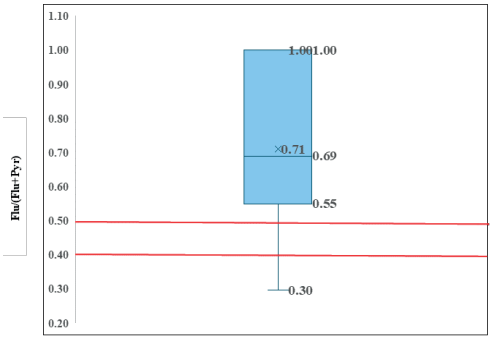

Figure 7. PAH diagnostic ratio plot of Flu/(Flu+Pyr)

The Benzo[*a*]anthracene/(Benzo[*a*]anthracene + Chrysene) ratio distinguishes between petrogenic and combustion (pyrogenic) sources, with a range indicating mixed sourcing. Values below 0.2 suggest petrogenic sources, values between 0.2 and 0.35 indicate mixed sources, while values above 0.35 point to combustion sources (Yunker et al., 2002). According to Figure 8, the same theory is confirmed once again, indicating that the source of PAH compounds is combustion.

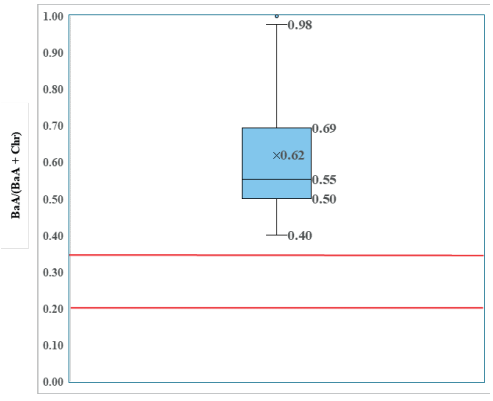

Figure 8. PAH diagnostic ratio plot of BaA/(BaA+Chr)

CONCLUSIONS

33.3% from analysed soil samples have normal concentration (<0.1 mg/kg), 66.7% have concentrations ten times higher than normal values.

The highest values of PAHs concentration were observed in S4 (Ficusului Blvd.) a very crowded boulevard and S12, S13 (IMGB), a well-known industrialized area from Bucharest.

The PAH distribution in Bucharest soils shows a minor contribution from LMW- PAHs (2–3 rings). Of these, phenanthrene is the contaminant present in all the analysed samples, even at low concentrations.

In contrast, there is a major presence of HMW-PAHs (4-5 rings), including fluoranthene, pyrene, benzo[a]anthracene, chrysene, and particularly benzo[b]fluoranthene.

The application of the three types of diagnostic ratios led to the same conclusion, namely that the source of PAHs pollution of the studied soil samples could be the combustion process as: vehicle exhaust (gasoline and diesel engines), residential heating (coal, wood, oil burning), industrial processes.

ACKNOWLEDGEMENTS

This research work was financed with the support of the Project PN 23 29 01 01- "Research on the soil emissions inventory of some persistent organic pollutants - an important stage of the national implementation of EU Regulation 1021/2019".

Abstract

This review examines the literature on particulate matter (PM), covering studies published between 2019 and 2024. Articles were selected based on their relevance to PM sources, chemical composition, atmospheric behaviour, and health impacts, prioritizing the studies in English. The review synthethizes findings on PM origin, including traffic, industrial emissions, constructing activities, and natural processes such as wildfires and volcanic eruptions. It also highlights the relationship between particle size and chemical composition, as well as the health-related effects of PM exposure, including respiratory and cardiovascular outcomes. The results underline the urgency of implementing measures to reduce PM emissions and protect public health.

Key words*: particulate matter; air; pollution; chemical composition, health impacts.*

INTRODUCTION

Air pollution represents a major issue affecting both the environment and human health. Particulate matter (PM) is one of the most damaging components found in air pollution. PM originates from a wide variety of sources, both natural and anthropogenic.

Due to its small size, PM can be inhaled easily, and its effects on human health can be severe, posing a significant risk. Numerous studies have been conducted to identify the wide range of effects caused by long-term exposure to PM, many of which have been linked to respiratory and cardiovascular diseases (Šarkan et al., 2023). Moreover, recent literature suggests potential links between PM exposure and metabolic disorders, including diabetes and obesity (Mahiyuddin et al., 2023).

Advanced wastewater treatment processes, such as the anaerobic-anoxic-aerobic (A_2O) (configuration studied by Marin et al., 2023) are pivotal in reducing environmental pollutants. By effectively removing nutrients like phosphorus from urban wastewater, these systems prevent eutrophication in aquatic ecosystems, which can lead to increased biological activity and the subsequent release of volatile compounds into the atmosphere. These compounds can act as precursors to secondary particulate matter formation, thereby contributing to air pollution. Thus, efficient wastewater treatment not only safeguards water quality but also plays an indirect role in mitigating airborne particulate matter levels, highlighting the interconnectedness of water and air pollution control strategies (Marin et al., 2023).

This review explores the origins, composition, and health impacts of PM, highlighting the significance of regulatory measures in protecting public health.

MATERIALS AND METHODS

Articles for this review were identified through searches in Scopus, Web of Science, DOAJ, and MDPI.

This review is based on the analysis of 13 articles published between 2019 and 2024, as listed in the bibliography. All included articles were directly selected for their relevance to particulate matter (PM), including its sources, chemical composition, atmospheric behaviour, and health impacts.

Inclusion criteria were articles addressing PM origin, particle size, chemical composition, or human health effects.
Exclusion criteria were studies not related to PM or human health.
The selected articles provide the data and figures presented in this review.

RESULTS AND DISCUSSIONS

This section provides a synthesis of the findings from various studies regarding the sources and health impacts of particulate matter (PM). The results are organised into several key themes, including the primary sources of PM, the health effects associated with exposure, and the long-term consequences for both individuals and populations.

Sources of Particulate Matter (PM)

Particulate matter (PM) consists of primary and secondary particles. Primary particles, especially ultrafine particles (≤0.1μm), are directly emitted from combustion processes, including transport, industry, power generation and heating. Secondary particles (2.5-10 μm) form through atmospheric chemical reactions. PM also contains dust, biological particles, and gaseous pollutants. Ultrafine particles can originate from gaseous precursors such as sulphur dioxide and nitrogen oxides. Natural sources include volcanic eruptions, forest fires, sea spray, pollen, and fungal spores (Chauhan et al., 2024).
Figure 1 illustrates the sources of PM pollutants and their atmospheric transport. Through chemical reactions, these particles interact with water and liquid molecules, leading to their accumulation in clouds. Wind currents then facilitate their upward movement (Amnuaylojaroen & Parasin, 2024).
Particulate matter (PM) is a major contributor to atmospheric pollution. In modern settings, residential heating and vehicular emissions are the primary sources, with higher concentrations in urban areas with dense traffic. Non-exhaust emissions result from resuspension of deposited particles, road abrasion, and tire or brake wear. Overall, PM pollution is largely driven by fossil fuel combustion.
(Šarkan et al., 2023).

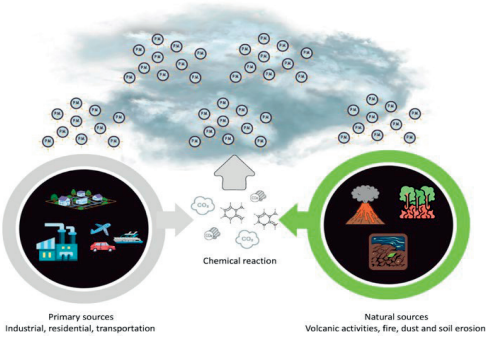

Figure 1. Emission sources of PM pollutants (Amnuaylojaroen T., & Parasin, N., 2024)

Table 1 provides a classification of ultra fine particles according to their types, subcategories, and particle diameters, facilitating a better understanding of their characteristics (Chauhan et al., 2024).

Table 1. Categories of Ultra fine Particles based on their type and size (Chauhan et al., 2024)

Type		PM Diameter(μm)
Particulate contaminants	Soot	0.01-0.8
	Smog	0.01-1
	Tobacco smoke	0.01-1
	Fly ash	1-100
	Cement dust	8-100
Biological contaminants	Viruses	0.01-1
	Bacteria and Bacterial spores	0.7-10
	Fungi and moulds	2-12
	Allergens (dogs, cats, pollen, household, dust)	0.1-100
Types of dust	Atmospheric dust	0.01-1
	Settling dust	1-100
	Heavy dust	100-1000
	Different gaseous contaminants	0.0001-0.01

Figure 2 shows that ultra fine particles (UFPs) come from both natural and anthropogenic sources. On the left are natural sources of PM, and on the right are human-made sources. In the middle, UFPs are shown as resulting from both types, underlining their mixed origin (Chauhan et al., 2024).

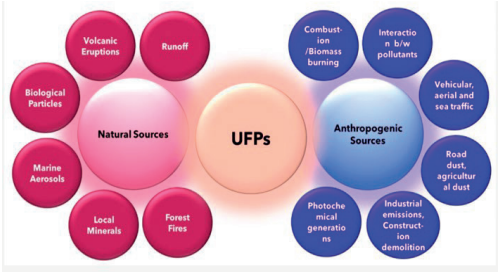

Figure 2. The main sources regarding the particulate matters (Chauhan, B.V.S. et al., 2024)

Health effects of PM exposure

Particle size is a key factor in PM toxicity. Smaller particles pose greater health risks as PM2.5 can reach the lower respiratory tract and settle in the bronchi, while particles larger than PM10 are mostly filtered by the nasal cavity. The chemical composition of PM further influences its effects. Poor air quality is a major global health threat, reducing life expectancy and surpassing even the risks of cigarette smoking (Šarkan et al., 2023).

Air pollution affects not only the respiratory system but also the cardiovascular system. PM exposure is linked to systemic inflammation, oxidative stress, endothelial dysfunction, and altered blood pressure, which can contribute to stroke and other cardiovascular conditions. The health impact of PM depends on particle size and composition. PM10 particles mostly deposit in the trachea and bronchi, while PM2.5 and ultrafine particles can reach alveoli and enter the bloodstream, spreading to other organs. PM may contain carbon monoxide, nitrates, sulphates, ozone, volatile organic compounds, heavy metals, and polycyclic aromatic hydrocarbons. Chronic PM exposure can trigger cellular stress, apoptosis, ferroptosis, pyroptosis, as well as DNA damage, epigenetic changes, and homeostatic disruption, increasing the risk of multiple disease (Lim & Kim, 2024).

The skin serves as a barrier against chemicals, pathogens, air pollutants, and UV radiation, while maintaining proper moisture levels. Keratinocytes, which make up 90% of the epidermis, respond to antigens by releasing cytokines and chemokines that regulate immune and inflammatory responses. Dysregulation of keratinocyte function can lead to excessive inflammation, contributing to skin aging and related disorders.

Figure 3 illustrates the relationship between particle size and their site of deposition in the human respiratory system. At the top, various particles such as molecules, viruses, bacteria, and pollen are shown according to their diameter, with reference to PM0.1, PM2.5, and PM10 size ranges. The bottom part of the figure illustrates how particles of various sizes accumulate in the respiratory tract. Particles between 10 and 30 µm are trapped in the oropharyngeal region; those between 2 and 10 µm reach the conducting airways; while ultrafine particles smaller than 2 µm can penetrate deep into the respiratory zone, including the alveolar ducts and sacs (Lim & Kim, 2024).

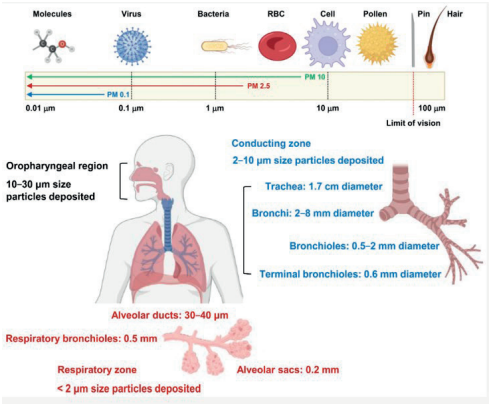

Figure 3. PM classification by aerodynamic particle size (Lim & Kim, 2024)

Constant exposure to particulate matter emissions provokes alveolar inflammation, induces disorders of the metabolic system and sets off the risk of cardiovascular diseases. In comparison, people with a history of chronic cardiovascular and respiratory diseases are much more vulnerable than others. They are significantly more susceptible to infections caused by PM exposure. Each of the two types of PM exposure, long or short term, has been associated with a high risk of cardiovascular and respiratory disease, along with the mortality rates. These associations were clearly demonstrated in earlier research, highlighting $PM_{2.5}$ as a significant contributor to non-accidental mortality (Mahiyuddin et al., 2023).

Figure 4 illustrates the human body with organs affected by particulate matter (PM) exposure, showing the brain impacted by cognitive

impairment and neuroinflammation, the neck with inflammation leading to irritation, the lungs affected by respiratory issues, the liver showing signs of hepatic damage, the skin with irritation and dermatitis, the vascular system inflamed and the heart at increased risk of damage or dysfunction (Lim & Kim, 2024).

The evaluation of exposure to pollution includes two divisions of health risk: non-carcinogenic and carcinogenic risks. The heavy metals Hg, Cu, Pb, Zn, Cr, Cd, and Ni are associated with chronic non-carcinogenic health effects. Additionally, Cd, Cr, and Ni pose a carcinogenic health risk, through dust inhalation.

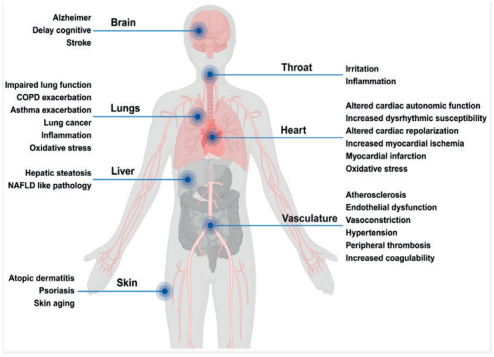

Figure 4. major affected organs by long exposure to PM (Lim & Kim, 2024)

The main routes of exposure to PM are ingestion, inhalation, and dermal absorption. The health risk assessment model is defined as follows:

$$ADD_{ing} = c*(IngR*CF*EF*ED)/(BW*AT) \quad (1)$$

$$ADD_{inh} = c*(InhR*EF*ED)/(PEF*BW*AT) \quad (2)$$

$$ADD_{derm} = c*(SA*CF*SL*ABS*EF*ED)/(BW*AT) \quad (3)$$

where:

ADD_{ing} = Daily contaminant intake via ingestion (mg/kg/day);

ADD_{inh} = Daily contaminant exposure via inhalation (mg/kg/day);

ADD_{derm} = Daily contaminant absorption through the skin (mg/kg/day);

c = contaminant concentration in the medium (e.g., soil, air, water);

IngR = Ingestion rate (amount ingested per day);

CF = Conversion factor (to ensure unit consistency);

EF = Exposure frequency (days per year of exposure);

ED = Exposure duration (total years of exposure);

BW = Body weight (kg);

AT = Averaging time (for non-carcinogens: ED × 365 days, for carcinogens: 70 years × 365 days);

InhR = Inhalation rate (volume of air inhaled per day);

PEF = Particulate emission factor (used for inhalation exposure modelling);

SA = Exposed skin surface area (cm^2);

SL = Skin adherence factor (mg/cm^2);

ABS = Dermal absorption factor (fraction of the contaminant absorbed through the skin) (Dunea, 2019).

Meteorological factors play a crucial role in disease occurrence due to PM exposure. Cold stress during winter is linked to a higher incidence of influenza and respiratory infections, which may contribute to cardiovascular complications. The accumulation of PM_{10} and its inverse correlation can be attributed to the low cloud cover and frequent fog events (Bodor et al., 2024).

Whereas the effect of air pollution on metabolic conditions has been extensively studied, its impact during pregnancy remains poorly evaluated. Pregnant women experience unique physiological changes, including increased energy intake, an accelerated basal metabolic rate, and natural insulin resistance, which may heighten their vulnerability to air pollutants. However, findings on this association remain inconclusive due to the limited number of studies focused on pregnant populations. Additional studies are needed to clearly understand the long-term exposure to PM on glucose metabolism during pregnancy and its potential effects on maternal and fetal health (Wu et al., 2024).

Long-Term Impact of PM on human health

PM pollution is higher in winter. Wind speed affects pollutant dispersion: higher speeds dilute pollutants, while lower speeds allow accumulation and prolong secondary chemical transformations (Fu et al., 2019).

Long-term exposure to PM10 (over than two years) increases non-accidental and cardiovascular mortality, particularly in individuals aged 40 and above. Older adults are more vulnerable, especially on hazy days, with higher risks of cardiovascular and respiratory diseases (Hu et al., 2023). Chronic PM2.5 exposure is linked to elevated blood pressure, thrombosis, insulin resistance, and oxidative stress in the lungs. Meta-analyses also indicate a higher risk of cardiorespiratory diseases even shortly after exposure to PM2.5 (Urbanowicz et al., 2024).

Extended observational studies over six years show that PM exposure worsens pre-existing lung conditions such as idiopathic pulmonary fibrosis (IPF) and other respiratory diseases. Fine particles can accelerate lung function deterioration and increase the risk of complications, highlighting the importance of reducing exposure for individuals with lung issues (Mariscal et al., 2024).

Certain populations are more susceptible to the harmful effects of PM. Children have developing lungs and immune systems, making them more prone to respiratory issues (Amnuaylojaroen & Parasin, 2024). Elderly individuals face higher risks of cardiovascular diseases due to prolonged exposure to PM2.5 and PM10 (Hu et al., 2023; Mahiyuddin et al., 2023). Pregnant women may experience adverse effects on fetal development from particulate exposure (Amnuaylojaroen T. & Parasin N., 2024).

To mitigate these risks, it is recommended that authorities implement air quality monitoring, stricter emission controls, and public awareness campaigns (Lim & Kim, 2024; Mariscal Aguilar et al., 2024). Sensitive groups should limit exposure to high pollution days, for example by staying indoors or using air purifiers (Mahiyuddin et al., 2023). Future research should focus on long-term health impacts in these vulnerable populations and evaluate the effectiveness of intervention strategies (Wu et al., 2024).

CONCLUSIONS

This research analyses the provenance, the composition, and the health impact of the pm on human condition after the pollution exposure.

PM derives from both natural and Anthropogenic sources, and it is classified into primary, secondary, and ultra fine particles. It results from various activities, including fossil fuel combustion, atmospheric chemical reactions, heating emissions, transportation, industrial processes, power generation, volcanic eruptions, and biological activity.

PM contains a wide range of contaminants such as dust, biological particles, gaseous pollutants, tire wear particles, carbon monoxide, nitrates, sulphates, volatile organic compounds, and heavy metals.

Health effects are mainly influenced by the size and chemical composition of PM.

Smaller particles are more hazardous upon inhalation, penetrating deeper into the body and affecting organs such as the brain, lungs, throat, heart, liver, vasculature, and skin.

Air pollution is linked not only to respiratory health issues but also to cardiovascular and cerebrovascular diseases. Moreover, prolonged exposure to PM induces systemic inflammation and DNA damage. Individuals with pre-existing chronic illnesses are particularly vulnerable to PM exposure.

Although PM exposure has also been studied in pregnant women, findings remain inconclusive due to the limited number of studies focused on this population.

Meteorological factors significantly influence the health risks associated with PM.

During winter, increased risk is observed due to cloudy days, low temperatures, and minimal wind speed, which allow pollutants to accumulate and suffer chemical transformations.

In comparison to short-term contact, long-term exposure has a deeper influence on human condition along with its outcomes linked to the age and medical history of the individual.

Abstract

This study presents an analysis of suspended sediment concentration and granulometric distribution along the Sulina branch of the Danube River, based on data collected using the AQUASCAT 1000S acoustic backscatter system. Measurements were conducted at six monitoring stations near or between the localities of Sulina, Gorgova, Crişan, Maliuc, Partizani, and an intermediate station between Sulina and Crişan. The AQUASCAT 1000S was employed to gather high-resolution acoustic data using its four frequency channels, ranging from kilohertz to megahertz, allowing for simultaneous observation of both fine and coarse sediment fractions. Data processing involved comparative analyses using different combinations of acoustic channels to evaluate their effectiveness in characterizing sediment concentration and size distribution across diverse hydrological and morphological conditions along the branch. Results reveal spatial variability in suspended sediment characteristics, influenced by local hydrodynamics and proximity to tributaries, human settlements, and natural channels. The study highlights the advantages and limitations of multi-frequency acoustic techniques in riverine sediment monitoring and contributes to the development of improved methodologies for sediment characterization in deltaic environments.

Key words*: AQUASCAT 1000S, Danube River, granulometry, multi-frequency analysis, Sulina branch, suspended sediment concentration.*

INTRODUCTION

The transport of suspended particulate matter (SPM) is a major problem for the aquatic environment, modifying the morphology of the seabed, marine habitats and the water quality index (WQI). In addition, there are also problems related to the health of aquatic flora and fauna because in the water, in addition to sand and silt, microplastics, heavy metals and even nuclear waste can be found as suspended matter, which can be consumed by fish and accumulate in their bodies.(Hunter et al., 2010; 2011; Iticescu et al., 2016; Popa et al., 2018; Arseni et al., 2020; Hussain et al., 2020; Călmuc et al., 2022; Lazăr et al., 2024). If people spend too much time in contact with such waters where the amounts of SPM are high or consume fish from these areas, the negative effects of these suspended matter can have negative effects on the human body (Falciola et al., 2022). In general, this toxic pollution is strictly anthropogenic, resulting from discharges of pollutants into waters and even naval transport. For such determinations related to the amount of SPM in water and sediment transport, modern acoustic technologies are becoming increasingly important in the assessment and monitoring of the aquatic environment, and equipment based on Acoustic Backscatter (ABS) technology, such as the AQUAscat 1000S, are essential for obtaining accurate data on SPM.(Smerdon & Thorne, 2008; Foote et al., 2010; Martini et al.,

2010; Hunter et al., 2012a; 2012b; Bux et al., 2015; Divinsky & Kosyan, 2019; Fromant et al., 2017; 2021; Van Dijk et al., 2024; Zhu et al., 2024). This equipment uses high-frequency sound waves to evaluate the intensity of the signal reflected by suspended particles such as fine sediments, organic materials or microorganisms. The instrument measures the sound reflected by sediments or other materials suspended in water at precise intervals, which can be set between 2.5 mm and 4 cm. For depth measurements, this interval can be several tens of centimeters, and for monitoring suspended sediments, the typical distance is about 1-2 meters. In the case of dredging slab estimation, measurements can reach up to 10 meters (Bux, 2016; www.Aquatecsubsea.com). This study aims to highlight the advantages and limitations of multi-frequency acoustic techniques in river sediment monitoring and contribute to the development of improved methodologies for sediment characterization in deltaic environments.

MATERIALS AND METHODS

Study area and localization

The field measurements, made on 23 August 2023, targeted the Sulina branch of the Danube River located in Danube Delta, Romania. Monitoring stations were strategically positioned along this channel to capture spatial variability in hydrological and sedimentological conditions. Each station was named based on the nearest locality.

The geographic coordinates of the Aquascat measurement sites are:

- Partizani sampling station (Partizani): 45.19330° N, 28.95869° E
- Maliuc sampling station (Maliuc): 45.17459° N, 29.11427° E;
- Gorgova sampling station (Gorgova): 45.18153° N, 29.17888° E;
- Crisan sampling station (Crisan): 45.17358° N, 29.42541° E;
- Interim Sulina sampling station (near Sulina): 45.18125° N, 29.51804° E;
- Sulina sampling station (Sulina): 45.16208° N, 29.68527° E.

A map of the measurement sites where Aquascat observations were carried out is presented in Figure 1. The map was made using a Geographic Information System (GIS) providing spatial reference relative to key settlements and hydrological features of the Danube Delta.

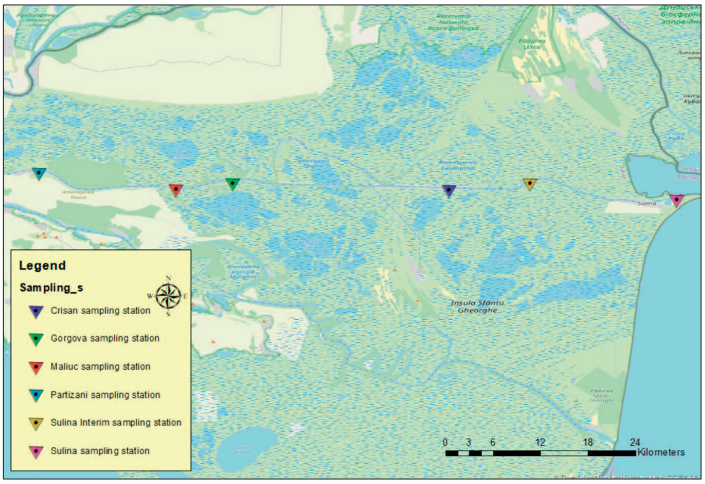

Figure 1. Location of the six sampling stations on Sulina branch located in Danube Delta

Equipment and data used

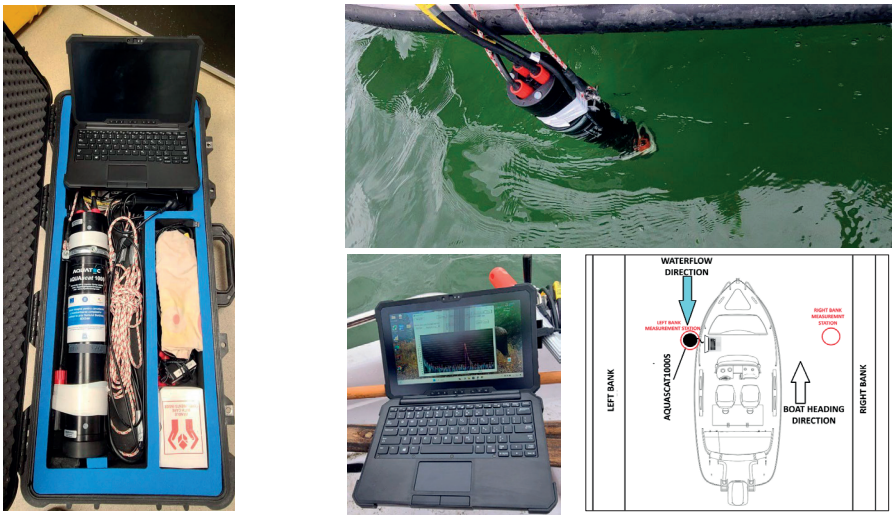
The AQUAscat 1000S is an advanced acoustic backscatter system designed for high-precision monitoring of suspended sediment concentrations (SSC) and particle dynamics in aquatic environments such as rivers, lakes,

estuaries, and coastal waters. It operates by transmitting sound pulses at multiple frequencies (typically between 300 kHz and 5 MHz) into the water and recording the intensity of the backscattered signals. Unlike light, sound propagates more slowly and is less attenuated in water, enabling the AQUAscat to generate continuous backscatter profiles rather than discrete point measurements.

SSC estimation relies on the frequency-dependent scattering properties of suspended particles. By analyzing the backscatter from multiple transmitted frequencies, the system differentiates particle sizes within a sensitivity range of 20–500 µm (radius), enabling the derivation of both particle size distribution and sediment concentration along the profiling range.

Designed to meet the demand for enhanced accuracy and efficiency, the AQUAscat 1000S significantly improves understanding of sediment dynamics, which are critical for assessing ecological processes and potential impacts on water quality and human health. Built with marine-grade materials, the AQUAscat 1000S is suitable for deployment in harsh environments and supports flexible installation (e.g., moorings, frames, or vessels). For this study, a vessel-mounted configuration was used, with the instrument secured to maintain vertical orientation and prevent transducer obstruction it can be seen in Figure 2. In this study, the AQUAscat 1000S was deployed at six monitoring stations along the Sulina branch (Partizani, Maliuc, Gorgova, Crișan, Interim Sulina, and Sulina), as illustrated in Figure 2. The main specifications of the device are detailed in Table 1.

The AQUAscat 1000S frequency range enables detection of a broad spectrum of particle sizes, from fine silt to coarse sand. High frequencies enhance sensitivity to small particles, while lower frequencies penetrate denser sediment clouds, allowing effective differentiation of particle sizes and analysis of sediment composition and transport.



Using time-gated signal processing, the instrument divides the water column into depth bins to generate high-resolution vertical profiles of suspended sediment concentration (SSC) and particle size. Depth range and resolution are configurable to suit specific research needs.

Data analysis using AquaTalk toolkit software

Real-time data acquisition is supported through the AQUAscatTalk interface (Figure 3), which visualizes backscatter intensity per frequency. Post-processing, including calibration and application of acoustic scattering models, converts raw backscatter into SSC and particle size values.

Table 1. AQUAscat 1000S specifications (adapted after www.aquatecsubsea.com)

Specification	Description and ranges
Sediment range	Sensitive to a wide range of grain sizes Size inversion typically feasible for 20 µm to 500 µm radius Typically 0.01 g/l to 20 g/l over 1 m, or more over shorter range
Frequencies	4 frequencies - 500 kHz, 1 MHz, 2 MHz, 4 MHz
Transducers	Ø10-25mm ceramic discs (beam width according to frequency) 4 fixed transducers
Gain	Software controlled transmitter and receiver gain adjustment
Range	150 cm (typical), up to 10 m at frequencies below 2 MHz depending on options
Transmission rate	128 Hz max pulse rate for each frequency (i.e. 512 pulses per second for four), subject to acoustic range limits. Minimum rate 1 Hz for calibration
Range cells	256 cells. 2.5 mm, 5 mm, 10 mm, 20 mm and 40 mm at 1500 m/s speed of sound. Start/end range set by software
Burst duration and interval	Defined by number of profiles requested. The duration is internally generated from once every minute to once every 255 minutes, user definable start time of first burst
Trigger output	A digital output allows triggering of external instruments
Additional sensors	Built-in turbidity sensor
Data comms	RS232 up to 115 kbaud; USB 1.1 typically 2-3 Mbaud
Housing options	1000m rated aluminium alloy housing.
Software	AQUAtalk ® for AQUAscat ® for logger interaction AQUAscat ® toolkit for data processing

Figure 2. AQUASCAT1000S: a) AQASCAT1000S equipament with all accesories and PC used for in field measurements; b) AQASCAT1000S equipment, PC and procedure (used for data recording) during deployment in measurement campaign on Sulina branch

The AQUAscatToolkit (Figures 3 and 4) is a MATLAB-based interface for processing and visualizing suspended sediment data from AQUAscat instruments.

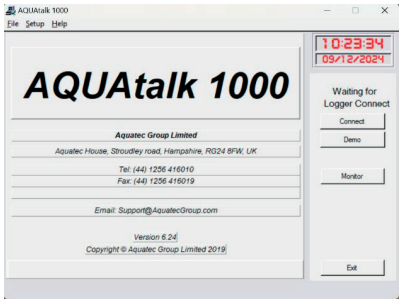

Figure 3. Software used for in-situ data measurement AQUAtalk 1000

It supports .aqa file handling, signal preprocessing, and SSC estimation.

Figure 3 shows first step of processing the raw data from the Partizani station, measured over a 10 m depth range during a 3-minute deployment. One-minute averaged profiles were generated by combining ~600 measurements per acoustic channel. Each channel targets specific sediment size ranges, enabling grain size distribution and concentration analysis. Final SSC values are computed by inverting backscatter data in the Calculated Suspended Sediment panel, providing an integrated sediment profile. Raw acoustic data from each 3-minute deployment was processed using the AQUAscatToolkit, with one-minute averaging and a 40 cm depth bin (Figure 5).

This initial preprocessing yields absolute backscatter (ABS) profiles, providing a first estimate of sediment distribution.

Suspended sediment data processing involved two main phases: (1) preprocessing, where backscatter profiles were averaged into one-minute intervals (~600 profiles per bin) to define vertical particle distribution from 40 to 1024 cm depth; and (2) post-processing, which included extensive averaging using ancillary data (temperature, pressure, salinity) to refine ABS profiles, followed by computational post-processing of raw data to derive high-resolution SSC and grain size profiles across the full 10.24 m water column.

Results were derived using the Calculated Suspended Sediment Profiles (SSCP) module, producing modeled grain size (μm) and concentration (g/L) for each 40 cm depth interval over a 10.24 m water column.

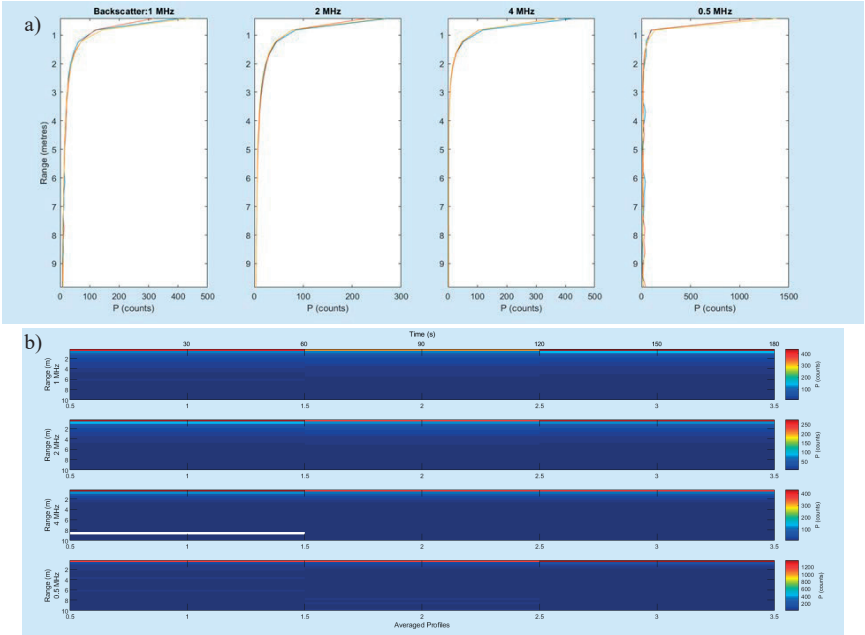

Figure 4. Measurement preprocessed results: a) Profiles of each channel recorded during monitoring campanin on 23 August 2023 at Partizani station, b) Backscater of each channel recorded during monitoring campanin on 23 August 2023 at Partizani station

RESULTS AND DISCUSSIONS

The results obtained from AQUAscat1000S measurements at each of the six of the measurement stations on Sulina branch presented provide detailed insight into the vertical and temporal distribution of suspended sediment concentration (SSC) and particle size within the water column. The data reflects both the intensity of sediment transport processes and the stratification of grain sizes under varying hydrodynamic conditions.

Figure 6 displays the SSC and means grain radius profiles (top panels), as well as their corresponding time-series distributions (bottom panels). The vertical SSC profile shows a marked increase in concentration with depth, reaching values over 200 g/L between approximately 8.1 m and 9.5 m, indicating significant near-bed sediment presence. In contrast, concentrations decrease sharply above 6 m, with surface values below 50 g/L, likely due to strong surface flows inhibiting particle settling. The mean grain radius profile reveals coarser sediments near the surface, with values between 150-200 µm in the 0.5-4.5 m depth range. Grain size gradually decreases below this zone, reaching a minimum of around 50 µm between 6.7 m and 9 m. Notably, a secondary increase in grain size, again nearing 200 µm, is observed below 9.5 m, suggesting active sediment resuspension or bedload interaction at the channel bottom.

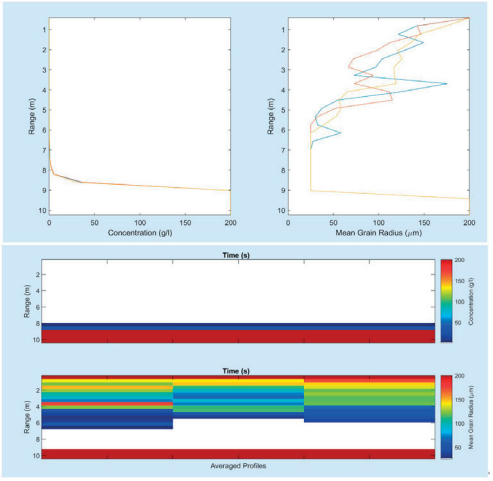

Figure 6. Profiles and time series of SSC grain size and concentration for Partizani station on 23.08.2023

These findings highlight a vertically stratified sediment structure, with finer particles suspended at mid-depths and coarse materials concentrated near the surface and bed. The distribution patterns reflect the interplay between flow velocity, sediment input, and depth-dependent turbulence, providing a representative snapshot of sediment dynamics in the Sulina branch at the time of measurement.

The measurements conducted at Maliuc station on 23 August 2024 reveal clear vertical stratification in both suspended sediment concentration (SSC) and particle size. As shown in Figure 7, SSC peaks near the channel bed, reaching values up to 200 g/L between 8.4 m and 10.2 m, while concentrations remain low (below 50 g/L) in the upper 8 m of the water column, consistent with enhanced surface flow limiting particle settling.

The grain size profile indicates coarser material near the surface, with mean grain radii reaching 200 μm in the top 0.5-2.5 m, followed by a mid-depth layer (2.5-5.7 m) of finer particles ranging from 50-120 μm. Below 5.7 m, grain sizes decrease significantly, dropping below 50 μm until approximately 9.2 m, where a second band of coarse particles (~200 μm) reappears near the bed (9.2-10.2 m), likely due to sediment resuspension or bedload interaction. These patterns show a typical two-layer structure, with coarse particles transported at the surface and near the bed, and finer sediments suspended in the mid-column, driven by local hydrodynamic conditions.

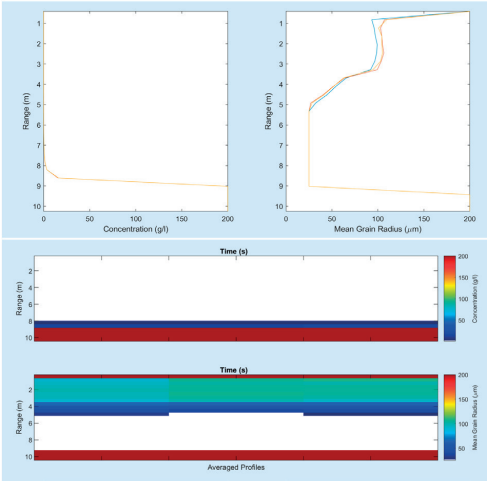

Figure 7. Profiles and timeseries of SSC grain size and concentration for Maliuc station on 23.08.2023

The vertical profiles and time-series recorded at Gorgova station (Figure 8) reveal a clear stratification of suspended sediment concentration (SSC) and grain size.

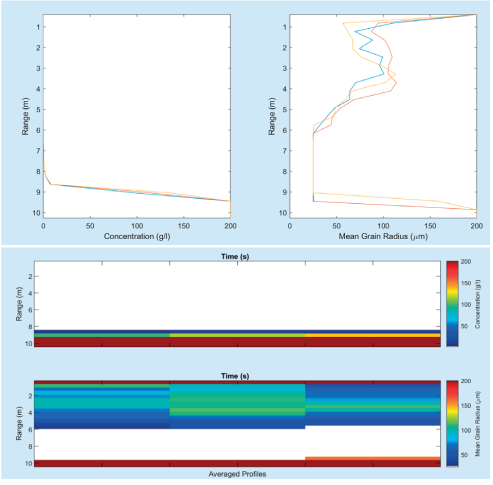

Figure 8. Profiles and timeseries of SSC grain size and concentration for Gorgova station on 23.08.2023

As shown in Figure 8, SSC values increase with depth, with concentrations of approximately 50 g/L observed between 8.5 m and 8.7 m, followed by a layer with concentrations

between 100-130 g/L from 8.7 m to 9 m. The highest SSC, exceeding 200 g/L, is concentrated near the channel bed (below 9 m), indicating active sediment resuspension or accumulation. Grain size profiles show coarse particles at the surface, with values near 200 µm in the upper 0.5-2 m, transitioning to a mid-depth band (2-6 m) where particle radii range between 50-120 µm.

Below 6 m, particle sizes decrease further, falling below 50 µm until 9.4 m. A distinct increase in grain size, again nearing 200 µm, is evident in the bottom layer (9.4-10.2 m), consistent with bedload material or localized turbulence effects. The SSC and grain size profiles recorded at Crișan station during the late summer survey indicate a clear vertical structure in sediment transport (Figure 9).

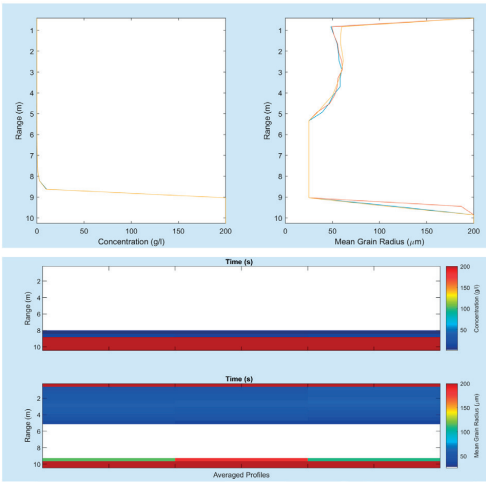

Figure 9. Profiles and timeseries of SSC grain size and concentration for Crișan station on 23.08.2023

SSC values begin to increase at depth, reaching ~50 g/L between 8.0 m and 8.7 m, with the highest concentrations exceeding 200 g/L near the channel bed (below 9 m). Near-surface concentrations remain low (below 50 g/L), likely due to higher surface flow velocities inhibiting particle settling. The anisys of calculated grain size profiles show the coarsest particles (~200 µm) at the surface in the 0-0.4 m depth bin, followed by a band of smaller particles (50-70 µm) between 0.4 m and 5.8 m. Below this, grain sizes decrease further, dropping below 50 µm between 5.8 m and 9 m, indicating a mid-column zone dominated by fine suspended sediments. A secondary increase in grain size is observed below 9 m, with values between 100-150 µm and peaking above 200 µm near the bed (9.0-9.8 m), suggesting active bedload transport or sediment resuspension in this deeper layer.

The profiles and time-series recorded at the Intermediary Crișan-Sulina station reveal pronounced vertical gradients in both suspended sediment concentration (SSC) and particle size (Figure 10).

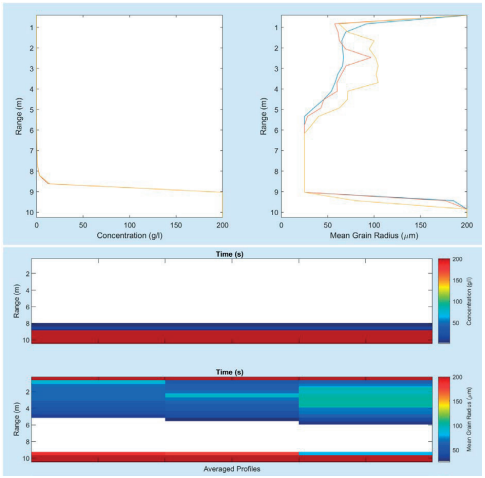

Figure 10. Profiles and time series of SSC grain size and concentration for Interim Sulina station on 23.08.2023

SSC values reach approximately 50 g/L between 8.7 m and 8.9 m, increasing to over 200 g/L near the channel bed (below 9 m), indicating significant sediment accumulation or resuspension in deeper layers. Surface concentrations remain low, under 50 g/L, likely due to enhanced turbulent mixing and flow velocity in the upper water column. Analysis on grain size distribution shows the coarsest material (~200 µm) at the surface within the 0-0.4 m bin. This is followed by a mid-layer (0.4-5.3 m) containing particles between 50-110 µm, and a further decrease below 5.7 m, where grain sizes drop below 50 µm, marking a zone dominated by fine sediments. At depths greater than 9 m, grain sizes increase again to 70-180 µm, with the bed layer exhibiting coarse material close to 200 µm, consistent with bedload transport dynamics.

At Sulina station, the suspended sediment concentration (SSC) and particle size profiles exhibit well-defined vertical patterns (Figure 11).

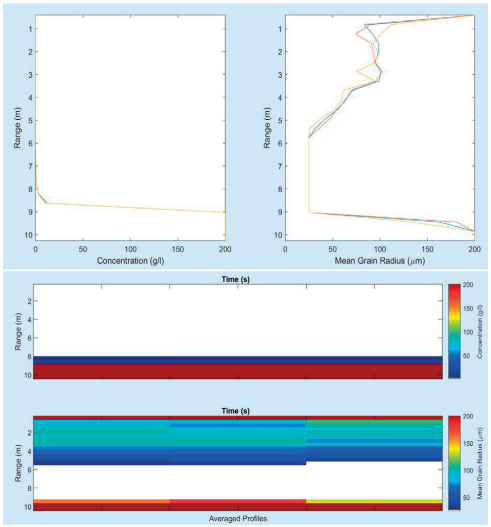

Figure 11. Profiles and time series of SSC grain size and concentration for Sulina station on 23.08.2023

SSC values begin to rise at depth, reaching approximately 50 g/L between 8.7 m and 9.0 m, and peak above 200 g/L near the channel bed (below 9 m), suggesting sediment accumulation in the deeper zone. In contrast, surface concentrations remain very low, under 50 g/L, likely due to stronger surface currents maintaining sediment in suspension or transporting it downstream. The grain size distribution reveals coarse particles (~200 μm) at the water surface within the 0-0.4 m layer, followed by a band of 50-110 μm particles in the 0.4-5.7 m depth range. Below this, grain sizes drop below 50 μm, indicating the dominance of fine sediment between 5.7 m and 9 m. At depths greater than 9 m, particle size increases again to 140-180 μm, with the bed layer (~10 m) showing grain sizes of ~200 μm, indicative of bedload transport or deposition.

These results confirm a vertically stratified sediment structure at Sulina, with coarse sediment layers at both the surface and bed, and a mid-column zone dominated by finer particles, shaped by local hydrodynamic conditions and channel morphology.

