**EDITORIAL BOARD**

**General Editor:** Razvan Ionut TEODORESCU

**Executive Editor:** Ana VIRSTA

**Managing Editor:** Augustina Sandina TRONAC

**Members:** Maria Jose ORUNA CONCHA, Radu Claudiu FIERASCU, Jana ŠIC ŽLABUR, Maria POPA, Fulvio CELICO, Catalina ITICESCU, Rupesh Kumar SINGH, Jelena LUBURA STOŠIĆ, Petrica VIZUREANU, Orhan ERCAN, Denis MIHAILESCU, Deodato TAPETE, Lucian COPOLOVICI, Jesus SIMAL-GANDARA, Alina ORTAN

**PUBLISHERS:**
**University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania - Faculty of Land Reclamation and Environmetal Engineering**
Address: 59 Marasti Blvd, District l, Zip code 011464, Bucharest, Romania
Phone: + 40 213 1830 75, E-mail: conference@fifim.ro, Webpage: www.fifim.ro

**CERES Publishing House**
Address: 106 Izbiceni Street, District 1, Bucharest, Romania
E-mail: edituraceres@yahoo.com, Webpage: www.editura-ceres.ro

**SCIENTIFIC & REVIEW COMMITTEE**

**SCIENTIFIC CHAIRMAN**
Prof. univ. dr. Sorin Mihai CIMPEANU

**MEMBERS***

- Stefano CASADEI – University of Perugia, Italy
- Carmen CIMPEANU – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Sorin Mihai CIMPEANU – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Andrea DOMINIJANNI – Politecnico di Torino, Italy
- Claudiu DRAGOMIR - University of Agronomic Sciences and Veterinary Medicine of Bucharest/ National Institute for Research and Development - URBAN-INCERC, Bucharest, Romania
- Eric DUCLOS-GENDREU – Spot Image GEO-Information Services, France
- Jean-Luc HORNICK – Université de Liège, Belgium
- Hossein KAZEMI – GUASNR, Gorgan, Iran
- Bela KOVACS – University of Debrecen, Hungary
- Raluca MANEA – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Tamara van OMMEREN-MYSLYVA – Ministry of Spatial Planning and Environment of Suriname
- Jovan Br. PAPIC – Ss. Cyril and Methodius University, Skopje, R. N. Macedonia
- Nelson PÉREZ-GUERRA – University of Vigo, Spain
- Nicolae PETRESCU – Valahia University Targoviste, Romania
- Dorin Dumitru PRUNARIU – Romanian Space Agency, Romania
- Andrei Victor SANDU – "Gheorghe Asachi" Technical University of Iași, Romania
- Simona MARCU-SPÎNU – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Umut Gunes SEFERCIK – Gebze Technical University, Turkey
- Ando SHIN – Tokyo University of Science, Japan
- Marisanna SPERONI – Centro di Ricerca Zootecnia e Acquacoltura, Consiglio per la Ricerca in Agricoltura e L'analisi Dell'economia Agraria (CREA), Italy
- Razvan Ionut TEODORESCU – University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania
- Péter UDVARDY – Óbuda University, Hungary
- Neven VOĆA – University of Zagreb, Croatia

**alphabetically ordered by family name*

# CONTENTS

## ENVIRONMENTAL SCIENCE AND ENGINEERING

1 NICKEL SPECIATION AND BIOAVAILABILITY IN SERPENTINE SOILS OF THE EASTERN AND SOUTHERN RHODOPES, BULGARIA - **Violina ANGELOVA** ..... 15

2 POTENTIAL OF SELECTED AROMATIC ASTERACEAE SPECIES FOR THE PHYTOREMEDIATION OF HEAVY METAL - CONTAMINATED SOILS - **Violina ANGELOVA, Maria IHTYAROVA**..... 23

3 INVESTIGATION OF HYDROCARBON POLLUTION IN THE OIL TERMINAL CONSTANȚA AREA USING ELECTRICAL RESISTIVITY METHODS AND HYDROSTATIC REGIME ANALYSIS - **Sorin ANGHEL, Andrei Gabriel DRAGOS, Gabriel IORDACHE, Bogdan Marius BARAITAREANU, Constanta Alexandra DUDU**..... 30

4 MINERAL COMPOSITION OF *VACCINIUM VITIS-IDAEA* FRUITS ACROSS DIFFERENT MOUNTAIN HABITATS - **Carla-Maria APARASCHIVE, Alina TRUTA, Irina MORAR, Tania MIHAIESCU, Claudia BALINT, Alexandra MURESAN, Catalina DAN, Adriana SESTRAS**..... 36

5 FROM WASTE TO RESOURCE: IMPLEMENTING SPENT GARNET (SG) AS A PARTIAL FINE AGGREGATE IN CEMENT-BASED MATERIALS — TECHNICAL, LEGAL AND COMMERCIAL PERSPECTIVES - **Cornelia BAERA, Aurelian GRUIN, Ana Cristina VASILE, Caius LUMINOSU, Ana-Andreea MIHARTESCU, Alexandra Marina BARBU** ..... 45

6 TECHNICAL FRAMEWORK FOR SUSTAINABLE VALORIZATION OF VINEYARD BY-PRODUCTS THROUGH SMALL-SCALE PROCESSING TECHNOLOGIES - **Carmen BALTATU, Gabriel Valentin GHEORGHE, Dragos MANEA, Larisa-Bianca IONICA**..... 59

7 SUSTAINABLE UNFIRED CLAY MASONRY INCORPORATING AGRICULTURAL WASTE: PHYSICAL AND MECHANICAL PROPERTIES - **Alexandra-Marina BARBU, Aurelia BRADU, Claudiu-Sorin DRAGOMIR, Augustina-Sandina TRONAC**..... 69

8 EFFECT OF SOIL TYPE AND MANAGEMENT ON POTENTIALLY TOXIC ELEMENTS (As, Cu, Zn) IN SOILS OF OLIVE GROVES IN DALMATIA, CROATIA - **Aleksandra BENSA, Nikolina JURKOVIĆ BALOG, Aleksandra PERČIN**..... 79

9 THE DUAL CHALLENGE OF CO2 AND OZONE: INSIGHTS INTO PHOTOSYNTHESIS, VOC EMISSION AND BIOCHEMICAL RESPONSES - **Flavia BORTES, Lucian COPOLOVICI, Cristian MOISA, Andreea LUPITU, Dana Maria COPOLOVICI** ..... 89

10 MOISTURE, LIPID CONTENT, AND MERCURY IN FRESHWATER FISH MUSCLE: INDICATORS OF ECOLOGICAL CONDITION IN THE LOWER DANUBE RIVER - **Andreea-Miruna CODREANU, Ștefania-Adelina MILEA, Cristina Mihaela LUNTRARU, Alin Constantin DÎRȚU, Cătălina ITICESCU** ..... 97

11 *DAPHNIA MAGNA* INDICATOR OF WATER POLLUTION WITH ZINC – **Paula COJOCARU, Alexandra-Andreea STRUNGARU, Gabriela BIALI, Maria Cătălina PASTIA** ..... 105

12 CARBON STORAGE IN FOREST STANDS ON DEGRADED LANDS - **Cristinel CONSTANDACHE, Ciprian TUDOR, Laurențiu POPOVICI, Raul RADU**..... 113

13 SEASONAL AND DIURNAL DYNAMICS OF SIZE-RESOLVED PARTICULATE MATTER IN AN URBAN AREA OF GALAȚI, ROMANIA, BASED ON CONTINUOUS RAPID-E MONITORING - **Mădălin CRISTEA, Adrian ROȘU, Sorin FRĂSÎNĂ, Bogdan ROȘU, Daniel-Eduard CONSTANTIN, Mirela VOICULESCU, Silvia DRĂGAN**..... 121

14 BACTERIAL MICROBIOTA IN AQUATIC ENVIRONMENTS AND THE BIODEGRADATION POTENTIAL OF SUSTAINABLE MATERIALS: INSIGHTS INTO ENVIRONMENTAL FATE - A REVIEW - **Andreea DOROFTE, Ira-Adeline SIMIONOV, Ștefan-Mihai PETREA, Cătălin PLATON, Cătălina ITICESCU** ..... 131
15 FOREWARNING ON SOME POLLUTANTS AND THEIR EFFECTS ON WATERFOWL - **Cristina Alina DUMITRACHE** ..... 144
16 MOBILITY AND TOXICOLOGICAL RELEVANCE IN THE EVALUATION OF HEAVY METAL TRANSFER FROM SOIL TO PLANTS - **Claudiu-Denis FILIP, Mirela Ana COMAN** ..... 151
17 ENVIRONMENTAL AND SOIL IMPACTS OF END-OF-LIFE LITHIUM-ION BATTERIES: QUANTITATIVE POLLUTION SCENARIOS, EMERGING CONTAMINANTS AND RECYCLING-ROUTE ASSESSMENT - **Roxana-Elena FRÎNCU, Carmen Otilia RUSĂNESCU, Ana VÎRSTA, Elena-Denisa PREDESCU, Daniela MIHAI, Sabrina Maria BĂLĂNESCU, Ionela Alexandra ION** 163
18 ELECTROCHEMICAL SENSORS FOR DETECTING ENVIRONMENTAL POLLUTANTS - A REVIEW - **Andrei-Daniel GEMAN, Andreea-Loredana COMĂNESCU, Constantin APETREI, Cătălina ITICESCU, Puiu-Lucian GEORGESCU** ..... 172
19 TREE COMMUNITY PATTERNS IN RELATION TO EDGE INFLUENCE IN A PERI-URBAN FOREST NEAR CLUJ-NAPOCA, ROMANIA - **Ioana-Loredana GHIURCO, Carla-Maria APARASCHIVE, Adela-Maria NEAG, Iulia-Ecaterina MORA, Păunița BOANCĂ, Sonia BODEA, Denisa JUCAN, Catalina DAN, Adriana ESTRAS** ..... 184
20 STUDY OF THE DYNAMICS OF SOME WATER QUALITY PARAMETERS IN THE PRUT RIVER AREA DURING 2014-2023 - **Dinu GÎRNEȚ, Lorena DELEANU, Gabriel MURARIU, Laura DANILESCU, Romana DRASOVEAN** ..... 193
21 DYNAMICS OF AIRBORNE MICROORGANISMS ACCORDING TO ENVIRONMENTAL CONDITIONS - **Bilyana GRIGOROVA-PESHEVA, Asen PESHEV, Georgi KADINOV, Ekaterina TODOROVA, Boyka MALCHEVA** ..... 202
22 *IN VITRO* PROPAGATION OF *EUONYMUS FORTUNEI* CULTIVARS FOR SUSTAINABLE URBAN GREENING AND DEGRADED LAND REHABILITATION - **Tatiana GROPA, Ion ROȘCA, Ioana-Cătălina NICOLAE** ..... 211
23 HYBRID RENEWABLE ENERGY SUPPLY SYSTEM - STORAGE REQUIREMENTS CONSIDERING SEASONAL VARIATION OF PV OUTPUT - **Mirela Laura IEREMCIUC, Ioan DAVID, Camelia ȘTEFĂNESCU, Mihai NEGURA, Dorina-Gabriela IONESCU, Mircea VIȘESCU** ..... 222
24 A LOW-COST, OPEN-SOURCE APPROACH FOR SENSOR-BASED LIGHT MANAGEMENT IN PROTECTED CULTIVATION SYSTEMS - **Bogdan ILIE, Yuxin TONG, Ana BUTCARU, Tiberiu ION, Ionuț Ovidiu JERCA** ..... 231
25 THE INFLUENCE OF INOCULATION WITH SYNTHETIC MICROBIOMES ON THE EVOLUTION OF SOIL CARBON SEQUESTRATION UNDER THERMAL STRESS - **Sorin MATEI, Gabi Mirela MATEI, Sorina DUMITRU, Victoria MOCANU, Monica DUMITRAȘCU** ..... 246
26 TRACING PESTICIDES AND PHARMACEUTICALS IN WATER AND SEDIMENTS OF THE DANUBE DELTA - **Stefania-Adelina MILEA, Valentina-Andreea CALMUC, Andreea-Miruna CODREANU, Catalina ITICESCU, Silvia DRAGAN** ..... 258
27 INACTIVATION OF GRAM-POSITIVE AND GRAM-NEGATIVE BACTERIA BY USING ARGON COLD ATMOSPHERIC PRESSURE PLASMA - **Cristina MOISESCU, Ovidiu STOICAN, Ana Valentina ZAMFIRESCU, Mihaela Marilena STANCU** ..... 266
28 OZONE STRESS IN PLANTS: SIGNALLING AND RESPONSE - **Senad MURTIĆ** ..... 274
29 PHYSICOCHEMICAL STABILITY AND EMULSIFYING ACTIVITY OF A BIOSURFACTANT OF SALINE ORIGIN - **Simona NEAGU, Mihaela Marilena STANCU** ..... 287
30 PLANT TISSUE CULTURE STRATEGIES FOR SUSTAINABLE MULTIPLICATION OF BLACK CHOKEBERRY (*ARONIA MELANOCARPA*) GERMPLASM - **Ioana - Cătălina NICOLAE, Maria TABĂRA, Nina CIORCHINĂ, Natalia ONICA, Melania GHEREG, Liliana BĂDULESCU** ..... 296

31 NATURA 2000 SITE DEALURILE STREHAIA–BÂTLANELE - UPDATED INFORMATION ON SPECIES AND HABITATS OF COMMUNITY INTEREST - **Marilena ONETE, Florian Paul BODESCU, Roxana-Georgiana NICOARĂ, Minodora MANU, Monica Angela NEBLEA** ..... 309
32 ASSESSMENT OF THE STATE OF ATMOSPHERIC AIR IN AN URBAN ENVIRONMENT DURING A FIRE AT A SOLID WASTE LANDFILL AND COMPARISON WITH AIR QUALITY INDICES - **Georgi PATRONOV, Diana KIRIN, Kenan SEZER, Petya ZAHARIEVA, Radoslava ZAHARIEVA**..... 319
33 INTERRELATIONSHIP BETWEEN SOIL MICROORGANISMS AND AIRBORNE MICROFLORA IN URBAN ENVIRONMENT - **Asen PESHEV** ..... 327
34 BIOMATERIALS – BASED COATINGS WITH INDOOR EMISSION CONTROL PROPERTIES - **Irina POPA, Vasilica VASILE, Claudiu-Sorin DRAGOMIR, Alexandra-Marina BARBU** ..... 335
35 PHYSICAL AND MECHANICAL CHARACTERISTIC ASPECTS FOR CLADDING PRODUCTS BASED ON RICE HUSKS AND HEMP STALKS - **Irina POPA, Vasilica VASILE, Claudiu-Sorin DRAGOMIR, Cristian GRIGORAȘENCO**..... 342
36 CORRELATION BETWEEN THE PHYSICAL PROPERTIES AND NPK NUTRIENT CONTENT OF ORCHARD SOILS FOR THE SELECTION OF APPROPRIATE SOIL DECONTAMINATION TECHNOLOGIES - **Maria POPA**..... 349
37 OCCURRENCE AND LEVELS OF HAZARDOUS ORGANIC COMPOUNDS IN SOILS FROM INDUSTRIAL AREAS - **Mihaela PREDA, Veronica TĂNASE, Nicoleta Olimpia VRÎNCEANU, Florența JAFRI**..... 357
38 IDENTIFYING THE NATURAL AND ANTHROPOGENIC SOURCES OF PARTICULATE MATTER: AN ANALYSIS OF POLLUTION ORIGINS AND ENVIRONMENTAL IMPACT - **Elena-Denisa PREDESCU, Carmen Otilia RUSĂNESCU, Roxana-Elena FRÎNCU, Sabrina Maria BĂLĂNESCU, Daniela MIHAI, Ionela Alexandra ION**..... 365
39 DETERMINATION OF CONCRETE PERMEABILITY WITH CERAMIC WASTE CONTENT - **Mircea SĂLCUDEAN, Maria POPA, Mirel GLEVITZKY, Daniela ONITA, Mihai Teopent CORCHEȘ** ..... 371
40 EXPERIMENTAL STUDY ON BRICKS MADE WITH BRICK WASTE AND SAWDUST - **Mircea SĂLCUDEAN, Maria POPA, Mirel GLEVITZKY, Mihai Teopent CORCHEȘ** ..... 378
41 DETERMINATION OF SPLITTING TENSILE STRENGTH OF PAVING BLOCKS CONTAINING CERAMIC WASTE - **Mircea SĂLCUDEAN, Mihai Teopent CORCHEȘ, Maria POPA, Mirel GLEVITZKY**..... 386
42 HYDROCARBON TOLERANCE AND BIODEGRADATION IN ENVIRONMENTAL *PSEUDOMONAS* STRAINS - **Mihaela Marilena STANCU, Simona NEAGU** ..... 393
43 SEASONAL VARIATION OF $CO_2$ SOIL FLUX AND VEGETATION RESPONSE AT BODOC AND BĂILE LĂZĂREȘTI - **Lia STELEA, Alexandra-Constanța DUDU, Corina AVRAM, Marius-Bogdan BĂRĂITĂREANU, Andrei-Gabriel DRAGOȘ, Gabriel IORDACHE** 403
44 EVALUATION OF THE PERFORMANCE OF WHEAT VARIETIES UNDER MINIMUM TILLAGE SYSTEM IN THE PEDOCLIMATIC CONDITIONS OF SĂCELE AREA, CONSTANȚA COUNTY (2021-2024) - **Traian Ciprian STROE, Oana MIHAI FLOREA, Liliana PANAITESCU**..... 416
45 ON THE IMPORTANCE OF ENVIRONMENTAL FACTOR PROTECTION IN KEY AREAS OF THE BORDER ZONE. CASE STUDY ROMANIA-UCRAINA, MARAMUREȘ MOUNTAINS - **Maria ȘEVERA, Mirela COMAN**..... 429
46 GEOTECHNICAL ENGINEERING AND SOIL MANAGEMENT: LEGAL GAPS AND ENVIRONMENTAL CONSIDERATIONS – **Daniel-Dumitru TOADERE, Nicoleta-Maria ILIEȘ, Ioan PETRAN**..... 436
47 MONITORING ENVIRONMENTAL QUALITY VIA NITRATE ACCUMULATION IN GREENHOUSE LETTUCE (*LACTUCA SATIVA* L.) - **Irina TOMASU, Mihaela DRAGOI CUDALBEANU, Simona MARCU SPINU, Zina PARASCHIV, Augustina Sandina TRONAC, Alina ORTAN** ..... 446

48 VALORIZATION OF STEEL FURNACE SLAG FOR CONSTRUCTION APPLICATIONS: TECHNICAL CHALLENGES AND OPPORTUNITIES - **Ana-Cristina VASILE, Raul ZAHARIA, Cornelia BAERA, Aurelian GRUIN, Paula SFIRLOAGA, Adelin STIRB, Alexandru ION** ..... 458
49 CULTIVABLE MICROALGAE FROM PEATLAND WATERS: MORPHOLOGICAL FEATURES AND PIGMENT PROFILES - **Ana Valentina ZAMFIRESCU, Cristina MOISESCU, Sorin ȘTEFĂNUȚ, Miruna-Maria ȘTEFĂNUȚ, Ana-Maria MOROȘANU** ..... 470

## DISASTER RESILIENCE AND SUSTAINABLE DEVELOPMENT

1 INTEGRATED GEOTECHNICAL AND STRUCTURAL APPROACHES FOR REDUCING SEISMIC VULNERABILITY OF HERITAGE BUILDINGS - **Stefan Florin BALAN, Bogdan Felix APOSTOL** 482
2 ASPECTS RELATED TO VEGETATION SUCCESSION, ON AGRICULTURAL LANDS, IMPROPERLY EXPLOITED AND ABANDONED, AFFECTED BY DROUGHT, IN NON-COLLECTIVIZED AREAS - **Flavia-Mălina CIOFLAN, Călin Ioan IOVAN, Sorin Lucian DOROG, Călin Gheorghe PĂȘCUȚ, Eugenia ȘERBAN** ..... 492
3 THE CHALLENGES OF CLIMATE CHANGE ADAPTATION IN ROMANIA'S LAND RECLAMATION SYSTEMS: BETWEEN GREY INFRASTRUCTURE AND NATURE-BASED SOLUTIONS - **Mihai Teopent CORCHES, Mirel GLEVITZKY, Mircea SĂLCUDEAN** ..... 506
4 SEISMIC RESPONSE ANALYSIS OF A LONG-TERM MONITORED BUILDING USING CO-LOCATED STRUCTURAL AND FREE-FIELD RECORDS - **Iolanda-Gabriela CRAIFALEANU, Claudiu-Sorin DRAGOMIR, Daniela DOBRE, Emil Sever GEORGESCU, Alexandra-Marina BARBU** ..... 518
5 A NOVEL CONCEPT FOR A SUBMERGED WAVE ENERGY CONVERTER - **Alexandru DIMACHE, Iulian IANCU** ..... 530
6 A DATA-DRIVEN ANALYSIS OF SEISMIC RESPONSE AND STRUCTURAL PERFORMANCE - **Daniela DOBRE, Iolanda-Gabriela CRAIFALEANU, Claudiu-Sorin DRAGOMIR, Emil-Sever GEORGESCU, Cornelia-Florentina DOBRESCU** ..... 537
7 STRUCTURAL PERFORMANCE ASSESSMENT OF ECOLOGICALLY STABILIZED ROAD LAYERS - **Daniela DOBRE, Lidia-Rodica RADU, Nicoleta-Adaciza IONESCU, Cornelia-Florentina DOBRESCU** ..... 545
8 CORRELATION BETWEEN DENSITY, ULTRASONIC PULSE VELOCITY, AND DRYING SHRINKAGE IN ECO-CLAY POURED-EARTH - **Aurelian GRUIN, Sorin DAN, Cornelia BAERĂ, Bogdan BOLBOREA, Ana-Cristina VASILE, Claudiu-Sorin DRAGOMIR, Evelin Anda LAZA** ... 551
9 INTERNAL AIR RECIRCULATION FOR CONDENSATION RISK CONTROL IN PASSIVE SOLAR GREENHOUSES: A DEW MARGIN-BASED ZONAL APPROACH - **Bogdan ILIE, Yuxin TONG, Ana BUTCARU, Tiberiu ION, Ionuț Ovidiu JERCA** ..... 560
10 INFLUENCE OF CONSTITUTIVE MODELS ON DEEP EXCAVATIONS: A COMPARATIVE STUDY - **Daniel-Marcel MANOLI, Nicolae RĂDULESCU-SINGURAN, Adrian Alexandru SAVU, Elena-Mihaela STAN, Cristian-Ștefan BARBU** ..... 574
11 THERMAL AND MECHANICAL PERFORMANCE OF GROUTING MATERIALS IN GEOTHERMAL BOREHOLES: IMPLICATIONS FOR HEAT TRANSFER EFFICIENCY AND ENVIRONMENTAL PERSPECTIVE - **Daniel-Marcel MANOLI, Alina TATOMIR, Elena-Mihaela STAN, Cristian-Stefan BARBU, Andrei-Dan SABAU** ..... 580
12 ASPECTS REGARDING CLIMATE RESILIENCE AND URBAN HEAT ISLAND EFFECT MITIGATION IN URBAN AREAS RENOVATION PROJECTS - **Izabella MARIN LAZĂR** ..... 586
13 INFLUENCE OF TESTING METHODS ON THERMAL PERFORMANCE CHARACTERIZATION OF SHEEP WOOL-BASED INSULATION - **Cristian PETCU, Andreea HEGYI, Horia PETRAN, Florin BĂLTĂREȚU** ..... 598
14 AQUIFER THERMAL ENERGY STORAGE SYSTEMS FOR NEARLY ZERO ENERGY BUILDINGS: A CASE STUDY ASSESSMENT FOR ROMANIAN CLIMATE CONDITIONS - **Cristian PETCU, Horia PETRAN, Andreea HEGYI, Florin BĂLTĂREȚU, Ciprian ENE** ..... 610