Statistical analysis of the sediment profile and transport dynamics

The Sulina branch, the only fully regulated and navigable channel of the Danube River in the Danube Delta, plays a key role in sediment transport and hydrodynamics. To assess sediment behavior along this branch, acoustic backscatter data from six stations were analyzed using Python. The analysis included vertical profiling of particle size and suspended sediment concentration (SSC), inter-station statistical comparisons, grain-size-based sediment classification (clay, silt, sand), and transport indicators such as cumulative mass and near-bed concentration, collectively offering insights into sediment distribution, flow intensity, and transport dynamics shaped by both natural and engineered conditions. Figure 12 presents overlaid line plots representing the vertical variation in particle size (μm) and suspended sediment concentration (g/l) for all six stations.

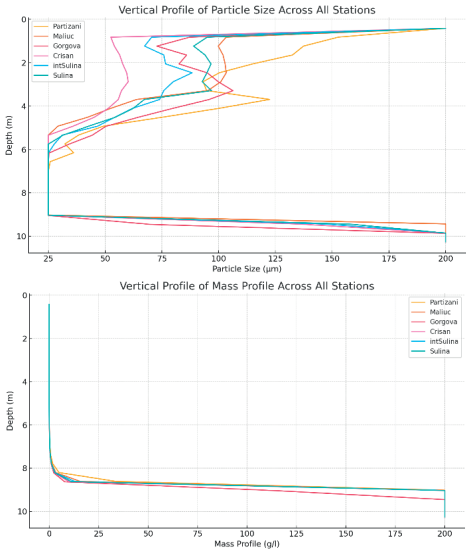

Figure 12. Vertical profiles of (a) particle size and (b) suspended sediment concentration (mass profile) across all six stations along the Sulina branch of the Danube River

Depth profiles are shown from surface to near-bed, revealing structural layering of sediment. Particle size tends to be coarser near the surface and bed, while SSC peaks at greater depths, especially below 8 m, where near-bed

resuspension is evident. The vertical separation between size and concentration layers reflects complex sediment transport regimes influenced by both turbulence and flow regulation. Partizani and Crișan show the most pronounced layering, suggesting localized energy gradients or bedload interactions.

To evaluate sediment variability along the Sulina branch, descriptive and inferential statistics were computed for each station, including measures of central tendency, dispersion, and depth correlations for both particle size and suspended sediment concentration (SSC). This statistical assessment offers insight into sediment heterogeneity, vertical structuring, and transport intensity under regulated flow conditions.

The results presented in Table 2 reveal that mean particle sizes ranged from approximately 63 to 90 μm, with highest variability observed at Partizani and Maliuc, suggesting greater sediment heterogeneity upstream. Suspended sediment concentrations (MP) exhibited large standard deviations and maximum values of 200 g/L at all stations, indicating the presence of high-density near-bed sediment layers.

Correlation analysis shows strong positive relationships between SSC and depth at all stations ($r \approx 0.64$-0.66, $p < 0.001$), consistent with typical stratified sediment profiles in energetic fluvial systems. In contrast, particle size-depth correlations were weaker and less consistent, reflecting more complex sediment sorting influenced by flow velocity gradients and local morphology. These statistical indicators support the presence of depth-dependent sediment stratification and highlight upstream-to-downstream shifts in sediment composition and concentration patterns along the Sulina branch. Classifying suspended sediments by grain size in our dataset allowed us to evaluate flow energy conditions, dominant sediment transport modes, and potential depositional environments along the Sulina branch.

Table 2. Statistical summary of suspended sediment parameters by station

Station	Mean Size (μm)	Std Size (μm)	Min Size (μm)	Max Size (μm)	Mean MP (g/l)	Std MP (g/l)	Min MP (g/l)	Max MP (g/l)	r(S,D)*	p(S,D)*	r(MP,D)*	p(MP,D)*
Partizani	90.23	64.08	25.00	200.00	33.67	74.39	0.0004	200.00	-0.224	0.2818	0.6637	0.0003
Maliuc	77.82	63.21	25.00	200.00	32.86	74.52	0.0002	200.00	-0.079	0.7074	0.6504	0.0004
Gorgova	74.71	55.15	25.00	200.00	29.10	68.37	0.0007	200.00	-0.173	0.4095	0.6398	0.0006

Int. Sulina	71.09	56.86	25.00	200.00	32.74	74.55	0.0006	200.00	-0.006	0.9784	0.6483	0.0005

*D - Water column depth or depth; MP - mass profile or concentration sediment particles; S - Size of the sediment particles.

Given the high-energy, regulated nature of this channel, we used standard granulometric thresholds - clay (<4 μm), silt (4-63 μm), and sand (>63 μm) - to distinguish between suspended, wash load, and bedload transport regimes.

Based on the measured particle size values at each depth, we categorized sediment samples into these three classes. For each station, we calculated the percentage contribution of clay, silt, and sand within the water column, enabling a clear assessment of the dominant sediment fractions and their vertical distribution across the branch. The results can be seen in Table 3.

The results confirm that sand-sized particles dominate the suspended load at all stations (>89%), indicative of a high-energy, turbulent regime capable of mobilizing and suspending coarse material. The low clay and silt content further suggests that fine sediments are either scoured or flushed downstream, consistent with the artificially regulated and navigable nature of the Sulina branch.

Table 3. Sediment classification by grain size

Station	Clay (%)	Silt (%)	Sand (%)
Partizani	1.52	4.55	93.94
Maliuc	1.52	4.55	93.94
Gorgova	1.52	7.58	90.91
Crișan	1.52	9.09	89.39
Int. Sulina	1.52	7.58	90.91

Slightly higher silt content at downstream stations may signal reduced turbulence or

localized deposition zones, but these remain minor. To assess sediment mobility and deposition potential along the Sulina branch, we calculated three key indicators based on our data: cumulative sediment mass (g/l) as a proxy for total load, near-bed average suspended sediment concentration (SSC) to identify potential resuspension zones, and the correlation between particle size and SSC to evaluate the relationship between sediment coarseness and concentration. These metrics enabled comparative analysis between stations, highlighting differences in transport energy, vertical sediment structure, and the contribution of coarser particles to the suspended load (Tabel 4).

Table 4. Sediment transport indicators

Station	Cumulative Mass (g/l)	Near-Bed Avg MP (g/l)	Size-MP Correlation
Partizani	841.86	166.74	0.438
Maliuc	821.48	163.14	0.545
Gorgova	727.59	144.64	0.473
Crișan	814.66	161.98	0.604
Int. Sulina	818.41	162.61	0.558

The upstream stations Partizani and Maliuc register the highest cumulative sediment loads, likely due to greater sediment input or upstream scouring. Near-bed concentrations exceeding 160 g/l across all stations confirm the presence of dense sediment layers at depth, characteristic of bedload interaction or resuspension zones. Moreover, the moderate-to-strong positive correlations ($r = 0.44$-0.60) between particle size and SSC suggest that coarser particles are frequently suspended when concentrations are high, pointing to intense turbulent mixing and localized energy peaks within the flow.

CONCLUSIONS

This study provided a detailed assessment of suspended sediment dynamics along the Sulina branch, the only fully regulated and navigable distributary of the Danube River. Using high-resolution acoustic backscatter data from six monitoring stations, we analyzed vertical profiles of suspended sediment concentration (SSC) and particle size, supported by statistical classification and transport indicators.

The results revealed a clear vertical stratification of sediments, with SSC peaking near the riverbed (often exceeding 160 g/l) and particle sizes ranging from fine silts to coarse sands. Statistical analysis showed strong positive correlations between SSC and depth, confirming concentrated sediment layers at depth across all stations. In contrast, particle size showed more variable vertical patterns, suggesting localized flow effects.

Sediment classification based on grain size demonstrated a clear dominance of sand (>63 μm) at all stations, consistent with the high-energy, engineered channel environment. Fine sediment fractions (clay and silt) were minimal, indicating efficient downstream flushing and limited deposition zones.

Transport indicators further supported these findings, with upstream stations exhibiting higher cumulative sediment loads, and moderate to strong correlations between particle size and SSC indicating the frequent suspension of coarse material under energetic flow conditions.

Together, these analyses confirm that the Sulina branch functions as a high-capacity sediment transport corridor, where flow regulation enhances both sediment throughput and vertical stratification. The findings have important implications for navigation management, dredging operations, and understanding sedimentary processes in modified deltaic systems.

Abstract

Urban air pollution poses a critical challenge due to rapid urbanization, increasing vehicular emissions, industrial activities, and infrastructure expansion. Accurately assessing pollution levels and pinpointing emission sources is essential for effective environmental management. This study integrates advanced remote sensing techniques with cost-effective sensor technologies to monitor air quality in an urban setting. Mobile measurements were conducted on April 18, 2024, using the UGAL MDOAS system and the Sniffer 4D sensor, both mounted on a vehicle. The UGAL MDOAS system employs Differential Optical Absorption Spectroscopy (DOAS) to detect atmospheric trace gases, while the Sniffer 4D utilizes electrochemical sensors to quantify pollutant concentrations. This study focuses on measuring and comparing NO_2, O_3, SO_2, O4 and PM levels from both instruments. The findings contribute to enhancing urban air pollution monitoring by demonstrating the effectiveness of hybrid measurement approaches in identifying pollution hotspots and improving air quality assessments.

Key words*: air pollution, urban monitoring, remote sensing, low-cost sensors, DOAS, air quality assessment.*

INTRODUCTION

In recent years, the increase in air pollution in urban areas has become a significant problem. The development and expansion of rural areas comes at the same time as increasing pollution and decreasing the quality of the environment in which we live. It affects the health of residents, causing everything from respiratory discomfort to chronic lung and even heart diseases (Adebayo-Ojo et al., 2022.; Bernstein et al., 2004; Brunekreef et al., 2022; Zhang et al., 2014). Among these dangerous pollutants are NO_2, O_3, SO_2 and particulate matter (PM) (Adebayo-Ojo et al., 2022; Al-Janabi et al., 2021). In addition to negative effects on human health in their primary state, these pollutants can transform, with the help of other substances in the air or ultraviolet radiation, into other much more dangerous pollutants such as photochemical smog, which has represented and represents a major problem in heavily industrialized rural areas with increased traffic (Rani et al., 2011; Tiao et al., 1975; Carlos Meier et al., 2017; D. Constantin et al., 2013; Constantin et al., 2020).

The main sources of these pollutants are industrialization, infrastructure development and expansion of urban areas as well as the increased number of vehicles, but there can also be natural sources such as fires, lightning or volcanic eruptions and even biological sources like microbial activity in soil. Advancing technology offers us increasingly advanced possibilities for monitoring air quality, including techniques and devices such as UGAL MDOAS and Sniffer4D v2.

This analysis aims to determine whether emission sources are identified by mobile monitoring. Also, the study aims to compare if the data from both equipment's are suited to identify emissions sources of know pollutants such as: NO_2, SO_2, O_3 and PM. Another direction is to compare the recorded data from both instruments to show how emissions are dispersed on altitudes depending on emission

source such as industry or car traffic (Constantin et al., 2017; Roșu et al., 2017; Roșu et al., 2020).

MATERIALS AND METHODS

Study area and measurement system configuration

The study aims to measure air pollution levels and identify emission sources in the city of Galati by using the measurements made on April 18, 2024, along the city's main street. The measurement route is presented in Figure 1 along with general wind speed and direction during measurement, also some with the local air quality stations (AQS). Unfortunately, that day all the were on maintenance routine and no data for comparison with our measurements was possible.

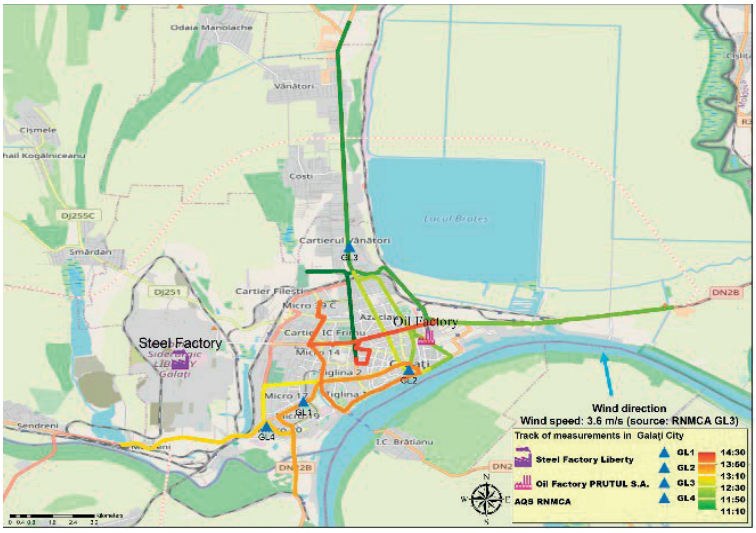

Figure 1. The route on which the measurements were taken correlated with the time interval

This study presents the results of mobile air quality measurements conducted in one of the largest cities in Romania using a remote sensing system developed by the Faculty of Science and Environment, University "Dunărea de Jos" of Galați called UGAL MDOAS, along with a multisensory system, Sniffer 4D. Both instruments were mounted on the same vehicle, allowing simultaneous data collection and facilitating direct comparison between the two systems. (Figure 2).

The UGAL MDOAS system uses differential optical absorption spectroscopy (DOAS) techniques to determine gas densities in the atmosphere with capabilities of measurement of the pollutants located in troposphere as molecules/cm^2, while Sniffer 4D uses electrochemical sensors to quantify pollutant concentrations in the air around the car where the system is mounted. These two complementary measurement techniques provide a more comprehensive understanding of air pollution dynamics by combining remote sensing with direct low cost *in situ* monitoring methods.

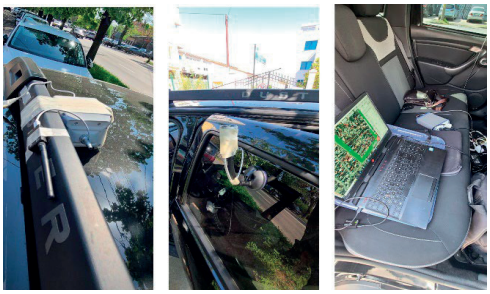

Figure 2. Mobile system setup for Sniffer4Dv2 and MDOAS UGAL

Equipment and data used

The equipment Sniffer4D V2 is an advanced gas detection and mapping system, designed to simultaneously measure up to 9 types of gases and particles at a time, providing real-time 2D

and 3D maps of their distribution. The system can monitor parameters such as: $PM_{2.5}$, PM_{10}, O_3, NO_2, CO, SO_2, VOCs, Odor (OU), CH_4, Cl_2, H_2S, H_2, HF, PH_3, Gas sampling, wind and speed direction and other customised parameters. Our system configuration has only the sensors for: PM_{10}, $PM_{2.5}$, O_3 NO_2 and SO_2. Other features that Sniffer4D V2 has are presented in Table 1.

The system is composed of multi-gas detection hardware and powerful analytical software, that can easily be integrated onto drones or ground vehicles for efficient inspections in various environments. (Godfrey et al., 2022; h*ttps://Enterprise.Dji.Com/Ecosystem/Sniffer-V2*; Jiang et al., 2024; Kulakova et al., 2024; Liu et al., 2024; Prisacariu et al., 2022; Yu et al., 2022).

In addition, by assessing spatial variations in pollutant concentrations, the study analyses the evaluation of stationary monitoring networks in capturing hotspots of transient emission events that would otherwise be overlooked.

Table 1. Specifications and capabilities of Sniffer4D V2 equipment (https://Enterprise.Dji.Com/Ecosystem/Sniffer-V2)

Category	Specification/Feature
Dimensions	157 × 103 × 87 mm
Weight	< 500 g
Ingress Protection	IPX2 (protection against vertically dripping water)
Explosion Proof	Yes (Ex-proof rated)
Casing	Aluminium alloy with anti-EMI shielding
Mounting	Internal suspension mechanism for shock and vibration isolation
Air Intake	Active air intake system
Connectivity	Supports GSM/cellular network connectivity
Data Management	- Automatic data backup to SD card (if installed) - Built-in data retrieval algorithm
Mobility Potential	Compact and lightweight design suitable for mounting on drones or mobile platforms

The DOAS technique, in particular the differential oblique column density (DSCD) retrieval method for measuring trace gases in upper atmosphere (troposphere). The system used, called UGAL MDOAS (employs Differential Optical Absorption Spectroscopy), was at "Dunărea de Jos" University of Galați, Faculty of Science and Environment (D. Constantin et al., 2013; D.E. Constantin et al., 2017; Roșu et al., 2017; Roșu et al., 2020). Configuration of the UGAL MDOAS system can be found below in Table 2 for main components and Table 3 for the details on the main component (spectrometer) of the UGAL DOAS instrument.

Table 2. The main components of the UGAL MDOAS

Component	Description
UV–Vis spectrometer	Avantes AvaSpec-ULS2048, one channel Black baffle: internal diameter: 9 mm, length: 2 cm
Telescope (baffle+lens)	Black baffle: internal diameter: 9 mm, length: 2 cm Avantes collimating lens; confocal length: 8.7 mm Telescope's field of view: 2.56°
Optical fiber	Avantes 600 µm chrome plated brass optical fiber, 1 or 10 m length
GPS	Mouse GPS for positioning of recorded data
PC	Laptop with win 10 or 11

Table 3. The main characteristics of the Avantes UV-Vis spectrometer

Specification	Description
Optical Bench	symmetrical Czerny-Turner, 75 mm focal length
Wavelength range	200-550 nm
Resolution	0.7 nm
Sensitivity	250,000 counts/µW per ms int. time
Detector	Back-thinned CCD [1] image sensor 2048 × 16 pixels, non-cooled
Signal/Noise	450:1
Integration time	1.82 ms–60 s
Interface	USB 2.0 high speed, 480 Mbps RS-232, 115,200 bps
Data transfer speed	1.82 ms/scan (USB2.0 [2])
Power supply	Default USB power, or with SPU2 external 12 V DC
Dimensions; weight	175 × 110 × 44 mm (1 channel), 855 g

RESULTS AND DISCUSSIONS

Using the data collected by both devices and using a GIS software we have made a series of maps that highlight spatial comparison of the recorded values for each parameter such as: NO_2, SO_2, O_3, O_4 and $PM_{2.5}$. The entire measurement timeline for the track analyzed on April 18, 2024, is represented using a color gradient, with measurements taken after 11:00 displayed in green and those after 14:00 shown in red, as illustrated in Figure 1. Spatial analysis of the data using maps enables a detailed evaluation of parameter variations and provides

a clearer understanding of their distribution in the troposphere and their dynamics near the surface.

These observations are essential for identifying and quantifying factors that influence air quality, such as industrial activity within the city, as well as the effects of other variables, including wind direction and the influence of urban topography on the positioning of emission plumes.

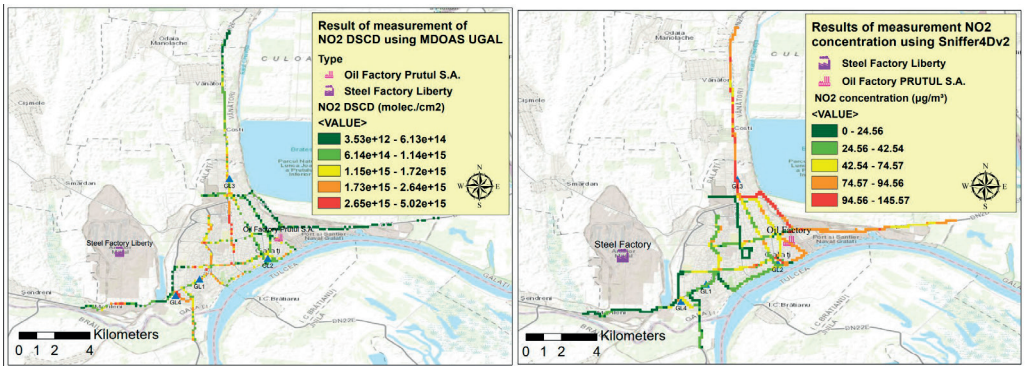

Figure 3. Spatial comparisons of NO_2 measured by the mobile system Sniffer 4Dv2 and MDOAS UGAL

As shown in Figure 3, the measurement units differ between the two instruments. This is because the Sniffer4Dv2 detects NO_2 concentrations at ground level, reporting values in µg/m³, whereas the MDOAS UGAL (UM) measures the vertical column density of NO_2 molecules over a 1 cm² cross-sectional area, expressed in molecules/cm².

Due to these differing units and sensing approaches, comparisons between the two instruments rely on colour-coded ranges. At the beginning of the measurement route, the MDOAS UGAL registers relatively low NO_2 values, with the first segments mostly falling into the green to light green range (3.53×10^{12} to 1.14×10^{15} molecules/cm²). In contrast, the Sniffer4Dv2 shows moderate to high concentrations for the same segments, predominantly within the orange to red classes (74.57 – 145.57 µg/m³), particularly in the northern and eastern parts of the city.

This discrepancy suggests that, during the measurement period, NO_2 was more concentrated near the surface, likely due to localized emissions such as road traffic and industrial activities. The MDOAS UGAL, measuring total column density, might underrepresent surface-level pollution when vertical mixing is limited or when pollutants are trapped in the lower atmospheric layers.

In the southern and central parts of Galați, especially after 12:40 (as inferred from route direction and segment labels), the MDOAS UGAL data reveal greater spatial variability. While most areas, including the zone near the Steel Factory Liberty, show low to moderate NO_2 columns (dark green to yellow), a localized hotspot (red) south of the industrial area indicates a significant vertical NO_2 presence, possibly from a point source or stack emissions. Meanwhile, the Sniffer4Dv2 continues to show elevated ground-level concentrations in these areas, especially near the oil factory, the steel plant, and key urban intersections, indicating intense surface-level NO_2 due to industrial and vehicular emissions. Some segments in the south and near the lake show improved air quality (green), suggesting either fewer emissions or better pollutant dispersion.

These contrasting observations highlight the different sensitivities and spatial resolutions of the instruments. The MDOAS UGAL is influenced by the vertical distribution of NO_2, while the Sniffer4Dv2 reflects surface concentrations, where human exposure is most relevant. The data suggest that during the measurement period, NO_2 pollution was largely confined to the lower atmosphere, emphasizing the dominant influence of ground-level sources such as traffic and localized industrial activity.

A spatial comparison of SO_2 measurements from both devices is presented in Figure 4.

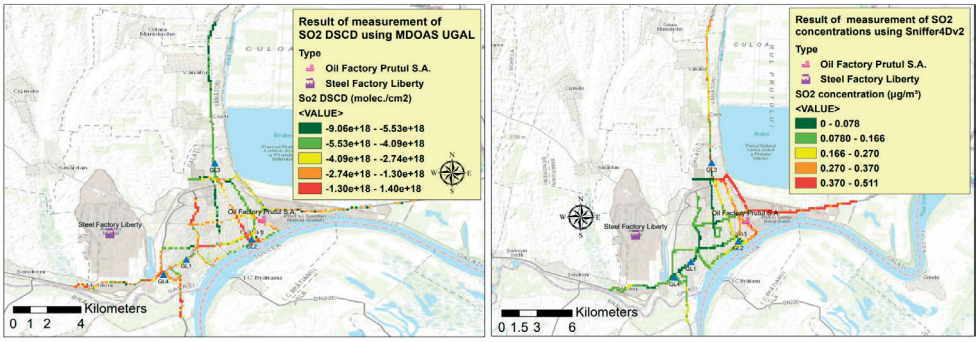

Figure 4. Spatial comparisons of SO_2 measured by the mobile sistems Sniffer 4Dv2 and MDOAS UGAL

Figure 4 presents a comparison of SO_2 concentrations measured by the MDOAS UGAL system (top) and the Sniffer4Dv2 (bottom). The MDOAS UGAL device measures SO_2 vertical column densities, which are especially sensitive to elevated emission sources such as those from industrial chimneys. Accordingly, it detects higher values of SO_2 (up to 1.30×10^{18} molecules/cm²) around industrial areas, particularly near the Steel Factory Liberty and the Oil Factory Prutul S.A., indicating the influence of high-altitude emissions. In contrast, lower values (as low as 4.86×10^{15} molecules/cm²) are observed on the road exiting the city to the north and in less industrialized zones during the first half hour of monitoring, suggesting cleaner atmospheric columns in those areas.

Meanwhile, the Sniffer4Dv2, which measures ground-level SO_2 concentrations, records significantly higher values (up to 0.511 µg/m³) in the eastern and north-eastern parts of the city, where emissions are likely trapped near the surface due to low wind speeds or limited vertical mixing. However, in the southwestern industrial area, Sniffer4Dv2 shows lower concentrations (mostly below 0.166 µg/m³), even though MDOAS UGAL reports high column densities in the same area. This contrast supports the conclusion that the industrial SO_2 emissions there are released at higher altitudes - above the sensitive range of the Sniffer4Dv2 but well captured by the DOAS system.

It is important to note that the Sniffer4Dv2, being a compact and portable sensor, is primarily designed for ground-level monitoring. However, its capability to be mounted on unmanned aerial vehicles (UAVs) such as drones offers the potential to detect elevated industrial plumes in future studies. This application will be further explored to assess vertical emission structures more comprehensively.

This comparison underscores the complementary nature of the two instruments: while the MDOAS UGAL is effective in detecting elevated plumes from point sources such as stacks, the Sniffer4Dv2 provides detailed information about ground-level exposure relevant for human health assessments, and potentially, in future configurations, about elevated sources as well.

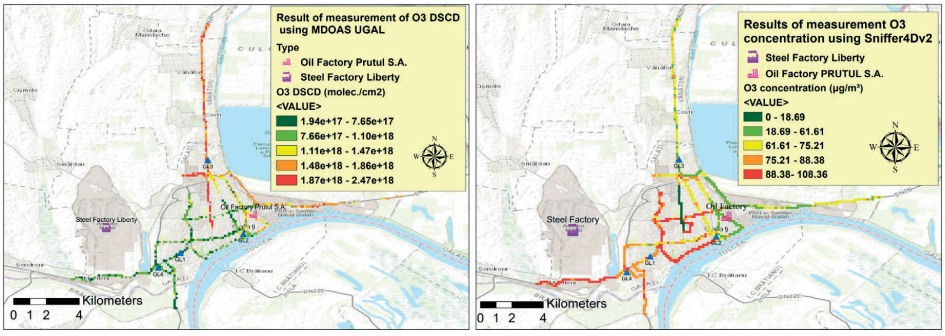

Figure 5. Spatial comparisons of O_3 measured by the mobile sistems Sniffer 4Dv2 and MDOAS UGAL

Figure 5 presents the spatial distribution of ozone (O_3) concentrations measured by MDOAS UGAL (top panel) and Sniffer4Dv2 (bottom panel). The results show a notable inversion in the spatial trends between the two instruments.

In the northern and eastern sections of the city, before 12:50, the MDOAS UGAL recorded higher ozone column densities, with values predominantly in the range of 1.46×10^{18} to 2.04×10^{18} molecules/cm², indicating elevated ozone presence in the vertical atmospheric column. In contrast, the Sniffer4Dv2 recorded lower ground-level ozone concentrations in the same areas, generally between 16.01 and 58.31 µg/m³, suggesting better air quality at the surface in those regions. After 12:50, the situation reverses: the MDOAS UGAL measurements show reduced column densities, mostly in the range of 7.66×10^{17} to 1.18×10^{18} molecules/cm², with only isolated moderate values at traffic intersections. However, the Sniffer4Dv2 records increased ground-level concentrations, with values reaching the highest range of 78.31–103.56 µg/m³, particularly in the central and southwestern parts of the route. These are indicators of poor air quality likely driven by surface-level ozone formation from traffic-related precursors and sunlight-driven photochemical activity.

This comparison emphasizes the different vertical sensitivities of the two instruments. MDOAS UGAL detects total atmospheric column densities, making it sensitive to ozone aloft, while Sniffer4Dv2 provides data directly relevant to human exposure at ground level.

The O_4 (oxygen dimer) is formed when two O_2 molecules interact and briefly bind together, typically under high-pressure conditions. Although O_4 is not stable as a separate pollutant, its absorption features are useful for atmospheric remote sensing, as its concentration is proportional to air density and can provide information about the vertical distribution of pollutants (Wagner et al., 2004). It also plays a role in radiative transfer and can indicate regions with higher aerosol presence (Wagner et al., 2004).

On the other hand, $PM_{2.5}$ is a particulate matter with a diameter less than 2.5 micrometres, which is comparable to O4, is a major air pollutant that may cause serious health risks. Due to their small size, $PM_{2.5}$ particles can penetrate deep into the respiratory system, reaching the alveoli and even entering the bloodstream. Long-term exposure is associated with respiratory and cardiovascular diseases, including asthma, bronchitis, heart attacks, and increased mortality (Pope and Dockery, 2006).

While O_4 is measured by the MDOAS UGAL instrument as a tracer of air mass density and potential aerosol interaction in the atmospheric column (Wagner et al., 2004), $PM_{2.5}$ is measured directly at ground level by the Sniffer4Dv2. When interpreted together, these parameters can help infer the vertical and horizontal distribution of particulate pollution: elevated O_4 may indicate dense air layers or aerosol-rich zones, which could be linked to high surface $PM_{2.5}$ concentrations under stagnant or stratified atmospheric conditions.

In our study, we also addressed this research direction by leveraging the unique capabilities of the MDOAS UGAL to retrieve O_4 column densities and the Sniffer4Dv2 to measure $PM_{2.5}$ concentrations, providing a more comprehensive perspective on atmospheric composition and air quality dynamics, as shown in Figure 6.

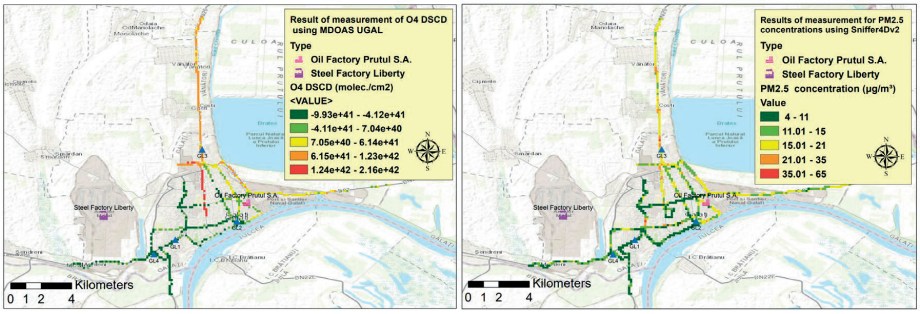

Figure 6. Spatial distribution of O_4 and $PM_{2.5}$ measured by MDOAS UGAL respectively Sniffer4Dv2

Figure 6 illustrates the spatial and temporal behaviour of two distinct atmospheric parameters: O_4 (oxygen dimer) measured by the MDOAS UGAL system (top panel), and $PM_{2.5}$ (particulate matter < 2.5 μm) measured at ground level by Sniffer4Dv2 (bottom panel).

The upper map shows a clear decreasing trend in O_4 differential slant column densities throughout the measurement period. Initially, the O_4 values are highest, exceeding 1.62×10^{42} molec./cm², but progressively decline, reaching the lowest range (4.85×10^{41} to 1.02×10^{42} molec./cm²) toward the end of the route. This pattern is likely influenced by increasing solar radiation and temperature, both of which can affect the stability of O_4. The oxygen dimer is transient and weakly bound, and under elevated temperature and strong UV radiation, it can dissociate more rapidly, leading to lower detected column densities as the day progresses. In contrast, the $PM_{2.5}$ ground-level concentrations measured by Sniffer4Dv2 show a more consistent spatial-temporal distribution. Higher values (15-35 μg/m³) are recorded at the beginning of the measurement period, with concentrations gradually decreasing to values below 15 μg/m³, predominantly within the 4-11 μg/m³ range by the second half of the route. This trend reflects the settling or dispersion of fine particulate matter, possibly aided by morning turbulence or changing traffic patterns.

A significant factor contributing to the observed differences between the instruments lies in their measurement geometry and altitude sensitivity. The MDOAS UGAL captures slant column densities through the atmosphere, with sensitivity up to approximately 2 km altitude. Therefore, it can detect pollution plumes situated aloft, which may not be captured by ground-based systems such as Sniffer4Dv2. Conversely, Sniffer4Dv2 records near-surface concentrations, reflecting immediate human exposure but missing elevated layers of pollution.

When Sniffer4Dv2 reports lower values than MDOAS UGAL, it may indicate that the pollution plume is located at higher altitudes - a condition potentially linked to emissions from tall industrial stacks. In particular, areas near factories may exhibit these discrepancies due to elevated release points of SO_2 and PM precursors.

Additionally, wind shear and vertical wind profiles can lead to significant variability in pollutant distribution. Wind direction and speed often vary with altitude and time of day. These variations may explain temporal shifts in the measured pollution and the spatial differences between zones with similar sources. For example, plumes emitted during the early morning might drift at higher altitudes due to thermal uplift, while later in the day, ground-level dispersion may dominate. Our future studies will include the research direction where we will incorporate meteorological data such as wind speed, wind direction, and temperature profiles to more accurately characterize the spatial distribution and intensity of emission plumes, as well as to identify their likely sources.

CONCLUSIONS

This study presented a comparative analysis of trace gases and particulate matter ($PM_{2.5}$) using two complementary mobile measurement systems: the MDOAS UGAL (based on Differential Optical Absorption Spectroscopy) and the Sniffer4Dv2 (a compact air quality system with electrochemical sensors). Despite differences in measurement principles and vertical sensitivity, both instruments consistently identified key pollution hotspots, particularly at major intersections and industrial areas, where emissions from traffic congestion and heavy-duty vehicles were clearly detected.

From the results, NO_2, SO_2, and O_3 measurements showed converging spatial patterns between the two instruments in high-traffic zones, confirming the influence of urban infrastructure and transportation on localized air pollution. The findings presented from the coupling between O_4 and $PM_{2.5}$ in which O_4 was analyzed from MDOAS UGAL data and $PM_{2.5}$ from Sniffer4Dv2, further highlighted how these systems offer complementary insights. The O_4 column densities decreased gradually over time, likely due to increasing solar radiation and atmospheric instability, while $PM_{2.5}$ showed a more stable distribution, initially peaking at 15-35 μg/m³ and declining below 15 μg/m³ toward the end of the route.

Discrepancies observed between the instruments - such as elevated O_4 or NO_2 column

densities where $PM_{2.5}$ or NO_2 ground concentrations remained low - can be explained by their distinct vertical sensitivities. MDOAS UGAL, which integrates slant column densities across atmospheric layers, is sensitive to elevated plumes from point sources such as industrial stacks, whereas the Sniffer4Dv2, positioned at ground level, detects near-surface pollutants more directly linked to human exposure. In cases where MDOAS recorded high values, but Sniffer4Dv2 did not, pollution was likely present at higher altitudes, potentially transported by wind or emitted from tall chimneys. Conversely, elevated surface concentrations with lower column values suggest that pollution remained confined near ground level.

To reduce such discrepancies and enable a more integrated vertical interpretation, future work will focus on converting Differential Slant Column Densities (DSCDs) into true vertical columns using satellite-derived stratospheric corrections (e.g., from OMI or TROPOMI data collected on the same day). Additionally, Air Mass Factor (AMF) simulations using radiative transfer modeling (RTM) will be employed to estimate near-surface pollutant concentrations from DOAS measurements with greater accuracy.

Moreover, integrating high-resolution meteorological parameters such as wind speed, wind direction, temperature, and atmospheric pressure will enhance pollutant transport modeling and source attribution. This multi-parameter framework will provide improved insight into both vertical and horizontal pollution dynamics.

Importantly, this study's dual-system approach has broader implications for urban environmental monitoring and policy development. By combining mobile, high-resolution surface-level data with atmospheric column measurements, the methodology enables a more comprehensive and scalable assessment of air quality. This is particularly valuable in urban areas with complex emission profiles or limited fixed monitoring infrastructure. The approach can support evidence-based urban planning and regulatory strategies, such as optimizing the placement of air quality stations, identifying priority areas for emission reduction, and informing traffic and industrial zoning decisions.

In summary, the integration of complementary remote sensing and low-cost sensor technologies offers a robust and flexible monitoring framework. It strengthens both scientific understanding and policy-making capacity, paving the way for more adaptive and informed air quality management in rapidly urbanizing environments.

ACKNOWLEDGEMENTS

The authors acknowledge the support of the project "Support for the operation of Romania's facilities within the ACTRIS ERIC research infrastructure", MySMIS code 309113, funding contract No. 309010/19.12.2024. The autors acknowledge that equipement used for this study are part of REXDAN Research Infrastructure (REXDAN RI) and European Center of Environmental Excellence (ECEE) from Faculty of Science and Environment, "Dunărea de Jos" University of Galați.

Abstract

In these papers, the bioclimatic index de Martonne was used to assess the hydrothermal conditions in some agricultural areas in Southern Romania and Northern Bulgaria during the period 1961-2020. The conditions from October to June were analyzed in view of the cultivation of winter cereals, as well as those from April to October, marking the time for growing spring crops. Additionally, indices were selected during some critical periods for both types of crops. The evaluation of the indices with the Mann-Kendall test and the Sen slope shows a significant (0.01) negative trend or an increase in the degree of unfavorability for growing winter crops in the Danube Plain. The indices during the period for growing rain fed spring crops 1961-2020 also show a negative, but insignificant trend.

Key words*: de Martonne index, Southern Romania, Northern Bulgaria, spring crops, cereal, trends.*

INTRODUCTION

Climate change and especially extreme droughts pose risks to agriculture, and spring crops grown under rainfed conditions are the most vulnerable. Also, due to the nature of its cultivation, winter cereals are not grown with supplemental irrigation and rely on rainfall alone. Dry periods and insufficient rainfall, especially during water-critical phases of crop development, lead to low yields. The relationship between temperature and rainfall, expressed as indices, often gives a good general idea of the hydrothermal conditions of individual regions; of the conditions of favourability as well as of the precise use of irrigation water. In the other hand, indices are mathematically verified indicators directly correlated with biophysical processes (Poggio et al., 2018). In this sense, many different indices and parameters are the subject of scientific interest, including in the regions of Northwestern Bulgaria and Southern Romania where large part of the areas are not irrigated. Studies on droughts show an expansion by the end of the 21st century in the Mediterranean region, and in particular in areas of Southeastern Europe such as Romania and Bulgaria (Charalampopoulos et al., 2023; Gao & Giorgi, 2008). Central Europe has good precipitation in all seasons and a maximum in July, while Eastern Europe has less precipitation distributed throughout the year than Northwestern Europe, but summer amounts are mostly higher (Mikolaskova, 2009). The same author reports that continentality in terms of precipitation increases to the east. A correct quantitative assessment of humidity conditions can be obtained by calculating various meteorological, hydrological and biometeorological indices. Therefore, they are the subject of scientific interest of many researchers studying the climate in different regions of Europe (Koleva & Alexandrov, 2008; Vlăduţ et al., 2017; Prăvălie et al., 2017; Mitkov & Topliyski, 2018; 2019; Radeva et al., 2018; Passarella et al., 2020; Chmist-Sikorska et al., 2022; Shopova et al., 2022. A study for Bulgaria for the period 1979–2023 found that the precipitation-evaporation difference is relatively stable and no increase in the water deficit in Bulgaria is observed on an annual basis (Nojarov, 2024).

Other authors (Drenovski, 2024) pay attention to the continental index during the warm and cold half-year, comparing several climatic periods: 1931-1985, 1995-2010 and 1990-

2023. The author found very slight fluctuations in the stations with transitional and Mediterranean type of precipitation. A decrease of about 0.1-0.2 on average is observed in the values of the continentality coefficient of precipitation (Cc) for the regions with temperate continental precipitation regime (Pleven). However, the weakening of the continental influence is not defined as a significant change in the precipitation regime during the two half-years. One of the main results of climate change, directly related to the cultivation of agricultural crops, is the occurrence of prolonged periods of meteorological and hydrological droughts and a decrease in soil moisture. The southern, southeastern and eastern parts of Romania are most vulnerable to drought. In very dry years, average yields of various crops barely reach 35-60% of potential yields (Ionita et al., 2016). Changes in Romania and Bulgaria after 1989 have a similar nature and bring many risks and challenges to agriculture and irrigation opportunities (Dumitrașcu et al., 2018; Kolcheva, 2024; Seymenov & Kolcheva, 2025). The anthropogenic factor responsible for the condition of irrigation systems can significantly affect yields through planning and provision of irrigation water. This publication aims to complement the hydrothermal assessment of some agricultural regions of Northwestern Bulgaria and Southern Romania using the de Martonne bioclimatic index during the main and critical periods of crop development. The study period is 1961-2020.

MATERIALS AND METHODS

Research area: The stations Turnu Severin, Craiova, Pitesti and Bucharest for the territory of Romania and Vidin, Montana, Vratsa and Pleven in Northern Bulgaria were analyzed (Figure 1). The climate of the studied agricultural regions is characterized by relatively cold winters and humid and hot summers. The regime of precipitation has a spring-summer maximum and the highest total amounts between April and July. The average summer air temperatures are higher than 22°C, and the precipitation is between 150 mm and >200 mm. The territories near the mountain ranges such as Pitesti and Turnu Severin have higher rainfall and shorter and cooler summers. Both orchards and vineyards are grown there, as well as spring and winter cereals.

Figure 1. The study area

Data used and study period: Average monthly air temperature °C; Monthly Σ precipitation in mm; Study period: 1961-2020. The data are derived from the ERA5 reanalysis (here used at a resolution of 0.5º x 0.5º). Climatological averages and trends should be considered in relation to inter annual variability (https://climateknowledgeportal.worldbank.org).

Methods: The bioclimatic index of De Martonne (De Martonne, 1926) was used, which describes the studied areas quite well (Croitoru et al., 2013). This index is considered of great relevance not only for environmental or climatological applications but also for agriculture and land resources management (Passarella et al., 2020). The equation was modified according to the coefficients proposed by the same authors (Croitoru et al., 2013):

$$IdM = 1{,}714 * \frac{\Sigma R}{T(GSS) + 10}$$

$$IdM = 1{,}333 * \frac{\Sigma R}{T(GSW) + 10}$$

$$IdM = 6 * \frac{\Sigma R}{T(IV + V) + 10}$$

$$IdM = 4 * \frac{\Sigma R}{T(SS) + 10}$$

where:

- T (GSS) represents average air temperature (ºC) during the growing season of spring crops;

- T (GSW) represents average air temperature (ºC) during the growing season of winter wheat;
- T (SS) represents average air temperature (ºC) during the summer season;
- ΣR represents precipitation in mm.

The climate classification of the regions is made according to Passarella et al., 2001, Baltas, 2007, Deniz et al., 2011, Rahimi et al., 2013, Zareiee, 2014, Nistor, 2016 (Table 1).

Table 1. De Martonne climate classification

Climate	Index range	Description
Arid or dry	IDM≤10	Needs continuous irrigation
Semi-arid	10 ≤IDM<20	Needs irrigation
Mediterranean	20 ≤IDM<24	Need supplementary irrigation
Semi-humid	24 ≤IDM<28	Need supplementary irrigation
Humid	28 ≤IDM<35	Need occasional irrigation
Very humid	35 ≤IDM≤55	Need infrequent irrigation
Extremely humid	IDM>55	Water self-sufficient

Statistical assessment of trends: The Excel template MAKESENS of the Finnish Meteorological Institute (Salmi et al., 2002) was applied for data processing. The bioclimatic indices were checked for direction and statistical significance of trends using the non-parametric Mann-Kendall test. The template tests for the presence of a monotonic increase or decrease using the non-parametric Mann-Kendall test and calculates the slope of a linear trend estimated using the non-parametric Sen method (Gilbert, 1987) at statistical significance levels of 0.001***, 0.01**, 0.05* and 0.1^{+}. The Z value indicates whether the trend is positive or negative, as well as whether it is statistically significant, and Q is a characteristic of the slope.

RESULTS AND DISCUSSIONS

In the regions of Northern Bulgaria and Southern Romania, main spring and winter cereal crops are grown. The development of winter wheat from sowing through dormancy to ripening and harvesting takes place during the period from October to June. In October, precipitation provides moisture for the germination and initial development of winter wheat (Croitoru et al., 2012). This month is considered the beginning of the moisture accumulation process, which ends with the resumption of active vegetation in the spring. The months of April and May are critical in terms of moisture conditions, because the reproductive period of crop development takes place in the same month - the processes of flowering, fertilization and milk maturity (Hershkovich, 1984; Georgieva, 2013). The same authors indicate insufficient moisture in May as the main yield-limiting factor. The hydrothermal conditions during the development period of cereals, expressed by the De Martonne dryness index for GSW, are shown in the Figures 2 to 5.

The index values classify the region as humid and very humid, with the best conditions for the development of winter wheat crops being observed in the stations of Pitesti, Montana and Turnu Severin. The period was wetter before 1980, with the most unfavorable conditions for Bulgaria between 1982 and 1994, and for Romania from 1991 to 2002.

When growing winter wheat, hydrothermal conditions during the critical periods of flowering and milk maturity are of great importance for biological and total yields. Lower temperatures and the good rainfall are a prerequisite for high yields. Therefore, the index values in this critical period have a pronounced impact on the final yield (Figures 6 and 7).

In the stations of northern Bulgaria, two peaks are observed in the periods around 1979 and 2014. The variations and contrast values are no exception and are characteristic of the periods before and after 2000.