15 CASE STUDY ON THE ASSESSMENT OF THE EFFECTS OF CONTROLLED BLASTING DEMOLITION ON NEARBY BUILDINGS - **Adrian SIMION** ..... 624
16 COMPARATIVE STUDY ON DETERMINING THE FIRE RESISTANCE OF MASONRY WALLS - **Adrian SIMION, Augustina-Sandina TRONAC, Claudiu-Sorin DRAGOMIR, Laurențiu Denis CHERPEC** ..... 632

## WATER RESOURCES MANAGEMENT

1 LONG-TERM CHANGES IN AREAS EQUIPPED WITH DRAINAGE AND DEWATERING SYSTEMS UNDER DIFFERENT LAND USES - **Mihaela BALAN, Oana Alina NIȚU, Cristian POPESCU** ..... 637
2 MOBILE WASTEWATER TREATMENT SYSTEMS FOR CIRCULAR WATER REUSE: TECHNOLOGIES, APPLICATIONS AND THE ROMANIAN GAP IN THE EUROPEAN CONTEXT - **Sabrina-Maria BĂLĂNESCU, Carmen Otilia RUSĂNESCU, Ana VÎRSTA, Daniela MIHAI, Ionela Alexandra ION, Elena Denisa PREDESCU, Elena Roxana FRÎNCU** ..... 645
3 PROCESS STABILITY IN LIVESTOCK WASTEWATER TREATMENT: A COMPARATIVE REVIEW OF CONVENTIONAL SYSTEMS AND MEMBRANE BIOREACTORS FOR DECENTRALIZED APPLICATIONS - **Sabrina-Maria BĂLĂNESCU, Carmen Otilia RUSĂNESCU, Ana VÎRSTA, Nicoleta-Alina UDROIU, Bogdan-Dumitru ȚIGĂNOAIA, Nicolae FARCAȘ** ..... 657
4 SALT LAKE MICROBIAL ECOSYSTEMS: IMPORTANCE AND CONSERVATION CHALLENGES - **Lucia-Roxana COJOC, Mirela-Mădălina MOLDOVEANU, Larisa-Isabela FLORESCU, Mădălin-Iancu ENACHE, Anca-Ioana LUCACI** ..... 667
5 INCREASING THE EFFICIENCY OF BIOLOGICAL SLUDGE STABILIZATION PROCESSES WITHIN WASTEWATER TREATMENT PLANTS - **Dragos DRACEA, Alin HAPCA, Sebastian MUSTATA, Augustina Sandina TRONAC** ..... 675
6 *CYANOBACTERIA* AS KEY FACTORS IN STRUCTURING PLANKTONIC COMMUNITIES IN THE DANUBE DELTA - **Larisa Isabela FLORESCU, Maria Iasmina MOZA, Mirela Mădălina MOLDOVEANU** ..... 685
7 SPATIAL VARIATION OF MICROBIAL COMMUNITIES IN THE BAHLUI RIVER ACROSS THE URBAN AREA OF IASI - **Andrei-Mihai GAFENCU, Andreea-Mihaela FLOREA, Florin-Daniel LIPȘA, Eugen ULEA** ..... 697
8 HYDRO-MECHANICAL ANALYSIS AND NUMERICAL SIMULATION OF WATER INFILTRATION PROCESSES IN RAILWAY EMBANKMENTS - **Dorian HAUSLER COZMA, Eugen Teodor MAN, Robert Florin BEILICCI, Erika Beata Maria BEILICCI** ..... 704
9 HYDRAULIC MODELING APPLIED TO THE DETERMINATION OF SANITARY PROTECTION ZONES FOR LAKE BUHUI - **Mirela Laura IEREMCIUC, Ioan DAVID, Robert Florin BEILICCI, Erika Beata Maria BEILICCI** ..... 710
10 RISK ASSESSMENT OF THE USE OF *RUTILUS RUTILUS* FOR FOOD FROM TWO ANTHROPOGENICALLY INFLUENCED DAMS - **Nikolina ILIEVA, Viliana PASKALEVA, Diana KIRIN, Radoslava ZAHARIEVA, Petya ZAHARIEVA, Georgi PATRONOV, Doychin TERZIYSKI** ..... 717
11 MONITORING THE ECOLOGICAL STATE AND ANTHROPOGENIC LOADING OF THE LUDA YANA RIVER THROUGH THE USE OF INDICATOR MACROZOOBENTHOS - **Diana KIRIN, Radoslava ZAHARIEVA, Petya ZAHARIEVA** ..... 725
12 MICROBIAL PATTERNS IN URBAN AND PERI-URBAN LAKES FROM SOUTHERN ROMANIA: IMPLICATIONS FOR WATER QUALITY AND ECOSYSTEM HEALTH - **Anca-Ioana LUCACI, Larisa Isabela FLORESCU, Mirela Mădălina MOLDOVEANU, Roxana-Lucia COJOC** ..... 736

13 XRF-BASED ASSESSMENT OF ELEMENT ACCUMULATION IN *PHRAGMITES AUSTRALIS* ACROSS FRESHWATER, URBAN, AND SALINE AQUATIC ECOSYSTEMS: IMPLICATIONS FOR NATURAL FILTRATION AND ENVIRONMENTAL RISK – **Mirela Mădălina MOLDOVEANU, Larisa Isabela FLORESCU, Raluca Alexandra MIHAI, Cristian BANCIU, Maria Iasmina MOZA, Doru Simon DOBRE, Cristina Alina DUMITRACHE, Rodica Daniela CATANĂ** ..... 749

14 GLOBAL CHALLENGES CONCERNING WATER RESOURCES AND THEIR MANAGEMENT: CASE STUDY – THE DANUBE - **Aurelia NICA, Isabelle METAXA, Alina ANTACHE, Adeline-Ira SIMIONOV, Cătălina ITICESCU, Ștefan-Mihai PETREA** ..... 761

15 METALS CONTENT IN THE SYSTEM WATER - SEDIMENTS - CHIRONOMIDAE - *PERCA FLUVIATILIS* - *PROTEOCEPHALUS PERCAE* FROM TOPOLNITSA DAM, BULGARIA - **Viliana PASKALEVA, Diana KIRIN, Petya ZAHARIEVA, Radoslava ZAHARIEVA, Marian VARBANOV** ..... 767

16 PHYSICOCHEMICAL DYNAMICS OF WATER QUALITY IN SAND AND GRAVEL POST-EXPLOITATION LAKES - **Karoly Alexandru RACZ, Emilia Valentina PANTEA, Nicu Cornel SABĂU** ..... 775

17 PHOTOCHEMICAL DEGRADATION OF IMIDACLOPRID IN WATER UNDER UV RADIATION THROUGH CFD MODELING **- Alexandru Florin SIMION, Angelica Nicoleta GĂMAN, Sorin SIMION, Marius KOVACS** ..... 788

18 COMPARATIVE ASSESSMENT OF ANNUAL DYNAMICS IN WATER QUALITY OF HERASTRAU LAKE, ROMANIA - **Iuliana VOICU, Mihaela DRAGOI CUDALBEANU, Andreea Adriana MAN, Nicoleta Daniela SARBU, Teodor COSTACHIOIU, Daniela FAUR, Carmen Laura CIMPEANU** ..... 803

19 STATE-OF-THE-ART APPLICATIONS FOR THE REHABILITATION OF IRRIGATION MAIN-CANAL CROSSINGS - **Elena-Maria VORNICESCU, Sorin Mihai CIMPEANU, Nicolae MARACINE, Marco MORARU** ..... 815

## REMOTE SENSING AND GEOINFORMATICS

1 COMPARATIVE ANALYSIS OF ALTIMETRIC VARIATIONS IN THE SLĂNIC PRAHOVA AREA BASED ON LEVELING MEASUREMENTS **- Mihai AVADANEI, Tiberiu POPESCU, Florina ȚERLE BURESCU, Florin SALA, Mihai Valentin HERBEI** ..... 821

2 INTEGRATED COMPENSATION OF TERRESTRIAL GEODETIC AND GNSS NETWORKS USING A MODULAR 3D SOFTWARE PLATFORM. CASE STUDY: UCC MĂNECIU NETWORK - **Gabriel BĂDESCU, Mihail SUSINSKI, Cristian VASILE, Emilia CONSTANTINESCU, Petre SĂVESCU, Gabriel TĂNASIE** ..... 832

SEISMIC SURVEY FOR SHALLOW INVESTIGATION OF $CO_2$ MIGRATION PATHWAYS IN BĂILE LĂZĂREȘTI, ROMANIA - **Marius-Bogdan BĂRĂITĂREANU, Ionelia PANEA, Alexandra Constanța DUDU, Andrei Gabriel DRAGOȘ, Gabriel IORDACHE, Lia STELEA, Sorin ANGHEL** 846

4 SMART INTEGRATED E-PERMITTING PLATFORM FOR URBAN PLANNING AND CONSTRUCTION MANAGEMENT - **Andreea BEGOV-UNGUR, Liana Luminita BOCA** ..... 853

5 A METHODOLOGICAL FRAMEWORK FOR TERRAIN MORPHOLOGICAL ANALYSIS IN RISK MAPPING BASED ON DEM-DERIVED GEOMORPHOMETRIC PARAMETERS - **Liviu BUZILA, Silvia Alexandra DREGHICI, Ciprian CORPADE, Levente DIMEN, Zoltan NYIKES** ..... 862

6 GIS-BASED NOISE MAPPING OF NATURA 2000 SITES EXPOSED TO A1 MOTORWAY TRAFFIC IN ROMANIA - **Cristina CĂLIN, Răzvan Lucian VOICU, Sorin Mihai CÎMPEANU** ..... 870

7 DIGITAL TRANSFORMATION OF TREE INVENTORY THROUGH GIS: OPTIMIZING FORESTRY PROCESSES VIA SPATIAL DATA COLLECTION, INTEGRATION AND ANALYSIS **- Silvia CHIOREAN, Tudor SĂLĂGEAN, Mircea-Emil NAP, Ioana POP, Florica MATEI, Răzvan PLOSCAR, Steluța-Maria SÎNGEORZAN, Vasile ȘIMONCA** ..... 877

8 REAL-TIME PATHOGEN RISK MAPPING IN CEREAL FIELDS THROUGH INTEGRATED UAV, GIS AND SMART FORECASTING TOOLS - **Dragoș Andrei CÎRCIUMARIU, Mirela PARASCHIVU, Constantin ȘULEA-IORGULESCU, Dorin SENDRESCU** ..... 885
9 APPLICATION OF PHOTOGRAMMETRIC TECHNOLOGIES FOR CROP MONITORING IN PRECISION AGRICULTURE - **Silvia Alexandra DREGHICI, Levente DIMEN, Liviu BUZILA, Tudor BORȘAN, Gianmarco PITTON** ..... 903
10 ASSESSING WINTER MICROCLIMATES AND URBAN-RURAL THERMAL DIFFERENCES: A MOBILE MONITORING PILOT STUDY IN SOUTH-EASTERN ROMANIA - **Sorin FRĂSINA, Adrian ROȘU, Bogdan ROȘU, Maxim ARSENI, Daniel-Eduard CONSTANTIN, Mădălin CRISTEA, Lucian SFÎCĂ, Cătălina ITICESCU, Silvia DRAGAN** ..... 912
11 SATELLITE-DERIVED TURBIDITY AS AN INDICATOR OF SMALL-SCALE GOLD MINING ACTIVITY AROUND THE BROKOPONDO RESERVOIR, SURINAME - **Tamara MYSLYVA, Christiaan Max HUISDEN, Marek MROZ, Gerald TJON A SAN, Fauzia Gatoen ABDOELRAHMAN** ..... 925
12 HIGH-RESOLUTION MAPPING OF VEGETATION TYPES, STRUCTURE, HEIGHT, AND DENSITY IN THE UASVM CLUJ-NAPOCA CAMPUS USING LiDAR, PHOTOGRAMMETRY AND MULTISPECTRAL SENSING - **Mircea Emil NAP, Tudor SĂLĂGEAN, Silvia CHIOREAN, Ioana POP, Florica MATEI, Cătălin VÂRBAN, Simion BRUMĂ, Elemer Emanuel ȘUBA** ..... 937
13 DEFORESTATION PREDICTIONS IN NORTHERN ROMANIA USING LONG SHORT-TERM MEMORY NEURAL NETWORKS - **Adina NITULESCU** ..... 946
14 THE ALTGORITHMIC LANDSCAPE OF A.I BASED LAND USE INTERPRETATION - **Ioana Delia POP, Tudor SĂLĂGEAN, Mircea-Emil NAP, Elemer-Emanuel ȘUBA, Cristian MALINAS, Lucia-Adina TRUTA, Silvia CHIOREAN, Ferenc KAITAR, Adela-Maria NEAG, Florica MATEI** 952
15 LAND USE CHANGES INDUCED BY CONSTRUCTION MATERIAL EXTRACTION IN SURFACE QUARRIES WITHIN THE INEU ADMINISTRATIVE TERRITORY (BIHOR COUNTY, ROMANIA) - **Karoly Alexandru RACZ, Claudia Simona TIMOFTE, Nicu Cornel SABĂU** ..... 967
16 HIGH-DENSITY AIRBORNE LiDAR POINT CLOUD FOR DIGITAL TERRAIN MODELS IN SMALL STREAM ASSESSMENT AND REHABILITATION - **Tudor SĂLĂGEAN, Ioana POP, Florica MATEI, Silvia CHIOREAN, Mircea-Emil NAP, Catalin-Stefanel SABOU, Andreea-Catalina MOSNEAG** ..... 976
17 UAV-DERIVED VEGETATION INDICES FOR SPATIAL ASSESSMENT OF WEED INFESTATION IN ARABLE CROPS - **Claudiu-Daniel UTOIU, Bogdan DRAGANCEA, Elena UTOIU, Catalin LAZAR, Mihai GIDEA** ..... 988
18 GIS-BASED SCREENING OF ROAD-INDUCED SPATIAL FRAGMENTATION IN NATURA 2000 SITES IN ROMANIA - **Răzvan Lucian VOICU, Cristina CĂLIN, Sorin Mihai CÎMPEANU** ..... 997

## MISCELLANEOUS

1 RESEARCH ON FREE SURFACE ENERGY DISSIPATION - **Nicolae ALBOIU, Daniel CORNEA, Georgiana Daniela VULPE** ..... 1003
2 EFFICIENT USE OF AGRICULTURAL LAND BY ORGANIZING AND DIMENSIONING CROP ROTATION - **Marius Nicolae CIOBOATĂ, Dragomir BRUMAR, Marilena Alina PRIOTEASA** 1011
3 THREE-DIMENSIONAL BUILDING MODELING AS A DIGITAL STRATEGY FOR ENHANCING RURAL TOURISM PROMOTION - **Levente DIMEN, Silvia Alexandra DREGHICI, Tudor BORȘAN, George COZA** ..... 1021
4 A DECISION-SUPPORT FRAMEWORK FOR SUSTAINABLE MANAGEMENT OF NATURAL SPORTS TURF UNDER TEMPERATE-CONTINENTAL CONDITIONS - A REVIEW AND CASE STUDY - **Alexandru DUMITRU, Mihai Sorin CÎMPEANU** ..... 1030
5 SPECIFIC REHABILITATION WORKS OF DEGRADED AGROSILVOPASTORAL SYSTEMS, IN NONCOLLECTIVIZED AREAS - **Călin Ioan IOVAN, Sorin Lucian DOROG, Călin Gheorghe PĂȘCUȚ, Flavia-Mălina CIOFLAN, Eugenia ȘERBAN** ..... 1039

***Abstract***

*Serpentine soils in the Eastern and Southern Rhodopes, Bulgaria, exhibit elevated nickel (Ni) concentrations and distinct mineralogical characteristics, dominated by serpentine minerals (antigorite, lizardite) and the Ni-rich willemseite. This study assesses Ni speciation, mobility, and potential bioavailability by analysing soil physicochemical properties, iron oxide mineralogy, and selective chemical extractions targeting exchangeable, DTPA-extractable, and iron oxide-associated Ni fractions. Results indicate that Ni distribution depends on pedogenetic development: in moderately developed soils, Ni preferentially associates with amorphous and poorly crystalline iron oxides, while in more advanced soils, well-crystallised oxides stabilise Ni and limit its mobility. The Feo/Fed ratio reflects oxide crystallinity and pedogenic stage, serving as a key control on Ni behaviour. Multivariate analyses, including PCA and cluster analysis, reveal a pedogenetic continuum linking mineralogical inheritance, iron oxide transformation, and Ni fractionation. This framework enables the prediction of potential Ni bioavailability and highlights the importance of pedogenesis and secondary mineral phases in regulating Ni dynamics. The findings improve understanding of Ni behaviour in temperate ultramafic soils and provide a basis for ecological risk assessment and sustainable management of serpentine ecosystems.*

***Key words****: bioavailability, nickel (Ni), Rhodopes Mountains, serpentine soils, soil geochemistry.*

## INTRODUCTION

Nickel (Ni) is widely distributed in the Earth's crust and plays an important role in biogeochemical processes in the soil environment. It is essential for plants and microorganisms, as it participates in the structure and activity of the enzyme urease and other key metabolic processes (Kabata-Pendias, 2011). At the same time, elevated nickel concentrations can be toxic, disrupting plant physiological functions, inhibiting nutrient uptake, and reducing soil microbial activity (Alloway, 2013). Therefore, understanding the factors controlling nickel distribution, mobility, and potential bioavailability in soils is crucial.

Nickel content strongly depends on the geological substrate. The highest concentrations are observed in soils formed on ultramafic and ultrabasic rocks such as peridotites, dunites, and serpentinites (Brooks, 1987). These rocks contain high levels of magnesium and heavy metals, including nickel, chromium, and cobalt. Weathering of these rocks leads to the formation of serpentine soils, characterised by high concentrations of potentially toxic elements, low Ca/Mg ratios, and limited content of essential nutrients (Alexander et al., 2007). The specific geochemical conditions of these soils strongly influence the plant and microbial communities typical of serpentine ecosystems.

The geochemical behaviour of nickel depends not only on its total content but also on its chemical forms. It can be adsorbed on clay minerals, associated with iron and manganese oxides, complexed with organic matter, or structurally incorporated into mineral lattices (Kabata-Pendias, 2011; Alloway, 2013). These forms differ in stability and mobility, determining their potential bioavailability to plants and their role in soil geochemical processes.

Quantitative assessment of metal mobility and bioavailability is commonly achieved using selective chemical extractions. Different extractants allow operational definition of metal fractions associated with specific soil components or characterised by varying mobility (McLean & Bledsoe, 1992). For example, the chelating agent diethylenetriaminepentaacetic acid (DTPA) extracts potentially bioavailable trace metal forms (Lindsay & Norvell, 1978), whereas neutral salts such as $Sr(NO_3)_2$ extract

exchangeable and weakly adsorbed forms. These approaches provide a more realistic assessment of the ecological significance of nickel compared to total concentrations.

Iron oxides also play a key role in nickel retention and distribution. They act as effective sorbents, limiting metal mobility and strongly influencing their stability (Alloway, 2013). Amorphous and poorly crystalline iron oxides can retain more labile nickel forms, while well-crystallised oxides stabilise the metal pool. Oxalate extraction targets nickel associated with amorphous and poorly crystalline Fe and Al oxides, while the sodium dithionite-citrate-bicarbonate (DCB) method dissolves free crystalline iron oxides (Mehra & Jackson, 1960; Schwertmann, 1964). Comparison of these fractions and the $Fe_o/Fe_d$ ratio provide valuable information on soil development and nickel stability.

Serpentinites and ultramafic rocks are widespread across the Balkans, including Bulgaria. The Rhodope Massif is a key area with localised bodies of serpentinites and ultrabasic rocks. In the Eastern and Southern Rhodopes, these lithological features form soils with elevated nickel and other trace elements (Angelova & Kovacheva, 2023). However, information on nickel distribution among soil fractions and the influence of iron oxides on its potential bioavailability remains limited.

Investigating nickel speciation and potential bioavailability in the serpentine soils of the Rhodopes is crucial for understanding the processes controlling its behaviour. A combined approach integrating selective chemical extractions, soil physicochemical properties, and mineralogical composition provides a comprehensive, process-oriented interpretation of nickel dynamics.

This study aims to analyse nickel speciation, mobility, and potential bioavailability in serpentine soils of the Eastern and Southern Rhodopes, with a focus on the role of iron oxides, pedogenesis, and mineralogical composition. To achieve this, the study evaluates total nickel content, its spatial variability, distribution among different chemical fractions via selective extractions, the influence of iron oxides and their crystallinity, and the relationship between soil physicochemical and mineralogical properties and nickel's potential bioavailability. Multivariate statistical analyses are applied to identify pedogenetic and functional soil groups that reflect gradients in soil development and nickel bioavailability.

## MATERIALS AND METHODS

### *Study area and sampling*

The study was conducted in ultramafic regions of the Central and Eastern Rhodope Mountains, southern Bulgaria. The investigated sites included Kazak, Goljamo Kamenyane, Avren, Chernichevo, Kardzhali, Fotinovo, Dyulitsa, Dobromirtsi, Asenovgrad, Cherven, Parvenets, and Gornoslav. The region is characterized by a transitional Mediterranean-continental climate, contributing to considerable spatial variability in environmental conditions.

Surface soil samples (0-20 cm) were collected from each site. Prior to analysis, the samples were air-dried, homogenized, and sieved to <2 mm.

### *Physicochemical soil analysis*

Soil physicochemical properties were determined using standardized analytical procedures. Soil pH was measured potentiometrically in water according to ISO 10390 (2021). Organic matter content was determined following BS EN 13039 (2011). Cation exchange capacity and exchangeable cations were determined using $BaCl_2$ extraction in accordance with ISO 11260 (1994).

Pseudo-total metal concentrations were determined after acid digestion following ISO 11466 (1995). Potentially available nickel was extracted using diethylenetriaminepentaacetic acid (DTPA) according to ISO 14870 (2001), while exchangeable nickel was obtained using 0.1 M $Sr(NO_3)_2$ extraction (van der Ent et al., 2019).

Iron oxide fractions were differentiated by selective chemical extraction. Amorphous iron oxides ($Fe_o$) were extracted using ammonium oxalate, whereas free iron oxides ($Fe_d$) were determined using the citrate-bicarbonate-dithionite method (Sparks, 1996). The crystalline iron oxide fraction ($Fe_{cr}$) was calculated as the difference between Fed and Feo. The Feo/Fed ratio was used as an indicator of pedogenic development and weathering

intensity. Elemental concentrations were measured using ICP-OES.

***Mineralogical characterization***

Mineralogical composition was analyzed by X-ray diffraction (XRD). Powder diffraction patterns were recorded over an angular range of 5-80° 2θ using Cu Kα radiation. Phase identification was performed using standard reference databases, and quantitative phase analysis was carried out by Rietveld refinement.

***Statistical analysis***

Differences among sampling sites were evaluated using one-way analysis of variance (ANOVA). Correlation analysis was applied to assess relationships between soil properties and the distribution of nickel fractions. Statistical significance was considered at $p < 0.05$.

## RESULTS AND DISCUSSIONS

***Soil physicochemical properties and total nickel content***

The main physicochemical characteristics of the serpentine soils from the Eastern and Southern Rhodopes are summarised in Table 1. Soil reaction varies within a relatively narrow range, from slightly acidic to slightly alkaline (pH 6.05-7.62), with a mean value of 6.84. Such pH conditions are typical for serpentine-derived soils and reflect the buffering effect of the Mg-rich ultramafic parent material (Brooks, 1987; Kabata-Pendias, 2011).

Organic matter content (LOI) is generally low to moderate (2.27-8.30%), characteristic of ultramafic soils with limited biological productivity and reduced potential for humus accumulation (Alexander et al., 2007). The cation exchange capacity (CEC) shows substantial variability (83.1-434.5 mmolc/kg), indicating differences in soil texture, mineralogical composition and degree of pedogenic development across the studied sites. Total Ni concentrations are high across all samples, ranging from 919.9 to 2397.2 mg/kg, with a mean of 1667.9 mg/kg. These values greatly exceed background concentrations typical for non-serpentine soils and clearly indicate a dominant geogenic control on Ni accumulation derived from the ultramafic parent material (Brooks, 1987; Alloway, 2013). Similar concentrations have been reported for serpentine soils into other ultramafic regions worldwide reflecting the structural incorporation of Ni in primary silicate minerals of the parent rock (Alexander et al., 2007; Bani et al., 2009).

Table 1. Descriptive statistics of physicochemical properties, iron oxides and nickel fractions in serpentine soils of the Eastern and Southern Rhodopes

***Distribution of nickel among chemical fractions and indicators of mobility***

Selective extraction results reveal a pronounced fractionation of nickel among the investigated soil phases (Figure 1). Boxplots show minimum, first quartile (Q1), median, third quartile (Q3), and maximum values for total Ni, oxalate extractable Ni (Ni–Ox; associated with amorphous Fe oxides). The potentially bioavailable fraction, determined by DTPA extraction, represents only a small proportion of the total Ni pool. Ni-DTPA concentrations vary widely (6.08-125.28 mg/kg), with an average of

46.96 mg/kg, indicating that despite the very high total Ni concentrations, its mobility and immediate bioavailability remain limited.

Nickel associated with amorphous and poorly crystalline iron oxides (Ni-oxalate) ranges from 103.5 to 667.5 mg/kg (mean 398.3 mg/kg). In contrast, nickel bound to free crystalline iron oxides (Ni-DCB) varies between 61.3 and 583.8 mg/kg (mean 335.8 mg/kg). This distribution indicates that a significant portion of Ni has been secondarily incorporated into Fe-oxide phases during pedogenesis.

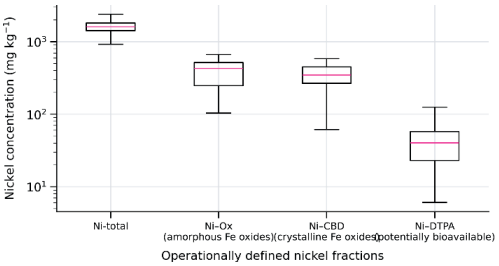

Figure 1. Nickel speciation in serpentine soils from the Eastern and Southern Rhodopes, Bulgaria

The exchangeable fraction extracted with $Sr(NO_3)_2$ is extremely low (0.01-4.32 mg/kg), confirming that easily mobile Ni forms represent only a negligible component of the overall Ni pool in these soils. These results highlight that total Ni content alone is not a reliable indicator of ecological risk or plant availability, as nickel speciation exerts a fundamental control on its environmental behaviour (Kabata-Pendias, 2011; Alloway, 2013).

### *Iron oxides and the $Fe_o/Fe_d$ pedogenic indicator*

Amorphous ($Fe_o$) and free crystalline ($Fe_d$) iron oxide contents show substantial variability among the studied serpentine soils. $Fe_o$ concentrations range from 1,512 to 6,552 mg/kg, while $Fe_d$ reaches values up to 41,096 mg/kg. Consequently, the $Fe_o/Fe_d$ ratio - commonly used as an indicator of iron oxide crystallinity and pedogenic development - varies widely between 0.09 and 1.27.

This variability indicates that the investigated soils represent a broad pedogenic spectrum, ranging from weakly developed serpentine regoliths dominated by crystalline Fe oxides to more evolved soils characterised by a greater contribution of amorphous and poorly crystalline Fe phases. Such variability reflects progressive transformations of Fe oxides during pedogenesis and highlights the dynamic role of these phases in regulating Ni stabilisation.

The relationship between $Fe_o/Fe_d$ and potentially bioavailable nickel (Ni-DTPA), illustrated in Figure 2, suggests that higher Ni-DTPA values occur mainly in soils exhibiting intermediate $Fe_o/Fe_d$ ratios. In this figure, boxplots show the minimum, first quartile (Q1), median, third quartile (Q3), and maximum values for oxalate-extractable iron ($Fe_o$), dithionite-citrate-bicarbonate-extractable iron ($Fe_d$), and their ratio ($Fe_o/Fe_d$), used as an indicator of iron oxide crystallinity and degree of pedogenetic development, with the y-axis presented on a logarithmic scale.

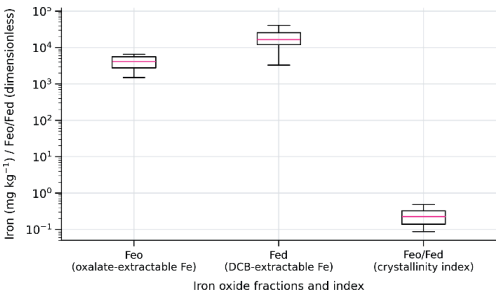

Figure 2. Distribution of iron oxide fractions and $Fe_o/Fe_d$ ratio in the investigated serpentine soils

These systems are characterised by a substantial presence of amorphous and poorly crystalline iron oxides, which act as highly reactive sorbents that temporarily retain nickel in relatively labile forms. This observation is consistent with mechanisms described in the literature, in which amorphous Fe oxides function as transitional reservoirs that control Ni mobility before its stabilisation in more crystalline phases (Chardot et al., 2007; Echevarria, 2018). Overall, iron oxides play a central role in regulating nickel mobility in serpentine soils. The wide variability of the Feo/Fed ratio reflects different stages of oxide transformation and soil ageing (Blume & Schwertmann, 1969; Schwertmann & Taylor, 1989). Amorphous and poorly crystalline Fe oxides provide large reactive surfaces and bind nickel less strongly than well-crystallised oxides, potentially enhancing its availability

(Chardot et al., 2007; Echevarria, 2018). With progressive pedogenic development and increasing crystallinity of Fe oxides, nickel becomes more efficiently stabilised, and its mobility decreases, in agreement with the conceptual model proposed by Echevarria (2018), which emphasises the role of amorphous Fe phases as key Ni buffers in moderately developed ultramafic soils.

***Multivariate analysis (PCA and cluster analysis)***

Principal component analysis (PCA; Figure 3), presented as a biplot with PC1 and PC2 axes showing both variable loadings and sample scores, integrates soil physicochemical parameters, Ni fractions, iron oxide characteristics, and mineralogical composition, revealing a clear pedogenic gradient that controls Ni speciation and potential bioavailability. The first principal component (PC1) is dominated by variables related to Fe oxides ($Fe_o$, $Fe_d$, $Fe_o/Fe_d$) and associated Ni fractions, highlighting the central role of iron oxide dynamics in Ni retention and redistribution. The second principal component (PC2) primarily reflects variations in pH, texture, and mineralogical composition, indicating the influence of lithogenic control and soil physicochemical conditions.

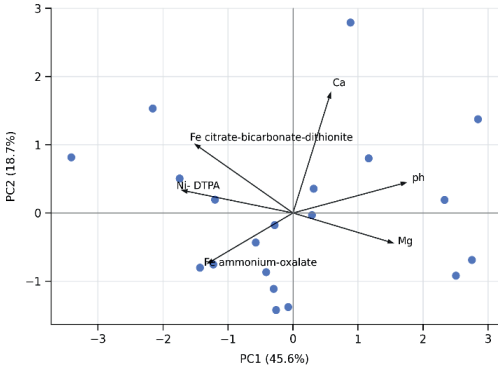

Figure 3. Principal component analysis (PCA) of serpentine soils from the Eastern and Southern Rhodope Mountains.

Cluster analysis (Figure 4), displayed as a hierarchical dendrogram based on standardized physicochemical parameters, Ni fractions, and iron oxide indicators, further supports the PCA results by grouping soils into several functional clusters that reflect differences in pedogenic development, mineralogical inheritance, and Ni mobility. These clusters form a pedogenic sequence ranging from weakly developed soils with relatively higher proportions of labile Ni to more stabilised systems where Ni is increasingly fixed in crystalline Fe oxides and secondary mineral phases. Soils at intermediate developmental stages form distinct clusters characterised by higher Ni-DTPA and Ni-oxalate values. In contrast, both less developed and more stabilised systems show a dominance of structurally and oxide-bound Ni. The consistency between PCA and cluster analysis confirms the existence of a pedogenic continuum controlling Ni stabilisation mechanisms in serpentine soils.

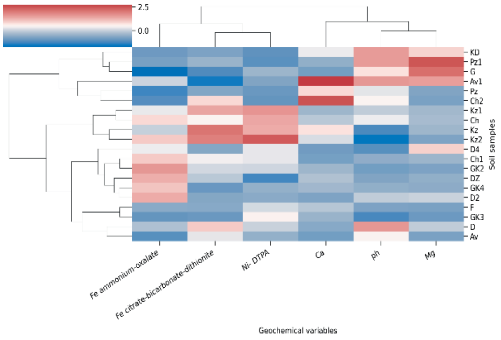

Figure 4. Hierarchical cluster analysis (HCA) of serpentine soils from the Eastern and Southern Rhodope Mountains

***Mineralogical composition and its influence on nickel mobility and bioavailability***

X-ray diffraction (XRD) analysis indicates that the mineralogical composition of the studied soils is dominated by primary ultramafic minerals typical of serpentinised parent materials. The dominant mineral phase in all soils is antigorite, with contents ranging from 19 to 86% and an average of approximately 60.6%. In several sites (Gornoslav, Dyulitsa, Parvenets) antigorite reaches particularly high proportions, indicating strong lithogenic control and relatively limited chemical weathering.

Lizardite occurs in fewer samples, with contents reaching up to 20%. Its presence, together with antigorite, indicates different serpentinisation pathways and variable stability of serpentine phases during pedogenesis. Both minerals belong to the serpentine group and represent

major structural hosts of Ni through isomorphic substitution of $Mg^{2+}$ by $Ni^{2+}$ within octahedral positions of the crystal lattice (Brooks, 1987; Kabata-Pendias, 2011).

A particularly important mineralogical observation is the identification of willemseite (Ni-rich serpentine) in several soils, with contents reaching up to 24%. Willemseite provides direct evidence for structurally bound nickel incorporated within the primary mineral lattice during rock formation. This mineralogical control explains the combination of high total Ni concentrations and very low exchangeable and DTPA-extractable fractions observed in the studied soils. Similar mineralogical controls on Ni behaviour have been reported in other ultramafic regions (Alexander et al., 2007; Bani et al., 2009).

Among the secondary phases, clinochlore plays an important role, reaching up to 48% in some samples (e.g., Golyamo Kamenyane). Clinochlore forms during secondary transformation of serpentine minerals and may retain Ni through surface sorption and partial structural incorporation. Quartz occurs as a secondary component (up to 55%), reflecting silica enrichment during weathering but contributing little to Ni retention. Montmorillonite is present only in minor amounts (< 9%), indicating limited development of advanced clay mineral phases and a relatively moderate pedogenic intensity.

Mineralogical composition, therefore, exerts a fundamental control on Ni behaviour by determining both the initial geochemical reservoir and its subsequent transformation during pedogenesis. The dominance of serpentine minerals indicates that a large proportion of Ni remains structurally bound within primary ultramafic silicate phases, exhibiting extremely low mobility and minimal bioavailability (Brooks, 1987; Kabata-Pendias, 2011).

With progressive weathering, part of the Ni released from primary minerals becomes incorporated into secondary phases. Clinochlore and Fe oxides act as intermediate geochemical reservoirs, temporarily retaining Ni. Amorphous and poorly crystalline Fe oxides function as reactive sorbents, whereas well-crystallised oxides provide more stable long-term fixation (Schwertmann & Taylor, 1989; Chardot et al., 2007).

This mineralogical-geochemical evolution forms a pedogenic continuum in which structurally bound Ni dominates in early stages of serpentine minerals, intermediate stages involve redistribution toward amorphous Fe oxides and clinochlore, and more advanced stages lead to the stabilisation of Ni in crystalline oxides and secondary mineral phases. Similar pedogenic sequences have been documented in temperate and Mediterranean ultramafic systems and provide a key framework for explaining the observed spatial variability in Ni mobility and plant accumulation (Chardot et al., 2007; Bani et al., 2013; Echevarria, 2018).

***Conceptual model of Ni stabilisation in serpentine soils***

The results obtained in this study allow the development of a conceptual model describing the mechanisms controlling nickel stabilisation in serpentine soils of the Eastern and Southern Rhodopes (Figure 5). The conceptual diagram illustrates the role of serpentine minerals (antigorite, lizardite, willemseite) as primary Ni reservoirs through structural incorporation, and highlights the contribution of secondary minerals and iron oxides in regulating Ni mobility. The model integrates mineralogical inheritance from ultramafic parent material with pedogenic transformations affecting Ni speciation and mobility.

In the initial stage, nickel is predominantly structurally incorporated into primary serpentine minerals such as antigorite, lizardite, and willemseite, where it substitutes for $Mg^{2+}$ in the octahedral positions of the crystal lattice. Under these conditions, Ni is largely immobile and poorly available for biological uptake.

During progressive weathering and pedogenesis, partial dissolution of serpentine minerals releases Ni into the soil system. A significant portion of this Ni is subsequently associated with amorphous and poorly crystalline Fe oxides, which act as highly reactive sorbents and temporary geochemical reservoirs. This stage is characterised by relatively higher proportions of labile Ni fractions, reflected in increased Ni-DTPA and Ni-oxalate concentrations.

With further pedogenic development, iron oxides progressively transform into more crystalline phases, enhancing the long-term stabilisation of nickel through stronger sorption and co-precipitation mechanisms. Consequently, Ni becomes increasingly immobilised in crystalline Fe oxides and secondary mineral phases, leading to reduced mobility and lower potential bioavailability.

Overall, this conceptual framework highlights the combined influence of lithogenic inheritance and pedogenic transformation processes on the distribution, mobility, and environmental behaviour of nickel in serpentine soils.

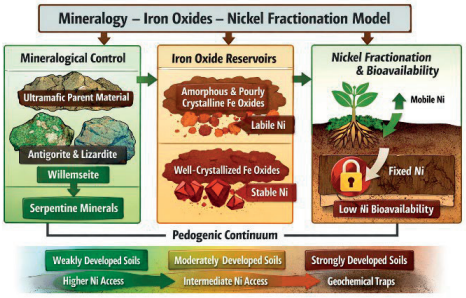

Figure 5. Conceptual model of nickel (Ni) behaviour in serpentine soils of the Eastern and Southern Rhodopes (Generated using Microsoft Copilot)

## CONCLUSIONS

This study provides a comprehensive assessment of nickel (Ni) speciation, mobility, and potential bioavailability in serpentine soils of the Eastern and Southern Rhodopes, highlighting the key role of mineralogical inheritance and pedogenetic processes.

The soils are characterised by high total nickel concentrations, confirming the dominant geogenic control exerted by the ultramafic parent material. However, the potentially bioavailable fraction of Ni is limited, indicating that total element content alone does not reflect ecological risk.

Mineralogical analysis shows that serpentine minerals - antigorite and lizardite - serve as the primary reservoirs of nickel through structural incorporation. The detection of willemseite provides direct evidence for stably fixed nickel and explains its low mobility. Secondary mineral phases, primarily clinochlore and iron oxides, act as intermediate geochemical sinks, modifying nickel distribution and regulating its mobility. Amorphous and poorly crystalline Fe oxides retain Ni in more labile pools, while well-crystallised oxides provide long-term stabilisation.

Multivariate analysis identifies a pedogenetic continuum, where intermediately developed soils exhibit higher potential Ni bioavailability, whereas poorly or highly developed soils function as stable geochemical “traps”. This continuum indicates that plant-accessible nickel is spatially heterogeneous and strongly controlled by mineralogy and iron oxide dynamics rather than total Ni content.

The proposed conceptual model, "mineralogy – iron oxides – nickel fractionation", provides a process-oriented framework for predicting Ni behaviour in temperate ultramafic ecosystems. The results are of both fundamental significance for understanding Ni biogeochemistry and practical value for ecological risk assessment and management of serpentine soils.

## ACKNOWLEDGEMENTS

This work has been carried out in the framework of the National Science Program "Critical and strategic raw materials for a green transition and sustainable development", approved by the Resolution of the Council of Ministers no. № 508/18.07.2024 and funded by the Ministry of Education and Science (MES) of Bulgaria.

***Abstract***

*Aromatic plants of the Asteraceae family have significant potential for phytoremediation due to their rapid growth, high biomass production, and resilience in contaminated soils. This study evaluated the capacity of Artemisia absinthium, Achillea millefolium, Tanacetum balsamita, Tanacetum vulgare, and Artemisia dracunculus to accumulate heavy metals in soils contaminated by industrial activities in Bulgaria. Field experiments were conducted at contaminated sites, where soil and plant tissues (roots, stems, leaves, and flowers) were analysed for Pb, Cd, and Zn using ICP-OES. Bioconcentration (BCF) and translocation (TF) factors were calculated to assess metal uptake and distribution from roots to aboveground biomass. The results demonstrate considerable accumulation of Pb and Zn, with A. absinthium and A. millefolium exhibiting the highest BCF and TF values, indicating their suitability as the most effective species for phytoextraction. T. balsamita and T. vulgare displayed moderate accumulation with limited translocation, suggesting their potential for phytostabilisation, whereas A. dracunculus showed minimal uptake. These findings provide important insights into metal accumulation and translocation in Asteraceae species and identify the most promising species for the sustainable management of industrially contaminated soils.*

***Key words****: Asteraceae, aromatic plants, heavy metals, phytoremediation, bioaccumulation, soil contamination.*

## INTRODUCTION

Soil contamination with heavy metals represents one of the most pressing environmental challenges resulting from industrialisation, mining, metallurgical activities, and intensive agriculture. Among the most prevalent soil pollutants are lead (Pb), cadmium (Cd), and zinc (Zn), which are highly persistent in the environment because they are not subject to biological degradation and can remain in soils for extended periods. Accumulation of these elements in soil ecosystems can reduce soil fertility, disrupt plant growth and development, and exert toxic effects on soil microorganisms. Furthermore, heavy metals can enter the food chain, posing a serious risk to human health (Raskin & Ensley, 2000; Terry & Banuelos, 2000; Ali et al., 2013; Yan et al., 2020).

Conventional remediation methods, such as excavation, soil washing, and chemical stabilisation, are often associated with high costs, substantial technical resources, and significant disruption of soil structure and ecosystem functions. Consequently, in recent decades, there has been growing interest in phytoremediation as an environmentally friendly and cost-effective technology for restoring contaminated sites. Phytoremediation employs plants to extract, stabilise, or transform contaminants in soil and water and is considered a sustainable alternative to conventional cleanup methods (Terry & Banuelos, 2000; Angelova, 2023; Angelova & Ihtyarova, 2023; Angelova, 2025; Bhat et al., 2025). Depending on the mechanism, phytoremediation may involve phytoextraction, phytostabilisation, rhizofiltration, or phytovolatilisation, each of which differs in how plants interact with contaminants (Bhat et al., 2025).

The effectiveness of phytoremediation largely depends on selecting suitable plant species. Ideal plants should exhibit rapid growth, high biomass production, well-developed root systems, and tolerance to elevated contaminant concentrations. Recently, there has been increasing scientific interest in using medicinal and aromatic plants for phytoremediation. These plants typically show high resilience to abiotic stress and can thrive on margminal or degraded soils. Moreover, their economic value associated with bioactive compounds, enables

the integration of environmental and economic benefits (Deng et al., 2024; Yadav et al., 2025). Particular attention has been given to species from the Asteraceae family, which are widely distributed and well-adapted to diverse environmental conditions. Many members exhibit high ecological plasticity, rapid growth, and substantial biomass production - key traits for successful phytoremediation. Genera such as Achillea, Artemisia, and Tanacetum include species used in traditional medicine and the production of pharmaceutical products. Studies indicate that these plants can accumulate significant amounts of heavy metals in various organs while maintaining resilience in contaminated environments (Salt et al., 1998; Sharma et al., 2023; Zhang et al., 2024; Bhat et al., 2025).