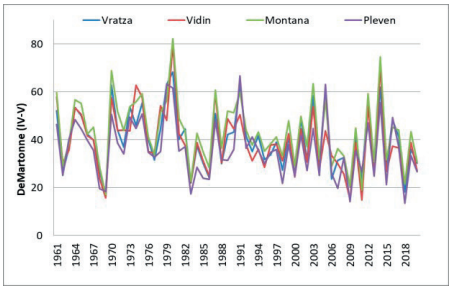

Figure 6. The distribution of the De Martonne aridity index April-May

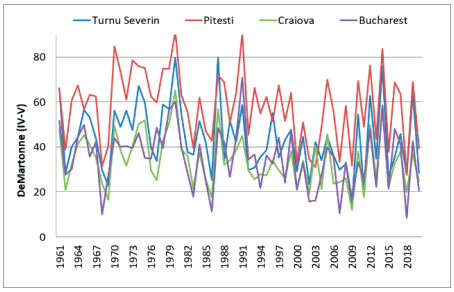

Figure 7. The distribution of the De Martonne aridity index April-May

The period 1991-2000 is the driest. The results show that during this period winter wheat crops develop in conditions ranging from semi-arid to semi-humid, with the most vulnerable being the regions of Craiova and Pleven. Based on some modeling studies (Constantin et al., 2025), in other agricultural regions of northern Romania, irrigation of winter wheat is recommended precisely during the critical months of April to May. Several extreme high values are observed in 1972, 1991 and 2005, with the lowest values in 1962, 1977, 1993, 2000 and 2011. In Southern Romania, the two wettest years were before 1990. The average values of the index define the region as Humid with the exclusion of Pitesti. The assessment of the index trends during the period April-May is similar to that of the index during the period September-June (Table 4).

Except for Vratza, Pleven and Pitesti stations, the trends for the study period are negative and significant at the 0.05 level.
The development of spring crops in the region of study occurs during the period from April to October (Hershkovich, 1984). The De Martonne index for this period is shown in Figures 8 to 11.

Table 4. Statistical assessment of the trend April-May

Mann-Kendal trend	*Sen's slope estimate*

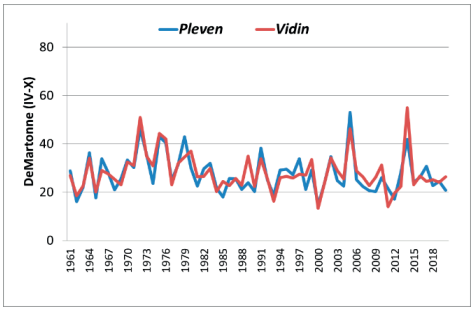

Figure 8. The distribution of the De Martonne aridity index CSS

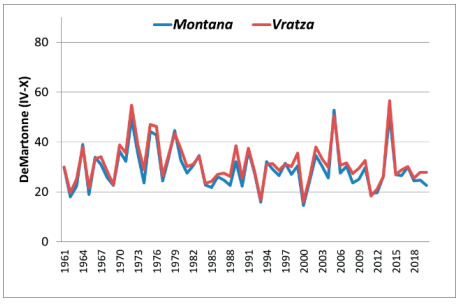

Figure 9. The distribution of the De Martonne aridity index GSS

During the period of growing spring crops, the driest was 2000. The prevailing years were years in which the conditions were Mediterranean and humid and which required irrigation. The exception is the Pitesti station, in which the conditions were very humid. For the period of maize growing before 2010, data series reveal mostly positive slopes, but few of them are statistically significant for the period 1961-2007 (Croitoru et al., 2013).

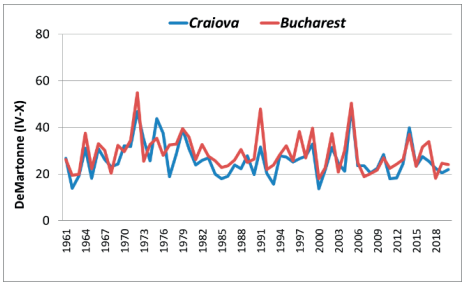

Figure 10. The distribution of the De Martonne aridity index (GSS) Craiova and Bucharest

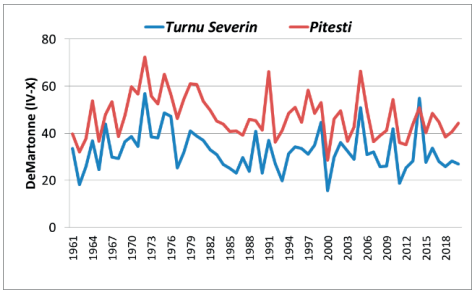

Figure 11. The distribution of the De Martonne aridity index (GSS) Turnu Severin and Pitesti

According to the data (Table 5), the trend reverses in a negative direction, with the slope remaining without statistical significance. The probable reason is the extreme values observed in recent decades.

Table 5. Statistical assessment of the trend (GSS)

Mann-Kendal trend	*Sen's slope estimate*		
De Martonne (IV-V)	**Test Z**	**Signific.**	**Q**
Turnu Severin	-1.6		-0.1
Pitesti	-1.9	+	-0.1
Craiova	-1.3		-0.1
Bucharest	-1.5		-0.1
Vratza	-1.5		-0.1
Vidin	-1.2		-0.1
Montana	-1.2		-0.1
Pleven	-1.4		-0.1

The assessment of the trend slope during the summer season (Table 6) corresponds to that

during the vegetation period of spring crops. At stations Pitesti and Bucharest, the negative trend has a significance level of 0.1. According to the index values during the studied period, the climate is classified from semi-arid to humid apart from station Pitesti where the conditions are predominantly humid to very humid (Figures 12 and 13). Two peaks are observed around 1976 and in 2005, better shown in the stations from Northern Bulgaria.

Table 6. Statistical assessment of the trend of the De Martonne aridity index (SS)

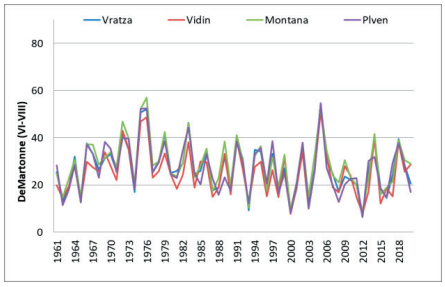

Figure 12. The distribution of the De Martonne aridity index June-August

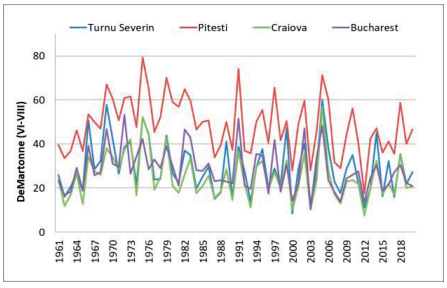

Figure 13. The distribution of the De Martonne aridity index June-August

Additional information related to plant security is provided by the number of cases with different types of climates during the study period (Figures 14 to 17). During the growing season of winter wheat, the conditions are predominantly extremely humid and very humid (Figure 14). In the stations Bucharest and Craiova, in about 40% of the cases the climate is semi-humid, and in the second station a number of years with an index below 20 and semi-arid climate conditions are also recorded. However, the second critical period in terms of humidity shows that even values below 10 - arid or dry conditions (Bucharest) are observed during the period (Figure 15).

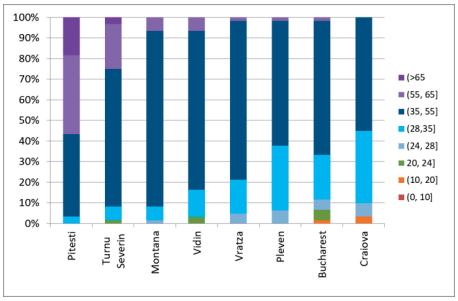

Figure 14. Distribution of climate types 1961-2020 according to De Martonne aridity index September-June

The best conditions are shown by Pitesti, Turnu Severin and Montana, and the most unfavorable years are found in Craiova and Pleven.

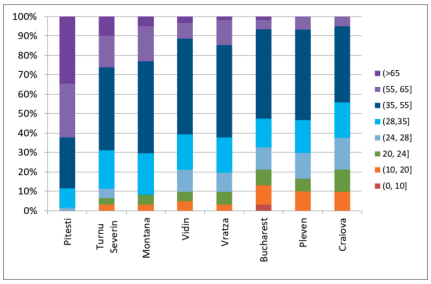

Figure 15. Distribution of climate types 1961-2020 according to the De Martonne aridity index April-May

The results show that the humidity conditions during the growing season are risky in rainy conditions (Figure 16).

Apart from Pitesti, where the climate is humid and very humid, irrigation is necessary in all other stations. Turnu Severin and Montana have predominantly semi-humid to humid conditions and a low need for irrigation. The most unfavorable conditions during the

growing season are observed in the stations Craiova and Pleven, where in over 80% of the years the climate is Mediterranean and semi-arid and the need for irrigation for the spring crops is mandatory.

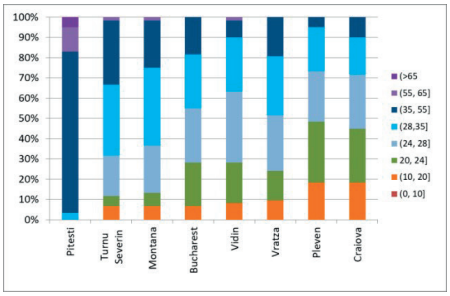

Figure 16. Distribution of climate types1961-2020, according to the De Martonne aridity index April-October

During the summer period, the stations with the most unfavorable conditions, years with an index below 10 and arid or dry conditions are Pleven, Craiova Vidin and Vratza (Figure 17).
In the region of Southern Bulgaria, the best conditions during the studied period are observed at Montana station. Conditions range from humid to extremely humid in the Pitești region.

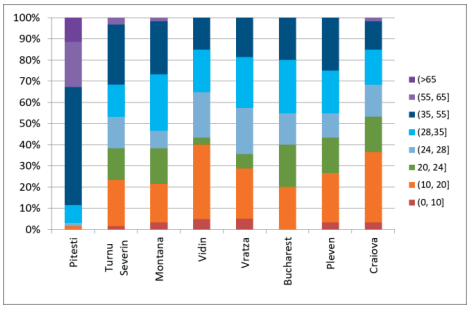

Figure 17. Distribution of climate types 1961-2020 according to the de Martonne aridity index June-August

CONCLUSIONS

An assessment of the hydrothermal conditions in the main agricultural regions of Southern Romania and Northern Bulgaria was made. The results show that the humidification conditions do not ensure the development of spring crops during their growing season and during the summer period. With the exception of Pitesti, where the climate is humid and very humid, irrigation is necessary for all other stations. Turnu Severin and Montana have prevailing semi-humid to humid conditions and a low need for irrigation. The most unfavourable conditions are during the potential growing season in the stations Craiova and Pleven, where in over 80% of the years the climate is Mediterranean and semi-arid and the need for irrigation for the spring crops is mandatory. The assessment of the trends shows a significant decrease in the index during the entire wheat growing period, as well as during the critical stages of earing and flowering in May and June. The observed negative trends during the growth and development of spring crops are not statistically significant. The same is observed during the summer period when only the regions closer to the mountain ranges such as Pitesti and Bucharest tend to be at statistical significance levels of 0.1. Despite the proven high temperatures, the distribution of the summer precipitation manages to maintain a negative insignificant trend for the entire period 1961-2020, most likely due to the higher extreme values in recent decades.

Abstract

Due to the requirements to reduce energy consumption, the thermal rehabilitation of existing buildings has gained momentum in recent years, both in Romania and at the European level (Petcu et. al., 2023). The most accessible and used technical solution for the thermal rehabilitation of residential buildings, is represented by the external cladding systems with polystyrene thermal insulation. For this type of buildings thermal insulation system, the most unfavourable and most common external actions are represented by compartment fires. The researchers of the Fires Research Laboratory within the INCERC Bucharest Branch, have carried out a series of experimental studies on a natural scale, in order to develop a method of testing ETICS systems for fires generated from fire compartments. Through these studies and experimental research, conclusive results were obtained regarding the development of compartment fires, the evolution of temperatures inside the combustion chamber and the propagation of fire on the combustible facades of buildings.

Key words*: experimental research, fire resistance, fire behavior, ETICS.*

INTRODUCTION

Internationally, there are a number of full-scale or intermediate-scale testing methods for assessing the fire performance of external thermal insulation composite systems (ETICS) based on EPS type polystyrene (Lalu et al., 2017). All these methods define fire exposure scenarios inside buildings, which are characterized by different thermal loads that generate flames that propagate on building facades (Yoshioka, 2011). In Romania, full-scale tests are not yet accepted through which to test the fire resistance of ETICS (Simion et. al., 2019). In this context, it is necessary that a full-scale testing method for ETICS be adopted in our country, so as to demonstrate the fulfilment of fire safety requirements in accordance with the harmonized testing standards at European level. To meet this objective, the Fires Research Laboratory within the INCERC Bucharest carried out, for the first time in our country, a series of theoretical studies and experimental tests within a research project funded by the Ministry of Research, Innovation and Digitalization, which reproduced as closely as possible to reality, the propagation phases of compartment fires on building facades. Through this testing method, conclusive experimental results were obtained regarding the development of the compartment fire and the evolution of temperatures on the combustible facade of a building. The general purpose of the project was to conduct experimental research on the fire safety of the built environment: concepts and methods of fire resistance testing, new materials and solutions, including fire-built environment interaction (Ovadiuc et al., 2024).

The objectives of the project were the following: construction of a full-scale test stand for fire resistance of ETICS; adoption of a full-scale test method similar to one of the most commonly used test methods internationally; justification of the choice of the test model for conducting the experimental test; conducting an experiment on the newly built test stand in order to evaluate the mode of compartment fire propagation on the combustible facade of a multi-storey building; provision of protection measures against compartment fires that can be adopted when putting into operation the exterior cladding systems of buildings;

proposals for the extension of the experimental study.

MATERIALS AND METHODS

The fire resistance test stand for ETICS was designed by the engineering team from the INCERC Fires Research Laboratory based on the provisions of the British test method standard BS 8414 and was built at the facade tower of the laboratory in several stages. The research test stand for testing the fire resistance of exterior cladding systems of buildings, was designed by the team of researchers after an analysis of the fire testing concepts of ETICS at European and even worldwide level. Thus, a stand was put into operation with characteristics similar to the stand regulated in BS 8414, with one difference (BS 8414-1, 2002). This difference lies in the fact that in the continuation of the side wing and 2 m opposite the combustion chamber, a reinforced concrete diaphragm is additionally placed over the entire height of the stand (8.5 m), which has the role of both accentuating the chimney effect during the experiment and protecting the combustion phenomenon from possible wind from the North (Figure 1).

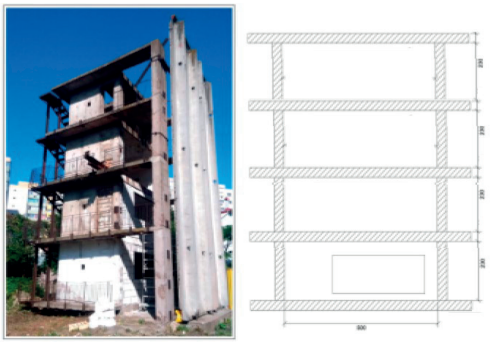

Figure 1. The construction used for the test stand

The ETICS installed on the two wings of the stand was made of 10 cm thick expanded EPS polystyrene (is a minimum thickness taken into account in current energy calculations that are made before thermal insulation of buildings), glued with adhesive and fixed with dowels to the BCA support layer (Michalak, 2021). The polystyrene was fireproof type EPS 80 – AF 80 with a density of 14.5 kg/m³ and was classified for reaction to fire according to SR EN 13501-1, class B-s2, d0. Over the EPS, a reinforcement layer consisting of an exterior fiberglass mesh (145 g/m²) embedded in adhesive mortar for plastering was installed with a crowbar. After the plastering mass had dried, a primer and a layer of structured decorative plaster type 2R were applied to it (Figure 2).

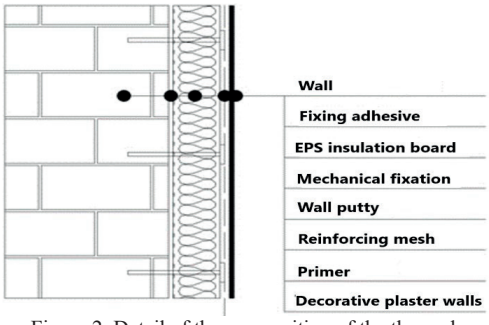

Figure 2. Detail of the composition of the thermal insulation system tested for fire resistance

The ETICS performed on the building for fire resistance testing was installed without non-combustible barriers between floors. Also, the polystyrene boards were installed in the worst case, namely on mortar beads, as is often done in current construction practice on site (Figure 3).

Figure 3. Test stand with ETICS prepared for fire resistance testing generated from the fire compartment

The ceiling of the combustion chamber was lined with 10 cm thick ceramic wool and the walls with 5 cm thick wool. The ceramic wool was fixed with high temperature resistant

refractory anchors. A 1.0 cm thick ceramic board was placed on the floor of the combustion chamber. In the test stand, researchers from the INCERC Bucharest conducted an experimental test to determine the compartment fire behaviour of an ETICS mounted on the facade of a building. During the fire resistance test experiment of the ETICS, a series of qualitative parameters were measured in order to evaluate the response of the construction materials from which the system was made up, to the propagation of fire in height. These parameters are: the moment of ignition of the system, the variation of temperatures in the fire compartment and in height, the variation of the mass of the thermal load, the height of the flames, detachment of elements from the system, losses of local stability and the amount of smoke released. The thermal load consisted of a softwood stack measuring 1.5 m (L) × 1.0 m (W) × 1 m (H) (Figure 4).

Figure 4. Wood stack

The wood was conditioned before combustion to reach a moisture content between 13 and 17% (Figure 5).

Figure 5. Wood conditioner

From the records presented above, the evolution of temperatures during the experiment results. The temperatures recorded under the specific conditions of the test (composition of the ETICS, choice of thermal load, geometric conformation of the stand as well as environmental conditions), highlight and provide data on the mode of propagation of fire in the combustion chamber, starting with the moment of initiation of the fire and ending with its regression (Figure 6).

Figure 6. Fire ignition

During the test, the variation in time of the following parameters was recorded:
- The temperature of the outer surface of the thermal insulation at 2.5 and 5 m above the combustion chamber (of the fire compartment);
- The temperature inside the thermal insulation at 5 m above the combustion chamber;
- The temperature inside the combustion chamber.

Also, during the test, the moment of ignition of the ETICS, the development of the fire on the facade and the moment of flash-over, the maximum height of the flames, the detachment of burning elements from the ETICS, the regression and extinguishing of the fire were monitored (Malgorzata et al., 2022).

The height of the flames in the fire compartment varied during the experiment and it was found that their maximum height was reached approximately in the 15th minute, when the flames propagated above the combustion chamber to a height of approximately 2.5 m (Figure 7).

During the experiment, an increasing evolution of the temperatures along the height of the

tested system under the action of the fire is observed.

Figure 7. The beginning of the fire propagation on the height of the ETICS on the front wall

It is also found that the propagation of the fire along the height and especially after the polystyrene thermal insulation began to burn generalized, influenced the increase in temperatures both on the external surface of the ETICS and from inside it (Figure 8).

Figure 8. The beginning of the fire propagation on the height of the ETICS on the side wall

During the test, component elements of the system were detached and burning particles fell from the system. Following the action of the fire on the thermal system, the expanded polystyrene thermal insulation layer did not withstand in terms of mechanical resistance and fire tightness over the entire height of the test stand (Figures 9, 10).

The amount of smoke released into the atmosphere was relatively constant, increasing slightly around the flash-over moment (Figure 11).

Figure 9. Complete combustion of the ETICS on the side wall to the fire compartment

Figure 10. Burning particles detached from the thermal system

Figure 11. Smoke plume stock

RESULTS AND DISCUSSIONS

Following the correlation of the temperature recording times presented in the tables above, with the photo-video recordings corresponding to the time points of the most important stages of the experiment, it results that a series of conclusions can be drawn regarding the behaviour of ETICS in the event of compartment fires, which can contribute to increasing the degree of fire safety of the built environment.

Following the action of the fire on the ETICS, it was found that the thermal insulation layer made of EPS polystyrene was burned and melted down to the support structure, in the area of direct action of the fire.

After the thermal insulation ignited, a significant amount of black and gray smoke was released. The tested system favoured the propagation of the fire both vertically and laterally. During the duration of the fire, burning detachments of the thermal insulation system were found.

The maximum temperatures were recorded in the combustion chamber was over 920°C. The maximum temperatures recorded 2.5 m above the combustion chamber was over 740°C (Figure 12).

Figure 13. Temperatures recorded 5.0 m above the combustion chamber

It is also noted that in a relatively short period of time (10 min) the entire thermal insulation facade located above the combustion chamber was destroyed by the fire.

Specialists draw attention to the results obtained, that in the case of installing ETICS on high-rise buildings, without installing non-combustible barriers between floors, there is a very high risk that combustible facades will burn along their entire height when exposed to compartment fires (Lalu, 2016).

CONCLUSIONS

Based on the experimental research carried out, unique results were obtained in Romania regarding the development of a fire on the combustible facade of a building, with results that can be transposed to a normative level and with applicability from the design phases of the buildings. Also, a unique stand was created in Romania for carrying out experimental research testing the compartment fire action of ETICS, open to both the academic and the economic environment.

In this way, INCERC Bucharest contributes to the development of a database that will support the establishment of criteria and performance levels for ETICS used to enclose residential

buildings, so that they can ensure a high degree of fire safety.

Abstract

Volatile Organic Compounds (VOCs) are organic chemicals with high vapor pressure, originating from natural and anthropogenic sources, and are major contributors to environmental issues like photochemical smog and atmospheric pollution. This study introduces an optimized TD-GC-MS method for detecting and quantifying VOCs in ambient air, employing internal standards and certified reference materials to ensure analytical accuracy and traceability. The method is designed to deliver exceptional sensitivity, precision, and reproducibility, suitable for diverse environmental conditions. Key improvements include optimized thermal desorption, fine-tuned chromatographic separation, and calibrated mass spectrometric detection. Aligned with Eurachem guidelines, the integration of internal standards mitigates instrumental variability, while certified reference materials ensure traceable calibration, enhancing result reliability. The research demonstrates the method`s applicability to air quality monitoring, environmental assessments, and public health research. The findings validate TD-GC-MS as a robust, reliable solution for continuous VOC monitoring and routine environmental applications, providing critical insights into pollution sources and impacts, particularly in urban and industrial contexts. This research addresses the needs of scientists, policymakers, and environmental professionals seeking effective tools to combat air pollution.

Key words*: air quality monitoring, environmental pollution, GC-MS, thermal desorption, Volatile Organic Compounds.*

INTRODUCTION

Volatile Organic Compounds (VOCs) are produced from both natural and anthropogenic sources (Piccot et al., 1992). Natural sources include microbial activity, marine phytoplankton, volcanic and geothermal emissions, as well as wildfires (Ling & Guo, 2014). Anthropogenic sources comprise petroleum extraction and refining, vehicle emissions, the production and application of solvents on different surfaces, incomplete combustion of fossil fuels or biomass, and the fugitive emissions of VOCs from plastic materials during regular use (Atkinson & Arey, 2003). In the atmosphere, non-methane volatile organic compounds (VOCs) react with nitrogen oxides (NOx) in the presence of UV radiation, leading to the formation of ground-level ozone (O_3), a key component of photochemical smog. This reaction significantly contributes to air pollution and has detrimental effects on human health, both aquatic and terrestrial ecosystems, and plays a crucial role in climate change (Li et al., 2018). Elevated ground-level ozone concentrations can deteriorate air quality and lead to severe health problems, including respiratory conditions, heart disease, and cancer (Alford & Kumar, 2021). Prolonged exposure to VOCs has also been linked to neurological disorders, liver and kidney damage, and developmental issues, particularly in vulnerable groups like children and the elderly (Agency for Toxic Substances and Disease Registry, 2007).
The health impacts of VOC exposure depend on the specific compound, its concentration, and the duration of exposure. Brief exposure to high levels of VOCs, including benzene, toluene, and formaldehyde, can cause symptoms like irritation of the eyes and throat, headaches, dizziness, and nausea (Alford & Kumar, 2021). Long-term exposure, especially in urban and industrial zones, is associated with more severe health consequences, such as diminished lung function, weakened immune response, and reproductive issues. Some studies suggest a link between chronic VOC exposure and neurodegenerative diseases, underscoring the

need for stricter air quality regulations (Mølhave, 1991; Li et al., 2018).

In this regard, accurate monitoring of VOCs is essential for pollution control, regulatory compliance, and public health studies. In Romania, VOCs in ambient air are regulated by Law 104/2011 regarding air quality, which establishes a threshold value for the hazardous compound benzene, while other compounds such as toluene, ethylbenzene, and xylene (BTEX) are subject to general European regulations. According to the same law, benzene, in particular, is required to be monitored in major urban areas, given its significant concentration from human activities like traffic and industrial operations (Law No. 104, 2011). Other VOCs of concern include dichloroethene, dibromochloromethane, carbon tetrachloride trichloroethene, ethylbenzene, chlorobenzene, styrene, naphthalene et. all. These compounds contribute to atmospheric pollution and must be carefully monitored to assess their environmental impact and ensure regulatory compliance (Maceira et al., 2017).

Nowadays, several methods are available to detect VOCs in ambient air, including portable sensors such as the Photoionization Detector (PID) and Flame Ionization Detector (FID), as well as analysers utilizing Fourier Transform Infrared Spectroscopy (FTIR) and Ultraviolet (UV) fluorescence (Qualley et al., 2019; Epping & Koch, 2023; Elia et al., 2024). Each method has different advantages, such as real-time monitoring, simultaneous measurement of multiple compounds, and not requiring complex sample preparation. However, they also have disadvantages, such as poor selectivity, sensitivity and reduced precision. On the other hand, Thermal Desorption Gas Chromatography coupled with Mass Spectrometry (TD-GC-MS) offers increased selectivity (in multiple reaction monitoring mode) and specificity (Jia et al., 2006). Additionally, the method is quite robust, reproducible, and traceable, which facilitates compliance with regulatory standards and enhances our understanding of air pollution dynamics. Moreover, it is crucial to monitor non-methane VOCs (NMVOCs) as defined in Law No. 104/2011, including aliphatic hydrocarbons (such as ethane, propane, and butane), aromatic hydrocarbons (such as benzene, toluene, and xylene), oxygenated compounds (such as ethanol and acetone), and halogenated compounds (such as CFCs and halons). These VOCs contribute significantly to the formation of tropospheric ozone, a harmful pollutant that can adversely affect human health, especially in regions with high levels of emissions (Zhou et al., 2023).

MATERIALS AND METHODS

The analysis of VOCs in ambient air using Gas Chromatography-Mass Spectrometry (GC-MS) requires calibration across multiple concentration levels, achieved through serial dilution of certified standard solutions. (Rodríguez-Navas et al., 2012; Cai et al., 2015; Chung et al., 2019). Thus, the following reference mixtures were used for calibration:

502.2 Calibration mix 30043, Batch A0189182;
502.2 Calibration mix 30044, Batch A0180278;
502.2 Calibration mix 30045, Batch A0181037;
502.2 Calibration mix 30046, Batch A0175597;
502.2 Calibration mix 30047, Batch A0189197.

The reference mixtures, manufactured by RESTEK, were diluted with Methanol SupraSolv 1.00837.1000, using Eppendorf Xplorer plus micropipettes 0.5-10 µL and Eppendorf Xplorer plus 0.2-5 mL pipettes.

TD glass tubes filled with deactivated glass wool (Restek, Deactivated wool 24324, Batch 365237-1) were used for the introduction of substances, and the calibration solutions were introduced by dispensing 1 µL of each solution using a Shimadzu 10 µL syringe (10F-S-0.63, Batch 51W-074109M).

Analytical analysis of Thermal Desorption (TD) Tubes was performed using the Shimadzu Thermal Desorption System TD 30R, with a temperature program of 10 minutes at 280°C and 70 ml/min, followed by trap cooling to -20°C (Brown & Crump, 1998). The analyses were carried out using the Shimadzu Gas Chromatograph Mass Spectrometer - TQ8050NX, coupled with an SH-5Sil MS chromatographic column for effective separation of VOCs. The mass spectrometer was operated in both SCAN mode, where a broad range from 50 m/z to 350 m/z was rapidly scanned to capture a full spectrum of ions in order to identify the retention time for each VOC compound, and Selected Ion Monitoring (SIM) mode, where the mass spectrometer focused on

specific ions of VOC compounds within this range to enhance sensitivity and selectively detect VOC compounds (Pleil et al., 1991). The gas chromatograph temperature program for VOCs separation is presented in Figure 1.

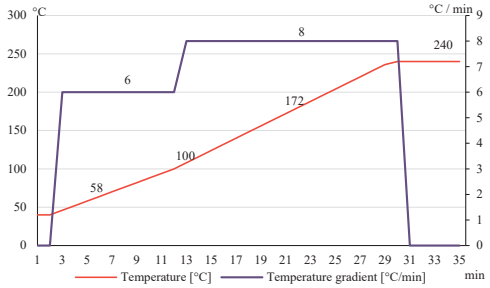

Figure 1. GC temperature profile for VOCs separation

Sampling of VOCs in ambient air was performed on TD tubes, Tenax 60/80 mesh, O.D x L ¼ in x 3 ½ in glass and Tenax TA/Carboxen1018, O.D x L ¼ in x 3 ½ in glass from Markes International (Figure 2), using the Acti-VOC Low Pump from Markes International (SN: 20220201001). The pump flow rate was calibrated for the desorption tubes using the 7000 Flowmeter from Ellutia (SN: 200235).

Figure 2. Tenax TA/Carboxen1018 and Tenax TA tubes

Additionally, helium 6.0 was used as the carrier gas, deuterated toluene as the internal standard from Linde Gaz Romania, also 4 mL glass vials and racks from Shimadzu were employed for sample storage.

RESULTS AND DISCUSSIONS

The optimalization of the chromatographic method was conducted to ensure its robustness, precision, and reliability. In this context, key performance parameters were evaluated according to established international standards (Eurachem/CITAC Guide; 2012; Eurachem, 2025; SR EN ISO 17025, 2018), along with the analytical conditions of the mass spectrometer used for detection. Linearity was assessed by evaluating the correlation coefficient (R^2), confirming the proportional relationship between analyte concentration and detector response within the defined range. Similarly, the limit of detection (LOD) and limit of quantitation (LOQ) were determined by analyzing the signal-to-noise ratios and the regression line intercept, which reflect the method's sensitivity in detecting and quantifying low analyte concentrations. The precision of the method was assessed by examining intra- and inter-day reproducibility, with the relative standard deviation (RSD) being used to evaluate variability across various concentration levels. Accuracy was confirmed through recovery studies, where theoretical concentrations were compared with measured values. In addition, specificity was evaluated to ensure the method's ability to effectively separate the analyte from potential matrix interferences.

In addition, the analytical conditions of the mass spectrometer, including ionization source parameters, collision energy, and mass resolution, were optimized and validated to ensure accurate and reproducible measurements. These conditions were carefully adjusted to achieve maximum sensitivity and specificity for the target analyte.

Development of solutions at multiple concentration levels

Multiple concentration levels were carried out starting from a stock solution of 2000 µg/mL, using the following calibration mixtures from Method 502.2: Calibration mix 30043 (Batch A0189182), Calibration mix 30044 (Batch A0180278), Calibration mix 30045 (Batch A0181037), Calibration mix 30046 (Batch A0175597), and Calibration mix 30047 (Batch A0189197). These mixtures were dissolved in methanol to create eight concentration levels: 0, 1.6, 3.5, 5, 8, 10, 19, and 32 ng, ensuring a comprehensive calibration range for the analyte. The VOCs (volatile organic compounds) were quantified across these levels to evaluate the

method's effectiveness in detecting and measuring these compounds.

Mass spectrometer tuning and optimization

The United States Environmental Protection Agency (US EPA) methods for VOC analysis in ambient air recommend adjusting the tuning conditions by modifying the perfluorotri-butylamine (PFTBA) target abundances to ensure that subsequent 1-Bromo-4-fluorobenzene (BFB) analysis meets the established relative abundance criteria (U.S. Environmental Protection Agency, 1999; 2003). Thus, the research supports the recommended BFB tune conditions using m/z 69 as the target mass and mass pattern adjustment, as presented in Table 1.

Table 1. 1-Bromo-4-fluorobenzene tuning conditions

Mass (m/z)	Intensity Ratio %
69	100
219	50
502	1.5
131	42
414	2.5
614	0.4

The tuning process was performed on the Shimadzu GCMS-TQ8050NX using an automated tuning procedure prior to sample analysis. The optimized conditions ensure stable instrument performance, enhancing sensitivity and accuracy in VOC quantification (U.S. Environmental Protection Agency, 2025). Regular tuning verification, following United States Environmental Protection Agency (US EPA) protocols, maintains compliance with analytical standards and ensures reproducible results throughout the study.

Studies have shown that these conditions produce a tune that meets the strict BFB relative abundance criteria for all VOC methods across multiple instruments and remains stable over an evaluation period of approximately three months (Shimadzu, 2023). Additionally, the tune file obtained was applied to the Thermal Desorption-Gas-chromatography-Mass spectrometry (TD-GC-MS) method, ensuring optimal ionization efficiency and accurate mass detection for VOC analysis.

The stability of the tuning parameters was maintained throughout the thermal desorption process, ensuring reliable quantification of target compounds.

Selectivity and specificity

The method's selectivity was achieved through the SH-5Sil (0.25 mm x 0.25 µm x 30 m) chromatographic column, renowned for its high efficiency and low bleed characteristics. The column facilitated the precise separation of complex VOC mixtures present in different matrices (ambient air), with distinct retention times (Table 2) for each compound (Figure 3). The effective resolution of individual VOC peaks within the chromatogram was crucial in preventing peak overlap and enhancing the method's sensitivity. This superior selectivity ensured the accurate identification and quantification of each VOC in the challenging environmental matrix.

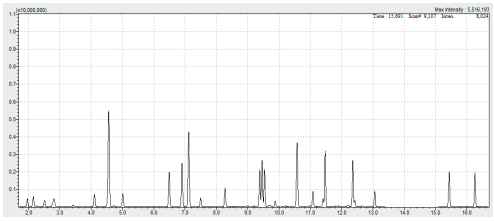

Figure 3. Separation of VOCs in ambient air

To further enhance the specificity and sensitivity of the analysis, the mass spectrometer was operated in Selective Ion Monitoring (SIM) mode. In this configuration, three ions were meticulously selected for each compound: one quantifier ion (e.g., 78 m/z for benzene) and two qualifier ions (e.g., 77 m/z, 51 m/z) to confirm compound identity (Figure 4), following the guidelines established by the TO-14, TO-15, and TO-17 methods for VOC analysis.

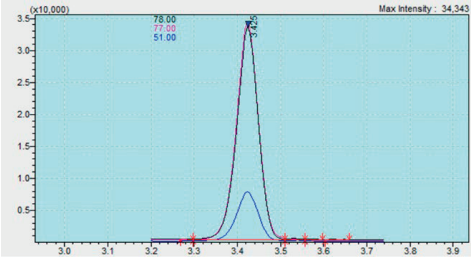

Figure 4. Benzene quantifier and qualifier ions (m/z)

This dual-ion approach ensures the integrity of the analysis by enabling compound-specific verification. The SIM mode provided substantial improvements in sensitivity, reducing background noise and minimizing potential interferences from non-target compounds. Through this integration of selectivity, chromatographic resolution, and ion-specific detection, the method achieved a high degree of specificity and reliability, making it suitable for the precise.

Linearity Assessment and Calibration Curve Validation for VOC Quantification

The linearity of the method was assessed by constructing a calibration curve through the injection of a series of calibration standards onto the thermal desorption tube at distinct concentration levels (0, 1.6, 3.5, 5, 8, 10, 19, and 32 ng), as detailed in the experimental procedure. The ambient air matrix was spiked with precisely known concentrations (theoretical concentrations) of target VOCs, while the internal standard method utilizing deuterated toluene was implemented to ensure robust and accurate quantification. The data obtained were then employed to generate calibration curves for each analyte (Table 2), ensuring that a comprehensive range of concentrations was thoroughly represented.

Table 2. Correlation Coefficient (R), Coefficient of Determination (R^2), and Retention Times for VOC Calibration Curves

Compound name	Retention time (min)	R Coefficient	R^2 Coefficient

Each calibration point for the VOCs was determined based on the quantifier ion (e.g., 78 m/z for benzene), which was selected to ensure precise and consistent quantification (Figure 5).

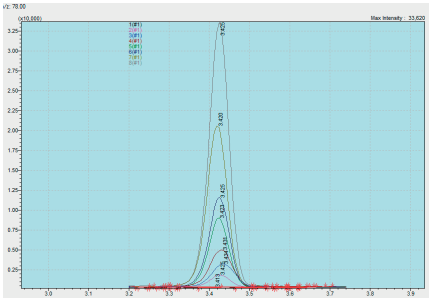

Figure 5. Peak identification quantifier ion 78 m/z

This methodological approach facilitated a comprehensive evaluation of the system's capacity to generate a consistent and linear response across the defined concentration spectrum, which is critical for the accurate and reliable quantification of VOCs in complex environmental matrices. The calibration curves were meticulously constructed by plotting the peak area of each analyte against its corresponding concentration (Figure 6), ensuring a broad concentration range was covered.

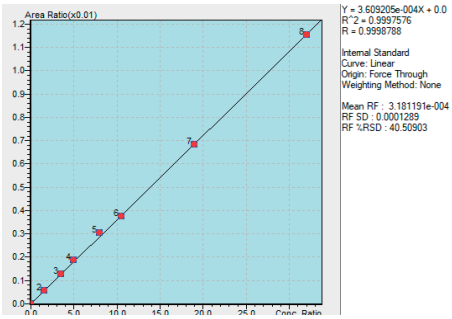

Figure 6. Calibration curve for benzene quantification

Additionally, the internal standard response was strategically employed to correct for potential variations, such as instrumental fluctuations or matrix interferences, thereby ensuring the precision of the quantification process.

The calibration data obtained were used to rigorously evaluate the linearity of the method across the specified concentration range, thereby affirming the precision and robustness of the analytical technique. The calibration curve, along with the comprehensive table displaying the correlation coefficients (R and R^2) for each analyte, was utilized to provide a detailed representation of the method's consistency for quantification of VOCs in ambient air.

Poor correlation coefficients were observed for 1,2-Dibromo-3-Chloropropane, tert-Butylbenzene, 1,2,4-Trimethylbenzene, and 1,3-Dichlorobenzene, and their signal intensities increased significantly, causing interference with the detector. This interference, likely caused by the injection of deuterated toluene (d8), compromised the accuracy and reliability of their quantification. For both technical and economic considerations, these compounds were excluded from the analysis to maintain the integrity and efficiency of the method.

Analytical Performance Parameters: Repeatability, Limit of Detection, Limit of Quantification, and Recovery

Ensuring the reliability and accuracy of an analytical method is essential in environmental monitoring, particularly when using Gas Chromatography-Mass Spectrometry (GC-MS) for the determination of volatile organic compounds (VOCs) in ambient air. The validation process involves assessing key performance parameters that define the method's precision, sensitivity, and accuracy. Among these, repeatability, limit of detection (LOD), limit of quantification (LOQ), and recovery are crucial for determining its suitability for air quality assessment and regulatory compliance (Eurachem, 2025).

Repeatability refers to the method's ability to produce consistent results when the same air sample is analyzed multiple times under identical conditions. It is a key aspect of precision and is expressed as the relative standard deviation (RSD) of repeated measurements. Repeatability is assessed both within the same day (*intra-day precision*) and across multiple days (*inter-day precision*) to ensure robustness. The results of these evaluations are summarized in Table 3, which presents the intra-day and inter-day repeatability data for VOCs in ambient air.

Limit of Detection (LOD) represents the lowest concentration of a VOC that can be detected but not necessarily quantified with confidence (Eurachem, 2025). It is a crucial parameter for evaluating the sensitivity of an analytical method, particularly when analyzing trace-level VOCs in urban and industrial environments. LOD is often determined using statistical approaches based on the signal-to-noise ratio or the standard deviation of the baseline noise.

Limit of Quantification (LOQ) is the lowest concentration of a VOC that can be quantitatively measured with acceptable accuracy and precision (Wang & Austin, 2006; Eurachem, 2025).

While the LOD merely indicates the presence of an analyte, the LOQ ensures that the VOC concentration can be determined with statistical confidence. Typically, LOQ is defined as a multiple (e.g., 10 times) of the standard deviation of the baseline noise or the calibration curve residuals.

Recovery measures the accuracy of the method by assessing how efficiently VOCs can be collected, desorbed, and quantified from air samples (Gallego et al., 2011; Eurachem, 2025). This is determined by spiking known amounts of VOCs onto sorbent tubes or into air sampling canisters, followed by analysis and comparison with the expected values. High recovery values indicate minimal losses during sampling, desorption, and analysis, ensuring reliable

quantitative results. Together, these parameters form the foundation of method validation, ensuring that the analytical technique employed for VOC analysis in ambient air is robust, sensitive, and precise.

By systematically evaluating repeatability, LOD, LOQ, and recovery, researchers can establish the credibility of their GC-MS method, making it suitable for air quality monitoring, exposure assessment, and regulatory reporting.

Table 3. Method validation for the analysis of Volatile Organic Compounds in ambient air

Compound name	Repeatability								LOD (ng)	LOQ (ng)	Recovery (%)
	Intra-day 1.6 ng	RSD (%) n = 6	Inter-day 1.6 ng	RSD (%) n = 6	Intra-day 10 ng	RSD (%) n = 6	Inter-day 10 ng	RSD (%) n = 6

The validation of the analytical method used for the determination of volatile organic compounds (VOCs) in ambient air has demonstrated high performance in terms of precision, repeatability, and sensitivity. The obtained values for the limits of detection (LOD) and limits of quantification (LOQ) indicate an adequate capability to identify and quantify compounds at

low concentrations, which is essential for ambient air monitoring (Demeestere et al., 2008; Kim & Park, 2020;). Furthermore, the achieved recovery rates, falling within an optimal range, confirm the accuracy of the method and the reliability of the results (Wang et al., 2018). Intra and inter-day repeatability, expressed through the relative standard deviation (RSD), has shown the stability of the method under various analytical conditions, further demonstrating its robustness. These aspects are crucial for applying the method in long-term monitoring studies aimed at assessing population exposure to VOCs and their impact on air quality and human health.

In conclusion, the validated TD-GC-MS method exhibits analytical characteristics that comply with international standards for VOC analysis in ambient air. Its high sensitivity and precision make it a reliable tool for monitoring volatile organic compounds in urban and industrial environments, providing essential data for the development of air pollution mitigation strategies and the protection of public health (Chung et al., 2019; Zou & Yang, 2022).

Field Monitoring of Volatile Organic Compounds (VOCs)

Field monitoring of volatile organic compounds (VOCs) is essential for assessing air quality and understanding the spatial and temporal distribution of these pollutants in different environments. The selection of monitoring sites, sampling techniques, and analytical methods plays a crucial role in obtaining representative and reliable data.

Preparation of Tenax Tubes: Calibration and Verification

The Acti-VOC pump was calibrated to a flow rate of 200 mL/min using the 7000 Ellutia electronic flowmeter to ensure accuracy and consistency in sample collection. Prior to conditioning, each Tenax tube was individually inspected to verify proper airflow and sorbent integrity (Figure 7).

The recorded parameters were systematically analysed, and the data distribution, along with the potential variability for the Tenax tubes, was evaluated and presented in Figure 8 to ensure reliability and reproducibility in the adsorption process.

Figure 7. Flow Rate adjustment and flow monitoring

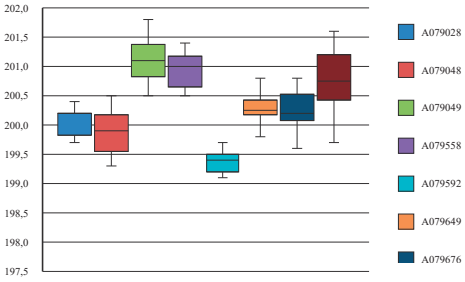

Figure 8. Flow assessment for Tenax TA tubes

To ensure consistency and verify the results, the same experiment was conducted on tubes containing both Tenax and Carboxen 1018, following the same procedure as for the tubes containing only Tenax. The data for the Tenax/ Carboxen 1018 tubes are presented in Figure 9, where the distribution and variability of the recorded parameters are analysed.

The flow rate measurements for the Tenax-only tubes and the combined Tenax and Carboxen tubes showed consistent performance throughout the experiments. While the Tenax-only tubes exhibited stable flow characteristics within the expected range, the inclusion of Carboxen did not significantly affect the flow dynamics.

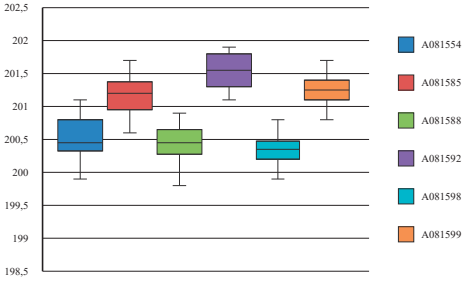

Figure 9. Flow assessment for TA Tubes/Carboxen1018

Both configurations demonstrated reliable flow rates, making them suitable for the collection of volatile organic compounds (VOC) from ambient air. These results confirm that both types of tubes are appropriate for accurate VOC sampling from ambient air, with minimal impact on the flow rate.

Conditioning of Tenax and Tenax/Carboxen Tubes for VOC Analysis

Tenax and Tenax/Carboxen tubes were conditioned using a Shimadzu Thermodesorber 30R. Desorption was performed at a temperature of 280°C and a flow rate of 70 mL/min for 20 minutes (Maria, 1996; SR EN 14662-4, 2005). The conditioning process was carried out in the reverse direction of the sampling flow to ensure complete desorption of any retained compounds and to prepare the tubes for subsequent analysis (SR EN 14662-5, 2005). According to the performed experiments, this method effectively removed any potential contaminants and ensured the integrity of the tubes prior to their use in VOCs sampling.