Despite growing interest in using aromatic plants for phytoremediation, several aspects remain underexplored. Most research has focused on classical hyperaccumulator or energy crop species, while the potential of aromatic plants, particularly Asteraceae, remains relatively poorly investigated. Information on the distribution of heavy metals among different plant organs and the efficiency of translocation from roots to shoots under naturally contaminated conditions is limited.

This knowledge gap is especially relevant for regions with long-term industrial and mining activities, where soils are often heavily contaminated with Pb, Cd, and Zn. In Bulgaria, numerous industrial and mining areas face significant environmental challenges from heavy metal accumulation, underscoring the need for sustainable, effective remediation strategies.

The present study addresses this gap by systematically evaluating the phytoremediation potential of selected aromatic Asteraceae species grown on industrially contaminated soils in Bulgaria. By analysing Pb, Cd, and Zn concentrations in roots, stems, and leaves and calculating bioconcentration (BCF) and translocation (TF) factors, the study provides a comprehensive assessment of these species' capacity to accumulate and translocate heavy metals.

The objectives of this study are: (i) to determine Pb, Cd, and Zn concentrations in different plant organs (roots, stems, leaves, flowers); (ii) to evaluate the species' ability to accumulate and translocate metals through BCF and TF calculations; and (iii) to identify species with the highest potential for application in the phytoremediation of heavy metal-contaminated soils.

The results will contribute to a better understanding of the mechanisms of metal accumulation and translocation and support the development of sustainable strategies for the management and restoration of industrially contaminated soils.

## MATERIALS AND METHODS

The study was conducted on soils located in the vicinity of a major industrial pollution source - the Non-Ferrous Metal Works near Plovdiv, Bulgaria. The sampling sites are situated at approximately 0.5 km from the emission source, where long-term industrial activity has resulted in significant accumulation of trace metals in the surface soil layer.

This site has been extensively investigated in previous studies focused on plant-based phytoremediation (Angelova, 2020; Angelova & Ihtyarova, 2023; Angelova & Ihtyarova, 2025), and is therefore considered a well-characterised system for assessing heavy metal behaviour under field conditions.

Seedlings of selected medicinal plants - costmary (*Tanacetum balsamita* L.), tansy (*Tanacetum vulgare* L.), yarrow (*Achillea millefolium* L.), wormwood (*Artemisia absinthium* L.), and tarragon (*Artemisia dracunculus* L.) - were obtained from a commercial nursery and planted in spring. Plant samples were collected during the flowering stage in the second and third years after planting and dried at room temperature to a constant air-dry mass.

Pseudo-total metal content in the soil was determined following ISO 11466. At the same time, concentrations of Pb, Zn, and Cd in plant organs (roots, stems, leaves, and flowers) were analysed after microwave-assisted acid digestion. Quantitative measurements were performed using inductively coupled plasma optical emission spectrometry (ICP-OES; Jobin Yvon Emission JY 38 S, France), with analytical accuracy validated using apple leaves as a certified reference material (SRM 1515, NIST).

Phytoremediation potential was evaluated using quantitative indices describing metal uptake, translocation, and accumulation in plant tissues (Raskin & Ensley, 2000; Terry & Banuelos, 2000). The phytoremediation assessment focused on three key indicators: the bioconcentration factor (BCF), the translocation factor (TF), and the aboveground accumulation factor (BAF). These parameters are widely applied in studies of heavy metal uptake and phytoextraction efficiency (Yoon et al., 2006; Kabata-Pendias, 2011; Ali et al., 2013). BCF quantifies root uptake relative to soil concentrations (BCF = Croot/Csoil). TF evaluates internal metal mobility and is calculated for individual organs (TF_stem = Cstem/Croot; TF_leaf = Cleaf/Croot; TF_flower = Cflower/Croot) as well as a total value (TF_total = Caboveground/Croot). BAF represents the accumulation of metals in the aboveground biomass relative to soil concentration (BAF = Caboveground/Csoil).

Together, these metrics provide a concise evaluation of metal uptake, translocation, and accumulation efficiency. BCF reflects the efficiency of metal uptake by roots relative to soil concentrations; values >1 indicate effective extractors, whereas values <0.1 denote stabilisers or metal excluders. TF characterises internal metal translocation, with TF_total summarising transport from roots to all aboveground tissues; TF_total >1 indicates efficient translocation, while TF_total <1 suggests predominant root retention and potential for phytostabilisation. BAF integrates uptake and translocation into a direct indicator of phytoextraction potential. Together, these metrics enable robust classification of species as accumulators, intermediates, stabilisers, or excluders, supporting their targeted application in sustainable soil remediation strategies.

## RESULTS AND DISCUSSIONS

### *Soil Contamination Characteristics*

Soils at the investigated site show markedly elevated concentrations of heavy metals as a result of long-term industrial activity in the region. The measured concentrations of Zn, Pb and Cd considerably exceed commonly accepted guideline values for agricultural soils reported in the literature, indicating severe contamination (Kabata-Pendias, 2011).

Zinc concentrations generally fall within the range typical for metal-impacted soils in proximity to metallurgical facilities, while lead and cadmium levels also indicate strong anthropogenic influence. Such elevated concentrations reflect the long-term accumulation of trace elements derived from emissions of the nearby Non-Ferrous Metal Works and associated industrial activities.

Similar contamination patterns for this site have been previously reported (Angelova et al., 2025), confirming that the studied soils represent a characteristic example of chronically polluted industrial areas. Under such conditions, only plant species with high tolerance to metal stress are able to persist, often developing adaptive physiological and biochemical mechanisms that enable survival in highly contaminated environments.

Measured concentrations (Table 1) further confirm that Zn, Pb and Cd levels exceed regulatory limits by several-fold. Such contamination levels are characteristic of soils affected by mining and metallurgical activities, where prolonged anthropogenic inputs lead to the accumulation of trace metals (Alloway, 2013). Elevated concentrations of Pb, Cd and Zn impose strong selective pressure on vegetation, favoring species capable of tolerating metal stress and regulating metal uptake. Plants growing under such conditions typically activate complex physiological and biochemical defense mechanisms, including metal binding, antioxidant responses and intracellular compartmentalization, which allow them to maintain metabolic function despite high soil contamination (Al-Khayri et al., 2023).

### *Heavy Metal Accumulation in Plant Organs*

Analysis of metal concentrations in different plant organs revealed substantial interspecific and metal-specific differences. The highest concentrations of Pb, Cd, and Zn were generally observed in leaves and roots, while stems contained considerably lower amounts (Table 1). This pattern is characteristic of plants actively translocating metals to aerial tissues (Angelova, 2020; Angelova & Ihtyarova, 2023; Ihtyarova & Angelova, 2023; Angelova, 2023; Angelova, 2025). Roots serve as the primary site of metal uptake from the soil solution, after which ions are transported to aboveground tissues via the xylem, where they accumulate in

leaves and other photosynthetically active organs. In some cases, leaf metal accumulation may also result from atmospheric deposition of metal particles, especially in industrially contaminated areas (Rahman et al., 2024). Similar accumulation patterns have been documented in aromatic Asteraceae, which demonstrate enhanced metal tolerance and the ability to regulate intracellular concentrations through detoxification and compartmentalisation mechanisms (Ali et al., 2013; Kumar et al., 2016).

Table 1. Concentrations of Pb, Cd, and Zn (mg/kg) in soils and different plant organs (roots, stems, leaves, flowers) of selected Asteraceae species grown on industrially contaminated sites

| Species/Element | | Soils | Roots | Stems | Leaves | Flowers |
|---|---|---|---|---|---|---|
| *Artemisia absinthium* | Pb | 2509.1 | 1913.0 | 123.5 | 4414.9 | 1223.3 |
| | Cd | 64.3 | 102.7 | 19.9 | 225.1 | 163.9 |
| | Zn | 2423.9 | 1495.2 | 76.1 | 2026.6 | 911.5 |
| *Achillea millefolium* | Pb | 2509 | 1000.3 | 230.8 | 405.6 | 1170.9 |
| | Cd | 64.3 | 102.6 | 82.7 | 133.0 | 89.8 |
| | Zn | 2423.9 | 506.4 | 196.1 | 737.6 | 1035.3 |
| *Tanacetum balsamita* | Pb | 2966.9 | 676.3 | 495.1 | 566.0 | 244.1 |
| | Cd | 92.0 | 58.4 | 77.1 | 59.7 | 18.4 |
| | Zn | 3196.1 | 500.7 | 395.1 | 664.6 | 159.7 |
| *Tanacetum vulgare* | Pb | 2966.9 | 237.1 | 71.8 | 425.0 | 310.6 |
| | Cd | 92.0 | 56.3 | 75.4 | 99.4 | 56.5 |
| | Zn | 3196.1 | 112.8 | 73.9 | 508.0 | 312.4 |
| *Artemisia dracunculus* | Pb | 2509.1 | 91.1 | 56.5 | 742.8 | 294.3 |
| | Cd | 64.3 | 3.9 | 15.5 | 39.0 | 35.1 |
| | Zn | 2423.9 | 50.9 | 68.5 | 556.1 | 304.6 |

### *Metal-Specific Uptake and Translocation Patterns*

*Artemisia absinthium* exhibited the highest Pb accumulation among the studied species, with leaf concentrations exceeding 4415 mg/kg and root concentrations of around 1913 mg/kg. The high translocation factor (TF_leaf > 2) indicates effective transport to aerial parts. This is unusual, as Pb generally has low mobility and is largely retained in roots due to strong binding to cell walls and limited xylem transport (Rahman et al., 2024). Enhanced mobility may involve organic ligands, such as phenolics and terpenoids, which facilitate Pb translocation. *Achillea millefolium* also accumulated considerable Pb, particularly in flowers, suggesting active translocation to reproductive organs (Salt et al., 1998; Angelova & Ihtyarova, 2023; Yadav et al., 2025). *T. balsamita* and *T. vulgare* retained Pb mainly in roots, characteristic of phytostabilisation strategies (Ali et al., 2013; Nikolić & Stević, 2015; Angelova & Ihtyarova, 2023; Angelova, 2025). *Artemisia dracunculus* showed minimal Pb uptake (BCF = 0.04) (Table 2), indicating limited Pb accumulation under the studied conditions.

Cd exhibited higher mobility than Pb. The highest concentrations were observed in leaves of *A. absinthium* (225.1 mg/kg) and *A. millefolium* (133.0 mg/kg), indicating efficient translocation to aboveground tissues. High Cd accumulation reflects effective detoxification mechanisms, including complexation with organic acids, amino acids, and phytochelatins (Clemens et al., 2013). Cd is relatively easily transported via the xylem to photosynthetic tissues (Tao & Lu, 2022). In *A. dracunculus*, Cd accumulated primarily in leaves and flowers despite low root concentrations, demonstrating efficient internal metal transport (Nagajyoti et al., 2010).

Table 2. Bioconcentration (BCF), translocation (TF), and aboveground accumulation (BAF) factors for Pb, Cd, and Zn in selected Asteraceae species cultivated on industrially contaminated soils

| Element | BCF | TF stem | TF leaf | TF flower | TF total | BAF |
|---|---|---|---|---|---|---|
| *T. balsamita* | | | | | | |
| Pb | 0.23 | 0.73 | 0.84 | 0.36 | 1.93 | 0.44 |
| Cd | 0.64 | 1.32 | 1.02 | 0.32 | 2.66 | 1.69 |
| Zn | 0.16 | 0.79 | 1.33 | 0.32 | 2.43 | 0.38 |
| *T. vulgare* | | | | | | |
| Pb | 0.08 | 0.30 | 1.79 | 1.31 | 3.41 | 0.27 |
| Cd | 0.61 | 1.34 | 1.77 | 1.00 | 4.11 | 2.51 |
| Zn | 0.04 | 0.66 | 4.51 | 2.77 | 7.93 | 0.28 |
| *A. millefolium* | | | | | | |
| Pb | 0.40 | 0.23 | 0.41 | 1.17 | 1.81 | 0.72 |
| Cd | 1.60 | 0.81 | 1.30 | 0.88 | 2.98 | 4.75 |
| Zn | 0.21 | 0.38 | 1.46 | 2.04 | 3.89 | 0.81 |
| *A. absinthium* | | | | | | |
| Pb | 0.76 | 0.06 | 2.30 | 0.64 | 3.01 | 2.30 |
| Cd | 1.60 | 0.19 | 2.19 | 1.60 | 3.98 | 6.36 |
| Zn | 0.62 | 0.05 | 1.36 | 0.61 | 2.02 | 1.24 |
| *A. dracunculus* | | | | | | |
| Pb | 0.04 | 0.62 | 8.15 | 3.23 | 12.01 | 0.44 |
| Cd | 0.06 | 3.97 | 9.96 | 8.95 | 22.87 | 1.39 |
| Zn | 0.02 | 1.34 | 10.93 | 5.99 | 18.26 | 0.38 |

Zn is an essential micronutrient with tightly regulated uptake. The highest concentrations were observed in *A. absinthium* leaves (>2000 mg/kg). Relatively high concentrations were also detected in *A. millefolium*, especially in leaves and flowers, indicating that Asteraceae species can accumulate Zn without visible toxicity symptoms, likely through intracellular compartmentalisation (Broadley et al., 2007; Balafrej et al., 2020).

### *Species-Specific Phytoremediation Strategies*

*Artemisia absinthium* demonstrated the highest capacity for heavy metal accumulation. The genus Artemisia is known for resilience to

abiotic stress, including metal contamination, activating protective mechanisms through enhanced synthesis of secondary metabolites such as terpenes and phenolics (Balafrej et al., 2020). *Achillea millefolium* also showed considerable potential for Pb, Cd, and Zn accumulation, making it promising for phytoextraction (Angelova & Ihtyarova, 2023). *T. balsamita* and *T. vulgare* exhibited moderate BCF and limited translocation, suitable for phytostabilisation (Nikolić & Stevović, 2015). *Artemisia dracunculus* showed low accumulation potential and is suitable for cultivation on moderately contaminated soils.

***Morphological Determinants of Metal Uptake***

Morphological traits significantly influence metal accumulation. Species with deep, branched roots, such as *A. absinthium* and *A. millefolium*, showed higher efficiency in metal ion uptake. Dense leaf trichomes enhance deposition of atmospheric metal particles, leading to higher Pb concentrations in leaves, particularly in industrial areas (Rahman et al., 2024). High transpiration rates facilitate transport of mobile metals such as Cd and Zn to aerial organs (Tao & Lu, 2022).

***Bioconcentration and Translocation Factors***

Bioconcentration and Translocation Factors BCF indicates a plant's ability to extract metals from soil, while TF reflects the efficiency of transport to aboveground tissues (Yoon et al., 2006). *A. absinthium* and *A. millefolium* exhibited BCF > 1 for Cd and Zn, along with high TF values (Table 2), confirming their phytoextraction potential (Angelova & Ihtyarova, 2023). In the case of Pb, although BCF values in *A. absinthium* were moderate, the high TF_leaf and TF_total values indicate efficient translocation from roots to aboveground tissues. This results in enhanced accumulation in leaves, which may exceed soil concentrations and reflects the strong accumulator behaviour of the species. As shown in Table 2, although the BCF value (0.76) indicates moderate uptake from soil, the translocation factors, particularly TF_leaf (2.30) and TF_total (3.01), demonstrate highly efficient transport of Pb from roots to aboveground tissues. In addition, the BAF value (2.30) indicates significant accumulation in the aerial biomass. This combination of moderate uptake and strong translocation results in the enrichment of Pb in leaves, leading to concentrations exceeding those in soil. Therefore, this behavior confirms the classification of *Artemisia absinthium* as an accumulator species rather than indicating an inconsistency. Furthermore, the contribution of atmospheric deposition in industrially affected areas may also enhance Pb levels in leaves. *T. balsamita* and *T. vulgare* had lower BCF and TF, typical of stabilisers (Nikolić & Stevović, 2015). A. dracunculus showed low BCF and TF, confirming limited metal uptake.

***Implications for Phytoremediation***

The results indicate that aromatic Asteraceae species can be integrated into sustainable strategies for managing metal-contaminated soils. High-accumulating species, such as *A. absinthium* and *A. millefolium*, are suitable for phytoextraction, whereas moderately accumulating species may serve in phytostabilisation (Ali et al., 2013; Nikolić & Stevović, 2015; Angelova, 2020; Angelova & Ihtyarova, 2023). An integrated analysis of BCF, TF_total, and BAF revealed clear differences among species. *A. absinthium* and *A. millefolium* showed the highest potential for Cd and Zn extraction, with elevated BCF, TF_total > 1, and BAF > 1 (Table 3). *T. balsamita* and *T. vulgare* exhibited moderate or partial extraction, while *A. dracunculus* displayed typical excluder behavior with low uptake but maintained internal translocation, suitable for stabilisation. These findings demonstrate the differentiated phytoremediation potential of *Asteraceae* species, indicating their promise as sustainable, multifunctional crops that combine metal tolerance with high aboveground biomass production.

From a practical perspective, the utilization of the resulting biomass depends on the level of metal accumulation and the target element. For species with high accumulation in aboveground tissues, such as *A. absinthium* and *A. millefolium*, direct use for food, feed or medicinal purposes is not recommended due to the risk of metal transfer. However, the biomass can be directed toward non-food applications, such as bioenergy production or essential oil extraction, where metals are not transferred into

the distilled product. In contrast, low-accumulating species such as *A. dracunculus* may be suitable for controlled use in moderately contaminated soils.

Table 3. Phytoremediation classification of selected Asteraceae species for Pb, Cd, and Zn, based on metal accumulation and translocation patterns.

| Species | Pb | Cd | Zn |
|---|---|---|---|
| *Artemisia absinthium* | Accumulator | Strong accumulator / Hyperaccumulator | Accumulator |
| *Achillea millefolium* | Intermediate accumulator | Strong accumulator | Accumulator |
| *Tanacetum balsamita* | Intermediate accumulator | Accumulator | Intermediate accumulator |
| *Tanacetum vulgare* | Mixed behavior | Accumulator | Mixed |
| *Artemisia dracunculus* | Metal excluder | Mixed behavior | Metal excluder |

Note: Classification is based on BCF, TF_total, and BAF values. Species with BCF > 1 and TF_total > 1 are considered potential phytoextractors, whereas species with BCF > 1 but TF_total < 1 are classified as phytostabilisers. Species with BCF < 1 are considered metal excluders. "Mixed" indicates species exhibiting contrasting behaviour depending on the metal or showing inconsistent BCF and TF patterns.

## CONCLUSIONS

The present study demonstrates clear interspecific differences among Asteraceae species in their capacity for heavy metal uptake, accumulation, and translocation under conditions of severe industrial soil contamination. *Artemisia absinthium* and *Achillea millefolium* exhibited the highest phytoextraction potential, characterised by efficient accumulation of Pb, Cd, and Zn and effective translocation to the aboveground biomass. In contrast, *T. balsamita* and *T. vulgare* showed moderate metal accumulation and limited translocation, indicating a phytostabilisation-oriented strategy. *Artemisia dracunculus* displayed minimal metal uptake and typical excluder behaviour, suggesting its suitability for cultivation on moderately contaminated soils rather than for active phytoextraction.

Morphological traits, particularly a well-developed root system, leaf surface characteristics, and high transpiration capacity, appear to play a critical role in regulating metal uptake and internal transport within plant tissues. Overall, the findings highlight the significant potential of aromatic Asteraceae species as multifunctional crops for the sustainable management of metal-contaminated soils. Their capacity to combine metal tolerance with productive aboveground biomass supports their inclusion in future phytoremediation strategies aimed at the ecological restoration of industrially impacted landscapes.

***Abstract***

*Soil and groundwater contamination with hydrocarbons represents a major environmental issue in port–industrial areas, with direct impacts on agricultural ecosystems and the quality of life of local populations. This study investigates the degree of pollution in the Oil Terminal Constanța North area, located outside the industrial enclosure, within a residential zone where the persistent smell of hydrocarbons indicates active contamination. Geophysical investigations were carried out using the Vertical Electrical Sounding (VES) method along four electrical profiles (P1, P2, P3, and P4), with a spacing of 10 m between measurement points. The main objective was to determine the geological structure, identify the groundwater table, and highlight its relationship with the hydrocarbon pollution plume. The inverted geoelectrical sections, characterized by low RMS values, reveal low-resistivity anomalies associated with hydrocarbon-saturated materials, predominantly located at the groundwater level. Correlation of the geoelectrical results with the hydrostatic level map indicates a groundwater flow direction oriented toward the Black Sea, facilitating pollutant migration. The results confirm the presence of active hydrocarbon pollution, with potential impacts on agricultural soils and the coastal environment.*

***Key words****: coastal environment, electrical resistivity sounding, groundwater migration, hydrocarbon contamination, pollution plume.*

## INTRODUCTION

One of the most persistent and difficult-to-control forms of environmental contamination is soil and groundwater pollution with hydrocarbons, particularly in port-industrial areas and in the vicinity of petroleum storage and transfer facilities. Hydrocarbons can persist in the environment for long periods, affecting groundwater quality, the physicochemical properties of soils, and consequently agricultural land use, food safety, and ecosystem health.

Hydrocarbon pollution presents an additional risk in coastal areas due to the direct interaction between continental hydrogeological systems and the marine environment. The groundwater table plays a key role in contaminant transport, as hydrocarbons preferentially migrate at this level in the direction of groundwater flow, forming a pollution plume (Ali et al., 2025). Under such conditions, contamination does not remain localized but can spread over large areas, affecting both agricultural soils and the receiving marine environment.

One of the most important industrial hubs for handling and storing petroleum products in Romania is the Oil Terminal Constanța area. Over time, long-term industrial activities have generated significant environmental contamination risks, particularly in areas adjacent to the industrial enclosure. Outside the site boundary, in the northern part of the Oil Terminal, a residential area characterized by apartment buildings and green spaces has developed, where the persistent smell of hydrocarbons indicates the presence of major subsurface pollution sources.

In this context, assessing the degree of contamination and the mechanisms of hydrocarbon migration becomes essential for the sustainable management of land with agricultural potential, as well as for environmental protection in the vicinity of industrial areas. Electrometric methods represent efficient, non-destructive tools for investigating subsurface structure, identifying the groundwater table, and delineating contaminated zones through electrical resistivity

contrasts (Alao et al., 2025). Vertical Electrical Sounding (VES) is frequently used in environmental studies aimed at characterizing hydrocarbon-saturated environments, which are typically associated with lower electrical resistivity values compared to unaffected materials. The correlation of geoelectrical results with hydrogeological data allows for the delineation of the pollution plume and the determination of contaminant migration direction.