System checks and quality control

In order to ensure the reliability and accuracy of TD-GC-MS measurements, routine system checks, and quality control procedures were performed daily or after every 20 thermal desorption tubes analysed. These procedures included instrument warm-up, carrier gas flow verification, vacuum pressure monitoring, and mass spectrometer performance assessment. BFB (4-bromofluorobenzene) tuning check (30026; Batch A0189204) was conducted in full scan mode according to the requirements of EPA Method TO-17, to verify mass calibration, resolution, and detector sensitivity. Ion abundance criteria, as outlined in Table 4, were applied to specific fragment ions and the tune was accepted only when all values fell within the predefined range.

Moreover, using the system performance mix (30075; Batch A0189066), retention times, peak heights and area were verified for the following compounds: Bromoform, Chlorobenzene, 1,1-Dichloroethane and 1,1,2,2-Tetrachloroethane. These parameters were evaluated to ensure consistency and accuracy of the system performance and analytical method in detecting analytes. Both BFB tuning and system performance checks were performed at 10 ng to ensure the precision and sensitivity of the system during analysis of target compounds in the environmental samples.

Table 4. Ion abundance criteria for 4-bromofluorobenzene

m/z	Spectrum check criteria
50	15 to 40 % of 95 mass 95
75	30 to 60 % of mass 95
95	Base peak, 100% relative abundance
96	5 to 9 % of mass 95
173	< 2% of mass 174
174	> 50% of mass 95
175	5 to 9 % of mass 174
176	95 to 101 % of mass 174
177	5 to 9% of mass 176

Monitoring Sites and Sampling Techniques for VOC Assessment

The placement of monitoring stations for volatile organic compounds (VOCs) is a critical step in assessing air quality. In this study, VOC samples were collected in two distinct locations within the Jiu Valley region: the industrial area near the Lonea mine and the urban/pedestrian area of the Petroșani city center. The sampling points were selected to evaluate VOC concentrations in both an industrial environment and an urban area with high pedestrian traffic.

At each of these points, multiple sequential samples were collected using both Tenax and Tenax/Carboxen tubes. For each location, a blank sample was also collected using one of the tubes to assess potential contamination during the sampling process. The active sampling was conducted with the Acti-VOC pump at a flow rate of 200 mL/min, and each sample was collected for a 15-minute period. After the sampling process, the tubes were analysed using Thermal Desorption Gas Chromatography-Mass Spectrometry (TD-GC-MS) to quantify and identify the VOCs present in the ambient air. This approach ensured that a comprehensive analysis of VOC levels was conducted at both the industrial and urban/pedestrian sites, providing valuable insights into the air quality in these different environments. The results of these analyses, including VOC concentrations at the respective sites, are presented in Figure 10.

Together, these parameters form the foundation of method validation, ensuring that the analytical technique employed for VOC analysis

in ambient air is robust, sensitive, and precise. By systematically evaluating repeatability, LOD, LOQ, and recovery, researchers can establish the credibility of their GC-MS method, making it suitable for air quality monitoring, exposure assessment, and regulatory reporting.

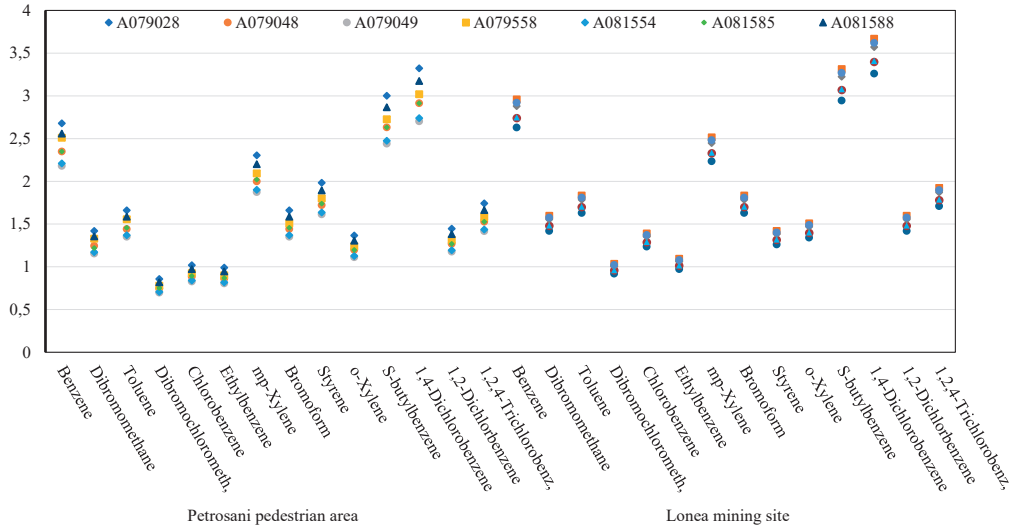

Figure 10. Analysis of Volatile Organic Compounds in ambient air on Petrosani and Lonea mining site

The measured concentrations of the investigated VOCs reveal discernible differences between the Petroșani pedestrian area (left cluster) and the Lonea mining site (right cluster). Each compound is represented by multiple data points (A079028, A079048, A079049, A079558, A081554, A081585, and A081588), thereby illustrating both inter-sample variability and site-specific emission characteristics.

Certain aromatic hydrocarbons (e.g., p-xylene, ethylbenzene, and benzene) appear more pronounced in the urban/pedestrian environment, potentially reflecting the influence of vehicular traffic, commercial activities, and population density. Conversely, the mining area exhibits elevated or comparable concentrations of halogenated compounds, such as 1,2-dichloroethane, suggesting contributions from industrial or mining-related processes. The overall range of values, extending from roughly 1.0 to 3.5 $\mu g/m^3$ underscores the necessity for robust sampling strategies and precise analytical methods to capture the nuances of VOC distribution.

Moreover, the fluctuations in measured concentrations highlight the impact of temporal factors (e.g., time of day, operational cycles) and microclimatic conditions (e.g., temperature, wind speed) on ambient VOC levels. This dataset thus reinforces the importance of employing comprehensive monitoring protocols, encompassing both spatial and temporal dimensions, to inform targeted mitigation measures and support evidence-based policymaking in air quality management.

CONCLUSIONS

This research aimed to develop and validate an optimized TD-GC-MS method for monitoring VOCs in ambient air. The applied methodology, which combined thermal desorption with gas chromatography-mass spectrometry and incorporated the use of internal standards and certified reference materials, ensured high analytical accuracy and traceability in calibration. The optimized method demonstrated excellent sensitivity - evident in its low detection and quantification limits - allowing for the reliable identification of VOCs at trace levels, as well as high precision and repeatability, with minimal variability observed in both short and long-term analyses. Additionally, the recovery rates obtained during

the method validation fell within optimal ranges, further confirming the accuracy and reliability of the analytical procedure. These performance characteristics comply with international standards in the field, which underscores the robustness of the method and its suitability for continuous air quality monitoring.

Key findings and contributions of this study include the provision of a robust, validated analytical solution for the systematic monitoring of VOCs in urban and industrial environments, thereby generating critical data for air pollution assessments. The field application of the optimized TD-GC-MS method confirmed its utility in obtaining detailed information on the spatial and temporal distribution of organic pollutants, which is essential for identifying emission sources and population exposure levels. Such information is highly relevant to public health, as more precise and reliable VOC monitoring contributes to a better understanding of the relationships between pollutant exposure and adverse health effects (e.g., respiratory, cardiovascular, or neurological issues), thereby supporting the development of risk mitigation strategies. Moreover, this study has significant implications for environmental regulations. The proposed method, which aligns with international guidelines (e.g., Eurachem), can be employed by regulatory bodies and laboratories to ensure compliance with air quality standards and to inform environmental policy. Overall, the successful validation of this optimized TD-GC-MS method represents a significant advancement in atmospheric pollution monitoring, offering a dependable tool for protecting both the environment and public health. The method proves to be highly effective and reliable for VOC monitoring in ambient air, providing exceptional sensitivity and precision, even at trace concentrations. Given its robustness, it is strongly recommended for continuous air quality assessments, particularly in urban and industrial environments, where accurate tracking of volatile organic compounds is crucial for public health protection and compliance with environmental regulations.

Abstract

The numerical modelling of the cylindrical shafts can be done using finite element method in axisymmetric or three-dimensional conditions. For this study, the 3D finite element method has been used to analysed the cylindrical shaft's behaviour regarding the earth pressure distribution, the vertical displacements of the soil and the horizontal displacements of the diaphragm wall. Thus, a parametric study has been carried out in which the cylindrical shafts radius, the length of the diaphragm wall and the excavation depth have been varied. For all the numerical models, the cohesive and cohesionless soil has been used. The results show the influence of all these parameters on the retaining walls' behaviour. Also, the influence of the soil type is explained.

Key words*: 3D finite element method, cylindrical shafts, lateral displacements, excavation.*

INTRODUCTION

Cylindrical shafts are used for specific constructions like pumping stations, tunnel access, underground parkings, launch points for the TBM, tunnel ventilation systems. Due to these specific functionalities and their shape, there is limited information regarding the cylindrical shaft's calculation methods and their behaviour. It is necessary to determine the earth pressure acting on the retaining wall and its lateral displacements. The classical earth pressure theories can be successfully used under plane strain conditions, but, in the case of cylindrical shafts, due to the arching effect developed around the retaining wall, these theories have to be updated.

The first studies regarding the earth's pressure distribution on cylindrical shafts were performed by (Westergaard, 1940) and later on improved by (Terzaghi, 1943). They have shown that the lateral earth pressure increases with depth and reaches a constant value. (Prater, 1977) consider that the lateral earth pressure is increasing up to a maximum value and then is decreasing until reaching a zero value at a depth equal to 8.5 of the excavation's radius.

There is a solid correlation between the lateral earth pressure distribution determined using physical modelling of cylindrical shafts and the one calculated using Terzaghi's theory (Tobar & Meguid, 2011). Also, the results obtained using finite element method are in good agreement with the one determined using physical modelling. The lateral displacements of the retaining wall increase with depth up to a maximum value which is located above the final excavation surface (Tangjarusrutaratorn et al., 2022).

Based on the measured vertical and horizontal displacements obtained from the centrifuge tests and in situ works, equations that can be used to calculate the vertical and horizontal displacements have been developed (New & Bowers, 1994; Le et al., 2019). Generally, these equations do not take into account the shaft diameter and the soil parameters and use empirical coefficients. Schwamb and Soga, (2015), made a comparison between multiple field measurements of the ground settlement and the equation propose by (New & Bowers, 1994). They have shown that the measured ground settlements are smaller than those calculated using the proposed equation and that the results are influenced by the shaft diameter. Schwamb and Soga, (2015), also performed a series of numerical back-analysis carried out using the finite element method in 2D axisymmetric conditions. They analysed the influence of different parameters such as diaphragm wall

thickness, wall stiffness and anisotropy, soil models or the diaphragm wall installation type. The results shown that the thickness of the diaphragm wall has a slightly effect on the wall deflections. The field data are in good agreement with the results of the analysis of an isotropic wall, while the analysis of an anisotropic wall overestimated the wall deflections indicating that the diaphragm wall behaved isotropically despite the joints between the diaphragm wall's panels. Assuming a wished-in-place wall is a reasonable simplification compared to modelling the diaphragm wall installation.

The finite element method (FEM) is a common calculation method used in geotechnical engineering which allows the soil-structure interaction modelling and requires to use complex constitutive models for describing the soil behaviour. One of these complex constitutive models is hardening soil model (HSM), which is used for this paper purpose also.

The circular shafts can be modelled using the finite element method in 2D axisymmetric or 3D conditions. This paper presents the results of a parametric study which has been conducted using the 3D finite element method.

MATERIALS AND METHODS

For this study, the 3D finite element method has been used to analyse the cylindrical shaft behaviour in terms of lateral earth pressure, displacements of the soil and of the retaining wall. The design software used for numerical modelling was Plaxis 3D.

A parametric study has been carried out in which the cylindrical shafts radius (r), the excavation depth (H) and the length of the diaphragm wall (L) have been varied. The excavation depth has values between 10 and 50 m and the length of the diaphragm wall was given values ranging from the excavation depth plus one meter to double of the excavation depth. Generally, the shafts radius has values between 10 and 500 m. For the 10 m deep excavation and the 20 m long diaphragm wall, the excavation radius ranges between 10 and 1000 m.

Generally, the soil parameters must be chosen based on the geotechnical study carried out on the analysed site. There are multiple methods of computing the characteristic values of the soil parameters, including the shearing resistance parameters (Olinic, 2014).

For the purpose of this study, the soil parameters have been chosen based on previous experience for two common soil types. Thus, for all the numerical models, the cohesive and cohesionless soil have been used.

The parameters for the two types of soil are shown in Table 1. For this study, the hardening soil model has been used. Totally, a number of 1392 numerical models have been carried out. Due to the large number of numerical models, Python 3.11.5 was employed to facilitate their calculus.

Table 1. Soil parameters used in the numerical analysis

Soil type	γ	γ_{sat}	E_{50}^{ref}	E_{oed}^{ref}	E_{ur}^{ref}	ν_{ur}	m	c'	ϕ'	R_{inter}
	[kN/m^3]	[kN/m^3]	[kPa]	[kPa]	[kPa]	[-]	[-]	[kPa]	[kPa]	[-]
Cohesionless	19.5	20.50	25000	25000	75000	0.30	0.5	5	30	0.67
Cohesive	19.5	20.50	15000	15000	45000	0.35	0.6	40	15	0.67

γ - unit weight; γ_{sat} - saturated unit weight; E_{50}^{ref} - secant stiffness in standard drained triaxial test; E_{oed}^{ref} - tangent stiffness for primary oedometer loading; E_{ur}^{ref} - unloading/reloading stiffness; ν_{ur} - Poisson's ratio for unloading-reloading; m - power for stress-level dependency of stiffness; c' - effective cohesion; ϕ' - Effective angle of internal friction; R_{inter} - strength reduction factor.

The diaphragm wall is modelled as a plate and the capping beam is defined as a beam element. For both, the linear elastic constitutive model has been used. The material properties are shown in Tables 2 and 3.

The dimensions of the numerical model are chosen according to the excavation depth: the model is extended to 5 times the excavation depth upstream of the retaining wall and 3 times below the excavation surface (Figure 1).

Table 2. Material properties of the diaphragm wall

Table 3. Material properties of the capping beam

Material	γ	E	height	width
	[kN/m^3]	[kPa]	[m]	[m]
Concrete	25	3.10e7	0.60	0.45

Regarding the model boundaries, the bottom boundary is fixed in all directions and the vertical boundaries are fixed on horizontal directions and free on vertical direction.

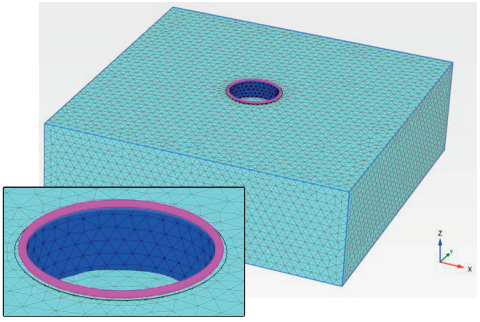

Figure 1. Numerical model – mesh generation

In order to perform finite element calculations, the numerical model has to be divided into finite elements. The relative element size of 0.02 has been chosen.

RESULTS AND DISCUSSIONS

The lateral earth pressure

Figure 2 show the lateral earth pressure diagrams acting on the retaining wall of a 10 m depth circular excavation (H), with 20 m wall length and 0.45 m wall thickness, in cohesionless soil. The excavation radius ranges between 10 and 100 m. Also, the active (γHk_a) and at rest (γHk_0) earth pressure diagrams are plotted.

The at-rest earth pressure coefficient has been calculated using the Jaky empirical relationship, $k_0 = 1 - \sin(\varphi)$, the same relationship used by Plaxis 3D, for both types of soil. Figure 3 shows the lateral earth pressure diagrams acting on the retaining structure with the same geometric parameters as in the Figure 2, but in the case of the cohesive soil.

The results obtained using FEM do not correspond to the ones obtained using the analytical solutions presented in the first section of this paper. Generally, the lateral earth pressure has values between the active and at rest earth pressure. Also, the lateral earth pressure varies approximatively linearly with depth.

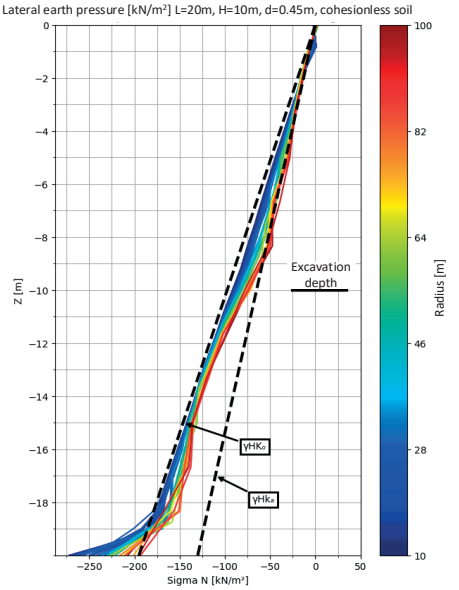

Figure 2. The lateral earth pressure diagrams for a circular excavation with H = 10 m, L = 20 m and r = 10÷100 m, cohesionless soil

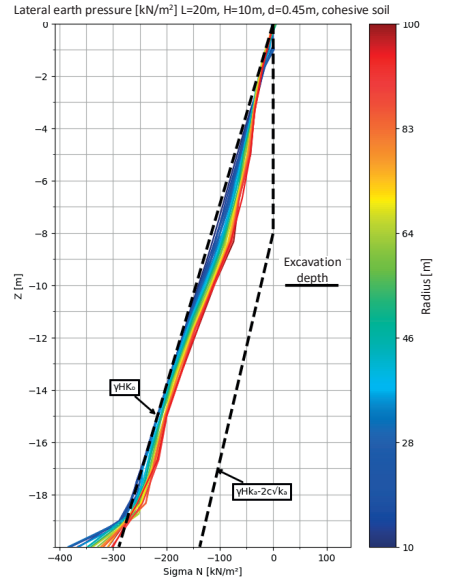

Figure 3. The lateral earth pressure diagrams for a circular excavation with H = 10 m, L = 20 m and r = 10÷100 m, cohesive soil

In the case of the cohesionless soil, for small values of the radius, the lateral earth pressure has values close to those of the at rest earth pressure. For larger values of the radius, the lateral earth pressure diagrams no longer vary linearly with depth. Also, at the final excavation depth, the values of the lateral earth pressure decrease to values lower than that of the active earth pressure. In the case of cohesive soil (Figure 3), the earth pressure variation with increasing radius is smaller and its values are close to those of the at rest earth pressure.

Horizontal displacements of the retaining structure

Figure 4 and Figure 5 show the lateral displacements diagram of the retaining wall of a 10m depth circular excavation (H), with 20 m wall length and 0.45 m wall thickness, in cohesionless soil. The excavation radius varies between 10 and 250 m (Figure 4) and between 10 and 1000 m (Figure 5).

Figure 5 shows also the lateral displacements diagram for a plane strain calculus of an excavation with the same characteristics.

For cylindrical shafts, the maximum value of the horizontal displacement of the retaining wall is located above the final excavation depth, due to the arching effect.

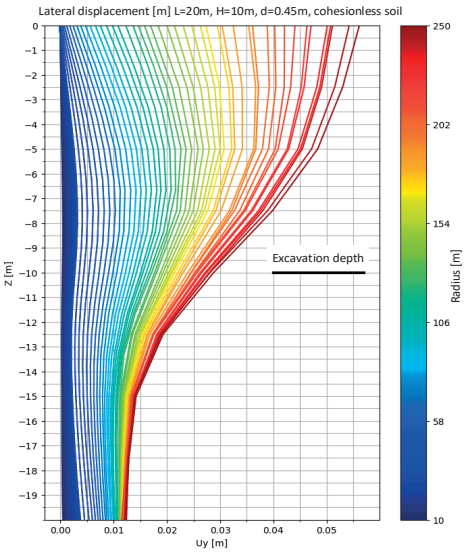

Figure 4. The lateral displacement diagram of the retaining wall, for a circular excavation with H = 10 m, L = 20 m and r = 10÷250 m, cohesionless soil

For a radius greater than 200 m, the shape of the lateral displacement diagram changes, the maximum value being located at the upper part of the retaining wall. This behaviour is specific to the plane strain conditions.

However, even for large radii up to 1000 m, the maximum value of the horizontal displacement is smaller than that obtained from the plane strain calculus, further indicating the presence of the arching effect.

The maximum horizontal displacement increases with increasing radius and excavation depth. For the same excavation depth, the variation of the maximum horizontal displacement with the radius is showing a trend.

Figure 6 and Figure 7 show the variation of the maximum horizontal displacement normalized with the excavation depth with the radius, for cohesionless and cohesive soil, for radius smaller than 100 m.

For each type of soil and each excavation depth, these variations show a similar trend and the differences between them are slight.

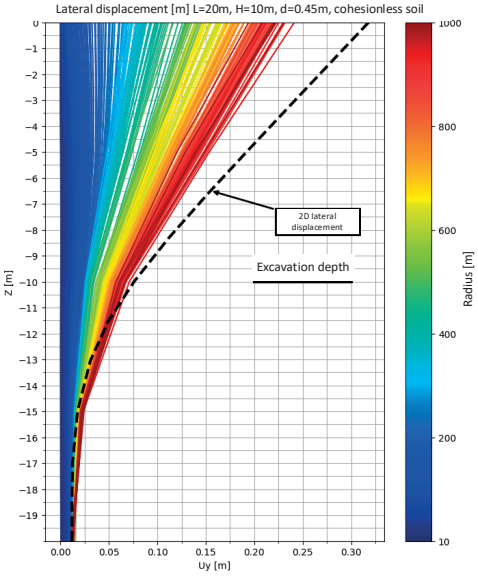

Figure 5. The lateral displacement of the retaining wall's diagram, for a circular excavation with H = 10 m, L = 20 m and r = 10÷1000 m, cohesionless soil

In order to found a function that can be used to approximate the maximum horizontal displacement depending on the excavation depth, on the type of soil and on the radius, for

each graph, the median values of the maximum horizontal displacements have been calculated and plotted on the graph.

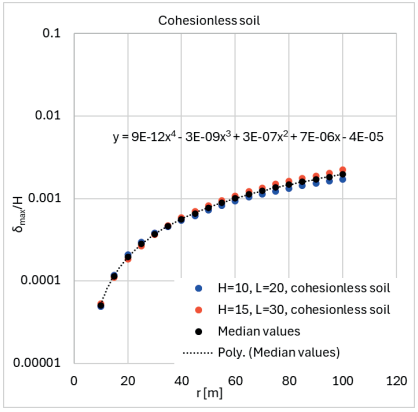

Figure 6. Variation of the maximum horizontal displacement normalized with the excavation depth, with the radius, r≤100 m, cohesionless soil

For these median values, a fourth-degree polynomial function has been determined. The resulted functions for each type of soil are presented below.

For cohesionless soil, the radii between 10 and 100 m and excavation depths between 10 and 15 m, the maximum horizontal displacement can be approximated with the following function:

$$\frac{\delta_{max}}{H} = 8.84E-12 \cdot r^4 - 2.54E-9 \cdot r^3 + 2.89E-7 \cdot r^2 + 6.70E-6 \cdot r - 4.26E-5$$

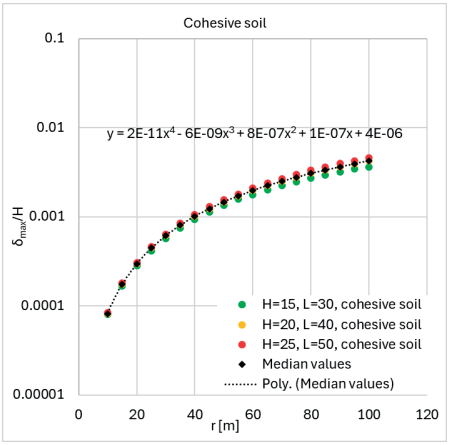

Figure 7. Variation of the maximum horizontal displacement normalized with the excavation depth, with the radius, r≤100 m, cohesive soil

For cohesive soil, the radii between 10 and 100 m and excavation depths between 15 and 25 m, the maximum horizontal displacement can pe approximate with the following function:

$$\frac{\delta_{max}}{H} = 1.81E-11 \cdot r^4 - 5.96E-9 \cdot r^3 + 8.39E-7 \cdot r^2 + 1.19E-7 \cdot r - 3.97E-6$$

The differences between the calculated and the approximated horizontal displacements are, generally, smaller than 10% and maximum 16% for radii greater than 60 m.

The maximum value of the horizontal displacement of the retaining wall is located above the final excavation level (Figure 8). For the same excavation depth, the maximum horizontal displacements occur at the same depth for both cohesive and cohesionless soil types.

For excavation depths smaller than 20 m, the maximum horizontal displacement with respect to the final excavation depth, is encountered for a ratio $z/H = (0.66 \div 0.86)$.

For excavation depths greater than 25 m, the maximum horizontal displacement with respect to the final excavation depth, is encountered for a ratio $z/H = (0.75 \div 0.93)$.

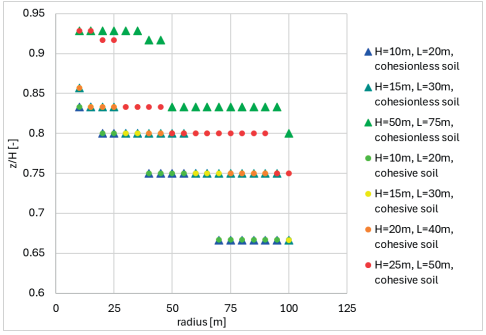

Figure 8. Depth at which the maximum horizontal displacement (z) occurs, normalized with the final excavation depth (H), depending on the radius, excavation depth and soil type

As the radius increases, the depth at which the maximum horizontal displacement occurs decreases but cannot be expressed as a function.

Vertical displacements of the ground behind the retaining structure

Considering the shape of the horizontal displacement diagram and its values at the top of

the wall, it is expected that the vertical displacement of the ground behind the retaining structure will swell in its immediate vicinity and then will start to settle at a certain distance away from the retaining wall. This behaviour is highlighted in Figures 9 and 10.

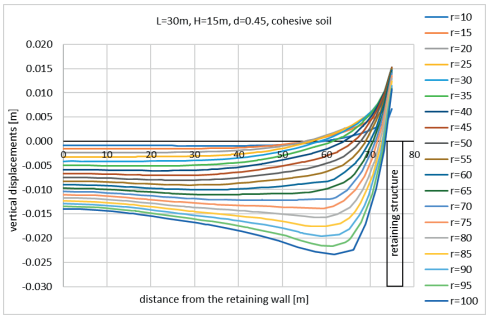

Figure 9. The vertical displacements of the ground behind the retaining wall, for a circular excavation with H = 15 m, L = 30 m and r = 10÷100 m, cohesive soil

The maximum vertical displacements for cylindrical shafts modelled in cohesive soil are greater than those obtained for circular excavation executed in cohesionless soil.

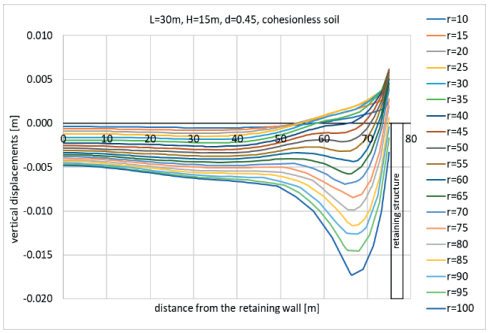

Figure 10. The vertical displacements of the ground behind the retaining wall, for a circular excavation with H = 15 m, L = 30 m and r = 10÷100 m, cohesionless soil

Depending on the type of soil and the radius, the maximum values of the vertical displacement of the soil occurs at different distance from the retaining wall. For small values of the circular excavation radius, the maximum vertical displacement occurs at a large distance from the retaining wall, between $(2 \div 5)H$, the ratio increasing with the excavation depth.

For large values of the circular excavation radius, the maximum vertical displacement occurs at a smaller distance from the retaining wall, between $(0.45 \div 1.40)H$, the ratio increasing with the excavation depth (Figure 11).

Figure 12 shows the relationship between the maximum vertical displacements (s_{max}) and the maximum horizontal displacements (δ_{max}), normalized with the excavation depth (H), for different excavation depths and circular excavation radii.

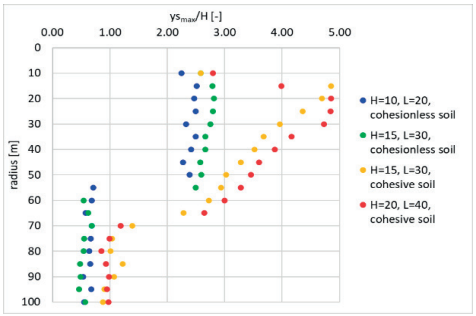

Figure 11. The distance at which the maximum vertical displacements occur from the retaining wall, normalized by the excavation depth (ys_{max}/H), for different excavation depths, depending on the circular excavation radius

The maximum vertical displacements are not equal to the maximum horizontal displacements, but there is the following relationship between them:

$$s_{max} = \frac{\delta_{max}}{2} \div \frac{\delta_{max}}{4}$$

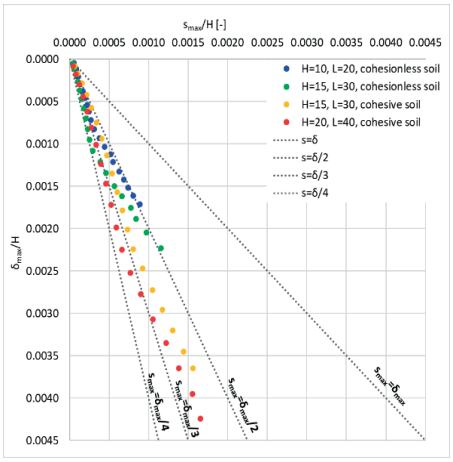

Figure 12. The dependence between the maximum vertical displacements (s_{max}) and maximum horizontal displacements (δ_{max}), normalized by the excavation depth (H), for different excavation depth and excavation radius

CONCLUSIONS

This paper presents a parametric study regarding the cylindrical shaft behaviour, in which the radius, the length of the diaphragm wall and the excavation depth have been varied. Also, two types of soil have been used: cohesionless and cohesive.

For this parametric study, the finite element method has been used to perform the numerical modelling and calculus.

The results show the lateral earth pressure acting on the retaining wall and its comparison with the at-rest and active earth pressure diagrams. Thus, for common shafts radii smaller than 100 m, the lateral earth pressure acting on the retaining wall varies approximatively linearly with depth and has values close to those of the at rest earth pressure.

For each type of soil, relationships that can be used to approximate the maximum horizontal displacement depending on the excavation depth, on the type of soil and on the radius were proposed.

However, these relationships are limited for a small interval of excavation depths and cannot be applied to a mixed stratigraphy.

Generally, in the immediate vicinity of the retaining structure, the vertical displacements of the ground swell. For small values of the shaft radius, the maximum vertical displacement occurs at a large distance from the retaining wall.

For large values of the circular excavation radius, the maximum vertical displacement occurs at a smaller distance from the retaining wall.

The ratio between the maximum vertical and horizontal displacements is not equal to one, as proposed in the technical literature.

Abstract

Air pollution is a significant environmental and public health threat, contributing to approximately 7 million deaths annually, as reported by the World Health Organization (WHO). Major pollutants such as particulate matter (PM10 and PM2.5), carbon monoxide (CO), ozone (O3), nitrogen dioxide (NO2), and sulfur dioxide (SO2) are linked to severe health conditions such as cardiovascular diseases, strokes, respiratory illnesses, chronic obstructive pulmonary disease (COPD), and cancer. Vulnerable populations - the elderly, children, pregnant women, and individuals with pre-existing conditions - face the highest risks. Long-term exposure to air pollution has been associated with a tenfold increase in health complications compared to short term exposure. While research has clarified many of the biological pathways through which pollutants affect human health, ongoing studies continue to explore the full extent of these effects. This study provides a comprehensive analysis of the latest data on the health effects of ambient air pollution, with a particular focus on Bulgaria. It identifies key trends, examines policy gaps, and evaluates the effectiveness of existing air quality regulations. By incorporating a comparative analysis of WHO, EU, and Bulgarian air quality standards, this research underscores the pressing need for stricter regulatory measures and enhanced mitigation strategies to curb pollution-related morbidity and mortality. The findings highlight the urgency of aligning national air quality policies with WHO guidelines to safeguard public health and drive sustainable environmental initiatives.

Key words*: ambient air pollution, air pollutants, air quality, diseases, health impacts, regulatory policies, WHO guidelines.*

INTRODUCTION

Air pollution is a major environmental factor that affects every individual and is a leading cause of numerous diseases worldwide. Globally, the main sources of air pollution are industry (large enterprises, TPPs, steel plants, petroleum refineries, cement factories), transport (road, air, maritime), households and agriculture. According to the WHO, each year 7 million deaths including 600,000 children are caused by polluted air (4.2 million from outdoor air pollution, and 3.8 million from indoor air pollution). Nine out of 10 people around the world live in regions where air pollution exceeds the WHO guidelines. More than 89% of deaths caused by air pollution occur in low- and middle- income countries (WHO, 2024a; Le et al., 2024). Some scientists believe that this number is even bigger estimating at least 9 million people to die every year from the air they breathe (UNEP, 2021; Vohra et al., 2021). Air pollution has also considerable economic impacts, reducing life expectancy, increasing medical costs and reducing productivity through working days lost across various economic sectors (EEA, 2020). The World Bank estimated global air pollution cost at $8.1 trillion in 2019, equivalent to 6.1% of global GDP. In individual countries, the economic burden of pollution associated with premature mortality and morbidity is significant, equivalent to 5-14% of countries' GDPs (WB, 2023). The Organisation for Economic Co-operation and Development (OECD) reported "that a 1 μg/m^3 decrease in annual mean $PM_{2.5}$ concentration would increase Europe's GDP by 0.8%, representing around €200 per capita per year as result of increases in output per worker, through lower absenteeism at work or increased labour productivity, due to lower air pollution" (EEA, 2020).

Pollutants with the strongest evidence for public health concern include particulate matter (PM), carbon monoxide (CO), ozone (O_3), nitrogen dioxide (NO_2) and sulfur dioxide (SO_2). Health problems can occur after both short- and long-term exposure to these various pollutants (Cesaroni et al., 2014; Schwartz et al., 2017; Burnett et al., 2018; Kermani et al., 2018; Zheng et al., 2021; Dass et al., 2021; Popa et al., 2021; Babu et al., 2022). For some pollutants (VOCs, PAHs, O_3), there are no thresholds below which adverse effects do not occur (Papadogeorgou et al., 2019; Manisalidis et al., 2020). Air pollution usually has a greater impact on people living in urban rather than in rural areas. The bigger air polluting sources (industry, traffic, household burning, etc.) and higher population density in the cities lead to high concentration and retention of the atmospheric pollutants (Olstrup et al., 2021; Kozlov et al., 2022; Carozzi & Roth, 2023; Akomolafe et al., 2024; Kar et al., 2024).
Numerous studies reveal the link between polluted air and human health. Air pollution is associated with many diseases affecting different human body systems and functions - respiratory system (Sierra-Vargas & Teran, 2012; Thurston et al., 2017; Heger et al., 2019; Popa et al., 2021; Lee et al., 2021; Kienzler et al., 2022; Lan et al., 2024), cardiovascular system (Shahrbaf et al., 2021; D'Acquisto et al., 2023; Bhatt, 2024; Sadeghi & Sadeghi, 2024), immune system (Dobreva et al., 2015; Ivanov et al., 2016; Glencross et al., 2020), reproductive system (Popa et al., 2020; Shetty et al., 2023), endocrine system (Saleem et al., 2024), nervous system (Solaimani et al., 2017; Thurston et al., 2017), cognitive functions (Meo et al., 2024), mental health (Keswani et al., 2022; Bai et al., 2024) as well as with increased mortality of the affected people (Turner et al., 2020; WHO, 2024b). Vandyck et al. (2022) point out that health considerations form a strong argument in favor of policy action to concurrently mitigate climate change and control air pollution.
EU's policy and legislation on reducing the emissions of harmful substances through the years give positive results; today the air is cleaner than it was two decades ago. Nevertheless, human health is still threatened by various air pollutants (EEA, 2022, 2023a, 2023b). In 2021, premature deaths attributed to exposure to fine PM decreased by 41%, compared to 2005 (EEA, 2023b). The Zero Pollution Action Plan aims to decrease premature deaths caused by exposure to fine particulate matter (PM) by 55% by 2030, compared to 2005 levels. However, despite continued emission reductions, a significant portion of the EU's urban population remained exposed to harmful concentrations of key air pollutants - $PM_{2.5}$, PM_{10}, O_3, NO_2, Benzo[a]pyrene (BaP), and SO_2 - in 2022 (EEA, 2024). In 2021 in the EU-27, total of 327,000 deaths were attributable to exposure to $PM_{2.5}$ (77.4% of all deaths), NO_2 (15.9% of all deaths) and O_3 (6.7% of all deaths) concentrations above 2021 WHO's guideline levels (EEA, 2023b). In 2020, the EC initiated a revision of the ambient air quality directives, aiming to align the air quality standards more closely with the WHO recommendations. As a result, a new Directive (EU) 2024/2881 of 23 October 2024 on ambient air quality and cleaner air for Europe was accepted. Further efforts will be needed to meet the zero-pollution vision for 2050 of reducing air pollution to levels no longer considered harmful to health.
Following the EU policy and legislation referring to the air quality improvement, Bulgaria reported a significant reduction of the air pollution in the last decades. Positive trends in air quality are attributed to active policies and measures at all levels, including legislative harmonization with European standards. The amendments made in the Air Purity Act (1996) emphasize municipal responsibility for air quality improvement, strengthen central government oversight, and the effective implementation of municipal programs (Zheleva, 2024). In 2022, the emissions of $PM_{2.5}$, SO_2, NO_x and NMVOCs have decreased by 30, 94, 53 and 26%, respectively compared to 2005. However, pollution with PM and partly with BaP continues to be a major problem for the ambient air quality in many settlements in the country. The main causes of excessive particulate pollution are solid fuel heating during the winter season and emissions from road and public transport (ExEA, 2024).
The brief review shows that addressing air pollution, which is the second highest risk factor for non-communicable diseases, is key to protecting public health. Despite the progress made, the problem with air pollution has not yet

been solved. The tools for achieving this goal include well-motivated policies, adequate legislation, effective practices (monitoring, control, etc.) and reliable and sustainable results. It turns out that there are differences at global (WHO), regional (EU) and local (individual countries) level, both in the regulation of air pollutant levels and interim targets for a gradual shift from high to lower concentrations and their associated health benefits. This gave us the basis to define the scope of our review: the paper first explores the key air ambient pollutants, then assesses their health impacts, partly in Bulgaria, make a comparative analysis of WHO, EU and Bulgarian standards, and concludes with policy recommendations for air quality improvement.

MATERIALS AND METHODS

This review summarizes and analyses the primary information from databases like Google Scholar, PubMed, ResearchGate, and Science Direct. The keywords used were air pollution, particulate matter, gaseous pollutants, human health risks, morbidity, mortality, and air quality standards. We have reviewed 245 studies, including journal articles, conference papers, WHO, EEA, USEPA and Word Bank reports, and country-specific reports, focusing on ambient air pollution and its impact on human health, respectively morbidity and mortality. After the selection, 104 literature sources (mainly from the recent years), including 88 scientific articles published in a peer-reviewed journals and 16 reports and data from different institutions were used.

RESULTS AND DISCUSSIONS

Classic air pollutants

Since 1987, WHO has periodically issued health-based air quality guidelines (AQGs) to assist governments and civil society in reducing air pollution and its adverse effects on human. Those guidelines are not legally binding standards but are a science-based tool that countries around the world can use to improve their policy and legislation aimed at air quality improvement. The new WHO guidelines, published in 2021 (WHO-AQG, 2021), recommend specific air quality levels regarding six pollutants ($PM_{2.5}$ and PM_{10}, NO_2, SO_2, CO and O_3) with the highest evidence for a negative impact on people's health. The WHO determines those pollutants as "classic" pollutants; briefly, they are characterized as follows:

Particulate matter (PM): PM is a complex mixture of solids and aerosols (organic, inorganic) composed of small droplets of liquid, dry solid fragments, and solid cores with liquid coatings. Particles vary widely in terms of size, shape and chemical composition (Estuardo-Moreno et al., 2022). PM may be either directly emitted from sources (primary particles) – natural (ground surface dust, volcanic activity, salts, etc.) and anthropogenic (industry, transport, energetics, household heating, etc.), or may be formed in the atmosphere through chemical reactions of gases (secondary particles) such as SO_2, NO_x, NH_3 and VOCs. According to their size, PM may be divided in 5 groups – supercoarse PM ($d_{pa} > 10$ μm; d_{pa} – aerodynamic particle diameter), coarse PM ($2.5 < d_{pa} \leq 10$ μm), fine PM ($0.1 < d_{pa} \leq 2.5$ μm), ultra-fine PM ($d_{pa} \leq 0.1$ μm) and nanoparticles (NPs) ($1 < d_{pa} \leq 100$ nm). PMs consist mainly of sulfates, nitrates, ammonia, sodium chloride, black carbon (BC), mineral dust and water (Sierra-Vargas & Teran, 2012; Khan et al., 2019; Manisalidis et al., 2020; Kumari & Sarkar, 2021; WHO, 2024a).

Nitrogen dioxide (NO_2): NO_2 is a reddish-brown, highly reactive water-soluble gas, and a strong oxidant. It results from both anthropogenic and natural processes; the main anthropogenic activity leading to NO_2 emissions being the combustion of fossil fuels from industrial sources (coal, gas and oil), vehicles and power plants (Mesas-Carrascosa et al., 2020; Babu et al., 2022).

Sulfur dioxide (SO_2): SO_2 is a toxic colourless gas with a sharp odour; it mainly originates from burning of fossil fuels that contain sulfur (coal, crude oil) in power stations and refineries. The volcanos and oceans are the main natural source of SO_2; it causes health problems in humans, animals and plants (Babu et al., 2022; WHO, 2024a).

Carbon monoxide (CO): CO is a colourless, odourless and tasteless toxic gas produced by incorrect combustion processes (transport, thermal power plants, combustion installations etc. (Babu et al., 2022; WHO, 2024a).

Ozone (O_3) – tropospheric: O_3 is formed through chemical reactions between hydrocarbons, CH_4 and NO_x under the influence of ultraviolet light; it is a strong oxidant and one of the major constituents of photochemical smog (Popa et al., 2020; Babu et al., 2022).

It is important to note that the new WHO AQGs do not include recommendations about pollutant mixtures as well as the combined effects of pollutant exposures, which is a serious omission as usually the people are exposed to a mixture of air pollutants that varies in space and time. Nevertheless, the achievement of the WHO AQGs permissible levels for all these pollutants is necessary to minimize the health risk for humans.

Impact of air pollution on health

In present days, the air pollution is one of the most serious ecological problems with significant impacts on the human health everywhere in the world, particularly in the urban areas. Some population groups are more affected by air pollution than others, because they are more exposed (lower socio-economic groups) or susceptible (older people, children and those with pre-existing health conditions) to environmental hazards (EEA, 2022). The degree of effect on the body depends on the pollutant composition, source and dose, level and duration of exposure to polluted air (Le et al., 2024). To solve the problem, two aspects must be considered - on one hand, to know how the individual air pollutants influence human health and on the other - how the mixtures of pollutants do that.

Air pollutants – human body effects

PM_{10}, $PM_{2.5}$, SO_2, NO_2, CO, and O_3 are the air pollutants considered most harmful to humans (Manisalidis et al., 2020; Ruwali et al., 2024; Saleem et al., 2024). There is suggestive evidence linking the individual air pollutants with human health status, which could be summarized as follows:

(PM): Exposure to fine particle outdoor air pollution is the largest environmental risk factor for premature death globally. In 2022, 96% of the urban population was exposed to concentrations of fine PM above the health-based guideline level set by the WHO (EEA, 2024). In the same year, around 4.7 million people died from exposure to fine particulate outdoor air pollution (28% of all deaths) and the average global life expectancy was reduced by approximately one year and eight months (UNEP, 2021). New research reveals some of the mechanisms behind PM's harmful effects on human health. Li et al. (2024) analyzed the long-term oxidative potential (OP) of water-soluble $PM_{2.5}$ and found that dust, gaseous pollutants (NO_2 and SO_2), black carbon and biomass combustion are the main sources of the OP of $PM_{2.5}$. It is well documented that short-term and long-term exposure to $PM_{2.5}$, PM_{10} and NPs have a significant influence on the human body. Exposure has been linked to a wide range of adverse health effects, including neurological disorders, exacerbation of asthma, and chronic obstructive pulmonary disease (COPD). It also contributes to reduced lung function, lung cancer, silicosis, and tuberculosis. Furthermore, it impacts the reproductive system and increases the risk of cardiovascular conditions such as cardiac arrhythmias, nonfatal heart attacks, and myocardial infarction. Additional effects include irritation of the eyes, throat, and nose, impairment of mucociliary and macrophage activity, neurodegenerative diseases, cerebrovascular conditions, cognitive decline, dementia, and disruptions in children's brain development (Solaimani et al., 2017; Zaheer et al., 2018; Kermani et al., 2018; Silva et al., 2020; Popa et al., 2021; USEPA, 2024). Hofmann et al. (2015) established a relationship between fine dust exposure and the incidence of stroke. Short, mid-, and long-term pre-exposure can significantly exacerbate small-airway inflammation, particularly in males, children, smokers, and individuals with pre-existing respiratory conditions (Lei et al., 2024). Prolonged exposure to PM10 and PM2.5 has been linked to a higher incidence of acute coronary events, even at concentrations below the EU regulatory limits (Cesaroni et al., 2014), as well as an increased risk of premature mortality (Vohra et al., 2021; Isaifan, 2023). Not only long-term exposure, but also acute increases in PM_{10}/$PM_{2.5}$ concentration (up to 10 $\mu g/m^3$) are associated with cardiovascular hospitalization or death with an increase of 1.63% per PM_{10} and 2.12% for $PM_{2.5}$, the most prominent on the day of exposure (Shah et al., 2013). Heger et al. (2019) suggested that the

concentration of PM_{10} in the air was an important predictor of the respiratory diseases. The proportion of deaths attributed to outdoor fine particulate air pollution varied by disease, with chronic obstructive pulmonary disease (COPD) accounting for 48%, lower respiratory infections for 30%, ischemic heart disease for 28%, and stroke for 27%. Additionally, 19% of deaths were linked to tracheal, bronchus, and lung cancer, 18% to type 2 diabetes, and 14% to neonatal disorders (UNEP, 2021).

(SO_2): That toxic gas affects susceptible people with lung disease, old people, and children, who present a higher risk of damage. Exposure to high concentrations of SO_2 in the air is associated with headache, anxiety, respiratory problems (facilitates bronchoconstriction, cough, affects the mucous membranes of the throat, nose and eyes) and cardiovascular diseases (Manisalidis et al., 2020; Popa et al., 2020; USEPA, 2024).

(NO_2): NO_2 creates respiratory problems as affects the mucous membranes of the nose, eyes and throat; increases bronchial reactivity and susceptibility to infections; provokes bronchitis, allergic rhinitis, chronic lung disease and even pulmonary edema and tuberculosis; affects some organs (liver, spleen) and the circulatory system (Lin et al., 2019; Manisalidis et al., 2020; Babu et al., 2022).

(CO): CO in the air penetrates very easily through the alveoli of the lung into the human circulatory system, has effects on hemoglobin by blocking oxygen transport (the affinity of CO to hemoglobin is about 250 times greater than that of oxygen). The result is hypoxia, ischemia and cardiovascular disease, effects on the fetus, headaches, nausea, vomiting, dizziness, weakness, vomiting, tuberculosis and eventually loss of consciousness; also, working with CO may result in fatal poisoning (Lin et al., 2019; To et al., 2020; USEPA, 2024).

(O_3): As a strong oxidant, O_3 affects predominantly the respiratory system, which is manifested with inflammation of the mucous membranes of the respiratory tract, causes coughing, chest discomfort, obstruction of the airways, damage to the epithelium lining the airways. It can also cause cardiovascular diseases (Popa et al., 2020; USEPA, 2024). The European research project APHEA2 found out a correlation between daily fatalities and ozone levels; a short-term rise in ozone concentration was connected to an increase in daily fatalities (0.33%), respiratory deaths (1.1%), and cardiovascular deaths (1.1%), (Babu et al., 2022).

Diseases associated with exposure to air pollution

Air pollution typically consists of a complex mixture of multiple pollutants, which together have a more pronounced impact on human health than individual pollutants alone. To evaluate these effects, two key indicators - mortality and morbidity - are commonly used (Thacker et al., 2006). A widely applied metric for assessing the combined burden of both mortality and morbidity is Disability-Adjusted Life Years (DALY), which quantifies the total number of years lost due to disease, injury, or exposure to harmful risk factors. One DALY represents the loss of one year of healthy life (EEA, 2023b) (Figure 1).

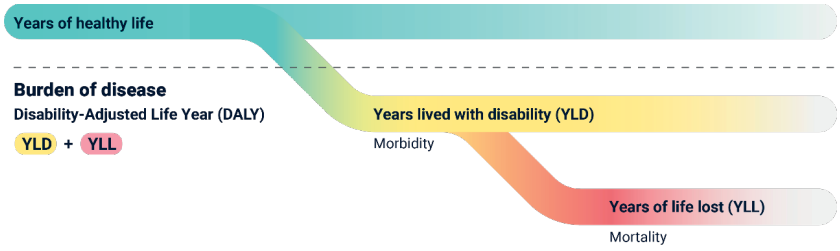

Figure 1. Burden of disease (DALY) as sum of years lived with disability (YLD) and years of life lost (YLL) (Source: EEA, 2023b)

Mortality: This indicator represents the number of deaths resulting from a specific disease or a group of diseases. In scientific studies, reports, and analyses, mortality is commonly expressed as premature deaths (PD) or years of life lost (YLL) to quantify the impact of early mortality.

Schwartz et al. (2017) established a causal association of local air pollution with daily deaths at concentrations below USEPA standards; the increase of the $PM_{2.5}$ and black carbon concentrations was associated with a 0.90% increase in daily deaths; a weaker association was observed for NO_2. In 2021, air pollution led to a significant number of premature deaths in Europe (excluding Türkiye): exposure to concentrations of fine PM above the 2021 WHO guideline level (5 $\mu g/m^3$) resulted in 293,000 premature deaths; exposure to NO_2 above the respective guideline level (10 $\mu g/m^3$) led to 69,000 premature deaths; acute exposure to O_3 (70 $\mu g/m^3$) caused 28,000 premature deaths (EEA, 2023b).

Morbidity: This is a very precise indicator to assess the public health deviation. Morbidity is generally divided in two categories - outpatient care and inpatient care (hospitalization). The morbidity is affected by changes in atmospheric pollutant concentrations (Thacker et al., 2006; Platikanova & Penkova-Radicheva, 2016). Numerous studies have established a strong link between air pollution exposure and morbidity. Platikanova et al. (2018) developed a mathematical model to predict morbidity rates in different residential areas based on correlations between air pollutants (PM10, SO_2, NO_2, and Pb-aerosol) and health outcomes. Short-term exposure to air pollutants and smog is strongly associated with conditions such as COPD, coughing, shortness of breath, wheezing, asthma, respiratory diseases, and increased hospitalization rates. Meanwhile, long-term exposure has been linked to chronic asthma, pulmonary insufficiency, cardiovascular diseases, cardiovascular mortality, and reproductive system impairments in both males and females (Manisalidis et al., 2020; Tran et al., 2023; Saleem et al., 2024). Recently, some researchers suggested that air pollution, especially with $PM_{2.5}$, may be associated with cardiac arrhythmias due to the oxidative stress, autonomic dysfunction, coagulation dysfunc-tion, and inflammation (Shahrbaf et al., 2021). Air pollution (O_3, NO_2, SO_2, and PM) may exacerbate asthmatic symptoms, to increase the morbidity and mortality and risk of hospi-talization associated with respiratory diseases (Lee et al. 2021; Yuan et al., 2024). Data, based on the ETC/HE report (Kienzler et al., 2022), showed that in 2020 in Europe, COPD associated with exposure to $PM_{2.5}$ was on the average 51.6 years lived with disability (YLDs) per 100,000 inhabitants ≥25 years (lowest value 1.2 Iceland - highest value 89.5 Serbia, Bulgaria 70.4); for NO_2 the highest morbidity burden resulted from diabetes mellitus with 54.6 YLDs per 100,000 inhabitants ≥35 years (lowest value 3.7 Estonia - highest value 145.5 Türkiye, Bulgaria 49.0), and for short-term O_3 exposure hospital admissions due to respiratory diseases were estimated at 18 cases per 100,000 inhabitants ≥65 years (lowest value 4 Iceland - highest value 29 Austria). For each specific air pollution-related disease, the relative contribution to poor health (the burden of disease) from mortality and morbidity can vary significantly. For instance, mortality is by far the dominant contributor for ischemic heart disease and lung cancer, while for asthma it is morbidity (EEA, 2023b).

Air quality and human health: a focus on Bulgaria

Bulgaria (111,000 km^2, population 6,440,000) is divided into six regions for atmospheric air quality (AQ) assessment and management: the agglomerations of Sofia (capital, 1,224,000 residents), Plovdiv (325,000 residents), and Varna (314,000 residents), and the North Danube, South-West, and South-East regions. The Bulgarian National Environmental Monitoring System assesses air quality (AQ) across these regions by 12 air pollutants according to the national and EU legislation, as follows: PM_{10}, $PM_{2.5}$, O_3, NO_2, SO_2, CO, benzo(a)pyrene (BaP), heavy metals (Pb, Cd, Ni), As, and benzene /C_6H_6/ as well as population exposure (ExEA, 2024).

In the last decades Bulgaria has constantly reduced the levels of air pollutants. Bulgaria's commitments under Directive (EU) 2016/2284 and the amended Gothenburg Protocol to the Convention on Long-Range Transboundary Air Pollution (LRTP) for emission levels of SO_2, NO_x, NMVOCs and $PM_{2.5}$ for 2022 have been fulfilled. Unfortunately, these changes occur slowly and despite improvements, pollutant levels still have significant adverse impacts on human health and the environment. The effects of air pollution are felt most strongly in urban

areas, where lives 73.3% of the population and the people experience significant health problems (ExEA, 2024; Zheleva, 2024). Large anthropogenic sources of air pollution are electricity and heat production, industry, domestic heating, road transport and agriculture. Thermal power plants (TPPs), including refineries, are the largest sources of SO_2 - 66% of the total amount emitted in the country; the main sources of NO_x are road transport - 38%, TPPs - 25%, agriculture - 18%, combustion processes in industry – 6%, and other transport - 4%; domestic heating is a major source of PM (47% of the total PM_{10} and 69% of total $PM_{2.5}$ emissions), other sources are the agriculture and road transport (ExEA, 2024).

Nowadays, PM air pollution continues to be a major problem for the air quality at the national level (Naydenova et al., 2018; Georgieva et al., 2021; Zheleva, 2024), especially during the winter months in the big cities– Sofia (Dimitrova & Velizarova, 2021), Plovdiv (Ivanov et al., 2023), Ruse (Takuchev et al., 2018; Nikolova et al., 2023), Stara Zagora (Stoykova et al., 2023; Ivanova et al., 2023), Pernik (Ivanov, 2016), and Vidin (Minkova et al., 2023; Kostova-Ivanova, 2024). In 2020, fine particle pollution caused the death of 71 per 100,000 people, a rate higher than that in Slovenia - 16, Croatia - 38 and Romania - 46, and lower than that in Serbia - 79 and North Macedonia - 120 (UNEP, 2021). In 2022, the population share exposed to excessive PM_{10} levels was substantially higher than the EU countries average (10-19% for 2015-2020), reaching 41% (2,640 million people). About 60% of the population in Bulgaria lives in areas with pollution levels above the target norm for benzo(a)pyrene (in EU countries it is 15-17% of the population for the period 2017-2021), and about 0.5% of the population lives in the areas with above-average annual NO_x levels (for EU it is between 0.8-8.0% of the population for the period 2015-2021). The others key pollutants - $PM_{2,5}$, O_3 and SO_2 did not exceed the relevant norm, while in EU up to 8.0% of the population was exposed to O_3 levels above the norm for the period 2015-2021. Notably, individuals in rural areas are exposed to higher levels of O_3 compared to urban residents. In cities, ozone levels are lower due to its depletion through the oxidation of NO to NO_2, which reduces its concentration (ExEA, 2024). Exposure to outdoor air pollution is associated with a broad spectrum of acute and chronic health effects ranging from irritant effects to death. Ivanov et al. (2016) observed an increase of the respiratory diseases, reduced immune defense and activation of the cardiovascular diseases among the population of Pernik town (81,700 residents) in the period 1980-2010, when the levels of PM and SO_2 in the air were over the standard. Platikanova and Penkova-Radicheva (2016) reported that the air pollution (PM, SO_2, NO_2, H_2S and Pb) of Stara Zagora (142,000 residents), one of the industrial centers in the country, located near the Maritsa-Iztok energy complex (4 TPPs), affects human health directly through pathological changes in the human organism. Epidemiological studies of Dobreva et al. (2015) demonstrated that the exposure to different air pollutants, including PM_{10} and $PM_{2.5}$ has been related to adverse effects on the immune system (modulate cytokine production and change the balance between pro-inflammatory TNF-α and anti-inflammatory IL-10 production) of adolescents, living in the cities of Stara Zagora, Kazanlak, and Chirpan. Takuchev et al. (2018) established statistically significant positive correlations between the concentrations of the investigated air pollutants (PM_{10}, $PM_{2.5}$, NO_2, SO_2, O_3, CO, CH_4, benzene and BC) in the town of Ruse and the health status of the patients in 73 of the 125 clinical pathways; the pollutant with the greatest impact on the health was the CH_4, often in combination with benzene and fine PM. Georgiev et al. (2025) found a general increase in hospital admissions for respiratory diseases, ischemic heart disease and cerebral infarction associated with higher pollution levels ($PM_{2.5}$, PM_{10}, NO_2, SO_2, O_3, and CO) in the cities Sofia, Plovdiv and Vidin during 2009-2018.

According to data of the European Environment Agency (EEA), in 2021 the estimated number of attributable deaths in Bulgaria resulting from $PM_{2.5}$ pollution (15.1 $\mu g/m^3$ annual mean value) was 10,800; resulting from NO_2 pollution (17.5 $\mu g/m^3$ annual mean value) - 2,200 and resulting from O_3 pollution (2,668 annual sum of daily maximum running 8-h average concentrations over 70 $\mu g/m^3$) was 460. The values for the absolute number of the attributable deaths resulting from $PM_{2.5}$, NO_2 and O_3 pollution are

calculated based on the number of the population of the different countries and because of that, they could not be compared. Logically, countries with larger populations (Poland, Italy and Germany) had a higher number of deaths than countries with smaller populations (Estonia, Finland and Sweden). A suitable indicator for between-countries comparison of deaths resulting from air pollution is years of life lost (YLL). In 2021 in Bulgaria, the YLL per 100,000 inhabitants attributable to exposure to $PM_{2.5}$ was 1,443, to NO_2 - 294 and to and to O_3 - 63. Those data were higher than the average values for EU-27 - by 2.47 times for $PM_{2.5}$, by 2.45 times for NO_2 and by 1.19 times for O_3. Referring to the neighboring countries, similar data were reported for Romania (1,111, 275 and 60, respectively) and higher for Serbia (1,938, 212 and 99, respectively) and North Macedonia (2,115, 169 and 88, respectively), (EEA, 2023). The comparison of the new WHO guidelines (2021) with the standards applicable in Bulgaria (Regulation No.12/2010) and with the new EU Directive (Directive /EU/ 2024/2881) revealed that the WHO AQGs are more stringent than the standards in Bulgaria and EU (Table 1).

Table 1. Comparison of WHO, Bulgarian and EU standards regarding air quality

Pollutant	Unit	WHO AQG, 2021		Bulgarian standard[a]	EU AQS, 2024[b]	
		Reference period	Recommendation		Target by 11.12.2026	Target by 01.01.2030
$PM_{2.5}$	$\mu g/m^3$	24-hour[c]	15	-	-	25[k]
		calendar year	5	20	25	10
PM_{10}	$\mu g/m^3$	24-hour[c]	45	50[e] (20%)[l]	50[e]	45[k]
		calendar year	15	40 (50%)[l]	40	20
O_3	$\mu g/m^3$	peak season[d]	60	-	-	-
		8-hour[c]	100	120[f]	120[f]	120[f]
NO_2	$\mu g/m^3$	24-hour[c]	25	-	-	50[k]
		calendar year	10	40	40	20
SO_2	$\mu g/m^3$	24-hour[c]	40	125[j]	125[j]	50[k]
		calendar year	-	-	-	20
CO	mg/m^3	8-hour	-	10[i] (60%)[l]	10	10
		24-hour[c]	4	-	-	4[k]

Notes: a - Bulgarian standard, Regulation No.12/15.07.2010; b - EU Air Quality Standard (AQS), Directive (EU) 2024/2881; c - 99th quantile range (e.g., exceeding 3-4 days/calendar year); d - the highest average O_3 concentration over 8 hours daily for 6 consecutive months; e - not to be exceeded on more than 35 days per calendar year; f - not to be exceeded on more than 25 days/calendar year, averaged over 3 years; j - not to be exceeded on more than 3 days per calendar year; i - maximum 8-hour average value within 24 hours; k - not to be exceeded more than 18 times per calendar year; l - permissible deviation (%).

The permissible annual levels for $PM_{2.5}$, PM_{10} and NO_2, and for O_3 (8-hour exposure) in the Bulgarian standard, in force since 2010, are higher than those in the 2021 WHO AQGs by 4.0, 2.67, 4.0 and 1.2 times, respectively; for the 24-hour norms – by 1.11 times for PM_{10} and by 3.12 times for SO_2. In fact, a similar picture can be observed in other EU countries, as the EU legislation is mandatory for all member-states. For example, Góra (2024) made the same conclusion when comparing WHO AQGs with the Polish standard. The norms of the classic air pollutants in the new EU standard (2024) are also higher than those in the 2021 WHO recommendations: for 2026 (the first target) the EU annual permissible levels exceed the WHO norms by 5.0 times for $PM_{2.5}$, by 2.67 times for PM_{10} and by 4.0 times for NO_2 (for a calendar year), and by 1.2 times for O_3 (for 8-hour exposure); for the 24-hour norms – by 1.11 times for PM_{10} and by 3.12 times for SO_2. The EU norms of the pollutants that must be reached in 2030 (the second target) are closer to those of the 2021 WHO recommendations, but remain higher: for the annual norms – by 2.00 times for $PM_{2.5}$ and NO_2, by 1.33 times for PM_{10}, and by 1.20 times for O_3 (8-hour exposure); for the 24-hour norms – by 1.67 times for $PM_{2.5}$, by 2.0 times for NO_2 and by 1.25 times for SO_2. Only the PM_{10} 24-hour norm is equal to the WHO standard (45 $\mu g/m^3$). In the EU 2026-first target/Bulgarian standard there neither average daily norms for $PM_{2.5}$, NO_2 and CO, nor average annual norms for SO_2 and O_3 (peak season). In the EU standard for 2030-second target, norms are included for all reference periods with one exception, there is no standard for O_3 (peak season). However, the new EU Directive makes

a serious progress in gradually reducing the permissible levels of classic air pollutants, comparable to the levels proposed by the WHO. According to the EU Zero Pollution Action Plan, the first goal must be reached until 11.12.2026, the second – until 01.01.2030, and the last one – until 2050 ("zero pollution"), when air pollution must be reduced to levels safe to human health and ecosystems (EEA, 2024).

Policy recommendations

There are many examples of successful policies that reduce air pollution (WHO, 2024a). Below, we present some well-addressed, specific and feasable solutions to improve the air quality and reduce the health risk to people.

For citizens: It all depends on the people, that's why, the civil society play a key role in achieving better air quality as it can pose a constant pressure on the authorities to improve the environment, respectively, the quality of life. To be able to carry out this activity, the people must be well informed about the air quality in the regions where they live, work or travel. Along with the traditional sources of information - TV, radio, internet, etc., a very reliable source is the European Air Quality Index (EAQI), available online in the internet. It reflects the potential impact of air quality on health, based on the lowest safety concentrations for five key pollutants - PM_{10}, $PM_{2.5}$, O_3, NO_2 and SO_2. The EAQI indicates the short-term air quality situation; it does not reflect the long-term (annual) air quality state, which may differ significantly (EEA, 2025).

For the industry: implementation of cleaner technology that reduce industrial smokestack emissions; stricter rules and control of the industrial emissions (Mahala, 2024).

For power generation: the promotion of clean energy use; increase the use of low-emissions fuels and renewable combustion-free power sources (solar, wind or hydropower); co-generation of heat and power.

For urban planning: improving the energy efficiency of buildings and making cities greener and more compact, thus energy-efficient; improving the management of urban and agricultural waste, including capture of methane gas emitted from waste sites as an alternative to incineration (for use as biogas); street sweeping and washing as methods for urban PM control - those practices are very effective for reducing the near-ground levels of fine PM and related pollutants (Bogacki et al., 2018; Lin et al., 2023; Das & Wiseman, 2024).

For the transport*:* promotion of the use of electric vehicles; prioritizing rapid urban transit, walking and cycling networks in cities; shifting to cleaner heavy-duty vehicles with low emissions and fuels with reduced sulphur content.

For the households*:* ensuring access to affordable clean household energy solutions for cooking, heating and lighting (electricity or gas instead of briquettes, pellets, etc.).

For health-care activities: putting health services on a low-carbon development path, which leads to a decrease in environmental health risks for patients, health workers and the community.

For future research directions: the use of artificial intelligence (AI) for air quality monitoring and prediction (Li et al., 2022; Awasthi et al., 2024; Rautela & Goyal, 2024; Olawade et al., 2024) as well as for the long-term impact of climate change on pollution patterns (Kaur & Pandey, 2021; Pinho-Gomes et al., 2023; Afifa et al., 2024; Ofremu et al., 2024; Stanisci et al., 2024; Ayyamperumal et al., 2024) is very promising and should be encouraged. Having in mind that air pollution is a pervasive public health issue with major economic consequences; it should remain a key target for global, regional and national health policy and standards.

CONCLUSIONS

In this review, we presented a detailed overview about the main ("classic") ambient air pollutants ($PM_{2.5}$, PM_{10}, SO_2, NO_2, and O_3,) and their influence (individually and in combination/ mixtures) on human health, expressed by two keys indicators - morbidity and mortality. Despite the reduction of the harmful emissions and improving the air quality in EU countries, including Bulgaria, the concentrations of some air pollutants (PM_{10}, $PM_{2.5}$, BaP) remain over the standard levels. In 2022, 96% of the urban population was exposed to concentrations of fine particulate matter ($PM_{2.5}$) above the 2021 WHO annual guideline of 5 $\mu g/m^3$. To meet the WHO goals, the annual reduction of the levels of the individual air pollutants must be between 1.2 times for O_3 to 5.0 times for $PM_{2.5}$ up to 2026

- the first target of 2024 EU standard and between 1.2 times for O_3 to 2.0 times for $PM_{2.5}$ and NO_2 up to 2030 - the second target of 2024 EU standard. For Bulgaria, the respective figures range from 1.11 times for PM_{10} to 4.00 times for $PM_{2.5}$ and NO_2. To curb the harmful effect of the air pollutants and to improve the health status of people, the policy, legislation and standards of air quality must follow the WHO guidelines. In this sense, the efforts of monitoring and decreasing the industrial/urban pollution in Europe and in the world must be continued, the European Green Deal must be joined, as initiatives and policies on reducing pollution and reaching environmental sustainability must facilitate the transition to sustainable, low-carbon economy. Some of the successful policies that can reduce air pollution, and consequently improve the health status of humans, refer to stricter rules and emission control; implementation of cleaner technology; promotion of clean energy (solar, wind or hydropower); expansion of the urban green spaces; street sweeping and washing; more extensive use of electric vehicles.

ACKNOWLEDGEMENTS

This paper was realized within the project 7AF/23 “Application of mathematical modeling for analysis and assessment of ambient air quality”, Trakia University, and co-financed by the National Program of the Ministry of Education and Science “Young Scientists and Postdoctoral Students-2”.

Abstract

Climate change in recent decades has had a significant impact on Romanian agriculture. In this context, Tulcea County, located in the south-eastern part of the country, has experienced a trend of increasing average annual temperatures, an increase in the number of days with temperatures above 30°C and a decrease in total annual precipitation. The study analyzed meteorological data, the evolution of crop structure, cultivated area, and yield trends over a 20-year period (1994-2023). The results showed an increase in average annual temperature from 12.39°C in 1994 to 13.8°C in 2023. Precipitation was low and showed significant variability, ranging from 215.8 mm in 2022 to 732 mm in 1997, with uneven distribution during the crop growing season. The area planted with cereals for grain varied considerably, influenced by both the predicted climatic conditions and the extent of irrigated land. Statistical analysis was performed using the Python software package, applying Pearson correlation tests to examine the relationship between climatic variables and agricultural yields. Linear regression methods were also used to identify long-term trends. The statistical tests showed that both increasing temperatures and decreasing precipitation were correlated with declining maize and wheat yields, highlighting the vulnerability of agriculture to climate change. Maize production ranged from a minimum of 323 kg/ha in 2003 to a maximum of 8,820 kg/ha in 2018. The overall trend indicates a slight decrease in average production ($R^2 = 0.41$, $p < 0.05$), correlated with increasing temperatures. Wheat showed a more stable yield, reaching a maximum of 4,738 kg/ha in 2021. The production trend was positive in periods with moderate rainfall ($R^2 = 0.63$, $p < 0.01$).

Key words*: climate change, cereals, precipitation trends, heat stress, crop yields.*

INTRODUCTION

Tulcea County, located in the eastern part of Romania, represents a region characterized by an arid climate and an agriculture that has devolved significantly throughout history. With an agricultural area of approximately 303.2 thousand hectares, the region faces challenges related to climate change, such as rising temperatures, decreasing precipitation, and the increasing frequency of extreme weather events.

Agricultural activity in the region has been documented since prehistoric times, with evidence coming from both historical records and archaeological sites. The Greek historian Apollonius of Rhodes, in the *Argonautica*, describes how Jason's sailors, while navigating the Danube Delta via the "Beautiful Arm" - probably the present-day Sfântu Gheorghe Arm - encountered flocks of sheep and shepherds, indicating early pastoral activity in the area (Filipescu, 1928; Lup, 2003). In addition, archaeological excavations in the ancient settlement of Hamangia (modern Baia, Tulcea County) provide tangible evidence of the Hamangia culture, a Neolithic civilization that flourished between the 4th and 2nd millennia BC, demonstrating an early reliance on agriculture and animal husbandry (Hasotti, 1997). These historical and archaeological findings underscore the deep-rooted agricultural traditions of the region, providing context for its long-standing adaptation to environmental and climatic changes (Lup, 2012).

Extensive international research highlights the profound impact of climate change on agriculture, particularly in arid and semi-arid regions (IPCC, 2021). The presence of water is inextricably linked to crop production in agricultural systems (Dușa & Stan, 2022).

Rising temperatures and declining water availability have been linked to reduced agricultural productivity and shifts in crop composition (Lal et al., 2007; Rosenzweig et al., 2001; Horoiaş et al., 2013; Ciocan et al., 2024). However, while these studies provide valuable insights at a global and regional scale, they often lack localized assessments that account for specific crop responses and tailored adaptation strategies at the county level. Tulcea County, characterized by significant climatic variability, remains underrepresented in such analyses despite its agricultural importance.

This study aims to address this gap by evaluating long-term climate trends and their direct impact on cereal yields (wheat, maize, and barley). By providing a data-driven, localized perspective, the research contributes to a deeper understanding of climate-induced shifts in cereal production and informs the development of adaptive strategies for sustainable agriculture in vulnerable regions.

To achieve these objectives, this study integrates Pearson correlation analysis and linear regression modeling to quantify the relationships between temperature, precipitation, and crop productivity. The findings indicate a significant correlation between rising temperatures and declining maize yields, while wheat production shows a more stable trend, benefiting from moderate precipitation levels. By highlighting these climate-yield interactions, the study provides valuable insights for policymakers and farmers in developing targeted adaptation measures and sustainable agricultural strategies in response to ongoing climate variability.

MATERIALS AND METHODS

To analyze the impact of climate change on the dynamics of cultivated cereals, data from multiple official sources were utilized. Meteorological data for the period 1994-2023, including annual average temperatures, total annual precipitation, and the number of days with temperatures exceeding 30°C, were obtained from National Institute of Statistics (INS, 2023b). Agricultural data, covering cultivated areas and average cereal yields per hectare, were extracted from the Statistical Yearbooks of Romania and the archives of the Tulcea County Directorate of Statistics (INS, 1990; 2023a). Additionally, information regarding land use and irrigation infrastructure was sourced from the National Agency for Land Improvements.

Statistical analysis was conducted using the Python software package, applying Pearson correlation tests to examine the relationship between climate variables and agricultural yields. Linear regression methods were also used to identify long-term trends.

RESULTS AND DISCUSSIONS

The climate of Tulcea County is characterized by a warm and dry climate, specific to areas with the most generous thermal resources but also the lowest precipitation levels compared to other regions of the country. A 30-year climatic analysis shows the following: the annual average temperature is 12.03°C, the average annual precipitation is 488.79 mm, and the average number of days with temperatures exceeding 30°C is 42.4 days per year.

During the 1994-2003 period, statistical analysis highlighted significant fluctuations in annual average temperatures, as illustrated in Figure 1. The year 1994 was characterized by a high annual average temperature of 12.39°C, marked by favorable climatic conditions. However, the 1995-1997 period experienced a notable decline in annual average temperature, from 11.27°C (1995) to 10.49°C (1997), the lowest recorded value in the analyzed period. These values were influenced by negative temperatures in January and December. Between 1998 and 2002, a progressive increase in temperature was observed, from 11.51°C (1998) to 12.27°C (2002), followed by slight variations between 11.68°C and 11.73°C in 2000-2001. In contrast, the year 2003 was notable for a drop in the annual average temperature to 10.78°C, driven by the low temperatures recorded in January (-1°C) and February (-4.5°C).

Between 2004 and 2023, statistical analysis identified the following trends: the years 2004-2006 and 2011 had annual average temperatures varying between 11.18°C (2011) and 11.59°C (2004), marking lower values compared to the subsequent period. The 2007-2013 period saw a significant increase in

temperatures, ranging from 12.03°C (2007) to 12.43°C (2013). Similarly, the years 2014-2023 recorded annual average temperatures consistently above 12°C, reaching a peak of 13.80°C in 2023. During this period, 2019-2023 had the highest temperatures, all exceeding 13°C.

Data analyzed from 1994 to 2023, using linear regression tests, indicate a significant upward trend in annual average temperatures (R^2 = 0.84, $p < 0.01$), increasing from an average of 11.27°C in 1995 to 13.8°C in 2023. This increase has been associated with a rise in the number of heatwave days, reaching 65 days in the years 2012 and 2022.

Moreover, the length of the growing season for key cereal crops, such as wheat, corn, barley, sunflower, and peas, has been affected by these changes, leading to earlier planting and harvesting periods.

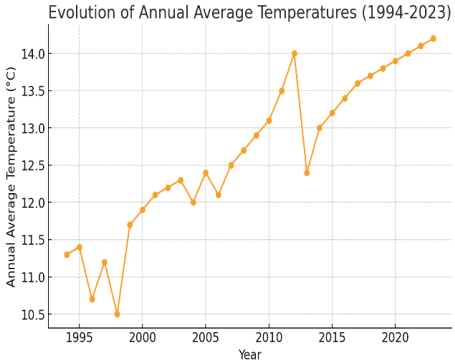

Figure 1. Evolution of annual average temperatures between 1994 and 2023

The period analyzed showed a decreasing trend in precipitation, as illustrated in Figure 2. Notably, between 1994 and 2003, annual precipitation varied from a minimum of 298.1 mm in 2003 to a maximum of 732 mm in 1997. In addition to temperature variations, the precipitation regime has also undergone significant changes. The analysis of rainfall data between 1994 and 2023 indicates a gradual decrease in annual precipitation from 480 mm in 1994 to 430 mm in 2023. This downward trend has contributed to an increased risk of drought and a reduction in soil moisture levels, impacting agricultural productivity. Years of drought, including 2003, 2004, 2009, 2011, and 2012, experienced total annual precipitation below 300 mm. Additionally, from 2014 to 2020, annual precipitation remained below 400 mm, impacting cereal crop yields and prompting the adoption of adaptive irrigation systems. The correlation with agricultural yields indicated that insufficient precipitation during drought years significantly reduced crop productivity. From 2004 to 2023, the declining trend persisted, with annual average values remaining below 488.79 mm. Notably, in 2022, precipitation dropped to just 215.8 mm. Linear regression analysis showed a moderate but significant decrease in precipitation (R^2 = 0.59, $p < 0.05$), declining from an average of 488.79 mm per year to values below 300 mm in drought years, such as 2022.

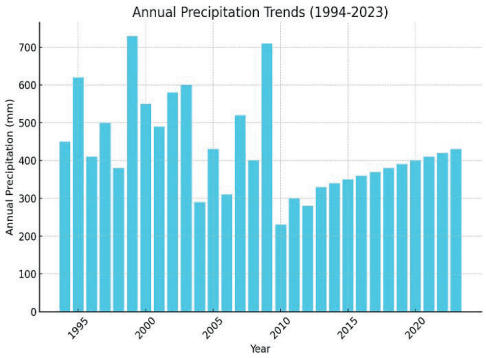

Figure 2. Evolution of average annual precipitation between 1994 and 2023

Along with high temperatures and low precipitation, the frequency of days with temperatures exceeding 30°C also contributes to the arid climate of Tulcea County. Notable instances were recorded in 1995, 1997, 2004, and 2005, with 25 days in 1995, 10 days in 1997, 13 days in 2004, and 24 days in 2005. During the rest of the analyzed period, the number of such days ranged between 30 and 65, including 60 days in 2016 and 2018, 62 days in 2019, and 65 days in both 2012 and 2022 (Table 1). In years with a high frequency of extremely hot days, these events were primarily concentrated between June and September.

The increase in the number of extreme weather events, including heatwaves, storms, and prolonged dry spells had led to higher

evapotranspiration rates, negatively impacting plant growth cycles and increasing the demand for soil conservation techniques, such as no-tillage farming and mulching.

Table 1. Number of days with temperatures exceeding 30°C in Tulcea County (1994-2023)

Year	No. of days	Year	No. of days	Year	No. of days
1994	34	2004	13	2014	40
1995	25	2005	24	2015	51
1996	31	2006	27	2016	60
1997	10	2007	57	2017	46
1998	31	2008	44	2018	60
1999	43	2009	39	2019	62
2000	36	2010	50	2020	57
2001	48	2011	43	2021	45
2002	43	2012	65	2022	65
2003	37	2013	42	2023	43

To evaluate the impact of climate conditions on agricultural yields, Pearson correlation tests were applied between annual average temperatures, annual precipitation, and the average yields of the main agricultural crops in Tulcea County. Additionally, linear regression analyses were conducted to identify long-term trends. These characteristics highlight the challenges associated with managing agriculture in this region, where high temperatures and precipitation deficits significantly affect crop production.

Statistical tests showed that both rising temperatures and decreasing precipitation levels are correlated with declining maize and wheat yields, emphasizing the vulnerability of agriculture to climate change.

Cultivated cereal areas have varied significantly, influenced by climate conditions. The areas cultivated with grain cereals showed notable variations depending on the evolution and forecast of climatic conditions. Available data indicates a direct correlation between fluctuations in annual average temperatures, precipitation levels, and the dynamics of cultivated areas.

Favorable annual average temperatures, ranging between 10.49°C (1997) and 12.18°C (1999), combined with precipitation levels between 454.3 mm (1995) and 640.9 mm (1999), supported the stability of cultivated areas. Thus, in 2000, the total area cultivated with grain cereals reached 162,310 ha, increasing further to 181,463 ha in 2001.

The year 2001 was marked by low precipitation (419.3 mm) and an annual average temperature of 11.73°C, as well as an increase in the number of days with temperatures above 30°C (48 days, compared to 10-36 days in previous years). These climate conditions led to a reduction in cultivated areas in 2002 to 166,001 ha.

The decline in precipitation and the rise in annual average temperatures continued to influence cultivated areas, reaching a minimum of 118,948 ha in 2007, a year characterized by average temperatures above 12°C and below-average precipitation levels.

Favorable precipitation and stable annual temperatures, ranging from 12.03°C to 12.30°C, led to a slight increase in cultivated area between 2008 and 2009, reaching values of 151,772-154,447 ha. During 2012-2013, cultivated areas increased significantly, reaching 181,757 ha in 2012 and 179,691 ha in 2013, due to a rise in precipitation from 537.9 mm in 2012 to 671.1 mm in 2017.

Between 2014 and 2023, annual average temperatures consistently exceeded 12°C, peaking at 13.8°C in 2023. Although cultivated areas temporarily increased from 151,986 ha in 2014 to 158,164 ha in 2018, severe drought and irregular precipitation patterns caused a decline to 131,884 ha by 2022 (Table 2).

An analysis of the crop structure indicates that wheat consistently ranked first in cultivated areas, primarily due to its greater drought resistance compared to maize. The area dedicated to wheat cultivation varied from 43,023 ha in 2004 to 92,120 ha in 2023. During periods of low precipitation, wheat occupied larger areas due to its ability to withstand drought conditions. The correlation between wheat cultivated area and annual temperatures was positive ($\rho = 0.52$, $p < 0.05$).

Maize was more sensitive to climatic conditions, with cultivated areas fluctuating between 29,458 ha (2010) and 90,487 ha (2004), depending on water availability forecasts. Due to maize's greater sensitivity to climatic conditions, its cultivated areas showed significant variations, with a strong correlation

between cultivated area and annual precipitation ($\rho = 0.76$, $p < 0.01$).

Due to the arid climate, rye found a place in this region, although the cultivated areas remained small, ranging between 15 ha (2000) and 200 ha (2023).

Barley and spring barley, being short-cycle crops with good resistance to high temperatures, heat waves, and drought, were cultivated on fluctuating areas between 2000 and 2023. However, the ratio between barley and spring barley changed over time based on economic demands.

Table 2. Structure of source cultivated areas with Grain Cereals in the period 2000-2023 (hectares)

Source: National Institute of Statistics, Romania. County Directorate for Agriculture – Tulcea. *Statistical Data (1994-2023).*

Since 2020, a new cereal, triticale, known for its drought and heat resistance, was introduced, with cultivation areas of 2,694 ha (2020), 1,200 ha (2021), 1,300 ha (2023), and only 800 ha (2022). The cultivated areas for triticale varied between 800 ha and 2,694 ha, while sorghum cultivation increased to 550 ha in 2023. The introduction of sorghum and triticale starting from 2020 reflects farmers' adaptation to arid conditions, as these crops are more drought resistant.

The average grain cereal yields in the period 2000-2023 were strongly influenced by climatic conditions, experiencing significant fluctuations. The lowest yields per hectare were recorded in 2003 and 2007, primarily due to high spring temperatures, which led to early drought onset. During May and June, tropical temperatures were reported, combined with very low precipitation levels.

Rye recorded a minimum yield of 958 kg/ha in 2003, while barley had a yield of 977 kg/ha in 2007, marking the lowest production levels for these crops during the analyzed period.

The increase in annual average temperatures and decrease in precipitation levels prompted the introduction and expansion of drought resistant crops, such as sorghum and triticale. These crops have demonstrated superior adaptability to thermal and hydric stress.

In 2018, the average maize yield reached a peak of 8,820 kg/ha, due to favorable climatic conditions, with moderate temperatures and adequate precipitation during the growing season. Maize yields fluctuated from a

minimum of 323 kg/ha in 2003 to a maximum of 8,820 kg/ha in 2018.

The overall trend indicates a slight decline in average yield ($R^2 = 0.41$, $p < 0.05$), correlated with rising temperatures. Wheat showed more stable yields, reaching a maximum of 4,738 kg/ha in 2021. The yield trend showed a positive correlation during periods of moderate precipitation ($R^2 = 0.63$, $p < 0.01$) (Figure 3).

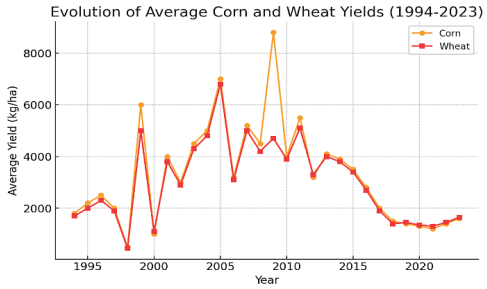

Figure 3. Evolution of average yield per hectare for corn and wheat crops between 1994-2023

The maximum wheat yield, of 4,738 kg/ha, was recorded in 2021, a year that also saw high yields for other crops: barley: 4,121 kg/ha, oats: 2,454 kg/ha, rye: 3,948 kg/ha, triticale: 3,925 kg/ha, and sorghum: 3,800 kg/ha (Table 3).

The agricultural yields in Tulcea County reflect the direct impact of climatic conditions on cereal crops. Drought years, characterized by high temperatures and insufficient precipitation, have significantly reduced yields, particularly for maize.

Adapting to climate change through the expansion of drought-resistant crops, the use of irrigation technologies, and the selection of high-performance varieties remains an essential strategy for ensuring the sustainability of agriculture in the region.

A strong negative correlation was found between annual average temperatures and average cereal production. This analysis suggests that annual average temperatures differently influence the production of corn and wheat, which is relevant for agricultural strategies and adaptation to climate change. Key observations: corn is negatively affected by temperature increases above 12°C, with a significant negative correlation ($\rho = -0.20$, $p < 0.01$). This can be explained by its high sensitivity to drought and heat stress, which can reduce yield. Wheat adapts better to rising temperatures, showing a moderate positive correlation ($\rho = 0.48$, $p < 0.05$). In the case of corn, there is a negative correlation ($\rho = -0,20$, $p < 0.05$), as can be seen in Figure 4, suggesting that very high temperatures have an adverse effect on corn production. This may indicate that, under moderate aridity conditions, wheat benefits from higher temperatures, either through a longer growing season or by optimizing physiological processes. Precipitation also plays a crucial role in cereal production. Reduced rainfall can exacerbate the negative impact of elevated temperatures on corn, making drought-resistant hybrids essential. For wheat, moderate water stress may still be manageable, but prolonged droughts could limit its yield potential despite its higher adaptability to temperature variations.

Future agricultural planning should consider both temperature and precipitation patterns to develop sustainable crop management techniques, such as improved irrigation systems, drought-resistant crop varieties, and optimized sowing periods.

Drought events during key growth stages, such as flowering and grain filling, significantly hinder production, as illustrated in Figure 5. This outcome is anticipated, as corn has high moisture demands, and inadequate precipitation during the growing season can cause severe water stress, ultimately reducing yields. Beyond the total rainfall amount, its distribution throughout the growing season is also crucial, as shown in Figure 6. The strong positive correlation between annual precipitation and corn yields ($\rho = 0.57$, $p < 0.01$) underscores the crop's reliance on adequate water availability, as illustrated in Figure 7.

The impact of high temperatures is particularly severe for corn, which is highly sensitive to thermal stress, especially in the absence of irrigation. Similarly, barley and winter barley followed a pattern akin to wheat, displaying a higher tolerance to adverse climatic conditions and demonstrating their adaptability to heat extremes (Figure 8).

For wheat, the correlation was lower ($\rho = 0.06$, $p < 0.05$) but still significant, indicating a lower sensitivity to water deficit compared to corn.

This suggests that wheat is more resilient to variations in precipitation, likely due to its growth cycle and ability to utilize soil moisture more efficiently. However, prolonged drought conditions or extreme weather events could still impact its yield, albeit to a lesser extent than corn. The number of heatwave days exhibited a strong and significant negative correlation with corn production ($\rho = -0.77$, $p < 0.01$) as can be seen in Figure 9, highlighting the crops vulnerability to extreme temperatures. In contrast, wheat showed a negative but statistically insignificant correlation ($\rho = -0.32$, $p > 0.05$), suggesting greater resilience to heat stress.

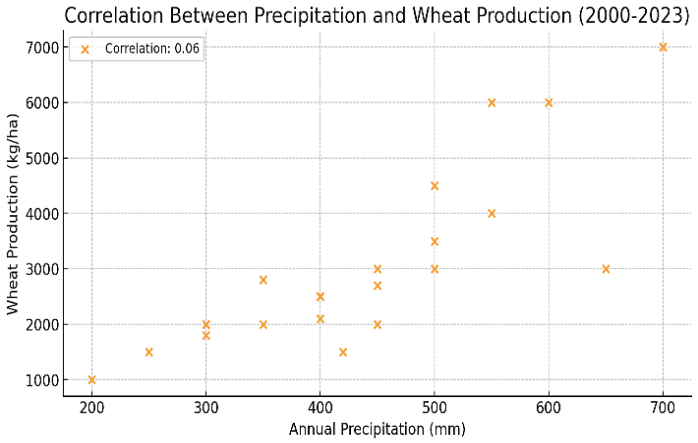

Figure 9. Corelation between average annual precipitation and wheat production between 2000-2023

CONCLUSIONS

The analysis of climate and agricultural data from 1994 to 2023 highlights a significant increase in average annual temperatures and a decline in precipitation, confirming global climate change trends. Average annual temperatures rose from approximately 10.49°C in the 1990s to 13.8°C in 2023**,** leading to intensified drought conditions and heat stress for crops. Annual precipitation dropped below the multiannual average of 488.79 mm, with considerable fluctuations from year to year. This uneven distribution of precipitation has negatively impacted crop development, particularly corn**,** which is highly sensitive to water deficits.

The area cultivated with grain cereals has been significantly influenced by climate conditions. In drought years with high temperatures, cultivated areas declined considerably**,** reaching a minimum of 118,948 ha in 2007. Due to its greater drought resistance, wheat occupied larger areas than corn during years with challenging climate conditions.

Agricultural yields reflect a partial adaptation to climate conditions, with significant fluctuations in productivity. Favorable years, such as 2018**,** allowed for maximum production levels (corn: 8,820 kg/ha, wheat: 4,738 kg/ha). In contrast, years with high temperatures and insufficient rainfall, such as 2003 and 2007, resulted in the lowest yields**,** emphasizing the vulnerability of crops to climate change.

The introduction of sorghum and triticale**,** crops more resistant to heat and water stress, represents a positive adaptation to the new climate conditions. However, their expansion remains limited, requiring greater promotion and support.

The findings suggest a complex relationship between climate variables and agricultural performance. Rising temperatures and decreasing precipitation pose major challenges for agriculture, leading to reduced productivity and changes in crop structure. Recent adaptations, such as the expansion of drought-resistant crops (sorghum, triticale), are essential strategies to ensure the sustainability of agriculture in Tulcea County.

The study highlights the necessity of implementing agricultural policies focused on expanding irrigation systems and modernizing existing infrastructure to mitigate water shortages during drought periods.

Key recommendations involve promoting efficient irrigation technologies, such as drip irrigation, to enhance water efficiency and strengthen agricultural resilience. Investing in research to develop wheat, corn, and other cereal varieties with increased tolerance to climatic stress.

Encouraging farmers to adopt alternative crops, such as sorghum and triticale, to reduce risks associated with extreme weather conditions.