The present study aims to investigate the degree of hydrocarbon pollution in the Oil Terminal Constanța North area by applying the Vertical Electrical Sounding method along multiple electrometric profiles (Figure 1), correlated with hydrostatic regime analysis.

Figure 1. Acquisition of electrometric data using an AGI MiniSting system

The objective is to determine the geological structure of the area, highlight its relationship with the movement of the pollution plume, and identify the groundwater level, with particular emphasis on migration toward the Black Sea and its implications for the environment and soils.

## MATERIALS AND METHODS

In the northern area of the Oil Terminal Constanța, geophysical investigations were carried out outside the industrial enclosure, within a residential area characterized by apartment buildings and green spaces, where persistent hydrocarbon odors were identified. The area is located in close proximity to the port zone and is influenced by the historical activities of storage and transfer of petroleum products.

The Vertical Electrical Sounding (VES) method was used to assess the subsurface structure and the degree of pollution, this electrometric method being well established in environmental and hydrogeological studies (Goldman & Neubauer, 1994). Measurements were performed along four electrical profiles, labelled P1, P2, P3, and P4 (Figure 2), arranged in the northern extremity of the Oil Terminal, both parallel and perpendicular to the main structural directions and to the estimated groundwater flow direction. To validate the geoelectrical interpretation, two control boreholes (F1 and F2), each reaching a depth of 4 m, were drilled at representative locations within the study area (Figure 2). The borehole information was used to correlate the interpreted electrical resistivity anomalies with the local lithology and groundwater table depth, thereby increasing the reliability of the geophysical interpretation.

Figure 2. Profile layout map

A spacing of 10 m between VES points was applied in order to achieve adequate spatial resolution for identifying lateral variations in electrical resistivity (Eze & Chinemelu, 2025). The electrode configuration was designed to allow investigation of the upper meters of the subsurface, where the groundwater table develops and where the presence of a hydrocarbon pollution plume is assumed. To characterize the saturated zone, the investigation depth reached approximately 4-5 m.

Two-dimensional electrical resistivity inversion was applied to process the field data, resulting in inverted geoelectrical sections for each measured profile (Figures 3-6). The quality of the inversion was assessed using the root mean square (RMS) error, which showed low values of 3.1% for Profile 1, 4.53% for Profile 2, 5.9%

for Profile 3, and 7.07% for Profile 4. These values indicate a good agreement between the measured and calculated apparent resistivity data. Overall, the obtained RMS errors confirm the stability of the inversion solutions and the reliability of the geoelectrical interpretation. For all four profiles, the obtained RMS values confirm the stability of the inversion solutions and the reliability of the geoelectrical interpretation (Loke, 2010).

The interpretation of the geoelectrical sections involved correlating local lithology with electrical resistivity values, borehole information, and hydrogeological conditions. Zones characterized by low resistivity values were interpreted as electrically conductive materials, which may represent water-saturated fine-grained sediments, saline groundwater, wastewater infiltration, and/or hydrocarbon-contaminated horizons. The anomalies detected in this study were interpreted as hydrocarbon-affected zones only where they spatially coincide with the groundwater table, the groundwater flow direction, and the known history of petroleum-related activities in the Oil Terminal Constanța area. Higher resistivity values generally correspond to drier, coarser-grained, or more compact deposits. Particular attention was given to identifying the groundwater table and its lateral variations. Particular attention was given to identifying the groundwater table and its lateral variations.

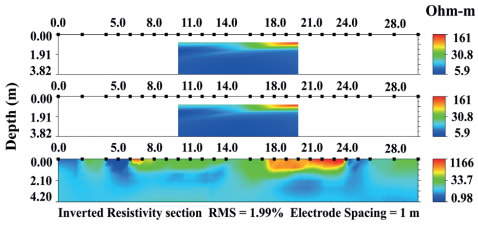

Figure 3. Inverted resistivity section - Profile 1

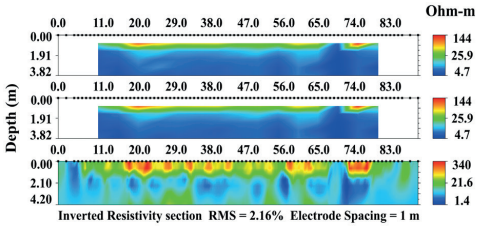

Figure 4. Inverted resistivity section - Profile 2

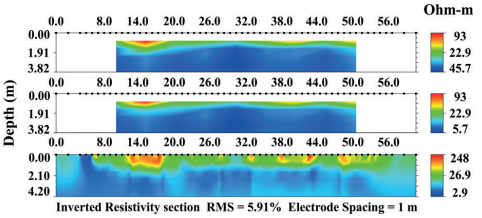

Figure 5. Inverted resistivity section - Profile 3

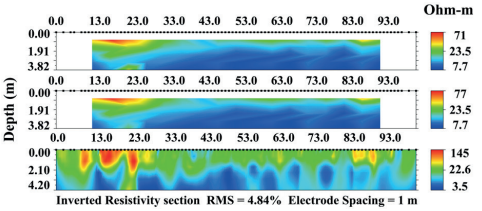

Figure 6. Inverted resistivity section - Profile 4

The analysis of pollutant migration direction was based on correlating the electrometric results with the hydrostatic level map, developed using available piezometric measurements. This correlation allowed the relationship between groundwater table position and resistivity anomaly distribution to be defined, as well as the identification of the dominant groundwater flow direction, oriented toward the coastal area of the Black Sea.

The study, based on electrometric methods and hydrostatic analysis, enabled a detailed assessment of subsurface structure and hydrocarbon transport pathways, providing a solid basis for interpreting the degree of pollution and its potential impact on the environment and on residential land use in the investigated area.

## RESULTS AND DISCUSSIONS

During the interpretation stage of the inverted geoelectrical sections obtained for the four Vertical Electrical Sounding (VES) profiles (P1, P2, P3, and P4), detailed information was obtained regarding the subsurface geology and the surface distribution of electrical resistivity anomalies within the investigated area. The results reveal significant lateral and vertical variations in resistivity values, which are related to lithological changes, hydrocarbon contamination, and groundwater distribution (Ali et al., 2025).

Zones represented by red shades, corresponding to high electrical resistivity values, are observed on all profiles and are predominantly located in the upper parts of the sections (Atekwana et al., 2000). These zones are associated with unsaturated soils, more compact deposits, and anthropogenic fill materials characteristic of residential environments. Such units are characterized by low moisture conditions and a low degree of contamination. Beneath these layers, zones represented by blue shades, corresponding to low electrical resistivity values, are systematically identified at depths ranging from approximately 1.5 to 4-5 m. These low-resistivity anomalies coincide with the groundwater table and are interpreted as water-saturated horizons contaminated with hydrocarbons. Similar geoelectrical responses have been reported in hydrocarbon-contaminated environments, where contamination may modify the electrical properties of saturated sediments through physicochemical and biogeochemical processes (Abdel Aal et al., 2004). The interpretation obtained in the present study is also consistent with the findings of Eze and Chinemelu (2025), who demonstrated that electrical resistivity techniques provide reliable information for identifying groundwater contamination and delineating the spatial extent of hydrocarbon-affected zones. Similar to their observations, the low-resistivity anomalies detected in the investigated area coincide with the saturated zone and reflect the influence of contaminant migration on the electrical properties of the subsurface. This agreement further confirms the applicability of the Vertical Electrical Sounding (VES) method as an effective tool for preliminary environmental investigations and hydrocarbon contamination assessment in petroleum-impacted areas. The inverted apparent resistivity sections corresponding to profiles P1, P2, and P3 display laterally continuous low-resistivity anomalies (blue shades), indicating the presence of a pollution plume developed over a large area along the groundwater table. The spatial extent of these anomalies suggests that contamination is not localized but distributed throughout the investigated area, following natural groundwater flow pathways. The low RMS values obtained for these profiles confirm the reliability of the inversion models and the accuracy of the geoelectrical interpretation. In the case of profile P4, a similar resistivity structure is observed, but with variations in the thickness and intensity of the low-resistivity zones (blue shades). These variations may reflect differences in permeability, local lithological heterogeneities, or hydrocarbon concentration. Extremely low resistivity values are interpreted as sectors where hydrocarbons are mixed with fine-grained sediments and groundwater, resulting in a marked increase in electrical conductivity. The geoelectrical results correlate well with the hydrostatic level map, revealing a clear relationship between the position of the groundwater table and the distribution of low-resistivity anomalies. The hydrostatic gradient indicates (Fetter, 2001) a dominant groundwater flow direction oriented toward the Black Sea (Figure 7).

According to the hydrogeological principles described by Fetter (2001), groundwater flow is primarily controlled by hydraulic gradients, which govern the transport of dissolved and free-phase contaminants within saturated porous media. The groundwater flow direction identified in the present study therefore provides a logical explanation for the observed distribution of low-resistivity anomalies and supports the interpretation that the hydrocarbon plume is migrating from the industrial area toward the coastal environment.

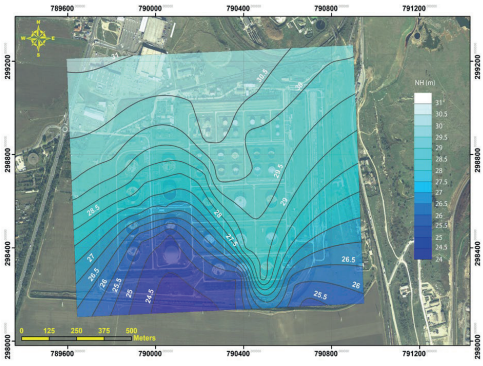

Figure 7. Hydrostatic water level map based on borehole data and piezometric studies

Consequently, the hydrocarbon pollution plume, highlighted by the low-resistivity zones (blue shades), is interpreted as migrating along the

groundwater flow direction from the industrial source area toward the coastal zone.

The migration of the pollution plume represents a significant environmental risk, as it facilitates the transport of hydrocarbons into residential areas, potentially affecting soils used for agricultural purposes as well as the coastal marine environment.

The integrated interpretation of the geoelectrical sections and the hydrostatic level map provides a consistent conceptual model of hydrocarbon migration in the investigated area. The spatial coincidence between the low-resistivity anomalies and the groundwater table indicates that contaminant transport is primarily controlled by the local hydrogeological regime rather than by isolated leakage points. The lateral continuity of the anomalies observed along profiles P1, P2, and P3 suggests the development of an extensive pollution plume migrating in the direction of groundwater flow toward the Black Sea. These findings confirm that the integration of electrical resistivity investigations with hydrogeological information represents a reliable approach for identifying hydrocarbon contamination pathways and provides valuable support for environmental monitoring and remediation planning in coastal industrial areas. These findings are consistent with previously reported geoelectrical models of hydrocarbon plumes in saturated sediments (Sauck, 2000). Furthermore, the migration pattern identified in the present study agrees with observations reported for other hydrocarbon-contaminated coastal and industrial sites, where groundwater acts as the dominant transport pathway and geoelectrical methods effectively delineate contamination plumes (Alao et al., 2025; Ali et al., 2025). The integration of VES data with hydrogeological information also reduces the ambiguity of geophysical interpretation by distinguishing lithological variations from contamination-related anomalies, thereby improving the reliability of environmental assessments and supporting remediation prioritization in complex industrial environments. The geoelectrical response observed in the investigated area is also consistent with previous studies reporting that hydrocarbon contamination modifies the electrical properties of subsurface materials, particularly within the saturated zone where contaminant migration is closely controlled by groundwater dynamics (Atekwana et al., 2000; Abdel Aal et al., 2004). In addition, the relatively low RMS errors obtained for all investigated profiles increase confidence in the inversion models and support the interpretation of the detected anomalies as environmentally significant features rather than inversion artefacts. Similar approaches have been successfully applied in contaminated industrial sites, demonstrating that electrical resistivity techniques provide reliable information on the geometry and lateral continuity of pollution plumes while minimizing environmental disturbance compared with intrusive investigation methods (Goldman & Neubauer, 1994; Loke, 2010). Consequently, the integrated application of geoelectrical investigations and hydrogeological analysis represents a robust methodology not only for contamination assessment but also for planning future monitoring campaigns and evaluating the effectiveness of remediation measures in areas affected by long-term petroleum-related activities.

## CONCLUSIONS

The Vertical Electrical Sounding (VES) investigations successfully characterized the shallow geological structure and identified the groundwater table within the investigated area.

Low electrical resistivity anomalies indicate the presence of hydrocarbon-contaminated saturated horizons, confirming active contamination in the northern part of the Oil Terminal Constanța area.

Correlation between the geoelectrical results and the hydrostatic level map demonstrates that contaminant migration is controlled by groundwater flow toward the Black Sea.

The integration of electrical resistivity investigations with hydrogeological analysis provides an effective approach for identifying hydrocarbon migration pathways and supporting environmental monitoring and remediation activities.

***Abstract***

*The present study investigated the mineral composition of Vaccinium vitis-idaea fruits collected from five mountain regions of the Romanian Carpathians, characterized by distinct environmental and geological conditions. Fruit samples were analyzed using portable X-ray fluorescence spectrometry (pXRF) to determine the concentrations of macro-, micro- and trace elements, including K, Ca, Fe, Mn, Zn, Cu, Ni, Sr and Rb. Climatic parameters describing the environmental context of the sampling sites were also considered. The results revealed clear differences in elemental profiles among the studied provenances. Potassium was the dominant macronutrient in all samples, whereas Ca, Mn and Rb exhibited noticeable spatial variability. Multivariate analyses (HCA and PCA) indicated that the elemental profile of lingonberry fruits reflects both environmental gradients and site-specific geochemical characteristics. In particular, rubidium showed the strongest differentiation among sites, suggesting a possible relationship between berry elemental composition and the geological characteristics of the habitats. The results highlight spatial variability in the mineral profile of wild V. vitis-idaea fruits across mountain environments and provide baseline information on their elemental composition in the Romanian Carpathians.*

***Key words****: Carpathians, environment, mineral composition, Vaccinium vitis-idaea, variability.*

## INTRODUCTION

*Vaccinium vitis-idaea* L. (lingonberry) is a perennial evergreen shrub of the *Ericaceae* family that is widely distributed throughout boreal forests and alpine regions of the Northern Hemisphere. The species typically grows in nutrient-poor, acidic soils and the berries are traditionally harvested from wild populations and are widely consumed in Northern and Central Europe due to their nutritional value and characteristic sour taste (Hjalmarsson & Ortiz, 2001; Nestby et al., 2019). Lingonberry fruits have received considerable scientific attention due to their high content of bioactive constituents, including phenolic acids, flavonoids and anthocyanins, which contribute to their high antioxidant capacity and potential health-promoting properties (Bujor et al., 2018; Kowalska, 2021). In addition to these compounds, lingonberry fruits also contain several mineral elements that contribute to their nutritional value and play important roles in plant physiological processes (Toncheva et al., 2016).

The concentration of mineral elements in wild berries can vary significantly depending on environmental conditions (Ekholm et al., 2007). Soil properties, nutrient availability and geographical location may influence the uptake and accumulation of macro- and micronutrients in plant tissues. Studies on lingonberries have shown that the concentration of elements such as K, Mn, Fe, Zn and Cu can vary between plant organs and sampling sites, reflecting differences in soil chemistry and environmental conditions (Lazarenko et al., 2021).

Environmental factors such as temperature, precipitation and altitude can influence plant physiological processes involved in nutrient uptake, transport and allocation within plant tissues. In mountainous ecosystems, these factors interact with soil characteristics and geological substrate to determine nutrient availability in the rhizosphere. As a result, plants growing under different habitat conditions may exhibit distinct patterns of mineral allocation between vegetative organs and fruits, reflecting both environmental constraints and species-

specific physiological regulation (Broadley et al., 2007; Luginina & Egoshina, 2013).

Despite the increasing interest in the nutritional and biochemical properties of lingonberries, information regarding the variability of mineral elements in fruits collected from different natural populations remains relatively limited. Investigating the mineral composition of lingonberries from different provenances can improve our understanding of spatial variation in element accumulation in wild populations and may also provide useful information on the nutritional value of these fruits. Therefore, the aim of this study was to characterize the mineral composition of *V. vitis-idaea* fruits collected from five mountain habitats in Romania and to examine whether differences in elemental profiles are associated with local environmental and lithological conditions. In this context, the study provides baseline data on the mineral profile of wild lingonberry fruits from the Romanian Carpathians.

## MATERIALS AND METHODS

### Study area and fruit sampling

Lingonberry (*Vaccinium vitis-idaea* L.) fruits were collected from five natural populations located in mountainous regions of Romania, each representing a distinct geographical area. The sampling sites were Groșii Țibleșului (GT; 47.551° N, 24.136° E), Valea Vinului (VV; 47.513° N, 24.851° E), Bilbor (BI; 47.115° N, 25.496° E), Cheia (CH; 45.427° N, 25.846° E) and Doda Pilii (DP; 46.662° N, 22.861° E). The coordinates represent the central point of the sampled area, while the abbreviations are used throughout the text to indicate the sampling site. Altitude was expressed as the midpoint of the reported elevation range for each sampling site (m a.s.l.).

Lithological information for each location was determined using geological maps and literature describing the geological structure of the Romanian Carpathians (Peters et al., 2018). These locations differ in terms of altitude, lithology and local environmental conditions, as presented in Table 1. Fruit sampling was conducted in August 2023, when berries had reached full ripeness (Figure 1).

The fruits were cleaned to remove visible impurities and dried in a ventilated oven at 60°C until constant weight was reached. The dried material was subsequently ground into a fine homogeneous powder using a laboratory grinder.

Table 1. Geographic and environmental characteristics of the sampling sites

| Site | County | Altitude | Lithology |
|---|---|---|---|
| Groșii Țibleșului | Maramureș | 1250 | Sedimentary |
| Valea Vinului | Bistrița-Năsăud | 1550 | Metamorphic |
| Bilbor | Harghita | 1150 | Metamorphic |
| Cheia | Prahova | 1450 | Sedimentary |
| Doda Pilii | Cluj | 1150 | Metamorphic |

At each location, three independent composite samples were collected to account for within-site variability. Each sample consisted of berries harvested from several individual plants distributed within an area of approximately 100 m² in order to obtain representative material for the local population. The fruits from each sampling point were pooled to form a composite sample representing that site replicate. After collection, the samples were transported to the laboratory for further processing.

Figure 1. Fully ripe *V. vitis-idaea* berries at the time of sampling

The powdered samples were stored in airtight containers at room temperature until analysis. Elemental analysis was performed using an ElvaX Mobile Portable XRF Spectrometer (Elvatech Ltd., Kyiv, Ukraine). Prior to analysis, the powdered material was loaded into sample cups and analyzed directly using X-ray fluorescence spectroscopy (Sapkota et al., 2019; Zhou et al., 2023). To ensure analytical reliability, all measurements were performed under identical instrumental conditions and each sample was analyzed in replicate scans. The instrument calibration and element quantification were carried out using the

manufacturer's software and factory calibration settings. Detection limits were estimated based on the lowest detectable concentrations recorded during the measurements. Quality control was evaluated through repeated measurements of selected samples, which showed consistent elemental readings within the expected analytical variability of portable XRF measurements.

**Climatic variables**

Environmental data for each location were obtained from the ERA5-Land reanalysis dataset provided by the Copernicus Climate Data Store (Muñoz-Sabater et al., 2021).

Climatic variables included mean daily air temperature (°C), representing the near-surface air temperature measured at approximately 2 m above ground level; cumulative precipitation (mm), corresponding to the total precipitation reaching the land surface during the analyzed period; mean daily surface solar radiation (MJ $m^{-2}$ $day^{-1}$), describing the incoming solar energy received at the land surface; and mean volumetric soil water content ($m^3$ $m^{-3}$), representing the proportion of water in the upper soil layer (0-7 cm).

These parameters were calculated for the period May-July by averaging daily values (temperature, solar radiation and soil moisture) and summing precipitation totals. This period corresponds to the main fruit development stage of *V. vitis-idaea*, when active nutrient transport and accumulation occur in developing berries, making it particularly relevant for assessing the mineral elements analyzed in this study.

The values were extracted based on the geographic coordinates of each sampling site, and the resulting parameters are presented in Table 2.

Table 2. Climatic variables of the sampling sites

| Site | Temperature (°C) | Precipitation (mm) | Solar radiation (MJ $m^{-2}$) | Soil moisture ($m^3$ $m^{-3}$) |
|---|---|---|---|---|
| GT | 15.6 | 379.09 | 20.07 | 0.35 |
| VV | 13.9 | 291.82 | 19.73 | 0.23 |
| BI | 14 | 359.35 | 19.62 | 0.29 |
| CH | 14.4 | 482.76 | 20.1 | 0.38 |
| DP | 15.1 | 497.83 | 19.57 | 0.38 |

The analyzed elements were grouped into three categories: macronutrients, micronutrients, and trace elements. Elemental concentrations were expressed on a dry weight basis (mg $kg^{-1}$ DW). Values below the detection limit were replaced by half of the detection limit (LOD/2) prior to statistical analysis in order to avoid bias caused by non-detectable values. Detection limits were estimated based on the lowest detectable concentrations obtained during the analytical measurements.

**Statistical analysis**

Differences in elemental concentrations among sites were evaluated using analysis of variance (ANOVA), followed by a post hoc multiple comparison test to identify statistically significant differences between means ($p < 0.05$).

To explore relationships between mineral composition and environmental variables, multivariate statistical analyses were performed. Principal component analysis (PCA) was used to identify patterns in the distribution of mineral elements and to assess the influence of climatic parameters on elemental variability. In addition, hierarchical cluster analysis (HCA) was applied to evaluate similarities among provenances and to visualize relationships between elements.

All statistical analyses and graphical representations were performed using PAST software - Paleontological Statistics, version 4.17 (Hammer et al., 2001).

## RESULTS AND DISCUSSION

**Macronutrient concentrations**

Potassium (K) was the predominant macronutrient in *V. vitis-idaea* fruits across all sampling sites (Figure 2a). The highest concentrations were recorded at Bilbor and Doda Pilii, exceeding 12,000 mg $kg^{-1}$ DW, while lower values were observed at the other three provenances. Comparable K levels have been reported for lingonberry fruits (approximately 6,400-6,700 mg $kg^{-1}$ FW) (Lazarenko et al., 2021), indicating that potassium represents the dominant mineral component in these berries. This high K content reflects its key physiological role in osmotic regulation and carbohydrate transport during fruit development.

Calcium (Ca) concentrations showed a different pattern among the sampling sites (Figure 2b), with the highest values recorded at Valea Vinului and Cheia (approximately 1,200-1,300 mg $kg^{-1}$ DW), while lower levels were observed

at Groșii Țibleșului, Doda Pilii and Bilbor. Similar Ca levels have been reported in fruits of other *Vaccinium* species, such as *V. oxycoccos* and *V. macrocarpon*, where concentrations range from approximately 480-1,160 mg kg$^{-1}$ DW (Karlsons et al., 2018). Calcium is primarily associated with structural functions in plant tissues, and its relatively moderate concentration in fruits reflects its limited mobility within the plant.