Reducing dependence on monocultures by introducing a diversified range of crops, capable of buffering the impact of climate variability.

Organizing training programs for farmers on sustainable agricultural practices, efficient resource management, and adaptation to changing climate conditions.

Integrating climate adaptation strategies into national and regional agricultural development policies to ensure long-term resilience.

These conclusions and recommendations emphasize the importance of climate adaptation in securing the sustainability of agricultural production in Tulcea County. By implementing these measures, the vulnerability of local agriculture can be reduced, fostering the conditions for sustainable agricultural development.

Abstract

Specific studies and research are necessary to find out the existing noise and vibrations coming from various zonal sources, in an urban area where a new building will be placed. Depending on the activity that will be carried out in the new building, it is necessary to obtain certain maximum values of the noise and vibration levels, inside the building, so that the psychoacoustic comfort of the inhabitants can be achieved during the period of use of the building. As part of a research contract, carried out by INCD URBAN INCERC, INCERC Bucharest Branch, for a client who wanted to build a new residential building for his family, on-site experiments were carried out at the client`s land located in Bucharest. The results of the acoustic measurements, the values of the noise levels, are presented in the article numerical and in graphic forms in the frequency range 12.5...20000 Hz. For vibrations the recordings are presented in the form of time-histories for accelerations and velocities, as well as Fourier spectra and response spectra.

Key words*: acoustics, vibrations, civil buildings, urban polluting sources.*

INTRODUCTION

The placement of a new building in an urban area requires specific studies and investigations to assess the existing levels of noise and vibrations at the site, originating from various local pollution sources (Zaharia, 2020). Depending on the intended use of the building, certain maximum permissible levels of noise and vibration must be established to ensure the psychoacoustic comfort of occupants throughout the building's operational lifespan (C125:2013).

The assessment of noise and vibration levels generated by metro networks at surface locations (or at specific elevations above ground) is a relevant issue in urban environments, where the propagation and potential attenuation or amplification of such disturbances may influence both the structural integrity of buildings and the acoustic comfort of their occupants (Mouzakis et al., 2019; Bratu et al., 2023; 2024).

To assess this impact, acoustic and vibration measurements were conducted during a preliminary phase of a real estate development project involving the construction of a G+2F residential building without a basement, situated within the metro's minimum safety zone.

The research aimed to determine the noise levels generated by two categories of noise and vibration sources:

1) surface-level sources, including street traffic and human activity;
2) underground sources, specifically metro traffic, with the tunnel running beneath the measurement site.

The location of the land on which the measurements were conducted is shown in Figure 1. At the time of the measurements, the site was devoid of any constructions. The surrounding urban area predominantly comprises civil buildings, including both residential and office structures. Directly opposite the site, across the street, there is a building designated as a kindergarten.

Consequently, during the acoustic measurements, the sources of ambient noise included street-level human activities; road traffic from both nearby and more distant streets; air traffic, with noise levels enhanced by reflection from the cloud cover; bird songs from the trees adjacent to the site; and activities from a construction site located within the area, at an approximate distance of 50-70 m from the measurement location.

Figure 1. Land positioning in the urban area and positioning of measurement points P1 and P2

The acoustic measurements were conducted simultaneously at two distinct points, positioned as illustrated in Figures 2a and 2b, as follows:

a) the first measurement point, P1, to determine the noise level coming from underground noise sources – the metro, was placed in a pit with approximate dimensions of: length L=1.60 m, width l=1.10 m and depth H=1.35 m, at a height of 0.15 m from the bottom of the pit (microphone 1 placed at Measurement Point 1); this positioning of the microphone was done in order to simulate the position of the microphone at the base of the foundation of the future building and to be able to select the noise produced by the metro traffic at this level as relevant as possible.

b) the second measurement point, P2, to determine the noise level from surface noise sources, was located above ground level, at a height of h=1.30 m, (microphone 2 located at P2); this positioning of the microphone was done in order to simulate the microphone position two meters from the main facade of the future building and to be able to select the most relevant noise produced by surface sources at this level.

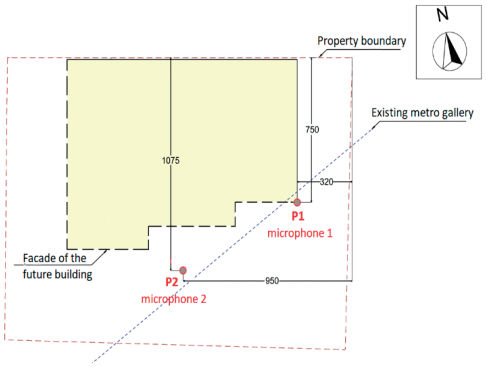

Figure 2a. Positioning of the measurement points, P1 and P2, on the site located in District 1 - Bucharest

Figure 2b. Positioning of the measurement point P1

To determine vibration levels, non-seismic sequential measurements were performed using four GMSPlus multichannel stations (GeoSIG), each comprising three data channels and internal triaxial transducers (model AC73i).

Vibration monitoring was carried out in distinct stages and at various locations, both during daytime and nighttime, under a range of conditions - from low-background noise environments to periods of active metro traffic - with time intervals of 10, 5, and 3 minutes between successive train passings. Stations ST02, ST03, and ST04 were installed at ground level, whereas station ST01M was positioned within an excavated pit at a depth of 1.35 m, as shown in Figure 3.

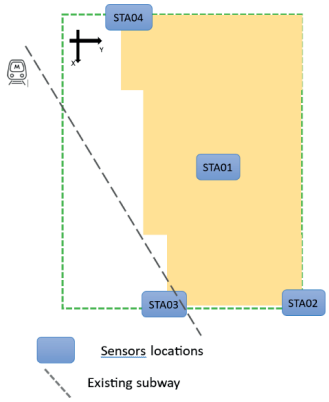

Figure 3. Location of GMSPlus digital stations/accelerometers (longitudinal direction - OY axis; transverse direction - OX axis)

MATERIALS AND METHODS

The in-situ acoustic measurement method used was provided for in the laboratory's acoustic procedure and in the legislation in force at the time the measurements were made, namely PTE– AC/03.02 and the measurement standards SR 6161-3:1982, SR 6161-1:2008, SR 6161-1/C91:2009 correlated with SR ISO 1996-2:2018 and with STAS 6156-86.

The following parameters were determined:

- L_{Aeq} - equivalent noise level (weighted average of noise levels recorded in a given time interval), recorded at the measurement point, in dB(A);
- L_{AF90} - background noise level, (exceeded in 90% of the measurement time), in dB(A);
- L_{AF10} - peak noise level, (exceeded in 10% of the measurement time), in dB(A).

"L_{Aeq}" corresponds to the notation "L_{ech}" in SR 6161-1:2008 and to the notation "L_{eqT}" in SR ISO 1996-2:2018; "L_{AF90}" and "L_{AF10}" correspond to the notation "$L_{N,T}$" in SR ISO 1996-2:2018.

The measurement situations were established in agreement with the future owner of the house and were determined in a such way as to be useful for the acoustic design of the future residential building.

For the noise measurements, two measurement points were established, to carry out effective acoustic measurements that could determine both the noise level coming from surface noise sources and the noise level coming from underground noise sources, namely the metro.

The determination of the equivalent noise level was carried out simultaneously at the two measurement points, P1 and P2.

The first measurement point, P1, was located on the ground in the area where the future building would be located with the facade and the corner of the building that could be most affected by the noise produced by the metro; In P1, the microphone was placed in a pit, with approximate dimensions of: length L=1.50 m, width l=1.50 m and depth H=1.35 m, at a height of 0.15 m from the bottom of the pit (microphone 1 placed at Measurement Point 1), arranged according to Figure 1, Figure 2a, Figure 2b and Figure 4. This positioning of the microphone was done to simulate the position of the microphone at the base of the foundation of the future building and to be able to detect the noise produced by the metro traffic at this level as relevant as possible.

Figure 4a. Positioning of measurement points P1 and P2

The second measurement point, P2, was placed on the ground above ground level, at a height of h=1.30 m, (microphone 2 placed at Measurement Point 2), arranged according to Figures 4a and 4b; this positioning of the microphone was done to simulate the microphone position two meters from the main facade of the future building and to be able to select the noise produced by surface sources at this level as relevant as possible.

The *in situ* acoustic measurements, implicitly the recordings of the equivalent noise level "L_{Aeq}", in dB(A), were carried out at night and during the day, on one day in April 2019, as follows: starting with the night time period (23:00-07:00) in the time interval 04:51-07:00, continuing in the day time period (07:00- 23:00)

in the time interval 07:00-08:35, according to the technical regulations in force at that date, respectively: STAS 6161-3:1982 "Acoustics in constructions. Measurement of noise levels in urban localities. Measurement methods", SR 6161-1:2008 "Acoustics in constructions. Measurement of noise levels in civil constructions. Measurement methods", SR 6161-1/C91:2009) and SR ISO 1996-2:2018 "Acoustics. Description, measurement and evaluation of ambient noise. Part 2: Determination of ambient noise levels", correlated with STAS 6156-86 "Acoustics in buildings. Protection against noise in civil and socio-cultural buildings. Admissible limits and acoustic insulation parameters".

Figure 4b. Positioning of measurement point P2

Considering the above, the sampling of the measurement intervals was done by choosing time periods of max. approx. 20, 15, 10, 5 and 1 minutes, depending on the measurement situation. It is mentioned that the measurement time intervals, specific for P1 and those for P2, do not overlap 100%, due to the slightly different stop-start times of the two sound level meters used for the recordings.

The following devices were used to measure and record the equivalent noise level:

- Sound calibrator Bruel & Kjaer type 4231 - 94 dB (+/- 0.2 dB), series 2671272;
- Real-time noise level analyzer, (Sound level meter), Bruel & Kjaer type 2250, series: 2559226;
- Real-time noise level analyzer, (Sound level meter), Bruel & Kjaer type 2250, series: 3010381;
- Thermo hygro barometer TESTO 622, series 39515263.

During the recording of noise levels, the outdoor temperature was between 9.9 and 10.3°C and the humidity between 83 and 87%. In this regard, it is mentioned that the day of the measurements was a cloudy day, with a compact cloud ceiling and with temporary light drizzle conditions.

During the acoustic measurements and recordings, a plywood was installed over the space in the pit where the measurement point P1 was positioned, as shown in Figure 5 and Figure 6, to create an *acoustic shadow* against the noise coming from surface sources.

Figure 5. Position of a plywood which was installed over the space measurement point P1, in day time

Figure 6. Position of a plywood which was installed over the space measurement point P1, in night time

For the microphone location at measurement point P2, mounted on a tripod, the microphone height from the ground was 1.30 m, as shown in Figure 7a and Figure 7b The microphone was protected with a windscreen.

Figure 7a. Position of microphone in measurement point P2, in night time

Figure 7b. Position of microphone in measurement point P2, in night time

On the other hand, the methodology for data acquisition and processing involves the following steps (Dragomir et al., 2019):

- Establish the locations of the seismic stations based on the objectives;
- Develop layout schemes for the sensors;
- Effectively position the seismic stations according to the pre-established schemes;
- Connect the stations to the equipment and laptop;
- Start the multichannel recording stations and the laptop, and launch the communication application with the equipment;
- Conduct recordings, verification, and calibration tests following the procedures specified by the equipment supplier;
- Trigger recordings to capture ambient vibrations, ensuring that at least five sets of recordings (two minutes each) are made at the same location;
- Verify each recording upon completion using the available monitoring tools;
- Process the data to generate graphical representations of the time histories of accelerations, velocities, and displacements;
- For each time history, specify the maximum amplitude obtained in that recording.

This structured approach will ensure accurate data collection and processing for seismic analysis (Dragomir et al., 2021; Dobre et al., 2015).

Regarding the values of the maximum regulated noise limits (valid in 2019 year), correlated with the residential function of the rooms in the future residential building, for specific periods (daytime and nighttime), for this studied case, the principal admissible limits are presented according to the regulations in force, respectively from C125 - 2013 "Normative regarding Acoustics in Constructions and Urban Areas" as follows:

1) "In cases where the background noise (in the absence of external noise sources) is less than 30 dB(A), the equivalent indoor noise level due to all noise sources external to the functional unit must not exceed the background noise level by more than 5 units".
2) Parameter 2: Noise level outside residential buildings, located in quiet residential areas in an agglomeration with a population of more than 100,000 inhabitants, measured at 2.00 m from the building facade (according to SR 6161-1 and SR 6161-1/C91):

$$L_{ech} = 50 \text{ dB(A)}$$

3) Parameter 4: The noise level outside residential buildings, measured at 2.00 m from the building facade (according to SR 6161-1 and SR 6161-1/C91), in the case of buildings located in areas where the background noise level, L_{AF90}, is less than 50 dB(A), will be chosen as the minimum value between the value of 50dB(A) and L_{ech} calculated with the relationship below:

$$L_{ech} = L_{AF90} + 5 \text{ dB(A)}$$

4) Parameter 5: In the case of the design of new buildings, the noise level outside residential buildings, measured at 2.00 m from the building facade (according to SR 6161-1 and SR 6161-1/C91):

$$L_{ech} = 50 \text{ dB(A)}$$

5) For Apartments in Residential Buildings, the permissible limit of the equivalent indoor noise level is 35 dB(A) (Cz 30).

According to the provisions of the standard SR 10009:2017 "Acoustics. Admissible limits of the ambient noise level", the admissible limit of the external noise level at the facade of the

residential building that is most exposed to the sound action of a noise source external to the building, respectively the equivalent continuous A-weighted acoustic pressure level, L_{AeqT}, is 50dB(A), for any type of residential building or similar to it, considering that the most exposed facade of the building is understood as that facade of the building that is closest to an external noise source.

"If the value of the background noise level L_{AF90T} is less than 45 dB, then the admissible limit is calculated with the relationship:

$$L_{AeqT}\ [dB] = L_{AF90T} + 5\ dB".$$

In addition, there is another Romanian legal act applicable to the residential buildings (Order of the Ministry of Health, no. 119 of February 4, 2014, for the approval of the Hygiene and Public Health Norms regarding the population's living environment, published in the Official Gazette of Romania, no. 127 of February 21, 2014, which states the following:

- "For the purposes of these norms, the following terms are defined as follows: a) living room: rooms with living room and bedroom functions".
- "The sizing of sanitary protection zones will be done in a such way that in the protected territories the limit values of the noise indicators will be ensured and respected, as follows: a) during the day, the A-weighted equivalent continuous acoustic pressure level (L_{AeqT}), measured outside the dwelling according to the SR ISO 1996/2-2018 standard, at 1.5 m height from the ground, shall not exceed 55 dB and the noise curve Cz 50; b) during the night, between hours 23:00 and 7:00, the equivalent continuous A-weighted sound pressure level (L_{AeqT}), measured outside the dwelling according to the SR ISO 1996/2-2018 standard, at 1.5 m above the ground, shall not exceed 45 dB and, respectively, the noise curve Cz 40".
- "For dwellings, the equivalent continuous A-weighted sound pressure level (L_{AeqT}), measured during the day, inside the room with the windows closed, shall not exceed 35 dB(A) and, respectively, the noise curve Cz 30. During the night (hours 23:00- 7:00), the L_{AeqT} noise level shall not exceed 30 dB and, respectively, the Cz curve 25".

One important criterion for evaluating the impact of vibrations on buildings is the velocity criterion (Dragomir et al., 2023; Bratu et al., 2024). Velocity is significant in this assessment because it provides a reliable indication across different vibration frequencies, and there is a strong statistical correlation with data related to structural degradation (Rybak, 2016). The allowable vibration levels are detailed in Table 1, according to DIN 4150-3/1999 regarding vibrations in buildings, and in Table 2, according to the norm on acoustics in buildings and urban areas (C 125/4-2013).

Table 1. Permissible vibration level (DIN 4150-3/1999)

Structure type	Frequency at foundation level			Combined frequency (at ground floor/upper floor level)
	<10 Hz	10...50 Hz	50...100 Hz	
Commercial, industrial buildings	20 mm/s	20...40 mm/s	40...50 mm/s	40 mm/s
Residential buildings	5 mm/s	5...15 mm/s	15...20 mm/s	15 mm/s
Buildings other than those in 1 and 2	3 mm/s	3...8 mm/s	8...10 mm/s	8 mm/s

Table 2. Permissible vibration level, Parameter 9 (C 125/4-2013)

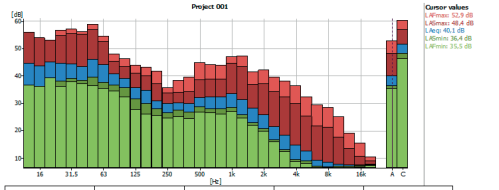
Historical monuments		Any building (except monuments)
1-50 Hz	50-90 Hz	1-100 Hz
<8mm/s	8-12 mm/s	<12-20mm/s

RESULTS AND DISCUSSIONS

The results of the acoustic measurements, the values of the noise levels, are presented in numerical and in graphic forms in the frequency range 12.5...20000 Hz, and for vibrations the recordings are presented in the form of time-histories for accelerations and velocities, as well as Fourier spectra and response spectra.

This chapter presents the results of the acoustic measurements carried out, for each of the specific measurement situations considered, in number of 19, each corresponding to one of the two sound level meters, (Project 1, …. Project 10, for measurement point 1, P1, and Project 1, …. Project 9, for measurement point 2, P2), with the recorded values.

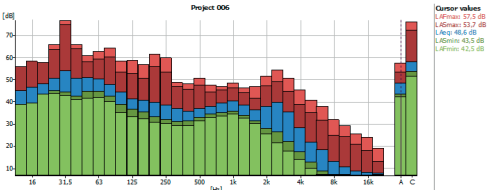
The results of the acoustic measurements were studied, considering the specificity of human acoustic perception, namely the spectrally recorded noise levels weighted in frequency with A-weighting specific to human hearing perception, L_{Aeq}, expressed in decibels (dB(A)),



specified in the legislation and technical regulations in force, as well as time-weighted noise levels.

Acoustic recordings were made for the central frequencies of the 1/3 octave band, respectively the nominal frequency range: 6.3 Hz, 8.0 Hz, 10 Hz, 12.5 Hz, 16 Hz, 20 Hz, 25 Hz, 31.5 Hz, 40 Hz, 50 Hz, 63 Hz, 80 Hz, 100 Hz, 125 Hz, 160 Hz, 200 Hz, 250 Hz, 315 Hz, 400 Hz, 500 Hz, 630 Hz, 800 Hz, 1000 Hz, 1250 Hz, 1600 Hz, 2000 Hz, 2500 Hz, 3150 Hz, 4000 Hz, 5000 Hz, 6300 Hz, 8000 Hz, 1000 Hz, 125 Hz, 16000 Hz, 20000 Hz.

Determining the number of metros that circulated during the hourly intervals of acoustic measurement and recording, for the specific number of metros on the two underground metro lines (round trip), the hourly intervals were correlated with the determination of the vibration level coming from the metro, received at the study site, were used.



Next, also for acoustic analysis reasons, considering *human psychoacoustic perception*, correlated with the human audibility range and time weighting, the time-weighted noise levels F and S, $L_{xy}(t)$, where x is A for A weighting, and y is F for Fast weighting, L_{AFmax} , L_{AFmin} , or S for Slow weighting, L_{ASmax} , L_{ASmin}, which take into account the exponential time constants and averaging times, expressed in seconds or milliseconds, corresponding to the equipment (sound level meters) used to perform acoustic measurements. The time-weighted acoustic level is a continuous function of time and is expressed in decibels (dB). For these reasons, in Figure 8 … Figure 15, which presents a part of the results of the acoustic measurements carried out, both the recorded values for the equivalent noise level, L_{ech} , in dB(A) are given, in order to be able to compare them with the values of the admissible limits specified in the technical regulations in force, and, additionally, the values of the other types of time-weighted levels, respectively L_{AFmax} , L_{AFmin} , and L_{ASmax} , L_{ASmin}. It can be estimated that L_{ASmin} is approx. equivalent to the minimum noise level, L_{AF95}, and L_{ASmax} is approx. equivalent to the peak noise level, L_{AF05}; also, L_{AFmin} is approx. equivalent to the minimum peak noise level, L_{AF99}, and L_{AFmax} is approx. equivalent to the maximum peak noise level, L_{AF01}. The noise levels recorded at measurement point P1, were between minimum L_{Aeq} = 30.3 dB(A) (in Project 1, in the early morning, hours 04:55) when the metro train was not running, and maximum L_{Aeq} = 41.9 dB(A) (in Project 10, in the morning, hours 08:35) when the metro train is running and also with specific street noise. The noise levels recorded at measurement point P2, were between minimum L_{Aeq} = 40.1 dB(A) (in Project 1, in the early morning, hours 04:55) when the metro train was not running, and maximum L_{Aeq} = 52.0 dB(A) (in Project 09, in the morning, hours 08:35) when the metro train is running and also from specific street noise. The noise levels recorded at measurement point P2, related to some of the 9 projects in the sound level meter whose microphone was placed in P2, are exemplary presented graphically, with the corresponding values tabulated, according to the sound level meter data, in Figures 8-10.

Additionally, analyses of each type of recorded noise levels were also performed (L_{Aeq}, L_{AF90}, L_{AF10}, L_{AFmax}, L_{AFmin}, and L_{ASmax}, L_{Asmin}) and represented on the same graph, for the same type of noise level, of its values recorded in the two measurement points, P1 and P2, for all 19 projects in the two sound level meters, (Project 1, … Project 10, for measurement point 1, P1, and Project 1, … Project 9, for measurement point 2, P2). These graphs are presented below, in Figure 11 to Figure 15.

From the analysis and comparison of the results obtained from the acoustic research and measurements carried out, corroborated with the values of the maximum noise limits regulated by the legislation in force and correlated with the living function of the rooms in the future residential building that is intended to be built, the following observations emerge:

a) Regarding the measurements carried out at measurement point P1, for underground noise sources, mainly coming from metro traffic and with somewhat significant influences also from the noise produced simultaneously aboveground (depending on the type of surface noise sources, coming from human street activities, road traffic, air traffic noise - an airplane, birdsong, etc.), the noise level produced by metro traffic will not influence the noise level inside the rooms of the future residential building that is intended to be built on the studied site; a judicious acoustic design, combined with vibration protection of all construction elements of the future residential building, will be able to meet the requirements regarding the maximum admissible noise levels inside the rooms of this building. It is mentioned that certain peak noise levels recorded were due to isolated actions (in the context of the entire

reference period, for which the admissible level is established), for example: birds chirping, sirens in street traffic, slamming car doors, noise from the construction site, etc.

b) Regarding the measurements carried out at measurement point P2 for the surface noise sources, coming from human street activities, street road traffic, air traffic noise (an airplane), birdsong, etc., the analysis of these values shows that the noise level outside residential buildings, $L_{ech} = L_{AF90} + 5$ dB(A), measured at 2.00 m from the building facade, will be able to be met according to the recommendations of the legislation in force, for the future residential building that is intended to be built on the studied site. It is mentioned that the noise produced by the metro will not significantly influence the noise level outside the future residential building, measured at 2.00 m from its facade. Also, through a judicious acoustic design of the closing construction elements and the facades of the future residential building, the requirements regarding the maximum permissible noise level inside the rooms of this building will be met. All noise levels presented in the previous chapters, levels existing in the technical regulations and legislation in force, will have to be met through a judicious acoustic design of the future residential building G+2F, without basement, which is intended to be located on the studied land in District 1 - Bucharest.

Regarding the part of the study dedicated to vibrations, the measurements made in the 20 files recorded in the two stages - quiet and metro/zonal traffic - led to time domains of accelerations, velocities and displacements, with response spectra in the range 0.016 - 100 Hz. By analysing the results obtained, it will be ascertained whether the vibration level falls within the admissible limits recommended by the technical regulations in force.

During the quiet phase, the highest velocity was noted in the z direction at STO1M (from the response spectrum), while the maximum values in the x and y directions were recorded at ST03 and ST02, respectively. In the metro/zonal traffic (noise) phase, the situation is presented comparatively in Figure 16.

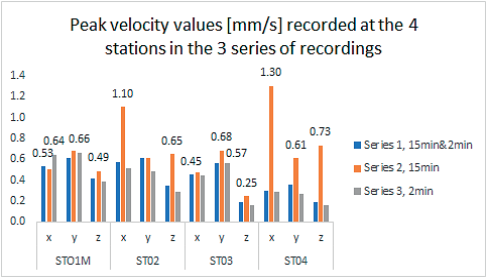

Figure 16. Variation of velocities in recordings

The analysis of the velocity time histories and the Fourier spectra revealed the following findings:

- the maximum velocity recorded in the excavated pit was 0.67 mm/s, while at the ground surface, in the center of the area, the recorded velocity was 1.27 mm/s;
- the Fourier spectra identified ranges for amplifications at 10 Hz, 30 Hz, and between 40 and 90 Hz.

The vibration propagation mode is highlighted. There is a trendline indicating a correlation between the maximum velocities recorded by the STO1M and STO3 sensors. The STO1M sensor measures velocities from a depth point, while the STO3 sensor measures them from a surface point. This trendline has a correlation coefficient of 0.84 (Figure 17).

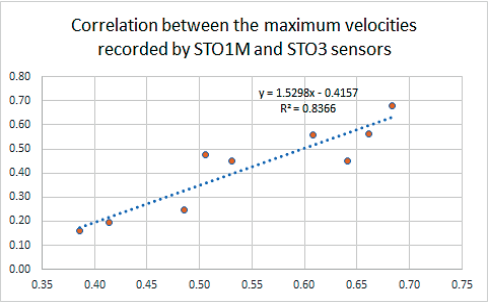

Figure 17. Propagation of vibrations between two points (STO1M and STO3 sensors)

Additionally, there is a trendline for the maximum velocities recorded by STO2 and STO4, both of which are situated at surface points along a diagonal of the study area. This trendline has a correlation coefficient of 0.88.

CONCLUSIONS

An acoustic characterization, as efficient as possible, of the studied area, namely the identification of the noise and vibration level in the study site in Bucharest, was achieved by performing acoustic measurements of the noise level coming from both surface noise sources and underground noise sources, namely the metro. The measurement situations were determined in a such way as to be useful for the design of a future residential building. The results of acoustic measurements show that the noise level produced by metro traffic will not influence the noise level inside the rooms of the future residential building that is intended to be built on the studied site in Sector 1 – Bucharest, because a judicious acoustic design, combined with vibration protection, of all construction elements of the future residential building, will be able to meet the requirements regarding the maximum admissible noise levels inside the rooms of the future building.

Although the recorded velocity values do not exceed the permissible limits (they are below 3 mm/sec), special attention is required in the design to avoid possible overlaps of vibration frequencies (from the soil-structure interaction).

INCREASING THE SAFETY LEVEL CONSIDERING SOIL-STRUCTURE INTERACTION IN HIGH SEISMIC HAZARD-PRONE AREAS

Stefan Florin BALAN, Bogdan Felix APOSTOL

12 Călugăreni Street, Măgurele, 077125, Ilfov, Romania

Corresponding author email: sbalan@infp.ro

Abstract

The work describes assessments and public policies that would account for safety increase and duration in the exploitation of structures. The level at which the soil-structure interaction is approached in actual normative/codes is highlighted. Proposals for approaching different ways to rise the protection level of structures to be in seismic zones were examined, starting from their location and design; this implies the knowledge of the site seismicity, earthquakes-related parameters prediction, the importance of (extended) geotechnical studies, etc. The interaction wave-structure is studied by using the model of harmonic oscillator coupled to an elastic medium. This analysis is meant to be relevant for the effects of seismic motion upon localized structure. Also, the model of an elastic structural element embedded at one end is envisaged and the normal modes and the eigenfrequencies of this independent module are highlighted. The response to oscillating shocks is computed for various ground excitations applied to its base. The response of two coupled modules, viewed as simplified structures thereby harmonic oscillators as well, to an oscillating shock is calculated, and amplification factors are highlighted.

Key words*: soil-structure interaction, wave-oscillator coupling, localized structures, risk evaluation, public policies.*

INTRODUCTION

The buildings behaviour is influenced by the site characteristics and the way it acts under strong seismic shaking. For certain geophysical characteristics, such as deep sedimentary basins, soft layered soils, amplification, inhomogeneities, or non-linearities presence, the level of hazard is increased. Therefore, the assessment of the seismic risk level is a challenging task. For Bucharest city, the old buildings and various types of design add to this state of things. The employed analyses, proposed actions to be taken, provisions and public policies are meant to lead to safety increasing and exploitation duration for the objective of interest. Thus, the soil-structure interaction (SSI) was considered in the project for the normative act "Seismic design code - part I - Design provisions for buildings Indicator P 100-1/2025" (P100-1/2025) developed by the Technical University of Construction Bucharest in 2024 (currently being in the consultation stages); therein this issue was approached explicitly for the first time in a Romanian design code. The present work can also be taken as a guide for the general contractor to be aware of what elements to look for when making the choice for the location of a future building or an urban or industrial complex. In this sense, compliance with the legislation/norms in force must be taken with the obligation/recommendation to add a thorough assessment of the following elements:

1) Local hazard, seismicity maps (peak values for recorded parameters, estimated intensities, etc.), microzoning (if any);
2) Possible prediction of future earthquakes (characteristics, ground shake level, amplifications) at the chosen location;
3) Geotechnical engineering studies, standard (required by the laws/codes/norms in force) or more complex according to the future requirements of the objectives to be built on the chosen area;
4) History of landslides and the risk of future ones on the chosen site, and measures to prevent them (if applicable);
5) Checking the area where the future site was chosen for the potential of liquefaction and if this phenomenon exists, what measures should be taken to reduce/exclude the risk of liquefaction in the event of a strong earthquake;

6) Measures to improve the bearing capacity of the soil if the respective site does not meet the conditions required in the project;
7) In the case of future objectives enrolled in Class I (Buildings with essential functions for which the preservation of integrity during earthquakes is vital for civil protection), detailed knowledge of the geological stratification of the soil deposit from the bedrock to the surface, especially for areas known to be soft soils is of uttermost importance. This should be done because of the potential of the soil layers to amplify the local seismic input at the site, which in some cases can lead to significant structural damage.
The site-structures interaction systems performance is assessed and thereby applied as a contribution to the safety level improvement for the structures located in the seismic areas or characterised by a high hazard level. Some features of both seismological and earthquake engineering interest are discussed that account for the vulnerability mitigation of the constructed medium since its design stage. The research studies that are carried out in the work refer to needs that involve the development of advanced methods for foreseeing interaction effects, the development of practical computational methods for estimating and incorporating these effects into the building design.

MATERIALS AND METHODS

Reference to soil - structure interaction in current codes/norms

The following section outlines how soil-structure interaction is addressed in Romanian legislation and selected international standards.
In the national normative "Seismic design code – part I – design provisions for buildings, indicative P 100-1/2013" there is no explicit treatment of the soil-foundation-structure interaction phenomenon (P100-1/2013).
In the draft "Seismic Design Code – Part I – Design Provisions for Buildings, Indicative P 100-1/2025" developed by the Technical University of Construction Bucharest in 2024, (P100-1/2025) (currently in the consultation stages at various professional levels) the notion of soil-structure interaction appears in several paragraphs as an additional calculation method in certain design situations.
Some examples of how this type of interaction was addressed in several international design codes are given below.
In Eurocode 8 (EUR 25204 EN – 2012), Seismic Design of Buildings soil-structure interaction appears in Chapter 4, "Introduction to the RC building example. Modelling and analysis of the design example"; 4.9. "Soil Structure Interaction". This subchapter presents qualitative/introductory elements about the phenomenon. Throughout Chapter 4, reference is also made to the soil-structure interaction phenomenon, and it is recommended that it be considered in certain practical situations.
National Institute of Standards and Technology (NIST, USA) has published guidelines on soil-structure interaction for building structures (Gcr, N. 2012; Stewart et al., 2012).
Techniques for simulating SSI phenomena in engineering practice are described. The recommendations are specifically addressed to the modelling of the effect of seismic soil-structure interaction on buildings. Realistic building examples are used to illustrate and test these recommendations.
One of the codes in Japan that specifically addresses soil-structure interaction is ISO 23469 (ISO 23469/2005). It provides guidelines for seismic actions in the design, including various types of structures that interact with the soil. This standard recognizes the importance of considering the effects of soil-structure interaction in seismic engineering. It complements ISO 3010, which focuses on seismic actions for superstructures of buildings and bridges. Designers use ISO 23469 to evaluate seismic loads on geotechnical works, considering factors such as soil displacement and the dynamic behaviour of buried structures.

Tasks to be accomplished for safety level increase

The features that need to be assessed within the oversight process of the soil-structure interaction are described; they may support the increase of the protection level of the buildings located in seismically dangerous areas.
1. Seismicity of the area. Studying the seismicity of the future site by complying with

the legislation/norms in force is essential, and if the objective is of particular importance, additional local/regional seismic hazard studies will be carried out (Welsh-Huggins & Liel, 2018; Joyner & Sasani, 2020).

2. Prediction of the earthquake's parameters. Predicting strong ground motion for future earthquakes is currently accomplished primarily by applying attenuation laws or parametric scaling relationship (Manea et al., 2022; Manea et al., 2025; Ardeleanu et al., 2005). These relationships related parameters describing the seismic source, such as the magnitude, to the location of a site relative to that source, to ground motion datasets (for example maximum (damped) spectral acceleration and the corresponding oscillation period). The current lack of recorded data, for some sites, at shorter or longer distances from the epicentres of strong earthquakes means that there is not enough hazard data to represent the presumed hazard of the most dangerous events. Dedicated computing programs and computational simulation, using various methods, offer a way to fill this data gap, for which structural engineers need histories of future ground motion.

3. Importance of Geotechnical Engineering Studies. The properties of the soil at a construction site substantially affect the performance of the construction and its associated facilities during earthquakes. However, these materials (soils) are usually the most variable in properties, the least investigated, and the least controlled of all materials in the built environment.

Knowledge of soil behaviour is key for a high-level structural design. Constructions and associated facilities (of all kinds) built in seismic regions on saturated sands, reclaimed land, and deep deposits of soft clays are vulnerable to damage from strong earthquakes. (Basu et al., 2014). Soils of the aforementioned types are common in marine environments and alluvial deposits, where large cities are often founded. For example, Mexico City is located on deep alluvial land (Beresnev et al., 1998). The Los Angeles Basin, consisting of unconsolidated sediments (Rukos, 1988) and Kobe city also are among these areas. The latter, comprises few not too deep different layers, was experienced liquefaction phenomenon occurred during strong Hyogoken-Nanbu earthquake (Ishihara et al., 1996). Damage to structures is worsened by soil liquefaction which causes the loss of foundation support and contributes to dramatic settlement of large buildings. Bucharest is crossed by 2 rivers (Dâmbovița with a length of 22 km and Colentina) and has several lakes on its territory, being located on an alluvial plain, formed by thick layers of sediments (sands, loess, etc.), with a preponderance of soft soils. Deep deposits of soft clays are particularly prone to amplifying the amplitude of seismic movement and decreasing the frequency content in the event of a strong earthquake, a situation that often leads to major damage to a structure, especially if resonance occurs between the soil and the structure.

4. Ground motion amplification. In addition to their tendency to cause structural damage, poor soil conditions are often associated with damage due to their tendency to amplify ground motions and/or to resonance with above infrastructure during strong earthquakes.

A spectacular example of ground motion amplification occurred during the 1985 Mexico City earthquake (M_W = 8.0, depth =20 km). The earthquake epicentre was over 400 km from the city, and the shaking amplitude at bedrock level in Mexico City was almost negligible (Anderson et al., 1986; Stone et al., 1987). However, since much of the city is built on soft soils that extend to considerable depths, these generated a seismic response that led to ground motion amplifications at frequencies close to those built structures. The structures display a strong resonance and were subjected to movements well above their design loads. Significant damage occurred, followed by the collapse of buildings, producing over 8,000 victims, and leaving over 50,000 people homeless. The significant increase in the potential for damage due to soft soil requires a better understanding of how local soil conditions modify seismic action and how these conditions can be identified, designed, and/or modified.

5. Considerations upon buildings. The 1994 Northridge (M_W = 6.7, depth = 18.2 km) (Mahin et al., 1998; Arboleda-Monsalve, 2020), 1995 Kobe (M_W = 6.9, depth = 21.9 km)

(Scawthorn et al., 1995; Aguirre & Irikura, 1997), and numerous other major earthquakes around the world illustrate that, despite advances in seismic design over the past decades, we need to develop a better understanding of the behaviour of built systems to ensure that new buildings are designed and old buildings are retrofitted to reduce their vulnerability to excessive damage and large economic losses during earthquakes.

5.1. ***Predicting the seismic capacity and performance of existing and new buildings***. Certain types of buildings are particularly vulnerable to major earthquakes: unreinforced masonry buildings, concrete frame buildings, precast concrete buildings etc. and many structures built before 1977 (the case of Romania) (Balan et al., 1982). Depending on their age, storage tanks, buried and above ground pipelines, and bridges may also be vulnerable.

Therefore, it is imperative to develop tools to identify buildings in this category, the facilities and supply lines (electricity, water etc.) that are vulnerable to cost-effective rehabilitation. Historic buildings present a particular challenge for seismic rehabilitation due to the limitations imposed on physical modification of the structure and the difficulty of structurally testing equivalent systems and components.

5.2. ***Assessment of non-structural building systems***. Most direct economic losses in buildings result from damage to non-structural systems, as opposed to structural systems (Balan et al., 1982). Even in earthquakes with minimal structural damage, non-structural damage can be substantial. The behaviour of non-structural components, such as architectural cladding, interior walls, and utility distribution systems, and their interactions with buildings, during earthquakes are complex phenomena. To adequately and better understand these interactions, they should be modelled (with accurate representation of both the structure and the non-structural components), at natural or smaller scale. Actions taken to protect non-structural elements from degradation during an earthquake must also consider a detailed cost-benefit analysis.

6. Performance of soil-foundation-structure interaction systems. Soil-foundation-structure interaction can have a significant effect on the seismic performance of building structures during strong earthquakes. Testing should be performed on representative structures and foundation systems to adequately represent the interaction on both the building and the foundation.

Currently, data on the response of soil-foundation-structure systems are quite scarce, and research needs include the development of advanced methods for predicting the effects of interaction, performing large-scale shake table tests and, where required, centrifuge testing of interaction mechanisms, developing practical computational methods for estimating the effects of interaction, and incorporating these effects into building design.

This issue will be particularly addressed in the next section.

7. Determining the performance of innovative materials and structures. Innovative materials and structures will include new intelligent uses and configurations of conventional materials and new "smart" developments of materials and structures. The use of smart materials and structures is an emerging concept in mechanical, aeronautical, and civil engineering.

Smart structures ("self-adaptive" or "intelligent") have the ability to respond to internal and/or external stimuli by varying their shape or mechanical properties. Smart materials can be used in sensors or actuators.

Examples of "smart" sensing materials include: optical fibre, piezoelectric ceramics, magnetorheological, electrorheological fluids and microelectromechanical systems (MEMS). The integration of these materials with sensing-actuating capabilities into conventional materials or structural systems will lead to smart structural systems. Research into "smart" materials has been conducted for many years, but few companies are putting these results into practice.

Cost-benefit analyses are needed to fully illustrate the relative benefits of these new technologies and materials and to systematically evaluate their innovative performance.

8. Risk assessment. The challenge in risk assessment is to provide decision-makers with accurate and understandable information about

risk exposure and alternative risk mitigation with the tools that will enable them to make prudent decisions based on this information.

More specifically, it is necessary to do the following:

• Develop risk assessment methods that are comprehensive, based on sound scientific and engineering principles, and usable by a variety of stakeholders.

• Development of the base of decision-making tools that leads to its reduction.

• Formulating a framework for risk mitigation and mitigation policies that can be implemented by the public and private sector.

Although strong earthquakes are rare events, their consequences can be devastating. Decision-makers are often complacent about earthquake hazard because a major earthquake may not have occurred in their lifetime or where they live.

Risk assessment requires knowledge of the following types of issues:

• The probability of earthquakes occurrence, their magnitude and location, the characteristics of the terrain in the area, the probability that they will cause tsunamis.

• Physical damage, with its direct consequences in terms of death, injury, loss of operational functionality and destruction of property.

• The social and economic consequences of direct physical damage, including losses due to damage to buildings, supply lines and other critical elements.

9. Public Policy. A major challenge for communities exposed to major earthquakes is the need to have risk reduction placed on the public, municipal, and legislative agendas.

Although research findings will advance over time, changes will only be achieved through policy development and implementation. Adopting policy measures, supported by cutting-edge technology, will significantly increase the capacity to prevent major disasters and thus reduce the devastating economic impact and social consequences.

One of the major difficulties in reducing the economic and social consequences of earthquakes is that disaster mitigation policies and preparedness are generally inadequate to meet the challenge of disasters for a community. The many directions that need to be addressed on the path to disaster policy formulation and implementation include: the appropriateness of relevant policy; educating decision-makers; educating stakeholders to gain support for the introduction of legislation; identifying appropriate alternatives that are consistent with the risk, exposure, and capacity of a community to implement these policies; and developing strategies for implementing legislation.

Proposals for public policies that can help promote an increasing safety policy are presented below:

• Setting the agenda. After any disaster, there is a reset of the agenda for those directly involved. It is necessary to be prepared and to take advantage of these moments. A community must understand its risks to determine how to mitigate them and how it can respond to emergencies. The technical basis comes from integrating all geological, structural, and sociological data and simulations that would provide a rational reason and an understandable basis for public and private policy decisions on preparing/mitigating shocks to large earthquakes:

• Policy justification. In formulating public policies, it is often necessary to undertake a cost-benefit analysis of the proposed policy or regulation;

• Defining alternatives. Policy decisions on earthquake mitigation must be based on sound and up-to-date technical knowledge;

• Educating the public. Most often, public policies are developed in response to public demand. The public can make and influence political decisions, but only if people are sufficiently well informed about the underlying problems and the solutions and their implications.

10. Landslide study. Evaluating geotechnical hazards is a crucial responsibility in the field of geotechnical engineering. This involves assessing the potential impacts of natural events, such as earthquakes and landslides, on construction projects. Hence the history of landslides and the risk of future ones on the chosen site, and measures to prevent them (if applicable) is useful to be known.

11. Liquefaction. Is important to check the area where the future site was chosen for the potential for liquefaction and if this

phenomenon exists, what measures should be taken to reduce/exclude the risk of liquefaction in the event of a strong earthquake. The prevention of liquefaction phenomena requires a combination of geotechnical measures and appropriate planning when building structures in areas susceptible to soil liquefaction. Finally, structures built in areas prone to liquefaction must be designed to withstand the forces and settling induced by this phenomenon. Special design techniques, such as deep piles, reinforced foundations or retaining walls, may be required to ensure the stability of structures (Youd at al., 2001; Ishihara et al., 1996).

12. Soil improvement measures. Measures to improve the bearing capacity of the soil if the respective site does not meet the conditions required in the project must be taken. Besides conducting geotechnical assessments, additional measures can be considered, such as soil drainage and reinforcement through the incorporation of granular materials or chemical binders to enhance its properties. Alternatively, soil compaction can be employed to increase its density

13. Utility supply lines. Best practices from utilities that have used mitigation measures to address the earthquake threat are needed to be known. To protect the utility will need to assess the potential damage to buildings and key assets. Utilities include water, wastewater, fuel, electricity, gas, and telecommunications systems. The basic components of utilities include supply and storage equipment, transmission lines, and the connections between these components. Underground utility pipelines and connections are often too weak or inflexible to withstand earthquake ground movements and differential settlements, causing them to crack or fail. Materials that are too flexible, however, also cannot handle additional displacements from earthquake forces. From ground shaking, pipes often crack at brittle joints or are crushed at the bell or pipe barrel. From liquefaction or lateral spreading, pipes often break or separate at the joints (Deelstra & Bristow, 2022).

Performance of soil- foundation-structure interaction systems

The effects of seismic waves on structures on the Earth's surface are studied by considering features of major interest in the assessment of seismic risk. The input generated by the phenomena that affect the structures can be appreciated in terms of physical and mathematical problems related to shocks, oscillations, and vibrations (Apostol, 2025a). In these circumstances the advanced study of the response of elastic elements to external mechanical excitations is pursued. Overall, the characteristics of the interest site (site to be chosen for the construction) directly influence the structures and construction materials behaviour, innovative assembles and utility supply lines included. Therefore, the necessity was inferred for taking into consideration the complex phenomenon of site-foundation-structure interaction and particularly the structural behaviour to seismic input or vibrations.

The protection of the buildings erected at the Earth’s surface is a continuous preoccupation in earthquake engineering for countering the destructive action of the earthquakes. The buildings are represented by vibrating units (or simply bars), which, under the seismic action may resonate; also, sub-surface inhomogeneities may behave as resonating embedded elements (Apostol, 2025a). In both cases we get local amplification factors, for displacement, velocity, and acceleration, which are evaluated in resonance conditions and may attain large values. The amplification factors are given by a combination of the shock duration, the height of the bar above the ground surface and the velocity of the elastic waves in the beam; they arise because of the excitation of the normal modes in the structure (Apostol, 2025a).

A distinct instance is devoted to the interaction of a harmonic oscillator model with an elastic wave, the associated amplification factors, and particularly the coupling of structure-site, viewed as localized harmonic oscillator coupled with the elastic medium.

The problem of selecting the type of seismic excitation is examined considering the possible expected damages. This innovative method is distinguished by its precise and high-quality outcomes. The approach utilizes and applies mathematical physics equations pertaining to oscillating beams, coupled oscillations, and medium-structure interactions. The significance

of this method lies in its ability to deliver valuable insights that can be used in the design and construction of buildings.

We consider as an appropriate model for investigating the response of a building to ground vibrations a simple structure assimilated to an embedded bar at one end. The input can be considered as various ground oscillations such harmonic oscillations and oscillating shocks characterized by a sharp wave front. This special case is the most interesting excitation, since it is deemed that such a shock may correspond to the seismic main shock with its long tail.

The model of the embedded beam provides a way of understanding the well-known amplification site effects of the earthquakes, as arising from the excitation of the normal modes in local inhomogeneities (Apostol, 2025a).

For the seismic excitations which have a general aspect of shocks, i.e. they are concentrated in at the initial moment of time, we assume first a shock-like ground motion:

$$u_0(t) = u_0 T\,\delta(t),\ u_0(\omega) = u_0 T,$$

where T is a measure for the duration of the shock. We get:

$$u(z,t) = \frac{1}{2}u_0 T[\delta(t - z/c) + \delta(t + z/c)] + \\ + u_0 \frac{cT}{l}\sum_n sin\omega_n t \cdot sin\omega_n z/c \qquad (1)$$

for the displacement along the bar, where $\omega_n = (2n + 1)\pi c/2l$, and n is any integer. Vibrations given by the normal modes with the eigenfrequencies ω_n are excited in the bar.

The summation over n in equation (1) gives a pulse going forth and back along the bar. The amplitude of the pulse is of the order u_0, while the amplitude of the normal modes is of the order $u_0 cT/l$.

For computing the amplification factors we introduce the parameter $g = \frac{cT}{l}$ and denote by $u_n(t, z)$ the contribution to the displacement of the n-th normal mode.

For modelling the seismic main shock with its long tail an oscillating shock with a sharp wavefront, attenuated in time with the rate α is employed; a ground motion given by $u_0(t) = u_0\theta(t)e^{-\alpha t}cos\omega_0 t$, is assumed, where $\theta(t) = 1$ for $t > 0$, $\theta(t) = 0$ for $t < 0$ is the step function and $0 < \alpha \ll \omega_0$. The solution is now:

$$u(z,t) \cong u_0 e^{-\alpha t}cos\omega_0 t \cdot \frac{tan\omega_0 l}{c}\cdot\frac{sin\omega_0 z}{c} - \\ - \frac{c}{2l}u_0\sum_n\left[\frac{(\omega_n-\omega_0)cos\omega_n t-\alpha sin\omega_n t}{(\omega_n-\omega_0)^2+\alpha^2} + \right. \\ \left. + \frac{(\omega_n+\omega_0)cos\omega_n t-\alpha sin\omega_n t}{(\omega_n+\omega_0)^2+\alpha^2}\right] sin\omega_n z/c \qquad (2)$$

for ω_0 different from all ω_n , and in which are included contributions from the poles $\pm\omega_0 - i\alpha$ of the shock and contributions from the normal modes with eigenfrequencies ω_n (the poles of $tan\kappa l$).

For $\omega_0 = \omega_n$ (resonance):

$$u(z,t) = u_0\frac{c}{l}\frac{1-e^{-\alpha t}}{\alpha}\cdot sin\omega_0 t\frac{sin\omega_0 z}{c}, \qquad (3)$$

from which can see that the displacement amplitudes at resonance are $\frac{c}{l\alpha}u_0$, i.e. in the amplification factor $g = cT/l$ the duration T is replaced by $1/\alpha$, as expected. We note that for $\omega_0 = 0$ the amplitude is reduced to $\left(\frac{c}{l\omega_n}\right)u_0$. Similarly, the response velocity and acceleration include factors $u_0\omega_0$ and $u_0\omega_0^2$, respectively, which now can be viewed as corresponding to the ground velocity and acceleration; the amplification factor for these quantities is $g = c/l\alpha$, as for the displacement.

Let us assume a bar with length l fixed at $z = 0$ to another long bar with length l_0; we denote the former bar by 1 and the latter bar by 2; The model of two coupled bars is employed as follows: bar 1 with length l fixed (at $z = 0$) extends above the ground surface, while bar 2 with length l_0 is buried in the ground.

The equations of elastic motion in the two bars are:

$$\ddot{u}_1 - c_1^2 u_1'' = 0, \ddot{u}_2 - c_2^2 u_2'' = 0 \qquad (4)$$

where $u_{1,2}$ is the displacement in the two bars; after imposing the appropriate boundary conditions, we get, for a force, for a shear displacement applied at the lower end $z = -l_0$:

$$u_1(z,\omega) = u_0(\omega)\frac{cos\kappa_1(z-l)}{cos\kappa_1 l cos\kappa_2 l_0 - \frac{\mu_1\kappa_1}{\mu_2\kappa_2}sin\kappa_1 l sin\kappa_2 l_0} \qquad (5)$$

$$u_2(z,\omega) = \\ = u_0(\omega)\frac{cos\kappa_1 l cos\kappa_2 z + \frac{\mu_1\kappa_1}{\mu_2\kappa_2}sin\kappa_1 l sin\kappa_2 z}{cos\kappa_1 l cos\kappa_2 l_0 - \frac{\mu_1\kappa_1}{\mu_2\kappa_2}sin\kappa_1 l sin\kappa_2 l_0}$$

The eigenfrequencies are given now by

$$\frac{tan\omega_n l}{c_1}\cdot\frac{tan\omega_n l_0}{c_2} = \frac{\mu_2\kappa_2}{\mu_1\kappa_1} = \sqrt{\frac{\rho_2\mu_2}{\rho\mu_1}} \qquad (6)$$

and amplification factors appear, similarly with a single bar. If bar 2 is much "softer" than bar 1 ($\mu_2/\rho_2 \ll \mu_1/\rho_1$) the (lowest) eigenfrequencies are given by $\omega_n = (c_2/l_0)\alpha_n$, where α_n are the roots of the equation $\alpha_n \tan\alpha_n = \rho_2 l_0/\rho_1 l$. If bar 1 is "softer", the eigenfrequencies are $\omega_n = (c_1/l)\beta_n$, where $\beta_n \tan\beta_n = \mu_2 l/\mu_1 l_0$.

We can see that the eigenfrequencies are controlled by the elastic properties of the "softer" bar. This result gives an indication regarding the vibration properties of bars with a composite structure (e.g., including voids).

In studies of seismic risk and hazard it is important to assess the effects of the seismic motion upon localized structures, either natural or man-made. Such structures are viewed herein as localized harmonic oscillators, with corresponding eigenfrequencies (characteristic frequencies). It is assumed that the seismic motion acts as an external force upon such oscillators and the resonant regime is highlighted.

For a realistic use of the coupled-oscillator model we consider two oscillators as corresponding to a building (oscillator 2) and its foundation (oscillator 1). For a stiff foundation, such that $\omega_1 > \omega_2$ the eigenfrequencies of the building are reduced to an appreciable extent (down to zero), while the eigenfrequencies of the foundation are increased by the coupling. For a soft foundation ($\omega_1 < \omega_2$) the situation is reversed, the eigenfrequencies of the building are raised by the coupling and those of the foundation are reduced. Let us assume that the foundation (oscillator 1) is subject to a force $\theta(t) f_0 e^{-\alpha t} cos\omega_0 t, \alpha \ll \omega_0$, arising from the ground motion. The full solution is obtained as:

$$u_1 = A_1 e^{i\Omega_1 t} - \frac{\omega_2^2}{k_2} B_2 e^{i\Omega_2 t} + f\frac{\omega_2^2 - \varpi_0^2}{\Delta} e^{i\varpi_0 t},$$
$$u_2 = \frac{\omega_2^2}{k_1} A_1 e^{i\Omega_1 t} + B_2 e^{i\Omega_2 t} - f\frac{k_2}{\Delta} e^{i\varpi_0 t} \quad (7)$$

with the notations $\Delta = (\varpi_0^2 - \Omega_1^2)(\varpi_0^2 - \Omega_2^2)$; $\varpi_0 = \omega_0 + i\alpha$, where $1/\alpha$ is the attenuation factor.

The constants A_1, and B_2 are determined from the initial conditions:

$x_{s,b}(t=0) = 0;\ \dot{x}_{s,b}(t=0) = 0.$

We focus on the resonance of the building, where $\omega_0 = \Omega_2 (\alpha \ll \Omega_2)$ and $\Delta \cong \alpha\Omega_1^2(\alpha - 2i\Omega_2)$; the initial conditions give $A_1 \cong 0$ and $B_2 \cong \frac{fk_2}{4\Omega_1^2\Omega_2^2}\left(1 + i\frac{\Omega_2}{\alpha}\right)$; hence we get the displacements:

$$u_1 = \frac{-f\omega_2^2}{4\Omega_1^2\Omega_2^2}\left(cos\Omega_2 t - \frac{\Omega_2}{\alpha} sin\Omega_2 t\right)(1 - e^{-\alpha t}) + +O(\alpha)$$

$$u_2 = \frac{fk_2}{4\Omega_1^2\Omega_2^2}\left(cos\Omega_2 t - \frac{\Omega_2}{\alpha} sin\Omega_2 t\right) \cdot \cdot (1 - e^{-\alpha t}) + O(\alpha) \quad (8)$$

We can see that the original damped excitation is lost in time and for a long time both the building and the foundation oscillate with the resonance frequency Ω_2 of the building; the amplitudes of the oscillations are enhanced by the attenuation factor $1/\alpha$, as expected; the oscillation amplitude of the foundation is controlled by the exciting force, while the amplitude of the building is controlled by the coupling constant. We note that we have considered the above oscillations without a damping factor; a damping factor affects the contribution of the normal modes and add to the attenuation factor of the excitation.

At resonance the coupled oscillators exhibit amplification factors, like the vibrating bar. The coupling lowers the low frequency of the system and raises the upper frequency (Apostol, 2025b).

With a direct reference to the subject addressed herein, and perhaps a more realistic assessment of the site-structure interaction we examine the approach involving the motion of a localized point harmonic oscillator coupled to a homogeneous elastic medium. Two new elements are introduced, one regarding the reaction of the oscillator upon the medium and another concerning a coupling function. It is shown that the reaction of the oscillator modifies its inertia, which in turn leads to a change in the oscillator's eigenfrequency; this change is controlled by the coupling function. The present treatment opens the way of introducing new, more realistic features in analysing the effect of the seismic motion upon localized structures, in particular the non-linear features of the coupling of the structure with its local site's motion (Apostol, 2025b).

Equation of motion for harmonic oscillator is considered as:

$$m\ddot{v} + m\Omega^2 v = gS(F\Delta u)_{r=r_0}; \quad (9)$$

where v is the oscillator's displacement from its equilibrium position, $(F\Delta u)_{r=r_0}$ is superficial force density the medium acts upon oscillator; S is the area of the contact surface between oscillator and medium, and the force $S(F\Delta u)_{r=r_0}$ that acts upon oscillator; g is the coupling function hence the force is written as $gS(F\Delta u)_{r=r_0}$. Of course, the area S must be much smaller than constructed surface and any other relevant wave lengths.

One must mention that coupling function *g* may achieve a complex structure; it may depend on the oscillator eigenmodes (frequency Ω), on the oscillator amplitude, on the local amplitude **u** of the waves and even on the time *t*. For simplicity, herein we consider a constant *g*; obviously g ≤ 1.

The elastic waves propagating on the surface exhibit a (two-dimensional) movement with the displacement vector **u**; while *F* stands for (generic) elasticity modulus, hence the wave velocity is $c^2 = \frac{F}{\rho}$, where ρ is the superficial mass density. The symbol delta (Δ) in the above equation is the laplacian.

Similarly, the oscillator reacts back upon the elastic medium through its inertia force $-gm\ddot{v}S\delta(r - r_0)$, localized at $\mathbf{r}_0$ and depending on the coupling function; hence we have a wave equation:

$$\rho\ddot{u} - F \cdot \Delta u = -gm\ddot{v}\delta(r - r_0) \quad (10)$$

The solution for the oscillator displacement is:

$$v(\omega) = \frac{-\omega_0^2}{\Omega^2 - \omega^2(1-g^2)} \times \frac{gS\rho}{m}\pi A\left[\delta(\omega - \right.$$
$$\left. -\omega_0)e^{\frac{i\omega_0 x_0}{c}} + \delta(\omega + \omega_0)e^{\frac{-i\omega_0 x_0}{c}}\right] \quad (11)$$

where the Fourier transforms were taken and the modulus of the wave vector $k = \omega/c$ introduced.

Hence one can see the change of the oscillator resonant eigenfrequency $\Omega \to \Omega/\sqrt{1-g^2}$ because of its interaction with the elastic medium (gets "renormalized"). By taking the inverse Fourier transform is obtained

$$v(t) = \frac{-\omega_0^2}{\Omega^2 - \omega_0^2(1-g^2)}\frac{gS\rho}{m}A\cos\omega_0(t - x_0/c) \quad (12)$$

Considering the contribution of the poles $\omega = \pm\Omega/\sqrt{1-g^2}$ we get the solution corresponding to the free oscillation at resonance; it occurs now at the modified eigenfrequency. One may specify that for a perfect coupling, $g = 1$, there is no resonance anymore.

RESULTS AND DISCUTIONS

In this paper certain site's features are analysed, that influence the behaviour of built structures, building materials, innovative structures, including utility supply lines, vital to communities. These analyses, measures and public policies are meant to contribute to increasing the safety and operational life of the objective in question.

The evaluation of the complex soil-foundation-structure interaction phenomenon must specifically consider the influence of the site characteristics themselves and especially under strong seismic movement. Thus, the proposals for approaching the different stages of the design-construction activity are examined to increase the safety and the operational duration of the objective in question.

The method and procedures for monitoring the soil-foundation-structure interaction are described, considering both the design elements and for the purpose of analysing the behaviour in operation.

It is well known that the effects of seismic waves on structures located at the Earth's surface represent a major interest in seismic risk assessment. These effects are herein evaluated considering typical excitation input upon simple (representative) structural models.

The contribution generated by the phenomena affecting the structures can be appreciated in terms of physical and mathematical problems related to shocks, oscillations, and vibrations, so the work proposes the advanced study of the response of elastic elements to external mechanical excitations.

In such a simplified picture introduced herein the reaction of the structure back on the elastic medium is particularly considered and the coupling of the structure to the elastic medium. Ways is shown of introducing these two elements in the analysis and describe the consequences, some surprising, of including these two more realistic features. The most important is the modification of the oscillator frequency with which the structure is

assimilated, due the coupling constant (which remains undetermined).
It is desirable of course, to avoid the resonance, i.e. the structure's characteristic frequencies must be different from the main frequencies of the seismic motion at the site of the structure (local seismic motion).
The normal/natural eigenmodes and the eigenfrequencies of the simplified model of an embedded elastic structure (embedded bar) are highlighted and the response to oscillating shocks is computed for several typical shock configurations. Special attention is devoted to the oscillating shock with a sharp wave front, deemed as a suitable model for the seismic main shock with its long tail. It is shown that in all cases the response of the bar is governed by an amplification factor, which includes cumulative information about the shock duration, height of the bar above the ground surface and the velocity of the elastic waves in the bar. The amplification of the response is due to the excitation of the normal modes (eigenmodes). The effect is much enhanced at resonance, for oscillating shocks which contain eigenfrequencies of the bar.
The model of coupled harmonic oscillators was formulated to investigate its response to an oscillating shock. It is shown that the lower frequency of the system is lowered by the coupling, while the higher frequency is raised. At resonance the coupled oscillators exhibit amplification factors, similar with the vibrating bar.
The results achieved in this paper concern urban seismology and specific analyses of earthquake engineering, constituting a starting point for the implementation of complex analysis methods of soil-structure interaction.
The present work can also be considered as a guide for the general contractor to know what elements to consider for when choosing the location of a future building or an urban or industrial complex.
This material can represent a methodology to be followed with the aim of increasing the degree of safety of structures located in seismic zones. It also considers important elements that could represent a potential danger to the safety of constructions, from the phase of site selection to the exploitation phase.

CONCLUSIONS

The points discussed herein refer to implementing the methods of complex analysis of the soil-structures interaction including the evaluation of dynamic structural characteristics and building monitoring.
The pursued targets, which consider the laws and regulations in force, give coherence to the approach from the point of view of the seismic analysis of the entire path from the location to the exploitation of the considered (structural) objective.
The treatment of the interaction phenomenon was considered within the project for the normative act "Seismic design code - part I - Design provisions for the present works Indicator P 100-1/2025" developed by the Technical University of Construction Bucharest in the year 2024; respectively, the phenomenon being treated explicitly for the first time in a Romanian project code.
One shall develop a good knowledge for the construction systems behaviour to assure an enhanced level of resilience for the new buildings. As regard the old buildings, they must be rehabilitated to mitigate their vulnerability at future strong earthquakes.
Research priorities in seismic engineering include: prediction of seismic capacity of buildings, performance of existing and new buildings, evaluation of non-structural systems, soil – foundation - structure interaction performance and determining the performance of future innovative materials and structures. It is important to ensure the protection of built objectives and maintain the safety of community utility supply lines and the risks that arise from not giving them special attention.
Within the study the importance of materials used in construction is emphasized and cost-benefit analyses are considered, regarding new technologies and materials. It is also proposed a manner of assessing the risks to which the built objectives are exposed and how they should be approached.
The present work brings into discussion a less known and used element, but which we consider equally important for the ways of increasing the degree of safety of structures located in seismic zones: public policies. These

must represent ways of raising awareness among communities, local/county councils, and politicians of the importance of funding future earthquake-safe works and of giving greater importance to building rehabilitation works, thus avoiding the risk of major damage to a future strong earthquake.

Abstract

This study highlights the durability and sustainability of mountain farms, focusing on agricultural diversification as a method of adaptation and development. Mountain regions in Romania face significant challenges, such as climate change, population migration, and declining agricultural incomes. Diversifying agricultural products proves to be an effective solution for increasing the resilience of these farms, enhancing both food security and economic stability. The article examines development strategies, public policies for mountain areas, and support initiatives, including a case study on their implementation. Through an integrated approach, this study emphasizes the necessity of combining agricultural traditions with innovation to ensure a sustainable future for mountain farms. In conclusion, agricultural diversification is not just a survival strategy but also an opportunity for sustainable development in mountain communities.

Key words*: agricultural diversification, durability, mountain farms, resilience, sustainability.*

INTRODUCTION

The mountainous regions in Romania are covering approximately 30% of the country's territory. However, these regions face significant challenges due to steep slopes, poor soil fertility, fragmented land ownership and harsh climatic conditions that limit the agricultural potential of these areas (Popescu et al., 2022; Oros, 2022). These areas face natural disadvantages (high altitude, harsh climate, poor soil fertility) and structural disadvantages (population migration, poorly developed infrastructure leading to reduced accessibility, very limited access to markets / poor access to markets).

The lack of a unified definition of mountain areas makes it difficult to develop coherent development strategies (Popescu et al., 2010). We can say that these regions are ecologically fragile and economically disadvantaged, resulting in higher costs of agricultural activity and limited economic opportunities (INS, 2019). More, demographic issues like the migration of young people to urban areas and the aging population have exacerbated socioeconomic difficulties in mountain communities (Academia Română, 2008). As mentioned by Antonescu (2022), depopulation in the mountain rural areas is related to the limited infrastructure, wich reduce access to quality education, healthcare, and the most important the absence of long-term public investment in community development.

At this time, agriculture remains the most important economic activity in the mountain regions of Romania, with 19.7% of the total utilized agricultural area while employing 18.5% of the economically active population (MADR, 2018). More than 65% of the farms are classified as small or very small, with less than 2 hectares of farmland. These farms are traditionally oriented to the production of cattle and dairy for meat and milk. It is important to understand that reduced access to agricultural resources (e.g., wool and dairy products), as well as low productivity, lead to a consistent reduction in the number of animals and low profitability for small farmers (MADR, 2020).

The mountain ecosystems in Romania are very important and are crucial for protecting

biodiversity, protecting water resources, and supporting rural economies. Around 50% of freshwater resources are found in these areas, as well as a variety of plant and animal life (RNDR, 2015).

The ecological importance of mountain areas is highlighted in the Carpathian Convention through a series of fundamental principles, which focus on the conservation and sustainable use of biodiversity and landscape, sustainable rural development, integrated management of natural resources, as well as transboundary cooperation and active public involvement. These principles reflect the commitment of the Carpathian states to protect and enhance the natural heritage of the region, thus ensuring that economic and social activities do not negatively affect mountain ecosystems (Carpathian Convention, 2025). Protected areas in mountain regions play an essential role in biodiversity conservation, but their effectiveness is influenced by numerous challenges, such as accessibility issues, demographic factors and economic difficulties, despite the fact that they have a high tourism potential. These conclusions are supported by GIS-based studies Geographic Information Systems (GIS). These aspects clearly limit the effective implementation of biodiversity protection measures and thus impose the urgent need for strategic interventions to ensure a balance between conservation and development. In this sense, policymakers must adopt that allow the protection of fragile ecosystems and, simultaneously, the sustainable use of natural resources through ecotourism and sustainable initiatives. By increasing awareness and using solutions based on accurate data, it will be possible to maintain the biodiversity of these valuable mountain regions as well as offering new opportunities for the development of local communities (Petrișor, 2009).

Much like in other parts of the world, these regions in Romania are at a greater risk of natural resource depletion owing to climate change, soil erosion, deforestation, and overgrazing. Economic factors coupled with rural depopulation contribute to agricultural land abandonment which poses a greater risk to these fragile ecosystems as well and amplifies these vulnerabilities (Oancea, 2003). A longitudinal study covering the period 1968-2018 shows how reduced human presence and farm activity in high-altitude areas directly accelerates soil erosion, biodiversity decline, and broader ecosystem dysfunction, increasing ecological fragility (Săvulescu et al., 2019).

The Common Agricultural Policy (CAP) of the European Union has made it possible to tackle these issues through cash prizes and assistance to long-term development. The National Rural Development Program (NRDP) 2014-2020 has assigned significant resources to mountain regions, concentrating on investments in infrastructure, young farmers, and small agricultural businesses (AFIR, 2022). Encouraging young entrepreneurs through successful implementation of sub-measure sM 6.1, referred to as referred to as “Support for Young Farmers” and entrepreneurs with positive activity sM 6.3 named as “Support for Small Farms” have greatly increased farm resilience (PNDR, 2015).

The diversification of agriculture has turned out to be one of the most viable means of making mountain farms more productive.

This strategy integrates traditional agricultural practices with innovative approaches, such as organic agriculture, agro-tourism, and value-added activities. In addition to increasing farm profits, diversification also aids in achieving food security, protecting the environment, and safeguarding culture (Gavrilescu, 2000; Oros, 2022).

In addition, it promotes global sustainability by reducing dependence on monocultures and increasing resilience to environmental and economic changes.

Despite the above-mentioned challenges, there are several obstacles such as: lack of access to markets, insufficient infrastructure, ambiguous and incomplete administrative procedures, which most often stand in the way of correct implementation. In addition, rural depopulation and population aging contribute to the reduction of the labor force, thus agricultural development is delayed (INS, 2019). It is clear that only through an integrated approach to policy support, through local community involvement and through innovative agricultural methods, these challenges can be overcome.

This paper studies the role of agricultural diversification in promoting the sustainability and resilience of mountain farms in Romania.

The paper attempts to identify some good practices and the potential for improvement, achieved by synthesizing the adoption and implications of a set of pioneering PNDR sub-measures.

The research contributes to a better understanding of sustainable rural development and has knowledge transfer implications for decision-makers and stakeholders involved in supporting mountain societies.

MATERIALS AND METHODS

This research uses a multidisciplinary framework to examine the resilience and sustainability of Romanian mountain agricultural systems, with a focus on the relevance of diversification in agriculture. Primary and secondary data were collected to establish an in-depth understanding of the financial, physical and socio-economic effects of diversification measures under the National Rural Development Programme (NRDP) 2014-2020.

Primary data are obtained from the Ministry of Agriculture and Rural Development (MADR), the Agency for Rural Investment Financing (AFIR) and the National Institute of Statistics (INS) (MADR, 2019; AFIR, 2022; INS, 2019). Secondary data were also obtained from academic sources, official reports and statistical reports (Oros, 2022; Gavrilescu, 2000; Oancea, 2003).

The research focused on key sub-measures of the NRDP, i.e., sM 4.1 (Investments in Agricultural Holdings), sM 6.1 (Support for Young Farmers), sM 6.3 (Support for Small Farms), and sM 7.2 (Investments in Basic Infrastructure).

The selection of these sub-measures is because they contribute significantly to the economic viability and long-term sustainability of the mountain farming business. In a bid to understand the effectiveness of these initiatives, several financial and physical performance metrics were analyzed, such as utilization levels of funds, project completion rates, and regional distribution of projects.

Quantitative data were analyzed through descriptive statistics in the form of means, percentages, and time trends to assess the implementation of the project and fund use. Table 1 shows the description of the main performance indicators of the sub-measures under investigation. Time-series analysis was conducted to emphasize the trend in approvals of projects and the use of funds during the implementation. Figure 1 shows the trends in annual approvals of projects with a clear spike in submissions for sM 6.3 and sM 6.1.

Table 1. Key Performance indicators for NRDP sub-measures

Indicator	Definition	Example sub-measure
Fund Utilization Rate (%)	Percentage of allocated funds utilized	sM 6.1, sM 6.3
Project Success Rate (%)	Approved projects / Total applications	sM 7.2
Regional Distribution (%)	Percentage of projects by region	sM 4.1, sM 4.2

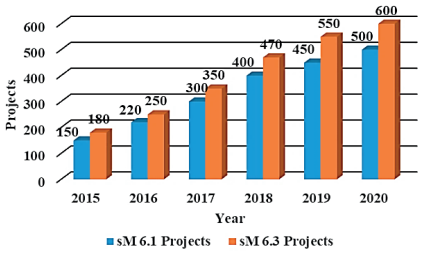

Figure 1. Yearly trends in project approvals for sM 6.1 and sM 6.3.

The geographical scope of the study are Romania's mountain areas, as delineated by the MADR's criteria, e.g., those with altitudes above 500 meters, slopes more than 15%, or other biophysical constraints. The study covered 948 administrative units (UATs) that were classified as mountain areas. Table 2 shows the spatial distribution of the UATs, and Figure 2 is a graphical representation of the percentage allocation by regions.

Table 2. Geographical distribution of mountain areas by region

Region	Total UATs	Percentage of total UATs (%)
Central	230	24.3
Northwest	198	20.9
Other Regions	520	54.8

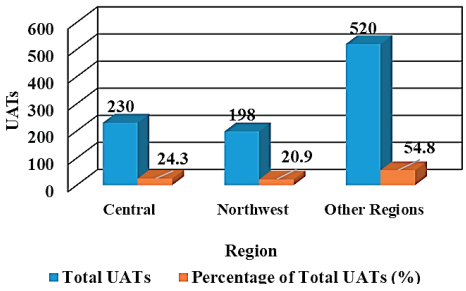

Figure 2. Regional breakdown of mountain UATs

To complement the quantitative analysis, qualitative information was collected through semi-structured interviews of 30 stakeholders, including farmers, local authorities, and agricultural association representatives. The interview themes were diversification barriers, socio-economic impacts of funding, and infrastructure issues. Table 3 presents the most significant issues brought up during the interviews, while Figure 3 shows the most prevalent barriers cited, including delayed funding, limited market access, and inadequate infrastructure (RNDR, 2015; MADR, 2020).

Table 3. Interview topics and stakeholder groups

Topic	Stakeholder group
Barriers to diversification	Farmers, local authorities
Impact of funding on livelihoods	Farmers, associations
Infrastructure challenges	Local authorities

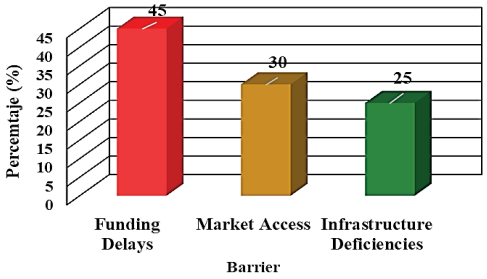

Figure 3. Common barriers identified during interviews

In addition, the analysis includes efficiency analysis by sub-measures, i.e., approval rates, fund utilization, and average project size. A comparative analysis of these efficiency measures is presented in Table 4, whereas Figure 4 presents the performance of each sub-measure relative to fund utilization.

Table 4. Performance of sub-measures in terms of efficiency

Sub-measure	Approval rate (%)	Utilization rate (%)	Average project size (€)
sM 4.1	52.9	63.6	140,712
sM 6.1	71.4	84.5	95,020
sM 6.3	68.6	77.9	57,764

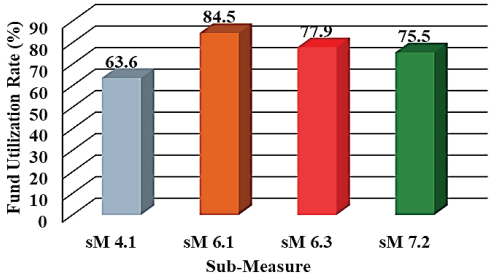

Figure 4. Performance of sub-measures in terms of fund utilization

RESULTS AND DISCUSSIONS

This chapter provides an examination of the application of agricultural diversification actions in Romania's mountain regions in the 2014–2020 programming period. The results are organized into three sections: financial and physical performance of the sub-measures of the NRDP, geographical distribution of the projects, and socio-economic effects of agricultural diversification.

Innovation in technologies, such as the production of enhanced agricultural construction material infrastructure, plays a critical role in driving sustainability (Cherecheș et al., 2021). The use of industrial wastes to add to clay-composite material provides a feasible way of promoting sustainable construction agriculture (Hegyi et al., 2023).

Results from this mixed-methods design give a comprehensive picture of the effects and challenges of farming diversification in mountain regions. Visualization instruments like bar graphs, pie graphs, and line graphs were utilized to facilitate interpretation of the results. Figure 5 illustrates project categorization with noteworthy financial input into infrastructure and small-scale farms, while Table 5 delineates the respective finance allocations.

Table 5. Funding distribution across project categories

Category	Total funding (€)	Percentage (%)
Infrastructure	300,000,000	40
Young Farmers	150,000,000	20
Small Farms	200,000,000	30
Cultural Heritage	50,000,000	10

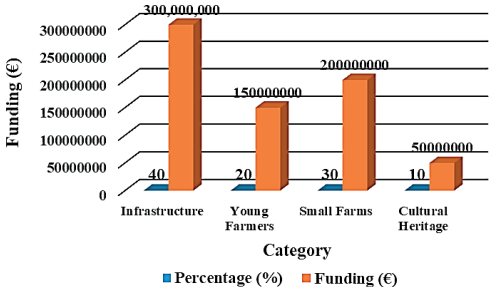

Figure 5. Funding distribution by category

This study, though buttressed with ample data gathering and analysis, is not free of limitations. Its dependence on government data can potentially lead to the exclusion of unofficial or unrecorded activities, and variations in data availability by region may impinge on the cross-region comparability of results. Still, the integration of qualitative and quantitative approaches provides ample probing into agricultural diversification in Romania's mountains.

Financial and physical performance of sub-measures

Implementation of NRDP sub-measures differed greatly in their financial and performance success, with significant disparity between various sub-measures and regions. As can be seen from Table 6, the fund utilization rates ranged from 63.66% for sM 4.1 to 84.50% for sM 6.1, indicating that schemes for the support of young farmers were realized more effectively than schemes for the support of bigger agricultural holdings.

Table 6. Financial and physical performance of sub-measures in mountain areas (2014-2020) (Source: AFIR, 2022)

Sub-measure	Financial allocation (€)	Projects submitted	Projects approved	Projects funded	Fund utilization (%)
sM 4.1	251,979,586	336	178	167	63.66
sM 6.1	100,362,967	3,579	2,557	2,268	84.50
sM 6.3	63,854,499	6,861	4,705	3,855	77.88
sM 7.2	148,355,461	121	90	84	75.50

The high performance of sM 6.1 ("Support for Young Farmers") is attributed to easier application processes and the availability of expert advisory services. Young farmers were able to get funding for diversification activities, e.g., agrotourism, organic production, and value-added production, which raised their competitiveness and income levels significantly. Figure 1 shows the increasing trend of approvals for sM 6.1 projects during the programming phase, which indicates higher awareness and demand for the project. Conversely, sM 4.1 ("Investments in Agricultural Holdings") was faced with complexity challenges in funding needs, which discouraged smallholder farmers from accessing assistance. Stakeholder consultations revealed that co-financing requirements and complicated paperwork were significant hindrances to small-sized agricultural businesses, particularly where administrative capacity is weak. Consequently, only 63.66% of financial resources were absorbed under this program, reflecting the need for process simplification (AFIR, 2022).

The performance of sM 6.3 ("Support for Small Farms") was remarkable, with a fund use rate of 77.88%. Through this scheme, small-scale farmers were able to modernize, purchase equipment, and diversify farm activities. The beneficiaries of the sM 6.3 experienced an average 25% income increase, as confirmed by qualitative interviews and financial data analysis. These findings emphasize the imperative function of targeted programs in strengthening the resilience of smallholder farmers (Oros, 2022).

Sub-measure sM 7.2 ("Investments in Basic Infrastructure") was used at a level of 75.50%, with emphasis placed on the development of rural roads, water supply, and other basic infrastructure. Although these investments are important for long-term rural development, their direct impact on agricultural productivity was lower than that of measures targeting farms directly. Stakeholders said that infrastructure development indirectly improved access to markets and lowered transport costs, which are major drivers of economic growth in mountains. The contrast between annual trends (Figure 6) highlights the diversity in the performance of the sub-measures. The consistent rise in project approvals for sM 6.1 and sM 6.3 reflects the

effectiveness of support schemes aimed at young and small farmers, which are tailored to the socio-economic realities of mountain regions. The relatively stable trend for sM 4.1, on the other hand, suggests ongoing challenges to access financing for relatively larger farm investments.

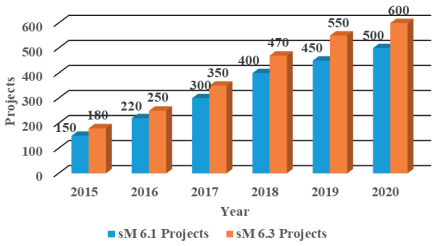

Figure 6. Yearly trends in project approvals for sM 6.1 and sM 6.3.

These findings point to the necessity for targeted policy measures to surmount regional disparities and administrative hurdles. Future editions of rural development programmes ought to consider the simplification of financing prerequisites, the expansion of advisory services, and the prioritisation of measures having direct applicability to the interests of young and small farmers.

Regional distribution of projects

The regional implementation of NRDP sub-measures showed notable disparities across mountain areas. Figure 7 illustrates the distribution of approved projects by region, highlighting the dominance of the Central and Northwest regions in terms of project approvals. These two regions accounted for the majority of approved projects, with significant contributions from sub-measures sM 6.1 and sM 6.3.

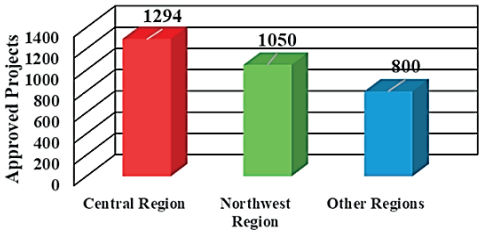

Figure 7. Distribution of approved projects by region (2014-2020)

This distribution is due to various reasons such as greater awareness levels, improved infrastructure, and increased access to avenues of funds in the Northwest and Central regions. In these regions, the local governments and agricultural associations were also actively engaged in assisting applicants by providing training workshops and consultancy services, thus boosting the success rate of applications (MADR, 2019). The agrarian potential of the areas was taken into consideration, as both sites are characterized by a high number of small-sized farms and young farmers, who are the primary target group for sM 6.1 and sM 6.3. For a better insight into the financial situation in relation to the project implementation, Table 7 gives a breakdown of the total funding allocated to different regions between the programming periods 2014-2020.

Table 7. Regional funding allocation for mountain areas (2014-2020) (Source: AFIR, 2022)

Region	Total funding (€)	Percentage of total allocation (%)
Central	98,563,215	32.1
Northwest	86,427,892	28.1
Other Regions	121,735,406	39.8

The Central region received the highest allocation of funds (32.1%), a reflection of its extensive participation in diversification and infrastructure investments.

This comes after the outstanding performance of the region in approving projects under sM 6.1, where young farmers reaped the most benefits.

Similarly, the Northwest region, which received 28.1% of the overall funding, had massive success in small farm modernization projects, which were implemented under sM 6.3.

While the bulk of the mountain UATs belonged to the "Other Regions" category (54.8%), they were assigned only 39.8% of the overall funding. This imbalance is proof of lingering problems such as lack of awareness of the available funding opportunities, poor advisory services, and infrastructural weaknesses that beset accessibility in these areas. The stakeholders in these areas were more likely to state difficulties in managing the complex application process and co-financing requirements, and this indirectly translated into lower approval rates for projects.

The skewed distribution of projects and finance identifies the need to decrease regional disparities. The Central and Northwest regions have benefited from their closeness to urban areas, which improved their market and logistical resource endowments. The regions also boast a history of structured farming operations and highly established farmer association networks, which played a crucial role in disseminating information about NRDP activities and providing technical assistance. On the other hand, "Other Regions" faced ingrained issues such as poorly developed infrastructure and advisory services' limited availability. Farmers from these regions indicated difficulties in product transportation to markets, expensive operations, and insufficient local facilitation in dealing with administrative demands.

In the interests of fostering equal access to finance and project opportunities for all mountain regions, policymakers can look to consolidate advisory services by sending regional advisors into rural areas to offer on-the-ground assistance to farmers. Investments in basic infrastructure such as roads, water pipes, and warehouses are key to reducing market access barriers and operating costs. In addition, increasing the frequency and coverage of informational campaigns in poorly performing districts will inform all eligible farmers about NRDP opportunities.

By tackling these imbalances, NRDP funding can achieve a more even effect on all mountain regions, promoting sustainable development and enhancing the well-being of farmers in less favored areas.

Socio-economic impact of agricultural diversification

Agricultural diversification has presently been introduced as a game-changing strategy to enhance the socioeconomic resilience of mountain farms in Romania. Incorporation of value-added practices such as organic farming, agrotourism, and processing of agricultural products has had a positively significant impact on farmers' incomes and created much greater opportunities for employment and the general economy. According to Figure 8, diversified farms, over a five-year period, reported an average income increase of 30% when compared with non-diversified farms.

Aside from financial advantages, diversification has acted as a stimulus for creating job opportunities in mountain areas. Small farms working in dairy processing, organic honey production, or agrotourism events have propped up local economies by creating demand for ancillary services. Farms benefiting from sM.63 ("Support for Small Farms") reported on average a 40% job increase, summarized in Table 8.

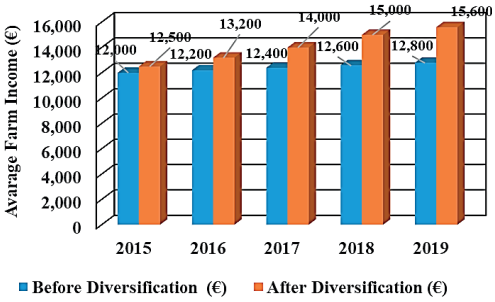

Figure 8. Changes in average farm income before and after diversification (2015-2019)

Table 8. Socio-Economic Benefits of Agricultural Diversification (Source: RNDR, 2015)

Indicator	Before diversification	After diversification	Change (%)
Average Farm Income (€)	12,000	15,600	+30
Employment Opportunities	3,000 jobs	4,200 jobs	+40
Market Access (Producers)	35%	60%	+25

A very recent development in this regard was particularly seen to create a positive impact in terms of access to markets. Farmers using strategies involving direct sales to consumers - either through farmers' markets or within the digital sphere - reported a 25% increase in the number of customers they reach. This is also another contribution to individual farm revenues and will enhance regional food security through an increase in the promotion of locally grown high-quality agricultural products (Oros, 2022).

Another critical benefit of agricultural diversification is that it can continue helping organizations engage in cultural heritage practices and techniques. For instance, program sM 7.6, which is involved in the investments of cultural heritage, led farmers to leave traditional

modes of production and integrate them into the modern to be effective. Some examples of this tend to indicate that artisanal cheeses, as well as the cultivation of varieties of crops deemed to have a historical context, allow for communities in mountainous areas to be economically viable. Yet, challenges continue. Farmers face barriers to diversification, such as financial limitations (45%), lack of adequate market infrastructure (30%), and limited technical assistance (25%), which underline the need for targeted policy measures to maximize socio-economic impact diversification, as shown in Figure 9.

In addition, climate change presents another growing challenge for mountain farming, as increasing variability in weather is affecting yields and profitability.

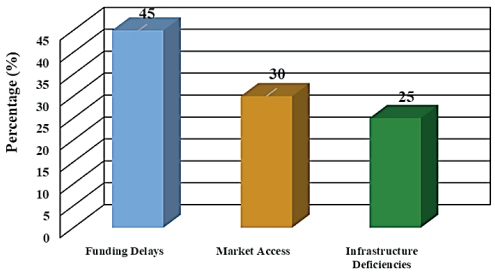

Figure 9. Proportion of projects affected by key issues

Diversified farms showed more resilience to these impacts, as their income streams were less reliant on a single crop or activity. For example, farms combining crop cultivation with agrotourism managed to survive droughts or floods better than others, with tourist income bolstering agricultural losses.

Moreover, diversification brings a more vibrant social dimension to the lives of rural people, whereby strengthening ties through collaboration among farmers, local authorities, and the organizations of regions. Cooperative marketing initiatives and collaborative knowledge-sharing platforms enhanced not only the economic outcomes but also advanced the social fabric of rural communities. The concerted efforts of the collective benefit regional diversification, spreading the whole gamut of advantages from individual farms to the region for inclusive and sustainable development.

For example, in the mountain regions of Sweden, traditional agriculture is threatened by the implementation of modern practices, leading to conflicts between biodiversity conservation and agricultural development. Society's expectations of farmers, such as providing recreational opportunities and maintaining cultural landscapes, create additional pressures. In addition, new support systems and regulations encourage the intensification of summer farms for modern meat production, which can lead to changes in the landscape and dissatisfaction among farmers (Rytkönen et al., 2016).

In rural areas, implementing biodiversity conservation measures can constrain agricultural development, generating environmental conflicts. These measures can limit agricultural land use and impose restrictions on traditional agricultural practices, thus affecting farmers' incomes and the sustainability of rural communities. To mitigate these conflicts, it is essential to develop policies that balance conservation objectives with agricultural development needs, promoting sustainable agricultural practices that protect biodiversity without compromising agricultural productivity (Barnaud & Couix, 2020).

CONCLUSIONS

This study pinpoints agrarian diversification as the very heart of promoting sustainability and building resilience for the mountain farms in Romania. This has been made possible by identifying contributions made and persisting challenges faced in the implementation and outcomes of NRDP sub-measures during the 2014-2020 programming period. The findings point to the benefits of diversification efforts in bolstering the socio-economic stability of the mountain communities. The farms that opened themselves to diversification strategies such as organic, agrotourism, and value-added production have raised their incomes to 30 percent. New job opportunities have also increased by 40% in the case of diversified farms, thus strengthening the local economy and reducing poverty in rural areas.

Despite those successes, the disparities in regional implementation are still evident. Central and Northwest areas accounted for most of the approved projects and funding allocations owing to better infrastructure, institutional

support, and higher awareness among farmers. In contrast, "Other Regions," which account for over half of mountain UATs, faced barriers like limited market access, poor infrastructure as well as administrative constraints, which resulted in much lower participation in NRDP programs. Addressing these inequalities is crucial to ensure equal funding and opportunity access across all mountain areas.

By diversifying these measures, a series of benefits for the environment and culture naturally appear. Through various Programs that support various aspects of traditional agricultural practices and investments in cultural heritage, the identity and uniqueness of mountain areas are maintained and at the same time new sources of income due to rural tourism and niche products specific to the respective areas are allowed to emerge. These programs highlight the dual role of diversification in promoting economic growth and sustainability. However, unfortunately, there will always be challenges such as financing delays, complex and cumbersome administrative processes and inadequate market infrastructure that always hinder the benefits of diversification. For example, farmers living in more remote areas have immense difficulties in accessing these resources and completing applications to feasibly apply diversification strategies.

Another important challenge is the impact of climate change, which exacerbates the already existing vulnerabilities of mountain agriculture. The most resilient farms are diversified farms, where income is spread across multiple activities and which are thus a buffer against environmental inequities. A good example is farms that combine agritourism with crop production and have spread the losses resulting from extreme weather events, thus suggesting crop diversification as a viable adaptation strategy. Maximizing agricultural diversification requires that, in future rural development programmes, the focus be on simplifying the administrative burdens associated with access to advisory services and investments in rural infrastructure. It is also necessary to expand training programmes and regional equity in the direction of focusing interventions on the needs of underperforming areas, and thus play equally important roles. The promotion of innovation in modern technology and techniques should generally be encouraged to increase productivity and competitiveness.

In conclusion, agricultural diversity is not simply a survival strategy, but clearly a transition towards sustainable development in all mountain regions.

Integrating traditional practices with modern innovations makes it possible for mountain communities to strengthen economic resilience, foster environmental conservation, and preserve cultural heritage. Lessons from the previous programming period of NRDP of 2014-2020 shall serve as fertile ground for future policies addressing the unique challenges mountain areas encounter. With continued support and collaboration, Romanian mountain farms can become a model in sustainable rural development at national and international levels.

Abstract

Since the dawn of industrialization, technological advancements have progressed rapidly, outpacing the planet`s natural resources` ability to sustain them. In the face of global warming, habitat destruction the imperative to invest in sustainable development practices has become increasingly evident. Clay-based construction materials are gaining traction at the national level, with their benefits recognized for the technical advantages and their contribution to the long-term durability of construction elements. The issue of vegetable waste is a large-scale, multifaceted challenge that continues to grow in urgency alongside rising consumption. Integrating vegetable waste into clay compositions exemplifies how traditional materials can be innovatively adapted to meet contemporary challenges. By combining ancient building techniques with modern knowledge and technology, clay composites can pave the way for a greener construction industry. This sustainable solution not only addresses pressing environmental concerns but also fosters a circular economy where waste becomes a resource. Through such practices, the construction industry can evolve into a model of resilience and sustainability for other sectors to follow.