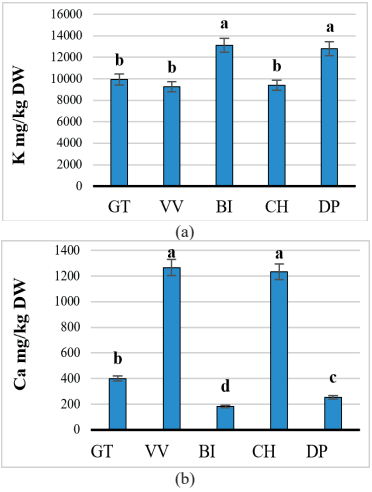

Figure 2. Macronutrient concentrations in *V. vitis-idaea* fruits: (a) potassium (K); (b) calcium (Ca). Mean ± SD (n = 3). Different letters indicate significant differences ($p < 0.05$)

**Micronutrient concentrations**

Iron (Fe) concentrations in lingonberry fruits were highest at Cheia and Bilbor, reaching approximately 150 mg kg$^{-1}$ DW (Figure 3a), whereas slightly lower values were observed at Doda Pilii and intermediate concentrations at Valea Vinului. The lowest Fe levels were recorded at Groșii Țibleșului, remaining below 100 mg kg$^{-1}$ DW. Although Fe is an essential element involved in electron transport processes and chlorophyll synthesis, its accumulation in fruits is generally limited because iron is preferentially retained in vegetative tissues such as leaves and roots. This pattern is consistent with previous studies on *V. vitis-idaea*, where Fe concentrations were substantially higher in leaves, stems and roots than in reproductive organs, indicating restricted translocation of Fe toward fruits (Kobayashi & Nishizawa, 2012; Kandziora-Ciupa et al., 2017).

Manganese (Mn) concentrations were highest at Valea Vinului and Bilbor, approaching 90-100 mg kg$^{-1}$ DW (Figure 3b), while the lowest values were observed at Groșii Țibleșului (40-50 mg kg$^{-1}$ DW). These concentrations are in line with previously reported Mn levels in lingonberries (Rodushkin et al., 1999) (approximately 87-160 mg kg$^{-1}$ DW). Manganese plays an essential role in photosynthetic processes and is often more strongly accumulated in vegetative organs than in fruits in *V. vitis-idaea*.

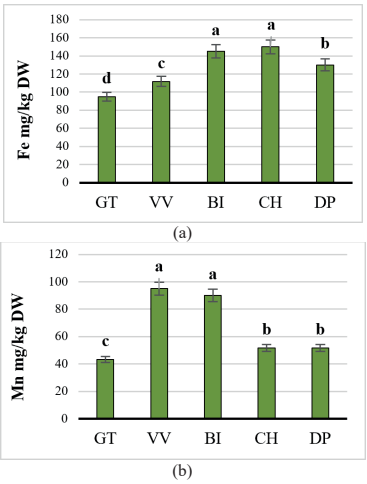

Figure 3. Micronutrient concentrations in *V. vitis-idaea* fruits: (a) iron (Fe); (b) manganese (Mn). Mean ± SD (n = 3). Different letters indicate significant differences ($p < 0.05$)

Zinc (Zn) concentrations ranged between approximately 10 and 18 mg kg$^{-1}$ DW (Figure 4a). The highest levels were recorded at Bilbor and Doda Pilii, while intermediate concentrations were observed at Valea Vinului and Groșii Țibleșului. The lowest Zn content was found at Cheia, with values close to 10 mg kg$^{-1}$ DW. These values fall within the range commonly reported for plant tissues, where adequate Zn concentrations are typically around 15-20 mg kg$^{-1}$ DW (Broadley et al., 2007). Zinc is an essential micronutrient involved in numerous enzymatic and metabolic processes in plants, and differences in its concentration may reflect variations in soil availability and environmental conditions among the sampling sites (Jungová et al., 2021).

Copper (Cu) concentrations ranged from less than 1 to about 6.5 mg kg$^{-1}$ DW (Figure 4b). The

highest value was measured at Bilbor, followed by slightly lower concentrations at Valea Vinului and Cheia, while the lowest Cu content was recorded at Doda Pilii. The generally low concentrations observed are consistent with the limited mobility of Cu in plants and its tendency to accumulate mainly in vegetative tissues rather than fruits. Copper plays an important role in plant metabolism as a cofactor of several redox enzymes involved in photosynthesis and oxidative stress regulation. Comparable Cu levels have been reported for *V. vitis-idaea* fruits, ranging from approximately 0.29 to 1.14 mg kg$^{-1}$ fresh weight (Drózdz et al., 2018).

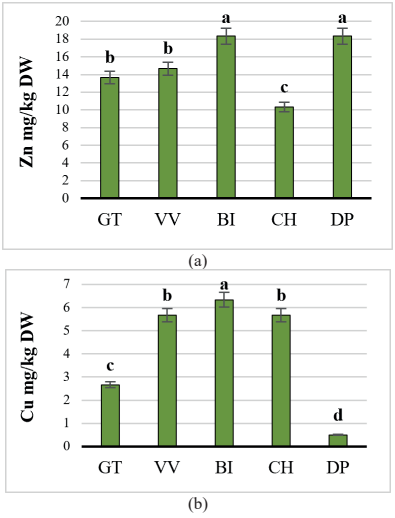

Figure 4. Micronutrient concentrations: (a) zinc (Zn); (b) copper (Cu). Mean ± SD (n = 3). Different letters indicate significant differences ($p < 0.05$)

## Trace element content

Nickel (Ni) concentrations were highest at Grosii Țibleșului, reaching approximately 1.1 mg kg$^{-1}$ DW, while lower values were observed at Cheia (Figure 5a). In the other sampling sites, Ni concentrations were below the limit of detection (LOD) of the analytical method. These concentrations are lower than those previously reported for lingonberries, where Ni levels ranged from 1.81 to 12.9 mg kg$^{-1}$ DW (Zeiner & Juranović Cindrić, 2018). Nickel occurs in plants at trace levels and functions as a cofactor of urease involved in nitrogen metabolism, while its accumulation in fruits is generally limited.

Strontium (Sr) concentrations were highest at Valea Vinului, and lower levels were observed at Bilbor while the other locations were below the limit of detection (Figure 5b). Strontium behaves chemically similar to calcium and can enter plant tissues through the same uptake pathways. Consequently, differences in Sr concentrations among sites may reflect variations in the geochemical composition of the underlying substrates and soil mineralogy (Capo et al., 1998; Burger & Lichtscheidl, 2019).

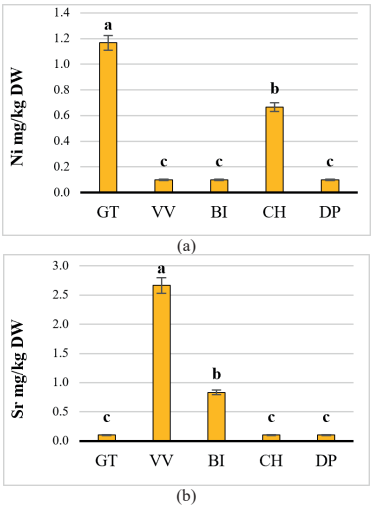

Figure 5. Trace element content in lingonberry fruits: (a) nickel (Ni); (b) strontium (Sr). Mean ± SD (n = 3). Different letters indicate significant differences ($p < 0.05$)

Rubidium (Rb) content was highest at Doda Pilii, reaching approximately 24-25 mg kg$^{-1}$ DW (Figure 6). Lower values were recorded at Grosii Țibleșului, Valea Vinului, and Bilbor, whereas Rb concentrations at Cheia were below the limit of detection (LOD) of the method. Rubidium behaves chemically similar to potassium and can be absorbed by plants through the same transport pathways. Consequently, variations in Rb concentrations among sampling sites are likely influenced primarily by differences in soil geochemistry rather than plant metabolic requirements. Elevated Rb levels, such as those observed at Doda Pilii, may therefore reflect differences in the mineral composition of the underlying substrate, particularly the presence of Rb-bearing silicate minerals in the soil (Kabata-Pendias & Pendias, 1992).

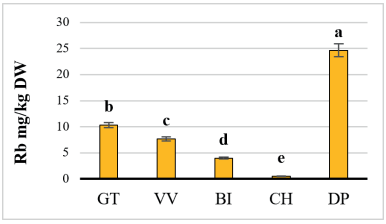

Figure 6. Rubidium (Rb) content in lingonberry fruits. Mean ± SD (n = 3). Different letters indicate significant differences ($p < 0.05$)

Several additional elements were detected sporadically and at very low concentrations. Arsenic and bromine were identified only in samples from Groșii Țibleșului, while molybdenum was detected only in Cheia. Given their rare occurrence and low concentrations, these elements were not included in further analyses.

**Multivariate analysis of mineral composition**

The hierarchical clustering analysis highlighted clear differences in the mineral profiles of *V. vitis-idaea* fruits among the sampling sites (Figure 7). Bilbor and Doda Pilii formed a closely related cluster characterized by relatively higher levels of K, Zn and Rb, indicating similar elemental signatures in the fruits collected from these locations. In contrast, Valea Vinului was clearly separated from the other sites due to elevated Sr concentrations, suggesting a distinct geochemical influence on the mineral composition of the berries.

A different elemental pattern was observed at Groșii Țibleșului, where comparatively higher Ni levels contributed to its separation from the other sampling sites. These clustering patterns indicate that the mineral composition of lingonberry fruits varies substantially among locations and likely reflects differences in local soil geochemistry and environmental conditions. Similar site-dependent variability in elemental composition of lingonberries has been reported in previous studies (Kabata-Pendias & Pendias, 1992; Rodushkin et al., 1999).

Principal component analysis (PCA) provided further insight into the relationships between mineral elements and environmental variables influencing the composition of *V. vitis-idaea* fruits (Figure 8). The first principal component (PC1), explaining 42.24% of the total variance, was associated with soil moisture, temperature and precipitation, together with higher contributions from K, Zn and Rb, suggesting a potential relationship between environmental conditions and the observed elemental variability. The alignment of these variables may indicate that soil water availability could influence the mobility and transport of these elements in the soil, potentially facilitating their uptake by plants. This relationship is particularly plausible for potassium and rubidium, which are known to be highly mobile in the soil solution and are commonly transported to plant roots through water-driven mass flow processes (Kabata-Pendias & Pendias, 1992). The position of Doda Pilii along this axis reflects higher contributions of these elements, suggesting that both climatic conditions and local substrate characteristics may influence nutrient accumulation in the berries. Differences in altitude among the sampling sites may also contribute indirectly to this pattern by influencing local climatic conditions such as temperature, precipitation and soil moisture.

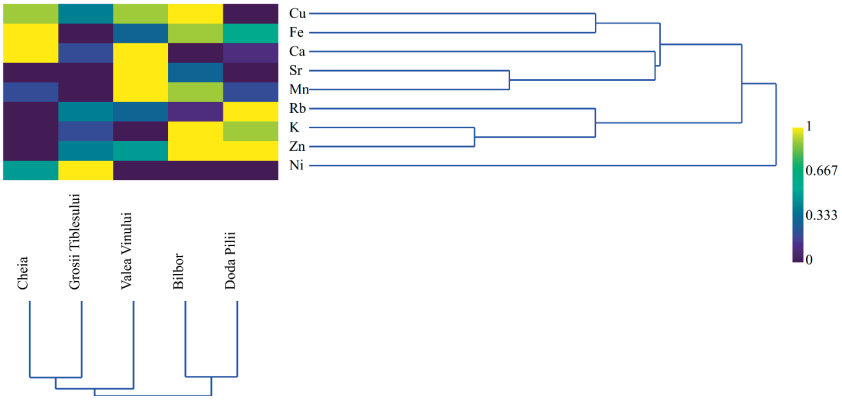

Figure 7. Heatmap and hierarchical clustering of mineral elements in *V. vitis-idaea* fruits from five sampling sites

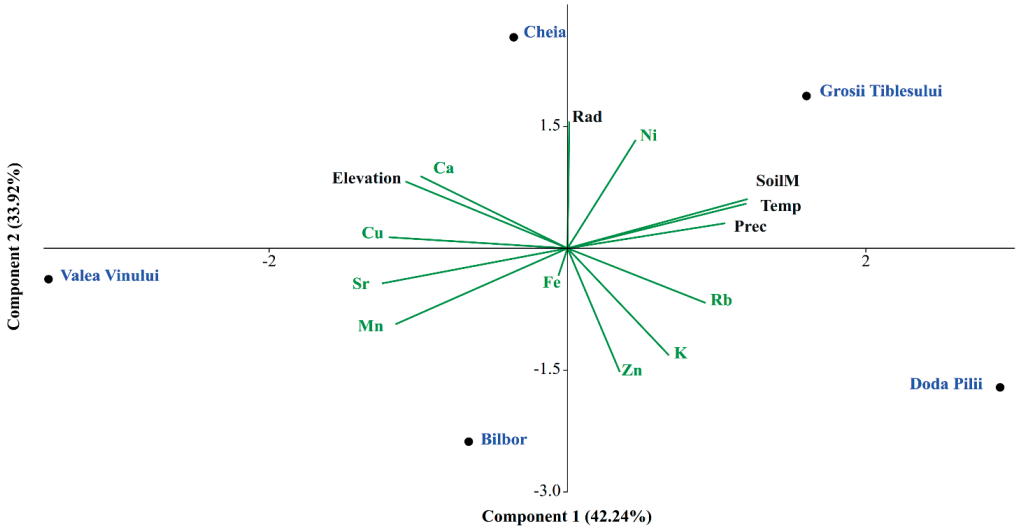

Figure 8. PCA biplot of mineral elements, environmental variables, and sampling sites in lingonberry fruits

The second principal component (PC2), accounting for 28.32% of the variance, was mainly associated with Ni, Ca and solar radiation, while Sr, Mn and Cu were oriented in the opposite direction. The separation of Sr from Ca, despite their chemical similarity, suggests that strontium accumulation in lingonberry fruits may be influenced more strongly by geochemical characteristics of the substrate than by plant physiological regulation. Considering the lithological differences among the studied sites, including sedimentary substrates at Grosii Țibleșului and Cheia and metamorphic substrates at Valea Vinului, Bilbor and Doda Pilii, the observed elemental patterns may partly reflect differences in the mineral composition of soils derived from these parent materials. Sites developed on similar lithological backgrounds may therefore exhibit comparable geochemical influences on element availability, while differences between sedimentary and metamorphic substrates may contribute to the variability observed in the mineral composition of the berries. The PCA indicates that the elemental profile of *V. vitis-idaea* fruits reflects the combined influence of climatic gradients, altitude-related environmental variation and lithological characteristics of the habitats, a pattern also observed in studies investigating mineral composition of wild berries using multivariate approaches (Vilkickyte & Raudone, 2021; Amundsen et al., 2023)

## CONCLUSIONS

This study provides new insights into the mineral composition of *V. vitis-idaea* fruits collected from different mountainous regions of Romania and highlights the influence of local environmental conditions on elemental accumulation in berries. The results confirm that potassium is the dominant macronutrient in lingonberry fruits, while other macro- and micronutrients occur in moderate concentrations consistent with previously reported ranges for the genus *Vaccinium*. The observed differences in elemental composition among sites indicate that the mineral profile of lingonberry fruits reflects site-specific environmental and geochemical conditions. In particular, the multivariate analyses revealed distinct elemental signatures associated with certain locations, suggesting that both climatic conditions and local substrate characteristics may influence nutrient accumulation in berries. The study also highlights the relevance of trace elements such as rubidium, strontium and nickel as potential indicators of geochemical variability in lingonberry habitats. Among these, rubidium showed the most pronounced spatial variation, which may be related to differences in soil mineral composition and the chemical similarity between rubidium and potassium during plant uptake. These findings indicate that the mineral composition of *V. vitis-idaea* fruits

reflects the combined influence of climatic gradients and lithological background across mountain habitats. The integration of elemental profiles with environmental variables highlights the potential of wild lingonberries as indicators of local geochemical conditions in natural ecosystems.

Although the present study provides useful baseline information on the mineral composition of wild lingonberry fruits from different mountain habitats, further studies including a larger number of sampling sites and complementary analyses of soil properties would help to better clarify the environmental and geochemical factors influencing elemental accumulation in the berries. Such approaches could contribute to a more comprehensive understanding of the relationships between habitat characteristics and mineral profiles in wild *Vaccinium* populations.

***Abstract***

*The growing demand for natural aggregates and stricter environmental regulations are driving the construction sector toward the valorisation of industrial by-products. This study investigates the technological transfer potential of Garnet sand waste (SG) as a partial substitute for natural fine aggregates in cement-based building materials, including mortars and concrete. Experimental results at laboratory and preliminary pilot scale demonstrate that controlled replacement levels of SG can achieve comparable or improved fresh and hardened properties relative to reference mixes, while meeting durability and performance requirements. Beyond technical validation, the paper examines the legislative framework governing waste reuse in construction, with particular attention to aggregate standards, waste-to-product transition, and conformity assessment procedures. Finally, commercial and market aspects are addressed, identifying barriers and drivers for industrial uptake, stakeholder acceptance, and potential business models within a circular economy context. The results provide an integrated pathway proposal for transforming Spent Garnet (SG) sand waste from an industrial residue into a viable construction resource, supporting sustainable material innovation and market implementation.*

***Key words****: cement-based materials, circular economy, fine aggregate substitution, market adoption, spent garnet (SG), sustainable construction, technology transfer, waste regulation.*

## INTRODUCTION

The construction industry remains one of the largest consumers of natural resources worldwide, particularly mineral aggregates used in concrete and mortar production. The growing demand for infrastructure and urban development has significantly increased the extraction of natural aggregates, generating environmental concerns related to landscape degradation, energy consumption, and greenhouse gas emissions (Corbu et al., 2014; Mattra et al., 2025). At the same time, industrial activities produce substantial quantities of mineral waste streams that are often disposed of in landfills, despite their potential reuse as secondary raw materials.

Within this context, the circular economy paradigm promotes the transformation of industrial by-products and waste into valuable resources (Potting et al., 2017; Morseletto, 2020). By closing material loops and reducing dependency on virgin raw materials, circular economy strategies can contribute to both environmental protection and resource efficiency in the construction sector. The reuse of mineral residues in cement-based materials has therefore gained increasing attention in recent years.

One such industrial residue is spent garnet sand generated from abrasive waterjet (AWJ) cutting operations. Garnets are widely used as abrasives medium due to their high hardness, chemical stability, and cutting efficiency (Perianu et al., 2014; 2017). However, after repeated use in AWJ processes, the material becomes contaminated with fine particles and loses its suitability for further abrasive applications. As a result, large quantities of spent garnet (SG) are

generated globally and are commonly classified as industrial waste, leading to disposal costs and environmental impacts (Baera et al., 2026a).

Previous studies have demonstrated that garnet residues generated by AWJ processes (AWJ-SG), with suitable granulometry and mineralogical composition, can partially replace natural aggregates in cement-based materials without compromising mechanical performance. AWJ spent garnets (AWJ-SGs) show considerable potential for application in cement-based materials (Ab Kadir et al., 2019; Lim et al., 2020; Budiea et al., 2021; Jamaludin et al., 2021; Kanta et al., 2022) as well as in alkali-activated concrete (Muttashar et al., 2017; 2018a, 2018b; Huseien et al., 2019), mortars (Kunchariyakun et al., 2020; Baera et al., 2025; 2026a), plasters, fibre-reinforced composites, and other construction materials.

Nevertheless, the transition from laboratory - scale investigations to practical implementation remains limited. In many cases, technological feasibility is demonstrated but the broader aspects required for industrial adoption - such as regulatory compliance, certification procedures, and market acceptance are insufficiently addressed (Baera et al., 2026a). In this context, the present study investigates the potential valorisation of single cycle AWJ spent garnets as partial substitute for natural fine aggregates in cement-based materials, including mortars and concrete. Beyond the technical evaluation of substitution viability, the study also addresses complementary dimensions, including technological transfer challenges, the legislative framework governing waste reuse in construction and product certification, and broader commercial and market-related considerations, all of which influence the practical implementation of circular economy principles. By combining these dimensions, the paper proposes an integrated pathway for transforming spent garnet from an industrial residue into a viable construction resource, supporting sustainable material innovation within a circular economy framework.

## CIRCULAR ECONOMY (CE) CONTEXT FOR AWJ SPENT GARNET (AWJ-SG)

The transition toward a circular economy requires the development of strategies that reduce waste generation and promote the efficient use of resources across industrial sectors. The integration of sustainable materials and innovative techniques in civil engineering contributes to environmental protection while enhancing resource efficiency and structural reliability, thereby supporting the transition toward more sustainable construction practices (Olinic et al., 2024). In the construction industry, one of the most promising approaches involves the integration of secondary materials derived from industrial processes into building materials. Such practices can simultaneously reduce waste disposal and decrease the consumption of natural aggregates.

Abrasive waterjet (AWJ) cutting is widely applied in manufacturing industries for the precise cutting of metals, ceramics, composites, and stone materials (Perianu et al., 2023). Garnet is commonly used as the abrasive medium due to its favourable mechanical and chemical properties (Chassé et al., 2018). During the AWJ process, garnet particles progressively fracture and become mixed with removed material and fine debris. In some cases, SG waste can be recycled and reused for its original application as AWJ abrasive, although few initiatives have focused on this type of material recovery. In most cases, after one AWJ use the resulting SG material is discharged as spent garnet waste.

From a material flow perspective, the lifecycle of garnet in AWJ operations typically includes four stages: extraction of natural garnet, use as an abrasive medium, generation of spent garnet waste, and final disposal. In many industrial facilities, the spent material is collected as sludge or dried sand and transported to landfill sites. This linear disposal pathway results in both environmental impacts and additional operational costs. Within a circular economy framework, spent garnet can be considered a secondary mineral resource. Several potential valorisation routes have been explored, including reuse as abrasive media after processing, use in sandblasting operations, and incorporation into construction materials. Among these options, the use of AWJ-SG as a fine aggregate substitute in cement-based materials presents significant potential, considering its proven suitability for integration and the large volumes of aggregates required in the construction sector. The integration of spent

garnets into mortar and concrete production can therefore represent a form of industrial symbiosis, offering a dual advantage, as illustrated in Figure 1: first, it diverts waste from disposal pathways, generating positive environmental and economic impacts from a waste management perspective. Second, it partially replaces natural aggregates, thereby reducing the pressure on natural resource extraction.

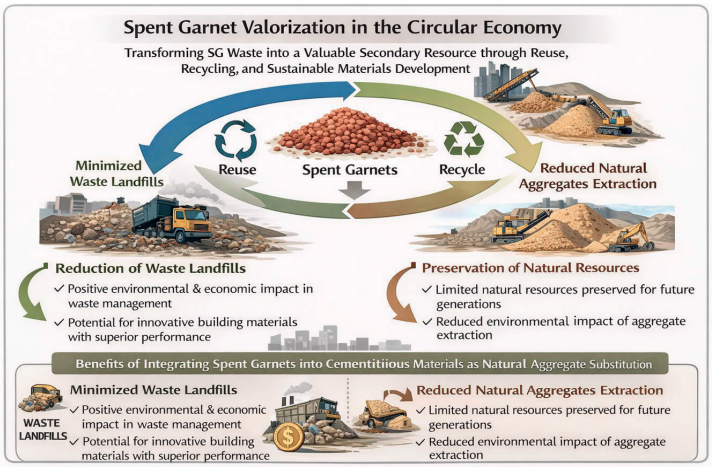

Figure 1. Circular Economy Framework for Spent Garnet Waste Valorization in Cementitious Materials (AI-generated image)

In Romania, the valorization of AWJ-SG waste in construction materials and products through the innovative substitution of fine aggregates was investigated within one of the research axes of project PN 23 35 04 01 (Figure 2), entitled "Development of innovative engineering solutions for eco-intelligent construction products through the efficient valorization of additions generated by local industries".

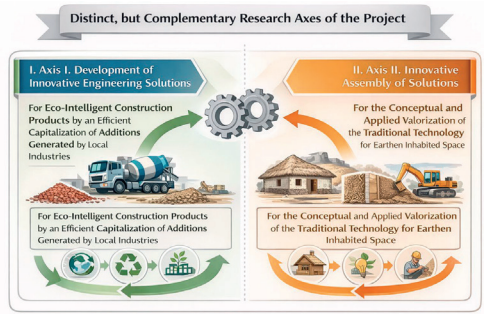

Figure 2. Schematic representation of the research axes of project PN 23 35 04 01 (AI-generated image)

The project is part of the Nucleu Programme under the National Research, Development and Innovation Plan 2022-2027 (ECODIGICONS), funded by the Romanian Ministry of Research, Innovation and Digitalization, and is aligned with European Union objectives and national strategic frameworks such as Romanian National Strategy on the Circular Economy (SNEC, 2022) and the National Strategy for Research, Innovation and Smart Specialization (SNCISI 2022-2027, 2022).

The project's main goal is to facilitate technological transfer and enable the practical implementation of the developed materials, products, and technologies through sustained collaboration among key stakeholders, including academia and research institutions, entrepreneurs, industrial users and end-consumers, suppliers, and social, economic, and political actors, as well as local and central authorities.

## MATERIALS AND METHODS

The procedure-based transition of abrasive waterjet spent garnet (AWJ-SG) from industrial waste to a construction resource is conceptualized through *a three-layer circular economy framework*, represented by a *technology-transfer diagram structured around three complementary layers* (Figure 3):

(i) *Technical layer*, addressing material characterisation, mix design optimisation, prototype validation, pilot-scale trials, and the transition from laboratory research to field implementation;
(ii) *Regulatory layer*, covering compliance with relevant standards, waste legislation, and the procedures required for product certification and conformity assessment; and
(iii) *Commercial layer*, focusing on supply-chain integration, stakeholder engagement, and the market adoption of AWJ-SG-based construction materials.

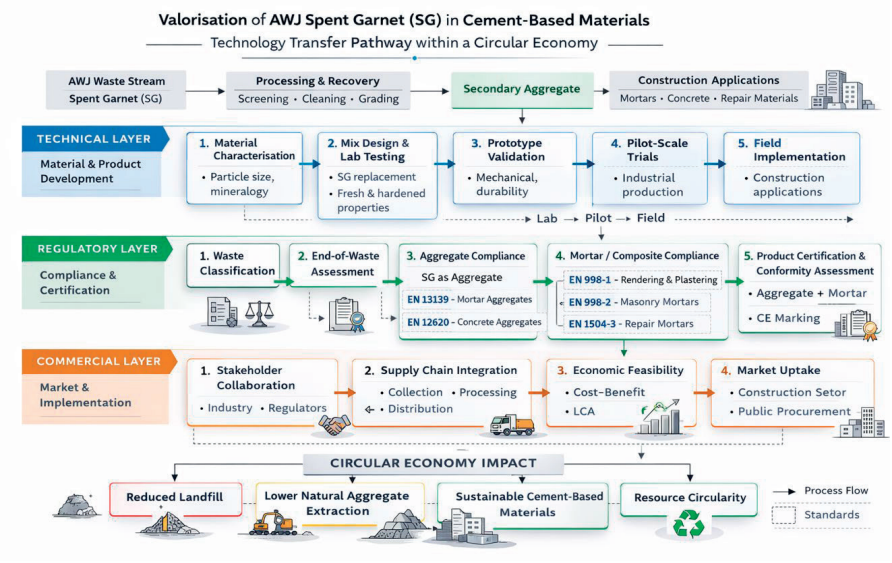

Figure 3. Spent Garnet Waste Valorization in Cementitious Materials:
Three-Layer Circular Economy Structure (AI-generated image)

The figure illustrates the transition of AWJ SG material from industrial residue to construction resource through three complementary implementation layers. The technical layer describes the progression from material characterization to field application. The regulatory layer distinguishes between compliance of SG as aggregate and compliance of the final mortar-based product, including relevant European standards for aggregates, rendering/plastering mortars, masonry mortars and repair mortars. The commercial layer captures the supply-chain and market conditions needed for industrial uptake. Together, these layers define the practical pathway for circular economy implementation of AWJ-SG in cement-based materials.

**I. Technical Layer: SG as Fine Aggregate Substitute in Cement-Based Mortars**

The technical implementation of abrasive waterjet spent garnet (AWJ-SG) as a secondary aggregate in cement-based mortars follows a progressive validation pathway that includes specific technical stages like *material characterization, mix design optimization, prototype validation and pilot-scale assessment* (Figure 4). The proposed methodological framework aims to verify the feasibility of transforming AWJ-SG from an industrial waste stream into a functional construction material within a CE context, while ensuring consistent performance and reproducibility of results.

***Material Characterisation***

The initial stage focuses on the *physical, chemical and mineralogical characterisation of AWJ-SG* in order to evaluate its suitability as a fine aggregate substitute in cement-based composites. Key parameters include particle size distribution (PSD), particle morphology, density and potential impurities resulting from the abrasive cutting process.

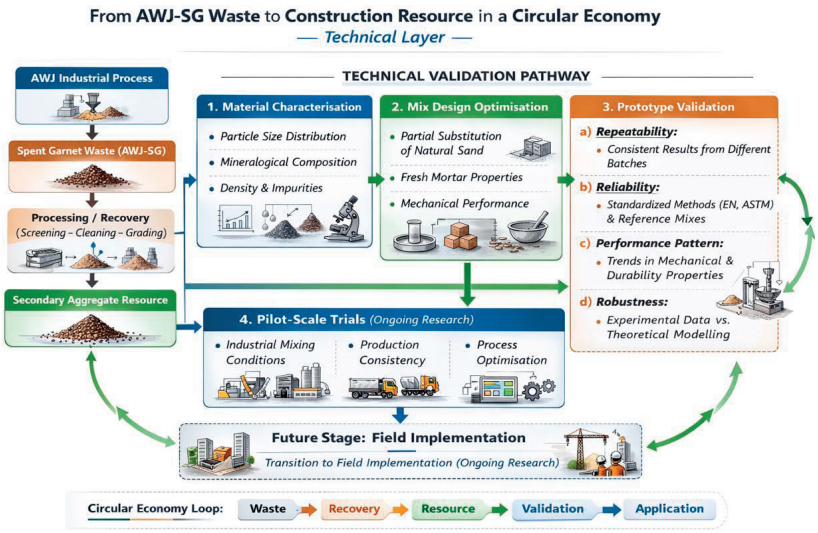

Figure 4. Circular economy pathway for valorisation of AWJ spent garnet (AWJ-SG) as a secondary aggregate: from waste generation to technical validation and pilot-scale implementation (AI-generated image)

These characteristics were analysed (Baera et al., 2026a) and identified the expected compatibility with the grading requirements of conventional mortar aggregates; also, the potential effects on fresh and hardened properties were also identified and discussed. Proper processing steps, such as screening and cleaning, were also considered to ensure consistent material quality before incorporation into mortar mixtures. market adoption of SG-based construction materials.

***Mix Design Optimisation***

To assess the feasibility of using spent garnets (SG) as a fine aggregate substitute, mortar mixtures were prepared with varying partial replacement levels (30% and 50%) of natural sand while maintaining acceptable aggregate grading. Conventional cement binders and typical water-to-binder ratios were used. Reference mixtures containing only natural aggregates were produced for comparison. SG was introduced by replacing a portion of the natural sand while keeping the binder content and overall mix proportions constant. This approach enabled evaluation of the influence of SG on fresh and hardened properties while minimizing the impact of other variables; the expected SG to cementitious matrix compatibility was identified (Baera et al., 2025; 2026a).

***Prototype Validation***

Prototype validation was conducted to confirm the feasibility and consistency of incorporating spent garnet (SG) as a partial fine aggregate substitute in cement-based mortars. The validation procedure was initiated and further developed (Baera et al., 2025; 2026a) to follow a structured methodology based on four general criteria. *Repeatability* was assessed by verifying that comparable performance results were obtained for successive SG batches collected at different times, both from the same and from different sources. *Reliability* was ensured through testing performed according to standardized procedures (e.g., EN and ASTM methods) and by comparing the results with those obtained from reference cement–sand control mixtures. *Performance pattern* was evaluated by analysing systematic trends in mechanical and durability properties as a function of SG substitution levels and the characteristics of the waste material. Finally, *robustness* was examined by correlating experimental observations with theoretical modelling in order to minimise the influence of uncontrolled experimental variability and confirm the consistency of the proposed material system.

The results (Baera et al., 2026a) are validating the SG mortar prototypes and the viability of the proposed integrating concept, at laboratory scale

and also are founding the technological transfer to the industry, ensuring the transitioning to pilot scale assessments.

***Pilot-scale assessment***

Pilot-scale assessment represents the next stage in the implementation pathway for the valorisation of AWJ spent garnet (AWJ-SG) as a secondary aggregate in cement-based mortars. This stage aims to verify the reproducibility of laboratory results under industrial mixing conditions, including *batching procedures, mixing energy, and material handling practices* typically encountered in mortar production facilities. Particular attention is given to *production consistency*, ensuring that the incorporation of AWJ-SG does not introduce variability in fresh or hardened properties across successive batches. Monitoring of parameters such as aggregate dosing, moisture control, and mixing duration is therefore required to maintain stable production quality. In parallel, process *optimisation measures* are being investigated, including adjustments to mixing sequences, particle grading control, and potential pre-treatment steps (e.g., screening or drying) to ensure uniform material behaviour at scale. These ongoing investigations aim to confirm that the performance trends observed in laboratory conditions can be reliably reproduced in industrial environments, thereby supporting the transition of AWJ-SG from experimental validation toward industrial implementation.

**II. Regulatory and Legal Layer for AWJ-SG Waste-to-Product Transition**

The regulatory layer establishes the legal and conformity framework required for the transition of AWJ spent garnet (AWJ-SG) from waste status to a construction resource. The corresponding regulatory validation pathway, illustrated in Figure 5, includes waste classification, evaluation of end-of-waste/by-product conditions, compliance with aggregate and mortar standards, and product certification in accordance with Regulation (EU) No. 305/2011.

***Waste Classification***

The first regulatory step involves the classification of abrasive waterjet spent garnet (AWJ-SG) within the waste management framework. In Romania, this process follows HG nr. 856/2002 regarding waste management records and the approval of the waste list, which is aligned with European waste legislation, particularly Commission Decision 2000/532/EC establishing the European List of Waste (LoW). Within this framework, AWJ spent garnet can be classified under code 12 01 17 - "waste blasting materials other than those mentioned in 12 01 16". *This classification establishes the regulatory basis for waste handling, traceability, and further evaluation of potential recovery or valorisation pathways*.

***End-of-Waste/By-Product Assessment***

Following waste identification, an end-of-waste or by-product assessment is required to determine whether AWJ-SG can transition from a waste material to a secondary resource suitable for construction applications. This evaluation considers criteria such as the intended use of the material, *compliance with technical specifications, absence of environmental or health risks, and the existence of a stable market demand*. Demonstrating that the processed material can be safely and consistently used as an aggregate substitute is essential for enabling its transition from waste status to a recoverable construction resource.

***AWJ-SG Aggregate Compliance***

Once the material is considered suitable for recovery, AWJ-SG must demonstrate technical compliance with relevant aggregate standards. For applications in cement-based mortars, the material must meet the requirements specified in EN 13139 - Aggregates for mortars, including particle size distribution, density, and cleanliness parameters. For potential applications in concrete, compliance with EN 12620 - Aggregates for concrete must also be assessed. These standards ensure that the recovered material meets the necessary physical and mechanical properties required for use as a construction aggregate.

***Mortar/Composite Compliance***

In addition to aggregate-level compliance, the performance of the final cement-based composite containing AWJ-SG must satisfy the relevant mortar standards, depending on the intended application.

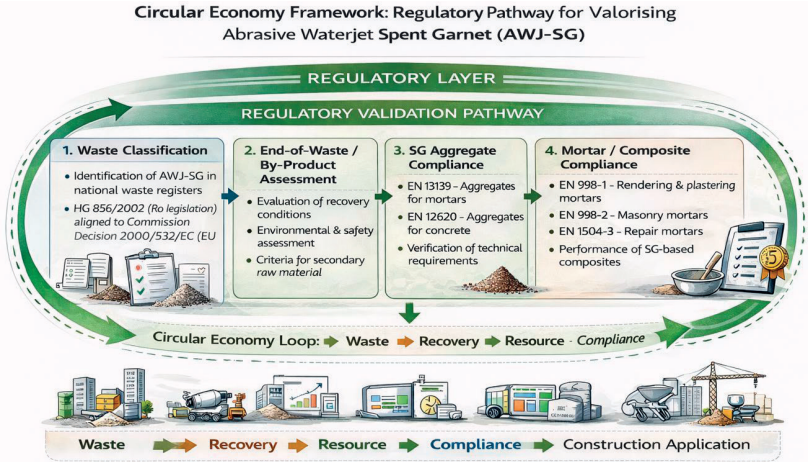

Figure 5. Circular economy pathway of AWJ-SG Waste-to-Product transition (as a secondary aggregate): Regulatory and Legal layer (AI-generated image)

Rendering and plastering mortars must comply with EN 998-1, masonry mortars with EN 998-2, and repair mortars used for concrete structures with EN 1504-3. Compliance with these standards requires the evaluation of mechanical strength, durability, and other performance characteristics to ensure that the incorporation of SG does not negatively affect the functional behaviour of the mortar.

***Product Certification & Conformity Assessment***

The final regulatory step involves product certification and conformity assessment, ensuring that both the aggregate component and the final mortar-based product meet the requirements for placing construction products on the market. This process is carried out in accordance with Regulation (EU) No. 305/2011 (Construction Products Regulation – CPR) and may involve testing, factory production control, and conformity verification procedures. Certification therefore addresses both aggregate compliance and mortar/composite performance, enabling the resulting product to be marketed as a compliant construction material within the European regulatory framework.

## III. Commercial Layer for AWJ-SG Waste-to-Product Transition

After establishing the regulatory framework for the valorization of AWJ-SG, the focus moves to the commercial layer, which examines supply-chain organization, stakeholder engagement, business model development, and the conditions necessary for market adoption of SG-based construction materials (Figure 6).

***Supply-Chain Integration***

The commercial implementation of AWJ spent garnet (AWJ-SG) valorisation requires the integration of the material into existing construction material supply chains. This involves *establishing logistical connections between abrasive waterjet processing facilities, waste recovery operators, and construction material producers*. Efficient supply-chain integration ensures that SG can be collected, processed, and delivered in a consistent form suitable for use as a secondary aggregate in cement-based materials.

***Stakeholder Engagement***

Successful market implementation depends on the active involvement of key stakeholders, including AWJ operators, waste management companies, construction material manufacturers, regulatory authorities, and end users. Stakeholder engagement is essential for building trust in the technical performance and environmental safety of SG-based materials, as well as for facilitating knowledge exchange and promoting acceptance within the construction sector.

***Supply-Chain Organisation***

The development of a reliable supply chain structure *is necessary to ensure the consistent availability and quality of AWJ-SG*.

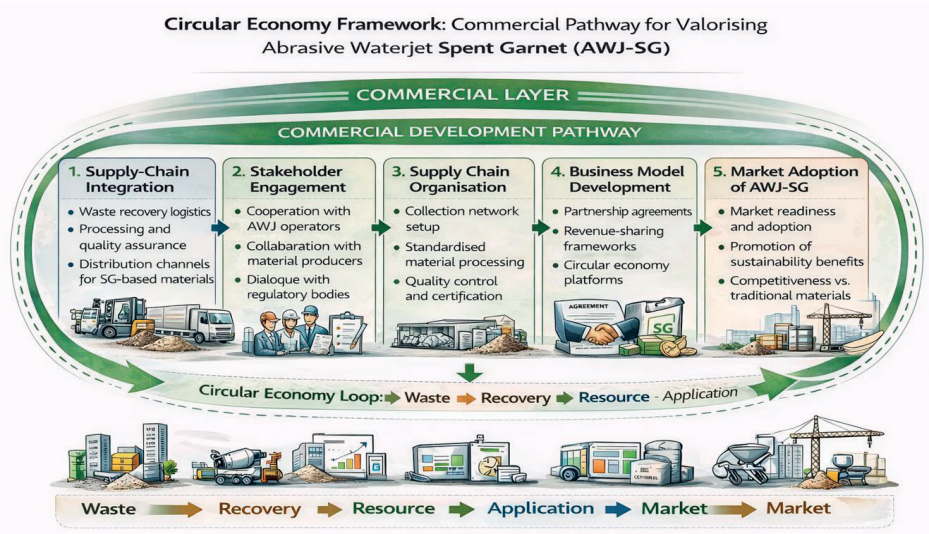

Figure 6. Circular economy pathway of AWJ-SG Waste-to-Product transition: Commercial layer (AI-generated image)

This includes the establishment of *standardized collection procedures, material processing operations, and quality control mechanisms* to guarantee that the recovered aggregate meets technical and regulatory requirements before entering the construction materials market.

***Business Model Development***

The valorisation of AWJ-SG also requires the identification of *sustainable business models* that balance economic feasibility with environmental benefits. Potential models may include partnerships between AWJ service providers and construction material producers, waste recovery agreements, or circular economy platforms that promote the reuse of industrial by-products. In addition, *social entrepreneurship initiatives* may represent a viable approach, particularly where waste recovery and material processing activities can generate local employment and support community-based circular economy practices. Such models combine environmental value creation with social impact, contributing to both resource efficiency and regional socio-economic development (Baera et al., 2026b) Overall, these approaches aim to reduce disposal costs while creating additional value from recovered materials.

***Market Adoption of AWJ-SG-Based Construction Materials***

The final stage involves the market uptake of construction materials incorporating AWJ-SG. This process depends on demonstrating *technical reliability, regulatory compliance, and economic competitiveness* compared to conventional materials. As confidence in the performance and sustainability benefits of SG-based mortars increases, their adoption may contribute to reducing the consumption of natural aggregates and supporting CE practices within the construction sector.

Together, the technical validation, regulatory compliance, and commercial integration layers form a coherent circular economy framework that enables the sustainable transition of AWJ spent garnet from an industrial waste stream to a viable construction resource.

## RESULTS AND DISCUSSIONS

### I. Technical Layer: SG as Fine Aggregate Substitute in Cement-Based Mortars

The results obtained from the experimental investigations confirm the technical feasibility of incorporating abrasive waterjet spent garnet (AWJ-SG) as a partial fine aggregate substitute in cement-based mortars. The evaluation followed the staged validation pathway described in the methodology section, including material characterisation, mix design optimisation, prototype validation, and preparation for pilot-scale assessment.

The *physical, chemical and mineralogical characterisation of AWJ-SG* performed in previous studies (Baera et al., 2026a) confirmed

via PSD determination, Scanning Electron Microscopy (SEM) analysis, X-Ray Diffraction (XRD) analysis and Fourier Transform Infrared Spectroscopy FTIR technique that the material exhibits properties compatible with the requirements of conventional mortar aggregates, that they are inert and safe for use in regular mixtures. The particle size distribution (PSD) of the processed SG fractions was found to fall within the grading range suitable for fine aggregates used in cement-based mortars. In addition, the angular particle morphology, typical of abrasive materials, may contribute to enhanced mechanical interlocking within the cementitious matrix. The density and mineralogical composition of the material were also consistent with the characteristics expected for silicate-based abrasive sands. Potential impurities associated with the cutting process are removed using the proposed specific procedure, which includes collection, screening and sorting, cleaning and verification, and storage operations, ensuring a stable and reproducible material suitable for mortar formulations.

Based on the material characterisation results, *the Mix Design Optimisation* stages led to mortar mixtures prepared using partial replacement levels of natural sand with AWJ-SG at 30% and 50%, while maintaining consistent binder content and water-to-binder ratios. The experimental results (Baera et al., 2026a) indicated that the incorporation of SG within these substitution ranges did not adversely affect the fresh properties of the mortars (visual aspect, consistency and fresh state density), while mechanical performance (compressive and flexural strength at early, regular and late ages) offered superior performance when compared to reference mixtures containing only natural aggregates. These observations confirm the compatibility between SG particles and the cementitious matrix, supporting findings reported in previous studies (Baera et al., 2025). The optimisation of the mix design therefore demonstrated that SG can be effectively integrated into mortar formulations without significant modifications to conventional mixture proportions.

The *prototype validation stage* aimed to verify the reproducibility and reliability of SG-based mortar formulations. Experimental testing carried out according to standardized methods (EN and ASTM procedures) confirmed that the incorporation of SG produces consistent performance trends across different batches of material. The validation procedure followed a structured framework based on four criteria: repeatability, reliability, performance pattern and robustness. Comparable results were obtained for SG batches collected from different sources and time periods, confirming the repeatability of the material behaviour. Reliability was ensured through the comparison of SG-based mixtures with conventional cement–sand reference mortars. Furthermore, systematic performance trends were observed with respect to SG substitution levels, while correlations between experimental results and theoretical expectations confirmed the robustness of the proposed material system. Overall, the results reported by Baera et al., (2026) validate the SG mortar prototypes at laboratory scale and demonstrate the technical viability of the proposed valorisation concept.