Key words*: clay composite, sustainable development, vegetable waste.*

INTRODUCTION

Since the beginnings of industrialization, technological advances have progressed rapidly, exceeding the planet's natural resource capacity to sustain them. If modern society, in its industrial phase, was a production-based society, today, on a global scale, we live in a consumer society. The late 1970s marked the start of the hyper-consumption era, associated with the significant development of capitalist economies, which operate in an economy driven by the continuous and aggressive stimulation of demand, the constant creation of new and often unjustified needs, and the excessive consumption of goods and services. This has led to multiple social and environmental problems (Popescu et al., 2010).

In this context, an essential condition for the sustainable development of modern human society is the need to promote and develop sustainable production and consumption, adapted to the requirements of ecological resource management and environmental preservation (Geissdoerfer et al., 2017).

According to data published by the National Institute of Statistics, agriculture accounted for approximately 5% of Romania's GDP in 2022, generating over 60% of the total municipal waste in the form of plant waste (Hegyi et al., 2023). The issue of waste, seen in its entirety, is complex and large-scale, becoming increasingly strident as consumption continues to rise. These biodegradable wastes contribute, through their decomposition, to the emission of greenhouse gases, such as methane, further exacerbating climate change (Lachheb et al., 2023). The reuse of these materials in construction can significantly reduce their environmental impact (Cobzaru et al., 2017).

MATERIALS AND METHODS

In the presented study are described five types of recipes, based on matrices of clay, lime, sand, and cement, with plant-based materials (such as

straw) incorporated into each. These formulations were designed to create composite materials with improved properties by utilizing sustainable, locally sourced resources. The specific compositions of the clay, lime, sand, and cement matrices used in each formulation are presented in Table 1.

Table 1. The composition of the clay, lime, sand, and cement matrices

Materials	Indicative	R1	R2	R3	R4	R5
Clay	A	10 kg	7 kg	4 kg	13 kg	16 kg
Lime	V	20 kg	26 kg	32 kg	14 kg	8 kg
Sand	N	5 kg	3.5 kg	2 kg	6.5 kg	8 kg
cement	CI	5 kg	3.5 kg	2 kg	6.5 kg	2 kg
Straw	P	2 kg	2 kg	2 kg	2 kg	2 kg
Water	A	8l	8l	8l	8l	8l

The compositions of the different recipes are as follows:

- *Recipe R1* contains 50% lime and 50% of a mixture of clay, sand, and cement;
- *Recipe R2* contains 65% lime and 35% of a mixture of clay, sand, and cement;
- *Recipe R3* contains 80% lime and 20% of a mixture of clay, sand, and cement;
- *Recipe R4* contains 35% lime and 65% of a mixture of clay, sand, and cement;
- *Recipe R5* contains 20% lime and 80% of a mixture of clay, sand, and cement.

These formulations were designed to balance the mechanical properties of the materials with sustainable practices by incorporating agricultural residues such as straw, thereby reducing environmental impact while enhancing the thermal and structural performance of construction materials. Each of the recipes varied in terms of the lime-to-clay ratio, which influences the material's strength and thermal conductivity.

Straw, generated in significant quantities from wheat production (with Romania ranking 4th in the EU in this regard), represents an available resource, with millions of tons produced annually. Straw-light clay is a mixture of straw and clay with a density of less than 1200 kg/m^3, (Azzolino et al., 2020). This density is considered optimal for light clay with straw, providing a good balance between thermal insulation and material strength. The mixture allows for efficient insulation and adequate compressive strength, preventing deformation and loss of thermal properties (Petcu et al, 2023). If the density exceeds 1200 kg/m^3, it is referred to as clay with straw. The resulting material is denser, stronger, with reduced insulating properties, and becomes heavier and harder to handle during construction.

Elements with densities under 600 kg/m^3 are not recommended because the resulting material would be too fragile and prone to sedimentation and rot of the straw due to moisture infiltration. In this case, the straw is more vulnerable to microbial attacks and pests (such as wood lice), which can affect durability (Tavakoli, 2015).

Although studies have been conducted on selecting the appropriate types of straw, more important than the type of straw is the structure of the nodes (Figure 1).

Figure 1. The structure of the nodes in wheat straw

Straws with rigid nodes are preferred to increase thermal insulation because they do not deform easily and keep the air trapped inside, prevent excessive compaction of the clay-straw mixture, as these do not easily deform under the weight of the clay (Barone et al., 2011). This improves the durability and thermal insulation properties of the material. They also contain cellulose and lignin, which reinforce the plant stem's structure. These components are resistant and help protect against rot and degradation under the influence of moisture. At the same time, lignin provides resistance and structural durability. As the plant matures, the lignin in the nodes becomes more concentrated, further strengthening the node structure and giving an advantage to older straws, which are better suited for construction.

The length of the straw should not exceed the thickness of the elements. The straw can be cut by various mechanical methods (with specialized machines or shredders) or manually (with scissors or other tools).

Adding straw to the mixture can significantly reduce the shrinkage of the clay. Since the fibers increase the bonding strength of the mixture, cracks are minimized. To avoid the internal rotting of the straw, fungal growth, and to reduce shrinkage, clay elements with straw additions are recommended to have a thickness of less than 25 cm (Minke, 2000).

The workability of the clay composite can be improved by additives. The shrinkage process is influenced by the amount of sand or other large aggregates, the water content, the types and amounts of clay minerals, the distribution of the granulation of the aggregates (Calatan et al., 2020). The analysis of the clay's composition can be performed through a series of field tests (Carraro et al., 2021), such as water content test, sedimentation test, and ball throwing test, as well as laboratory conditions: Atterberg plasticity test, Proctor compaction test, and drying shrinkage test.

The addition of chopped straw contributes to increasing the bonding strength of the mixture, reducing the appearance of cracks (Figure 2 and Figure 3).

Figure 2. The introduction of straw into the composition

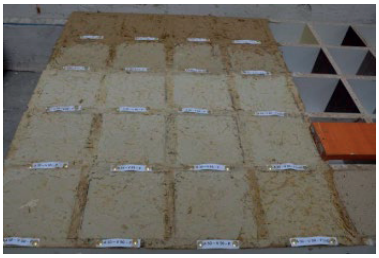

Figure 3. Casting of the samples

To enhance stability, straw is incorporated into the composition using a mechanical mixing process. The stabilizers coat the clay minerals, preventing water infiltration and minimizing volumetric changes.

Water resistance can be increased by altering the distribution of the earth and sand granulation. The straw bale technology (Minke, 2000) involves placing straw bales on the foundation and covering them with a layer of clay. This protects the straw from moisture and helps improve thermal insulation. The technology is fast and efficient, and the straw bales provide a stable frame and good protection against extreme temperatures.

The "Clay-Straw" technology (Goodhew & Griffiths, 2005) involves mixing straw with clay to produce a composite mass used for manufacturing tiles or panels. These elements are dried and subsequently installed on-site. This technology enables the rapid construction of walls while providing a user-friendly material with good thermal performance.

The "Tuf with Straw" technology combines tuff with straw to produce a lightweight yet strong construction material (Belayachi et al., 2016). The tuff helps stabilize the structure, and the straw improves flexibility and insulation. The structured elements are then assembled on-site and protected with a layer of clay or other materials to make them more durable.

The "Rammed Earth with Fibers" technology involves combining raw clay with fibers such as straw or hemp, which are then compacted within a mold to construct solid walls (Tesoro et al., 2021). Although traditional rammed earth technology uses earth without fibers, adding fibers increases flexibility and crack resistance. The clay is mixed with sand and fibers to create a more durable and elastic material. Water is added to help form the mixture. The clay-fiber mixture is placed into a mold and compacted with a hammer or a mechanical device to ensure density. The wall is built layer by layer, with each layer being compacted to increase its density and strength. Controlled drying helps achieve solid and durable walls.

The "Adobe" technology involves mixing unbaked clay blocks with fibers to improve cohesion and strength (Illampas et al., 2009). The blocks are poured into moulds and left to dry in the sun, then used to build self-supporting

walls. This is a traditional and cost-effective construction method, with reduced costs. Adobe blocks have excellent insulation properties and are resistant to extreme temperatures. The cement addition aims increase the compressive strength, improve mechanical performance and durability of the traditional material without compromising thermal insulation properties. Cement reduces porosity and improves water resistance, making the material less susceptible to cracking and deformation under load while providing protection against environmental factors such as moisture and temperature fluctuations. The use of cement in unburned clay with straw elements must be well calculated so as not to decrease the thermal performance of the material (Mircea et al., 2021). Too much cement quantity can reduce the insulating capacity of the straw, which could negatively affect the energy efficiency of the construction. The ideal is to find an optimal balance between straw, clay, and cement to achieve a strong and durable material with good thermal properties.

RESULTS AND DISCUSSIONS

The behaviour of composite thermal insulation materials based on plant fibers in a clay-lime matrix has been studied by performing the following measurements at the material level, in accordance with the laboratory procedures and relevant standards (Bailly et al., 2024; Zhao et al., 2021).

The linear dimensions were determined using a caliper with an accuracy of 0.01 mm, densities of samples dried at 80°C were measured using the gravimetric method, mass was determined using a balance, thermal conductivity, and thermal resistance of samples dried at 80°C were evaluated using the thermofluxmetric method.

Finally, the compressive strength was measured by applying a uniformly distributed load to the samples, which was gradually increased until rupture (Table 2, Figure 4 and Figure 5).

All these procedures allow for a comprehensive characterization of materials and a detailed understanding of their mechanical and thermal performance.

Together, these detailed measurements allow for a complete picture of the physical-mechanical characteristics of the material to be obtained for determining its suitable applications in sustainable and energy-efficient constructions. They are also suitable and for selecting the optimal material for the specific conditions of the project and ensuring a balance between mechanical performance and thermal efficiency.

Table 2. Maximum load at failure and compressive strength

Recipe	Length (mm)	Width (mm)	Thickness (mm)	Area (mm^2)	F (kN)	f_b (N/mm^2)
R1	145.6	146.36	146.35	21,308	18.1	0.85
R2	146.64	145.47	147.33	21,332	13.7	0.64
R3	145.29	148.3	143.73	21,548	13.3	0.62
R4	145.32	147.27	146.88	21,401	14.8	0.69
R5	146.88	145.96	146.6	21,581	16.1	0.75

Figure 4. Testing of R2 samples

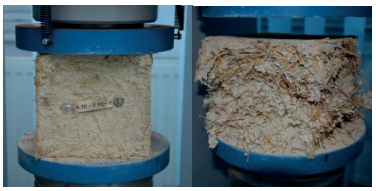

Figure 5. Testing of R3 samples

The data from Table 2 shows that the maximum load at failure (F) and compressive strength (f_b) vary depending on the recipe, with compressive strength values ranging between 0.62 and 0.85 N/mm^2, indicating differences in the structure and mechanical behaviour of the tested materials. These differences can be attributed to the variability of the ingredients in the composition of each recipe, which directly influences the material's structure, mechanical behaviour, and stability against environmental factors.

Recipe with 50% lime and 50% of clay, sand and cement mixture shows the best compressive strength, indicating superior mechanical performance, while recipe with 80% lime and 20% of clay, sand and cement mixture has the lowest strength, which could impact its use in demanding structural applications.

Data from Table 3 highlight significant variations in thermal conductivity (0.1332-0.2306 W/mK) and thermal resistance (0.27-

0.46 m²K/W), suggesting that certain recipes are more efficient in thermal insulation than others. Recipe with 80% lime and 20% clay, sand, and cement mixture shows the best performance as a thermal insulator, while recipe with 20% lime and 80% clay, sand, and cement mixture is the least efficient in this regard.

Table 3. Thermal conductivity and thermal resistance

Recipe	Thickness (m)	Thermal conductivity (W/mK)		Thermal resistance (m^2K/W)	
R1	0.0625	0.1577	0.1535	0.40	0.41
R2	0.0636	0.1492	0.1453	0.43	0.44
R3	0.0610	0.1369	0.1332	0.45	0.46
R4	0.0615	0.1742	0.1696	0.35	0.36
R5	0.0623	0.2368	0.2306	0.26	0.27

Recipes with lower conductivity have higher thermal resistance, making them more suitable for applications where thermal insulation is important.

The results suggest that higher lime content enhances thermal resistance, while higher cement content improves mechanical strength. The key takeaway is that a moderate use of lime and cement allows for a balance between durability and environmental sustainability.

The studied recipes may represent an excellent option for sustainable and eco-friendly construction, with improvements in both mechanical and thermal performance. However, using this mixture requires a balance between ecological advantages and technical requirements, with particular attention to the materials used and their environmental impact. A moderate use of cement and lime can help achieve a balance between durability, performance, and ecology.

CONCLUSIONS

The mixture containing 50% lime and 50% clay, sand, and cement demonstrated the best mechanical performance, while the mixture with 80% lime and 20% clay, sand, and cement provided the best thermal insulation. The selection of the appropriate material depends on the intended application: for high mechanical strength, the 50% lime and 50% clay, sand, and cement mixture is the optimal choice, whereas for enhanced thermal insulation, the 80% lime and 20% clay, sand, and cement mixture is preferable.

To enable the creation of new domestic products and methodologies, with lower costs compared to imports, targeting the balance between accessibility, cost, performance, durability, and optimizing insulating materials composed of renewable raw material resources, further experimental research is needed, either in the laboratory or on-site, to provide new insights regarding the maintenance of thermal, mechanical, and hygroscopic characteristics over time.

THE IMPACT OF EXTREME WEATHER PHENOMENA ON THE MANAGEMENT OF CONIFEROUS STANDS

Ghiţă Cristian CRAINIC

University of Oradea, Faculty of Environmental Protection,
26 General Magheru Street, 410048, Oradea, Romania

Abstract

Coniferous stands are relatively vulnerable to the impact of extreme weather events, often being affected by windfalls, because the spruce species (Picea abies L.) has a trailing root system. As a result, high-intensity winds cause windfalls on compact surfaces and the breaking of tree crowns and trunks. Windfalls in spruce stands also affect the forest soil, on considerable surfaces. The case study was carried out in spruce stands in the Horea Apuseni Forest District, Alba County, which were affected by windfalls and breakages. The objectives of the case study refer to the impact of the extreme weather events of 2011-2017 on spruce stands, forest soil and implicitly on the management of the affected forest unit. The wood affected by these extreme phenomena was valued at a price specific to the assortments and quality of accidental wood products, registering considerable financial losses. Also, a microrelief specific to wind fellings was formed, with a extremely negative impact on the ecological rehabilitation process of the affected spruce stands. The regeneration process of these stands was carried out over a relatively long period, 10-12 years, with very large financial efforts

Key words*: extreme weather events, spruce stands, forest soil, accidental wood products, ecological rehabilitation.*

INTRODUCTION

Spruce-dominated coniferous stands in mountainous areas are highly susceptible to windthrows and windbreaks caused by extreme weather events.

In recent years, the frequency of extreme weather events has increased, and as a result/ thus, their effects have significantly influenced the stability of spruces. As a result, spruce stands in the stages of youth and maturity, which are characterized by relatively high thickness and density, are relatively vulnerable to windthrows and windbreaks.

The increasingly evident emphasis of climate change exerts a direct influence on the frequencies and intensities of extreme weather events in areas covered with forest vegetation in Europe. As a result, major issues have been reported in spruce (*Picea abies* L. Karst) stands.

Although they are considered some of the most important forest formations in Northern Europe, in terms of ecological and economic importance, they present a high vulnerability to the action of strong dominated winds (Krišans et al., 2020). Because the spruce species has a trailing root system, uprooting and felling caused by potentially destabilizing environmental factors, such as strong winds, high-intensity storms, heavy rainfall, and especially combinations thereof, are frequently reported (Figure 1) (Cristea, 2004).

Figure 1. Root system of a windthrown spruce tree (Crainic, G. C., 25.07.2011, plot 80A, Production Unit I Vadul Moţilor, Horea Apuseni Forest District, Alba County)

The image in Figure 1 indicates that the windthrown spruce specimen has a superficial root system, with roots developed horizontally and without a distinct central taproot.

As a result, the cause of the low degree of ecosystem stability of spruce stands to the destabilizing action of high-intensity winds is due to the architecture of the spruce roots, which is essential for their anchoring in the soil and their stability. In well-drained and deep soils, spruce roots develop optimally, and the volume of the root system, consisting of roots and soil, is large, ensuring high anchoring and stability. Consequently, on shallower soils, with rock relatively to the surface, the volume of tree root systems is reduced, and the anchoring and stability of trees is considerably reduced (Krišans et al., 2020).

Figure 2. Spruce stand in plot 83A, affected by windthrow and windbreak (Crainic, G. C., July 25, 2011, Production Unit I Vadul Moţilor, Horea Apuseni Forest District, Alba County)

Climate change is recognized as one of the biggest problems the world is facing nowadays, representing a potential threat to the environment (Psistaki et al., 2024). These favor and trigger a series of extreme weather phenomena, which represent major stress and destabilization factors for forest ecosystems, causing both immediate and long-term effects (Barbagallo et al., 2024).

Windthrows and windbreaks, as direct effects of extreme weather events, cause major changes in the growth, development and evolution of coniferous stands. In this context, both isolated trees and compact stands are affected, with a particularly strong ecological, social and economic impact.

In Romania, in recent years, a series of windthrows and windbreaks have been reported in spruce stands. These events impacted large areas of spruce forests in the Apuseni Carpathians during July 2011 (Figure 2) and September 2017, affecting stands at multiple developmental stages (Crainic et al., 2024).

Exploitable stands were also affected, on various areas in the Curvature Carpathians (a transitional zone between the Eastern and Southern Carpathians of Romania) in February 2020, such as the upper basin of the Bâsca River where large-scale windfalls were recorded in 1995 (Ciocirlan & Câmpu, 2024).

Recent research conducted in the Curvature Carpathians, mainly pure spruce stands, located on land with a slope between 16 and 30°, highlights the fact that the impact of extreme weather phenomena had a maximum intensity when the wind came from the north - northeast direction, and reached a maximum speed of 32 m/s (Ciocîrlan & Câmpu, 2024).

In recent decades, windthrows and windbreaks, followed by bark beetle infestations, represented by the species *Ips typographus* L. in softwood stands, have caused widespread disturbances in forest ecosystems. As a result, the Earth's carbon balance has been significantly affected, modifying soil respiration, with direct implications for the decrease in gross primary productivity in the affected stands (Bozzini et al., 2023; Tomes et al., 2024).

Dead wood from trees affected by extreme weather events influences the increase in soil heterogeneity, due to the formation of a specific microrelief due to windfalls (Geambaşu, 1984; Kikeeva et al., 2024). A series of soil properties are also determined by the physical and chemical characteristics of wood during its decomposition, under the direct influence of environmental conditions and

microorganisms in forest ecosystems (Sicoe et al., 2023; Kikeeva et al., 2024).

Recent studies confirm that fallen spruce logs, in moderate and advanced stages of degradation, have a direct influence on the horizontal distribution and heterogeneity of the soil cover with herbaceous and shrub species, in the area bordering them. Consequently, dead spruce wood influences the coverage of the bordering areas with acidophilic and slightly acidophilic species. It was also found that the impact of wood in different stages of decomposition on soil heterogeneity parameters can be traced up to 20 cm from the tree (Kikeeva et al., 2024). Storms in recent years have also affected the stands of conifers of the *Pinus halepensis* and *Pinus sylvestris* species in the Mediterranean forest area. Their effects on soil characteristics were evident, as a result of which the percentage of clay increased in the gaps where the trees were felled, and the value of the concentrations of the elements K and Mg decreased. As a consequence, especially the soil surfaces that were affected by the destruction of the *Pinus halepensis* stands became less fertile, being dominated by species of bacteria specific to the new conditions created (Camarero et al., 2021).

Studies conducted in balsam fir - *Abies balsamea* (L.) Mill stands, which grow over large areas in Quebec and are very vulnerable to the impact of strong winds, highlight their differentiated stability, depending on the growing season, season and the specific climatic elements, especially precipitation. As a result, the moment of recovery from bending of balsam fir trees (*Abies balsamea)* is relatively greater in winter than in summer (during the growing season) for the same characteristics of the dominant wind (Duperat et al., 2020).

Although harsh winter conditions, with low temperatures and heavy snow, are considered to pose an additional risk to the stability of trees and, implicitly, of the branches, the increase in the resistance and rigidity of the stem and root system during freezing temperatures and the change in wind flow through the forest, due to snow on the canopy and on the ground during this period, is evident (Duperat et al., 2020).

There are cases where windthrows and windbreaks can significantly interfere with management practices applied in some forest ecosystems. In situations where the impact of extreme weather events is frequently reported, without any human intervention, management and regeneration cutting of stands carried out without adequate management for the respective seasonal conditions, can lead to an increase in the ecosystem instability of the respective stands (Ruel, 2020). As a result, a series of concerns are currently being reported for promoting a management of forest ecosystems using natural disturbances related to their stability (Ruel, 2020). It is obvious to promote an adaptive management for this particular situations which are in many cases even extreme (Pomara & Lee, 2021).

Adopting a management approach, that has as its main objective the minimization of damage induced by strong wind storms in various forest ecosystems, can be based on the knowledge and results obtained from the vast research and studies carried out to date in this field. Consequently, the use of complex management templates, obtained based on the simulation of the conditions for facilitating and achieving fellings and ruptures caused by strong prevailing winds, can be successfully exploited for the design of optimal strategies for sustainable management of forest resources (Ruel, 2020).

The use of wind damage prediction and simulation models, such as ForestGALES_BC, for a series of boreal stands in North America, for both normal and extreme wind speeds, has made it possible to create the premises for adopting optimal decisions and strategies regarding risk management and planning for competitive forest management (Anyomi et al., 2017). The results of the simulations in the studied stands present the following three scenarios:

- at a wind speed of 5 m/s, the estimated amount of felling varied from 0 to 20% of the area;
- for winds with a speed of 20 m/s, the damage increased to 2 to 90% of the area;
- for winds of 40 m/s, the damage varied from 10 to 100% of the area (Anyomi et al., 2017).

The area affected by windthrows, and respectively their intensity, varied depending on the type of stands. As a result, the stands that present high ecosystem stability are those

represented by deciduous, hard-core species (Anyomi et al., 2017).

The genetic diversity of tree populations is one of the most important factors determining the stability and sustainability of forest ecosystems. The results of recent studies on the possible changes in the genetic diversity of naturally regenerating populations of spruce and Scots pine in various habitats indicate that a pronounced genetic diversity in regenerating populations provides a basis for the formation of stands capable of adapting to constantly changing climatic conditions (Verbylaite et al., 2017).

Naturally regenerated spruce and Scots pine seedlings, which were randomly analyzed from a spatial point of view, presented the same genetic diversity as the presumed maternal populations. Therefore, the genetic differentiation between trees from maternal populations and the naturally regenerated seedlings from them was low for the two species. More than this, information about the genetic dynamics of natural populations of Scots pine and spruce species that were studied may be important for the analysis and assessment of possible changes in genetic diversity at a local scale, which were induced by the disturbance of ecosystem stability and the interruption of the climax state and, respectively, by the modification of vegetation conditions in the new habitats related to the stands on which they were established (Verbylaite et al., 2017).

The variability in site conditions, genetic diversity of coniferous stands, and the forest management strategies employed are key factors in enhancing stand resilience to extreme weather events.

The solutions proposed by current forest strategies, to protect and promote ecosystem services and biodiversity, require a deep understanding of how global climate change will affect the dynamics and processes in forest ecosystems (Girona et al., 2023).

MATERIALS AND METHODS

This case study was conducted in nine coniferous stands within Production Unit I Vadul Moților, managed by the Horea Apuseni R.A. Forest District in Alba County (Figure 3), which were severely impacted by windthrows and breakages resulting from the extreme weather event of July 20, 2011.

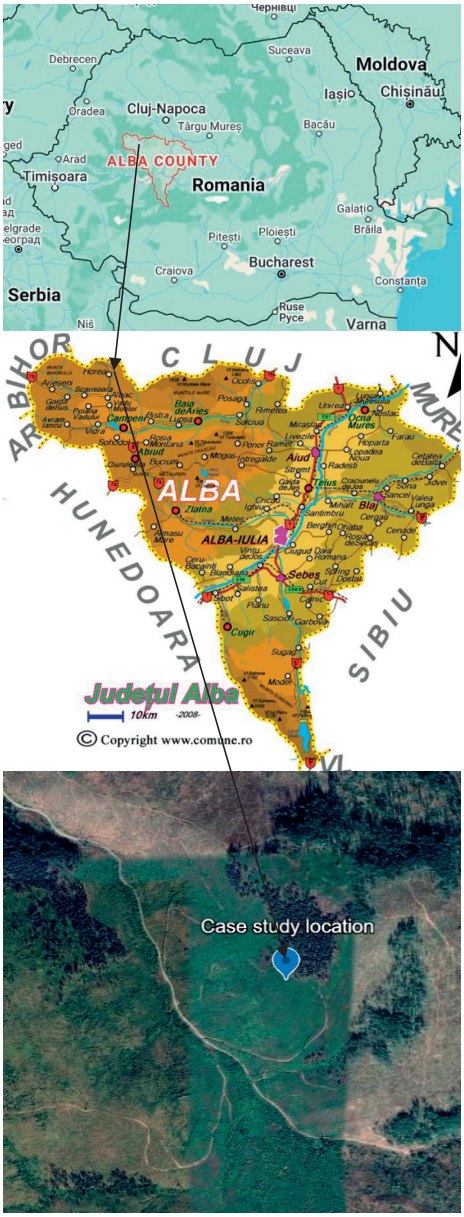

Figure 3. Case study location (https://www.google.com/search...; https://www.comune.ro/?/judet/ijud1/.; https://earth.google.com/web/search/Cabana...)

The objective of this study is to analyze the impact of the July 20, 2011 extreme weather

event on the management of coniferous stands severely affected by windthrows and windbreaks.

Field surveys were conducted to identify the affected stands, followed by stationary observations to determine the specific interventions required for their rehabilitation.

The experiment involved a complete inventory of the affected trees and the implementation of ecological rehabilitation measures.

Since the studied stands were entirely affected by windthrow and windbreak, for the quantitative-and implicitly, economic-assessment of the damaged timber, the technical regulations in force within the forestry sector and the Forest Code require a complete inventory of these areas.

All trees affected by the extreme weather event of July 20, 2011, were inventoried, and their volumes were calculated using the SUMAL 1.0 software. The economic value of the assessed timber was determined in accordance with the legal regulations in force at that time.

To study the factors and conditions that contributed to the occurrence of windbreak and windthrow events, elements of the forest site were analyzed, specifically the vegetation conditions and the characteristics of the forest vegetation. For the studied stands, the corresponding forest management plan was analyzed in detail, in parallel with field observations.

Rehabilitation efforts included the removal of harvesting residues, completion of regeneration through planting, and the management of mixed stands until they reached a closed-canopy (massif) condition. Materials used for the study included the project and management map of Production Unit I Vadul Moţilor (Horea Apuseni Forest District, Alba County), accounting records, forestry work contracts, relevant technical regulations, and specialized software for the quantitative and economic evaluation of the damaged timber.

RESULTS AND DISCUSSIONS

Analysis of the seasonal and vegetation conditions of the affected stands, summarized in Table 2, revealed that all plots shared similar stand types, soils, and forest classifications. The average elevation ranged from 1,300 to 1,475 meters, while slope gradients varied between 12 and 23. According to Figure 4, 34% of the plots faced east, 33% north, 22% southwest, and 11% northeast, indicating two predominant and two intermediate exposure types (Table 2). Most affected plots were located on undulating slopes in a proportion of 89% and the undulating upper slope in a proportion of 11% (Table 6).

Regarding the composition of the affected stands, 45% are almost pure, 44% are mixed and 10% are pure (Figure 7 and Table 2).

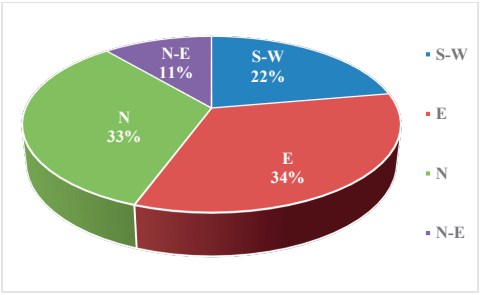

Figure 4. Distribution of affected plots according to exposure

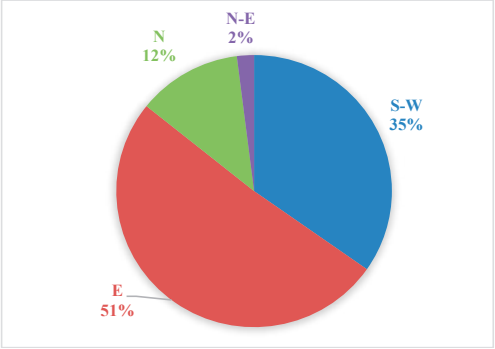

Figure 5. Volume distribution of affected trees by stands exposure

According to the results shown in the diagrams in Figures 4 and 5, the NE exposure accounts for 11% of the surface area of the affected stands, while the volume of affected trees in stands with this exposure represents 2% of the total volume.

Based on field observations, the direction in which the trees were windthrown is NE-in areas shaped like parallel strips. Consequently, the wind that caused the damage blew with high intensity from this direction.

Recent studies on spruce stands in two management units within the Curvature Carpathians - located opposite to the prevailing wind direction and situated at elevations between 1,300 and 1,500 meters on cambisols and spodosols - have yielded differing results. The same environmental factors were found to influence the intensity of windthrows and breakages inconsistently, with some factors proving statistically insignificant or relevant to only a small portion of the observed variation (Ciocîrlan & Câmpu, 2024).

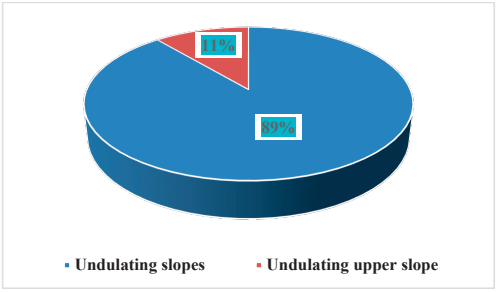

Figure 6. Distribution of affected plots according to landform

Consequently, based on current research and considering recent climate change trends, it remains challenging to accurately determine the relative contribution of predisposing factors and immediate triggers to wind-induced fellings and breakages across the studied stands.

As a consequence, it is relatively difficult to accurately determine the proportion of predisposing and triggering factors responsible for windthrow and windbreak in the studied areas based on the analysis of research conducted in stands affected by extreme weather events - both coniferous and broadleaved - within Production Unit (P.U.) VII Văratec, Sudrigiu Forest District, Bihor Forest Directorate, from 2017 to the present (Research contract no. 9, 19.07.2019), and considering the trend of climate changes in recent years.

Following the analysis of the affected stands and the complete inventory of windthrown and broken trees, the presence of accidental wood products was confirmed.

Given that the age of these stands exceeded half of their exploitable rotation age, the resulting timber was classified as 'Accidental I' products (Figure 8).

In accordance with current forestry regulations, such products are assimilated to the main wood harvest and are therefore deducted from the allowable cut volume established in the existing forest management plan (Paluš et al., 2020; Law 331/2024 Forestry Code, 2025).

After processing the field data, the values related to the volumes for each plot were obtained. The total volume of trees inventoried and considered as accidental products I, in the nine affected stands, is 28,466 m^3, on an area of 147.30 ha (Table 1). The market price was primarily influenced by wood quality, which declined significantly due to damage from windthrows and windbreaks (Figure 9a).

Ecological rehabilitation of the affected stands involved a range of targeted interventions (Govedar et al., 2018; Research contract no. 9 19 07 2019). The use of tree species for the regeneration of wind-damaged stands must ensure increased ecosystem stability. As a result, the compositions used must be made up

of tree species with ecological behavior adapted to environmental conditions in areas vulnerable to the effects of extreme weather phenomena, in order to ensure consolidated ecosystem stability (Ikonen et al., 2020; Konôpka et al., 2021).

Priority was given to promoting biogroups of naturally regenerated spruce, established effectively through wind-assisted seed dispersal (Figure 8). As a result, natural regeneration was successfully achieved on a total area of 57.10 hectares (Table 4), in the upper part of the slopes, bordering the unaffected stands, which produced abundant fruit during the period 2011-2014. In areas where natural regeneration did not occur, reforestation was implemented through staged artificial planting, using species-specific approaches tailored to site conditions.

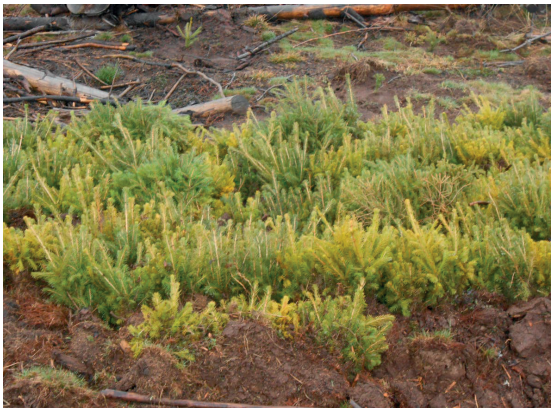
Figure 8. Trees broken and felled following extreme weather events, in the stand of plot 63 A (G. C. Crainic, July 25, 2011, Production Unit I Vadul Moţilor, Horea Apuseni Forest District, Alba County)

The artificial regeneration process involved a series of specific forestry operations, including the following technical works:

- C1IIIb - clearing land in preparation for afforestation;
- C21.a+b1 - developing or redeveloping storage glaciers for seedlings;
- C20IIb3 - excavating trenches for seedling storage;
- C23Ic12 - transporting seedlings by manual carrying;
- C24Ia1 + C24IIa - storing seedlings in trenches and preserving them in glaciers;
- C70Ic - planting seedlings in planting spots on unprepared land designated for reforestation;
- C70Ic - planting seedlings in hearths in unprepared land, in lands intended for reforestation.

In areas where incidental wood products had been harvested and natural regeneration did not occur; it was necessary to mitigate the negative impacts of logging.



To ensure optimal conditions for artificial reforestation, logging residues and abandoned wood - primarily from broken trees - were collected and deposited in uprooting cavities and small clearings (Figure 9a). Stages of carrying out regeneration and maintenance works on areas where accidental products have been harvested are suggestively illustrated in the images in Figure 9.

Much of the wood, particularly from visibly damaged or weakened trees, was left in various parts of the impacted plots. As a result, this aspect affected the health of the neighboring stands and, respectively, of the future mixed regenerations that were established between 2012 and 2024.

Consequently, in the spring of 2015, an attack of the spruce sapling borer - *Hylobius abietis* L. on spruce saplings, artificially regenerated (Figure 10).

Figure 10. Attack of the species *Hylobius abietis* L. on spruce seedlings, in artificial regenerations in the affected plots (G.C. Crainic, 03.04.2014, plot 84B, Production Unit I Vadul Moţilor)

To prevent these pests, poisoned baits were used, made from fresh spruce bark that had been treated with insecticide (Figure 11). As a result, the effects of the attack were limited to an area of 2.00 hectares, on which the regeneration of the spruce species was completely compromised.

Another consequence of maintaining considerable quantities of wood in the affected plots was the reduction of the area on which it was necessary to establish forest vegetation in the following decade.

Bare-rooted seedlings of spruce, fir and larch species were planted on an area of 90.20 hectares (Table 4). The number of seedlings planted per hectare was 5000, which were arranged in a rectangular arrangement (in the corners of a rectangle), at 1 m per row and 2 m between rows.

The saplings used for the afforestation works were purchased by the owner of the forest fund, respecting their area of origin.

Figure 11. Combating the attack of the *Hylobius abietis* L. species with poisoned baits, made from fresh spruce bark, which has been treated with insecticides (G.C. Crainic, 03.04 .2014, plot 84B, Production Unit I Vadul Moţilor)

86B	4.90	5.20	
Total	**57.10**	**90.20**	-

Until they were transported to the plantation site, the saplings were kept on the ice, in optimal conditions, in accordance with the technical regulations in force. On the day they were planted, they were transported and stored in the ditch, in the afforestation site, with the

roots covered with soil to protect them from degradation (Figure 9c).
Biogroups of larch seedlings were placed on the areas exposed to the wind (Figure 12), fir seedlings were planted in the wetter, relatively shaded portions, and spruce seedlings were planted on the surface difference (Figure 13).
The works necessary for the management of natural and artificial regenerations until the achievement of the under-canopy stage were represented by:
- completion of regeneration through plantations of bare-root seedlings of spruce, fir and larch species;
- C58Ib-clearing of forest species of grassy, shrub and woody species over the entire surface;
- C58IIb3-clearing of forest species of grassy, shrub and woody species around the seedlings;
- C46c-review of natural regenerations and plantations.

Figure 12. Larch seedlings planted in an area exposed to the wind, in plot 86B (G.C. Crainic, 03.04 .2014, Production Unit I Vadul Moților)

The work to complete the natural and artificial regeneration was carried out by planting bare-root saplings on the areas where it is missing on an area greater than 9 m^2 (Figure 14). The working technique is similar to that of integral plantations. Consequently, completions were carried out with saplings of the three previously mentioned coniferous species.
The excessive grassy, shrubby, and woody vegetation around the spruce sapling groups, which were established naturally and artificially, was removed was carried out manually and mechanized with power tools with cutting discs (Figure 9d), as appropriate.
These works were carried out towards the end of the vegetation season, starting on September 15, for reasons that depend on the evolution of the climate in the mountainous areas, but equally on local experience.

Figure 13. Spruce seedlings planted in an area without natural regeneration, in plot 85B (G.C. Crainic, 03.04.2014, Production Unit I Vadul Moților)

The works to review the natural and artificial regeneration aimed to remove the remains of grassy, shrubby and woody vegetation from the saplings, after the snow melted, and bring them to a vertical position. During these works, all the surfaces undergoing regeneration were covered, and these were effectively carried out only in the areas where the saplings were affected.
The achievement of the under-canopy state for natural and artificial regeneration on the surface of the affected plots was carried out in successive stages, during the period 2014-2024, due to the climatic conditions in this interval.
In accordance with Order no. 2537 of September 28, 2022, the under-canopy state for natural regeneration of coniferous trees is considered achieved when the height of the

seedlings is 1.00-1.20 m, and in artificial regenerations the height of the seedlings varies between 1.20-1.40 m (Figure 9b).
Consequently, work was necessary to complete the regeneration in considerable areas, due to high temperatures and lack of precipitation during the vegetation season. These climatic elements were the main limiting factors that conditioned the final success of the established silvicultural crops.

Figure 14. Spruce saplings, planted during the regeneration completion works, to protect a stump (G.C. Crainic, 03.04 .2014, Production Unit I Vadul Moţilor)

All works carried out between 2012 and 2024 were considered investment works and were financed from the conservation fund, which was set up in the amount of 25% of the total value of the incidental wood products I, considered as main products, from the affected plots. Therefore, the conservation fund corresponding to the volume of wood recovered is 1,206,326.25 ron, the equivalent of 281,476.13 euro.
The recovery of spruce wood from the affected plots at an average price of 169.51 lei/m^3, or the equivalent of 39.55 euros/m^3, was carried out under extreme conditions, given its quality (Figure 8). If the price of the softwood wood is considered, obtained from main products, it is found that it has at least double the value compared to that of accidental products I. It is also found that the wood from the affected plots was recovered at a lower price, thus registering a consistent economic loss.
Recent studies conducted in Italy have also highlighted that following the storm in 2018, in the Upper Valtellina area, during the period 2019-2020, losses due to wood destruction were recorded, amounting to 5.10 million euros for the Valdisotto location, 0.32 million euros for Valfurva and 0.43 million euros for Sondalo, respectively. These losses were also added to those caused by the lack of carbon sequestration on the affected areas (Barbagallo et al., 2024).
Although the high diversity of tree species cannot necessarily cushion the economic consequences due to extreme weather phenomena (Fuchs et al., 2024), it nevertheless constitutes a factor of stability in spruce stands in the mountain area.
To promote an adaptive forest management, it is necessary to consider the concept of expected loss. This is an appropriate measure for integrating risk when establishing tree species and determining the optimal period of the production cycle (Möllmann & Möhring, 2017).
An alternative (differentiated) forest management can provide a specific value of resilience to storm adaptations. As a result, the specific goals of the cultivation and management of the stands and their structure, respectively, aim to maximize tree growth and resistance to various stresses and disturbances, rather than optimizing their productivity (Hahn et al., 2021).
To reduce the risk of future windthrows in the spruce stands, it is recommended to improve young plantation composition by introducing 30-40% beech species (Govedar et al., 2018).
The efficiency of the establishment works of forest vegetation on the surface of the affected plots could be achieved if there were conditions for direct sowing, with certified seeds of spruce, fir, larch and beech species.
It is also necessary to analyze the post-disturbance time period and the intensity of the disturbance (Camarero et al., 2021), in order to evaluate the growth and development dynamics and respectively the resistance of future stands, in a spatio-temporal approach.
Currently, it is necessary to promote forestry policies and strategies that ensure the reduction of investment risks for forest owners, in order to promote stable forests, with a diversified

structure, that provide multiple ecosystem services (Fuchs et al., 2024), under optimal conditions of administration and management.
The efficient implementation management of ecological restoration projects in the case of the forests affected by the devastating effect of climate change must be oriented towards both nature and the market. Consequently, ecological and economic objectives will be harmonized at a regional scale, in order to promote sustainable development in the region with high functional efficiency (Zhao et al., 2025).

CONCLUSIONS

The direction of the wind that caused the damage in the studied stands was from the NE exposure, which, according to the compartment descriptions in the forest management plan, accounts for 11% of their surface area.
In the context of global climate change, accurately determining the predisposing and triggering factors of windthrow and windbreak in spruce stands in the mountain zone is relatively difficult for various geographical areas.
The implementation of ecological rehabilitation works in spruce stands affected by extreme weather events presents a series of specific challenges related to the vegetation conditions and the morphological and ecological characteristics of these species.
Natural regeneration has been highly effective in 38.80% of the affected area, particularly in the upper part of the slopes, at distances of 300-400 meters from the unaffected spruce stands, which produced abundant seed during the period 2011-2014.
Although the Forest Code stipulates that the conservation and regeneration fund for forests should represent between 10-25% of the value of harvested wood, including main and accidental products I, for the ecological rehabilitation of the affected stands studied, this percentage is insufficient.
For optimal ecological rehabilitation of spruce stands that have been completely affected by various calamities, the conservation and regeneration fund must cover the cost of all necessary works, as established by the projects and execution estimates prepared for this purpose.
Given the current climate instability, the specific strategies for forest management of coniferous stands vulnerable to destabilizing factors must be integrated into adaptive forest management.
In extreme and exceptional situations, the conservation and regeneration fund for forests can be represented by the total value obtained from the sale of accidental products I, regardless of the owner or the administrator of the forest fund. This aspect must be urgently implemented in the Forest Code.
The consolidation of the ecosystem stability of spruce stands in the mountain zone, affected by various calamities, must be carried out as quickly as possible by introducing beech species through direct sowing under the canopy, and by expanding existing mixtures of spruce, fir, and beech species.

ACKNOWLEDGEMENTS

The studies and research were carried out with the agreement and collaboration of the management of the Horea Apuseni R.A. Forest District, Alba County, and the field staff of the Vadul Moţilor Production Unit I.
We also thank the representatives of the economic operator specialized in forestry works S.C. ECOPROD FOREST S.R.L., headquartered in Bihor County, who carried out all the forestry works in 2014 and 2015 in the case study location, based on service contracts and related additional documents, for their help and collaboration.

Abstract

Structural Health Monitoring (SHM) is a technology and methodology designed to assess the condition of structural systems by evaluating potential damage that may occur after an earthquake. Building Information Modeling (BIM) tools provide storage and visualization capabilities for digitally representing a building, incorporating raw data such as photographs, measurements, point clouds, and damage information. This paper presents a framework aimed at enhancing traditional databases. It integrates data collected from various sensors installed within a structure, employing post-processing techniques like finite element analysis to evaluate the health of both structural and non-structural elements. Additionally, the soil conditions are taken into account during these assessments. The collected information is then incorporated into a BIM environment featuring an improved interface that enhances connectivity between the two system architectures. This integration utilizes standardized file formats as defined by ISO standards. Developing scientific and experimental databases for building structures is an emerging trend in global research and a key component of the Romanian National Strategy for Seismic Risk Reduction. Digital building information models facilitate real-time updates and improve coordination among intervention teams following significant earthquakes.

Key words*: monitoring, digital data, damage, earthquake.*

INTRODUCTION

Structural health monitoring (SHM) is a non-destructive in-situ methodology and technology designed to assess the condition of structural systems by evaluating potential damage that may occur before or after an earthquake. It features a modular architecture that includes components related to sensors, data acquisition and transmission, data processing and control, data management, evaluation and maintenance, among others (Georgescu et al., 2010; Dragomir et al., 2019; Arif & Craifaleanu, 2023; Chacon et al., 2023; Sun et al., 2025). Any discrete or progressive changes in the structural parameters are considered potential condition indicators for damage identification.
Nowadays, at URBAN-INCERC, SHM is conducted by using the ARTeMIS Modal Pro software, which is currently in the process of implementation within an experimental project for real-time damage detection in instrumented and monitored buildings (Dragomir et al., 2019; Dragomir & Dobre, 2023). The analysis of modal and deflection shapes, along with damage detection through the identification of changes in the dynamic characteristics of a structure - using data from ambient vibrations or seismic motions - includes several important features.
These features consist of notifications when a specified control value is exceeded and warnings about potential damage to the structure, as highlighted in Figure 1. Incorporating the phenomenon of soil-structure interaction into structural analysis, either through analytical methods or real-time monitoring using sensors positioned in the free-