Following laboratory validation, the next stage *involves pilot-scale assessment*, aimed at verifying the reproducibility of the experimental results under industrial production conditions. This stage focuses on evaluating industrial mixing procedures, batching practices and material handling conditions typically encountered in mortar production facilities.

The current research phase developed a mixing procedure different from the standardized method (paddle mixer, rotational speed 140/280 rpm; revolutionary motion 61.5/123 rpm, according to EN 196-1). The objective was to create a simpler and more accessible manufacturing approach, better suited for technology transfer to industrial operators. The proposed technology involves mixing with a mortar mixer in a standard container (bucket/mixing vat) and includes the following steps: Step 1 - Dry mixing (natural sand + SG-AWJ addition); Step 2 - Dry mixing (aggregate + cement); Step 3 - Addition of water (and additive, if applicable); Step 4 - Visual inspection for proper consistency and absence of lumps.

The *critical characteristics* of standard AWJ-SG mortars required for calibrating the proposed technological transfer, as well as *the validation criteria*, are defined in the proposed ***Primary Validation Procedure***:

1 Properties in the fresh state: Visual appearance; Consistency; Bulk density (fresh state);
2. Properties in the hardened state: Bulk density (hardened state) and water absorption; Compressive strength (at 7 and 28 days); Flexural strength (at 7 and 28 days).

**Validation criterion:** Similar performance trends (a stable pattern) must be obtained, even if absolute values vary slightly between batches, within an acceptable margin of ±15%.

Ongoing study considers particular attention for ensuring production consistency, for preventing variability in fresh and hardened properties when AWJ-SG is incorporated into mortar formulations at larger scales. In parallel, process optimisation measures are being investigated, including adjustments to mixing sequences, aggregate grading control and potential pre-treatment operations such as additional screening or drying of the SG material. The successful scaling of these processes would support the *transition from experimental validation to industrial implementation*, enabling AWJ-SG to be integrated into cement-based materials as a secondary aggregate. From a circular economy perspective, this transition contributes to reducing landfill disposal of industrial abrasive waste while simultaneously lowering the demand for natural aggregate resources in the construction sector.

## II. Regulatory and Legal Layer for AWJ-SG Waste-to-Product Transition

The regulatory assessment indicates that the valorisation of abrasive waterjet spent garnet (AWJ-SG) as a secondary aggregate in cement-based mortars can be supported by the existing European and national regulatory framework. This stage of the research focuses on identifying the legal conditions under which AWJ-SG can transition from an industrial waste stream to a construction resource, while ensuring compliance with applicable waste management legislation and construction product standards. The results presented here outline the proposed regulatory pathway, which will be further investigated and validated in subsequent stages of the research.

### *Waste Classification*

The regulatory pathway begins with the identification of AWJ-SG within the waste management framework. In Romania, this process is governed by HG nr. 856/2002, which regulates waste management records and establishes the national waste list, aligned with the European List of Waste defined by Commission Decision 2000/532/EC. Under this classification system, AWJ spent garnet can be assigned to code 12 01 17 – waste blasting materials other than those specified in 12 01 16, providing the legal basis for its traceability and further evaluation for recovery.

### *End-of-Waste/By-Product Assessment*

A key step in the regulatory transition involves assessing whether AWJ-SG can satisfy the conditions required for end-of-waste or by-product status. This evaluation considers the intended application of the material, compliance with technical standards, and the absence of environmental or health risks. Preliminary technical results (Baera et al., 2026a) indicate that, following appropriate processing and grading, AWJ-SG may meet these conditions, supporting its potential recognition as a secondary resource within circular construction practices.

### *AWJ-SG Aggregate Compliance*

For construction applications, the processed material must demonstrate compliance with the relevant European aggregate standards. In the case of cement-based mortars, this includes EN 13139 - Aggregates for mortars, while potential applications in concrete require evaluation according to EN 12620 - Aggregates for concrete.

The application of these standards, in conjunction with Regulation (EU) No. 305/2011 (CPR) and relevant national legislation, entails:

- initial type testing (ITT) for essential characteristics (grain size, fines content, sand equivalent, absorption, chloride content, sulfate content, total sulfur, hazardous substances, etc.);
- implementation of a Factory Production Control (FPC) system;
- obtaining FPC certification through the AVCP 2+ system;
- issuing the Declaration of Performance (DoP) and affixing the CE marking.

Therefore, artificial/recycled aggregate cannot be lawfully used in construction mixtures without demonstrating, through documented evidence, compliance with the requirements of

the applicable harmonized standards and the consistency of its performance. Ongoing research aims to further assess the conformity of AWJ-SG with these standards and to define the quality control measures required for its use as a secondary aggregate.

***Mortar/Composite Compliance***

Beyond aggregate-level requirements, the performance of mortars incorporating AWJ-SG must comply with the relevant product standards, depending on the intended application. The incorporation of 30-50% of recycled garnet aggregate AWJ-SG into hydraulic-binder-based mortars results in a new product that is distinct from a regulatory standpoint and must be evaluated and certified separately from the raw material used. Depending on the mortar's intended use, the following harmonized standards apply: EN 998-1 for rendering and plastering mortars, EN 998-2 for masonry mortars, and EN 1504-3 for repair mortars used in concrete structures.

In this context, certification of the final product involves:

- determination of mechanical performance (compressive strength, adhesion, modulus of elasticity, etc.);
- evaluation of physical properties (density, capillary absorption, vapor permeability, shrinkage);
- verification of durability (freeze-thaw cycles, compatibility with the substrate);
- determination of the performance class (e.g., M5, M10, CS II, R3, R4, etc., as applicable);
- implementation of the system for assessing and verifying the constancy of performance appropriate to the product;
- issuing a separate Declaration of Performance for the resulting mortar.

It is essential to emphasize that the aggregate's compliance with EN 12620 or EN 13139 does not automatically imply the resulting mortar's compliance with EN 998 or EN 1504. The performance of the final product must be demonstrated experimentally and certified independently.

Preliminary laboratory results suggest that SG-based mixtures can achieve the required performance levels, although further testing is necessary to confirm compliance under broader application scenarios.

***Product Certification and Conformity Assessment***

The final stage of the regulatory pathway concerns product certification and conformity assessment in accordance with Regulation (EU) No. 305/2011 (Construction Products Regulation – CPR). This process addresses both the certification of the aggregate component and the verification of the performance of the final mortar-based product. Future research will therefore focus on identifying the appropriate certification procedures and factory production control requirements necessary for the market placement of AWJ-SG-based construction materials.

Overall, the regulatory layer highlights the legal and conformity conditions required to enable the circular valorisation of AWJ-SG, while also defining the main directions for further investigation needed to support its transition from waste management practices toward certified construction products.

**III. Commercial Layer: AWJ-SG Waste-to-Product Transition**

The commercial dimension of AWJ-SG valorisation addresses the practical conditions required to move from laboratory validation and regulatory compliance toward market implementation. At the current stage of the research project, the commercial layer remains *exploratory*, identifying potential pathways for integrating AWJ-SG into construction material value chains. The results presented here therefore outline preliminary directions for further investigation, reflecting the multidisciplinary approach adopted within the project.

The cost-benefit analysis of AWJ-SG Valorisation in construction materials and products is currently ongoing, based on comparative assessments against conventional aggregates. No definitive conclusions are available at this stage.

***Supply-Chain Integration***

Initial assessments indicate that the effective valorisation of AWJ-SG requires the integration of abrasive waterjet processing facilities with waste recovery operators and construction material producers. Establishing these logistical links is essential to ensure that the recovered material can be collected, processed, and

supplied in a consistent form suitable for use as a secondary aggregate. Further investigations will focus on identifying the most efficient configurations for such supply-chain integration at regional or industrial scales.

***Stakeholder Engagement***

Preliminary consultations highlight the importance of involving key stakeholders, including AWJ operators, waste management companies, construction material manufacturers, and regulatory bodies. Stakeholder engagement is particularly relevant for building confidence in the technical performance and environmental safety of SG-based materials. Continued dialogue with these actors will be necessary to support knowledge exchange and to facilitate acceptance of secondary aggregates within the construction sector.

***Supply Chain Organisation***

The analysis also suggests that the establishment of a structured supply chain is required to ensure the consistent availability and quality of AWJ-SG. This includes defining standardized collection, processing, and quality control procedures for the recovered material. Future work will therefore examine potential operational models capable of maintaining stable supply while meeting the technical and regulatory requirements identified in the previous layers.

***Business Model Development***

Several potential business models have been identified as promising directions for the valorisation of AWJ-SG. These include collaborative arrangements between AWJ service providers and mortar producers, waste recovery partnerships, or circular economy platforms promoting the reuse of industrial by-products. In addition, social entrepreneurship initiatives may represent a viable pathway, particularly where waste recovery and processing activities can generate local employment and support community-based circular economy practices. Further research will evaluate the economic feasibility and scalability of these models.

***Market Adoption of AWJ-SG-Based Construction Materials***

The market uptake of SG-based construction materials will ultimately depend on demonstrating technical reliability, regulatory compliance, and economic competitiveness compared with conventional materials. Although preliminary results indicate that SG-based mortars meet the required performance levels, broader market acceptance will require additional validation, pilot-scale production, and stakeholder engagement. Consequently, the commercial layer remains an ongoing research direction, aimed at identifying the conditions under which AWJ-SG can be successfully integrated into construction markets and contribute to circular economy practices in the sector.

## CONCLUSIONS

This study investigated the potential valorisation of abrasive waterjet spent garnet (AWJ-SG) as a secondary fine aggregate in cement-based mortars, adopting a multidisciplinary approach that integrates technical validation, regulatory assessment, and commercial considerations. The results confirm that the transition of AWJ-SG from an industrial waste stream to a construction resource is technically feasible and conceptually supported by the existing legal and market frameworks, although further investigations are required to advance toward full industrial implementation.

From a technical perspective, the laboratory investigations demonstrate that processed AWJ-SG exhibits physical and mineralogical characteristics compatible with conventional fine aggregates used in cement-based mortars. Mortar mixtures incorporating SG at partial replacement levels showed acceptable fresh and hardened performance, confirming the compatibility between SG particles and the cementitious matrix. The validation framework based on repeatability, reliability, performance pattern, and robustness further confirmed the consistency of SG-based mortar prototypes at laboratory scale, providing a solid basis for subsequent pilot-scale investigations.

Beyond the material performance assessment, this study contributes to the integration of circular economy principles into construction material design. By proposing the reuse of AWJ abrasive residues as secondary aggregates, the research demonstrates the potential for industrial symbiosis between manufacturing processes and construction material production, contributing to reduced landfill disposal and decreased consumption of natural aggregate resources.

A key contribution of the work lies in the analysis of the regulatory pathway for waste-to-product transition. The study identifies the legal framework governing the classification, recovery, and certification of AWJ-SG-based materials within the European construction sector, highlighting the relevance of waste classification procedures, end-of-waste or by-product assessments, compliance with aggregate and mortar standards, and product certification in accordance with Regulation (EU) No. 305/2011. This regulatory mapping clarifies the conditions under which SG-based materials could be placed on the market as compliant construction products.

In addition, the research explores the commercial dimension of SG valorisation, identifying key elements required for practical market integration. These include supply-chain organisation, stakeholder engagement, the development of viable business models-including potential social entrepreneurship initiatives-and the gradual market adoption of SG-based construction materials. Although this component of the study remains at an exploratory stage, it provides an initial framework for understanding the economic and organisational conditions necessary for successful implementation. One limitation of this study is that the economic assessment of AWJ-SG valorisation has not yet been completed. Comparative analyses with conventional aggregates are currently underway, and definitive conclusions regarding the cost–benefit performance are therefore beyond the scope of the present work.

Overall, the research proposes a three-layer technology-transfer framework-technical, regulatory, and commercial-designed to support the practical implementation of AWJ-SG valorisation within a circular economy context. By combining laboratory validation with regulatory analysis and preliminary commercial considerations, the study contributes to bridging the gap between experimental material research and real-world industrial application.

Future work will focus on pilot-scale assessments and industrial implementation, further evaluation of regulatory compliance pathways, and the development of operational supply chains capable of supporting the market introduction of SG-based construction materials. Through these continued investigations, AWJ spent garnet may evolve from an industrial waste stream into a valuable resource for sustainable construction practices.

***Abstract***

*The management of vineyard by-products represents an important environmental challenge in viticultural regions, where large quantities of organic residues are generated annually. From an environmental engineering perspective, the sustainable valorization of these by-products offers significant opportunities for reducing waste streams while improving resource efficiency. This paper proposes a technical framework for the sustainable valorization of vineyard by-products through the implementation of small-scale processing technologies. The framework integrates engineering criteria such as processing efficiency, energy demand, and technological adaptability with environmental considerations including waste reduction, resource recovery, and alignment with circular economy principles. The proposed approach is illustrated through a representative application scenario focusing on grape seed processing for oil production, highlighting the potential of small-scale technologies to convert viticultural residues into value-added products. The results emphasize the role of appropriately selected processing technologies in minimizing environmental pressure associated with vineyard waste and supporting sustainable agricultural systems. The framework provides a structured basis for further applied research and technology development in viticulture-related waste management.*

***Key words****: environmental engineering, grape seed valorization, sustainable processing, vineyard by-products, waste reduction.*

## INTRODUCTION

The expansion of the global wine industry has led to a substantial increase in the generation of organic residues, particularly vineyard by-products such as grape pomace, stalks, and lees. These materials, which may account for up to 30% of the initial processed grape mass, represent a significant environmental challenge due to their high organic content and rapid biodegradability (Bustamante et al., 2008; Nirmal et al., 2025).

The accumulation of such residues, especially during harvest seasons, creates pressure on local waste management systems and raises concerns related to greenhouse gas emissions, soil contamination, and inefficient resource utilization (Moletta, 2005; Beres et al., 2017). Romania ranks among the top ten wine-producing countries in the European Union, with approximately 180,000 hectares of vineyard area and an annual wine production exceeding 4 million hectolitres (OIV, 2023). This production volume generates substantial quantities of grape pomace estimated at over 150,000 tons per year, the management of which represents a persistent challenge for small and medium-sized wine producers, particularly in viticultural regions such as Muntenia, Moldova, and Oltenia where processing infrastructure remains limited.

From an environmental engineering perspective, the management of vineyard by-products requires a transition from conventional disposal practices to integrated valorization strategies. Traditional approaches, including composting, distillation, or uncontrolled land spreading, often fail to fully exploit the resource potential of these materials and may generate secondary environmental impacts if not properly controlled (Negro et al., 2003; Provenzano et al., 2024). In addition, the high moisture content and biochemical activity of grape pomace can accelerate fermentation processes, leading to greenhouse gas emissions and the formation of leachates containing organic acids and phenolic compounds (Dwyer et al., 2014; Teixeira et al., 2014).

Recent advances in circular economy research emphasize the importance of transforming agri-food residues into value-added products, thereby reducing waste streams and improving overall system efficiency (Galanakis, 2012; Mirabella et al., 2014). In the context of viticulture, vineyard by-products are increasingly recognized as a source of valuable compounds, including lipids, polyphenols, dietary fibers, and antioxidants, which can be recovered through appropriate processing technologies (Rockenbach et al., 2011; Fontana et al., 2013). Such approaches contribute not only to waste reduction but also to the development of sustainable bio-based value chains aligned with European circular economy policy objectives (Puglia et al., 2021; Abbate et al., 2025).

Grape pomace, the main residue of the winemaking process, consists of seeds, skins, and stems that retain a significant fraction of the original grape constituents after juice extraction. Its composition varies depending on grape variety, climatic conditions, and processing techniques, but consistently includes compounds with high industrial and nutritional value (Pardo et al., 2009; Martin et al., 2020). Among these fractions, grape seeds are of particular interest due to their oil content, typically ranging from 8% to 15% on a dry matter basis, and the presence of bioactive molecules with antioxidant properties (Malićanin et al., 2014; Kapcsándi et al., 2021). These characteristics make grape seeds suitable for valorization through mechanical or physico-chemical extraction processes, with cold-pressed grape seed oil increasingly recognized as a high-value functional food ingredient.

Various technological pathways have been explored for the recovery of valuable compounds from vineyard residues, including solvent extraction, supercritical fluid extraction, enzymatic treatment, and mechanical pressing (Passos et al., 2010; Mushtaq et al., 2020). While these methods demonstrate high recovery efficiencies under controlled conditions, their implementation is often limited to industrial-scale operations requiring significant capital investment, energy input, and specialized infrastructure (Cerutti et al., 2013; Spigno et al., 2017). Consequently, their applicability in small and medium-sized vineyards remains restricted, and access to valorization technologies for farm-level operators continues to be a barrier to sustainable by-product management.

In contrast, small-scale processing technologies offer a promising alternative by enabling decentralized valorization directly at the source of biomass generation. Such systems can reduce transportation requirements, lower associated emissions, and facilitate the integration of valorization processes into local agricultural practices (Laufenberg et al., 2003; Ahmad et al., 2020). Mechanical screw pressing, for example, represents a relatively simple and energy-efficient method for oil extraction that can be adapted to farm-level applications without the use of chemical solvents, with specific energy consumption values reported below 0.15 kWh per kilogram of processed seeds under optimized conditions (Kamal-Eldin, 2006; Bjelica et al., 2019).

Despite the increasing interest in vineyard by-product valorization, existing studies tend to address either the physicochemical characterization of grape pomace fractions (Rockenbach et al., 2011; Martin et al., 2020) or the optimization of individual extraction technologies under laboratory conditions (Passos et al., 2010; Mushtaq et al., 2020), without integrating engineering performance with environmental assessment at the process level. Kokkinomagoulos and Kandylis (2023) provide a comprehensive review of winery waste valorization pathways, yet no unified framework combining processing efficiency, energy demand, technological adaptability, and environmental indicators has been proposed specifically for small-scale. In particular, the interaction between processing efficiency, energy demand, technological adaptability, and environmental impact is not sufficiently explored within a unified analytical framework applicable to farm-level or regional valorization scenarios (Dimić et al., 2020).

Addressing this gap requires the development of structured methodologies capable of supporting decision-making in the selection and implementation of appropriate technologies. The integration of engineering indicators, such as processing efficiency and specific energy consumption, with environmental metrics including waste reduction and resource recovery, is essential for evaluating the

sustainability of valorization pathways (Mironeasa et al., 2010; Orsavova et al., 2015). Such an approach enables a more comprehensive understanding of the trade-offs involved in biomass processing systems and provides a quantitative basis for comparing alternative technological configurations at the same scale of operation.

The aim of this study is to develop and validate a technical framework for the sustainable valorization of vineyard by-products through the application of small-scale processing technologies, integrating engineering indicators: processing efficiency, specific energy consumption, and technological adaptability, with environmental metrics including waste reduction rate, resource recovery index, and circularity coefficient. The applicability of the framework is demonstrated through a representative scenario involving mechanical grape seed oil extraction using the NF80 screw press, applied to Riesling 1 and Fetească Regală 1 grape varieties sourced from the Research and Development Station for Viticulture and Oenology (ICDVV) Valea Călugărească, Romania.

## MATERIALS AND METHODS

### Vineyard by-products considered in the study

The present study focuses on vineyard by-products generated during the winemaking process, particularly grape pomace, which consists of seeds, skins, and stems remaining after the pressing stage. These residues may represent approximately 20-30% of the initial grape mass processed in wineries and contain valuable biochemical components such as oils, phenolic compounds, fibers, and proteins (Laufenberg et al., 2003; Martin et al., 2020).

Among the different fractions of grape pomace, grape seeds were considered the most relevant component for the representative application scenario analyzed in this study. Grape seeds are characterized by a significant content of lipids and bioactive compounds, which makes them suitable for valorization through mechanical oil extraction technologies (Pardo et al., 2009; Kapcsándi et al., 2021). In addition to oils, grape seeds contain antioxidants, polyphenols, and essential fatty acids, contributing to their potential use in food, cosmetic, and pharmaceutical applications (Malićanin et al., 2014; Bjelica et al., 2019).

Prior to processing, grape seeds are typically separated from grape pomace using mechanical separation equipment and may undergo conditioning stages such as drying and cleaning in order to reduce moisture content and remove impurities. Literature data indicate that the optimal moisture content for mechanical oil extraction generally ranges between 6% and 10%, depending on the grape variety and the extraction technology used (Mushtaq et al., 2020).

In addition to grape seeds, the framework also considers the potential utilization of secondary residues generated during processing, such as press cake. This by-product may be further used as organic fertilizer, soil amendment, or raw material for bioenergy production, contributing to improved resource recovery within vineyard systems (Puglia et al., 2021) content. It only contains example text and proper formatting.

### Representative processing technology

To illustrate the proposed framework, a representative small-scale processing technology was considered, namely a mechanical screw press used for oil extraction from grape seeds. Mechanical pressing technologies are widely applied for processing oil-bearing materials due to their relatively simple construction, moderate energy consumption, and the absence of chemical solvents (Passos et al., 2010). The main processing stages considered in the framework, together with the associated input and output streams, are summarized in Figure 1.

Small-scale screw presses are particularly suitable for decentralized agricultural systems because they allow on-site processing of biomass with relatively low investment costs and minimal infrastructure requirements. Such systems are typically composed of several main components: a feeding hopper, a screw conveyor placed inside a cylindrical pressing chamber, an outlet nozzle for solid residues, an oil collection system, and an electric motor that provides the mechanical energy required for operation.

For this study, experimental data obtained at INMA Bucharest were used, involving the NF80 mechanical screw press (0.37 kW, 220V)

equipped with interchangeable screw configurations (pitch 16 mm and 22 mm) and outlet nozzles with diameters of 10, 12, and 15 mm.

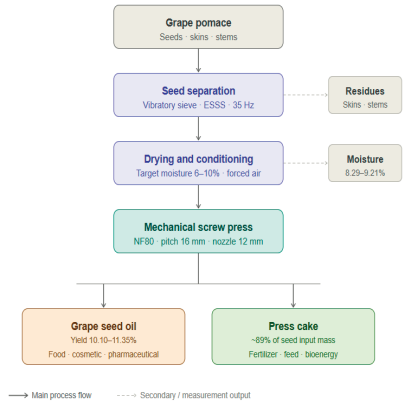

Figure 1. Conceptual process flow for grape seed valorization using the NF80 small-scale screw press, from pomace conditioning to the recovery of oil and press cake.

The separation of seeds from conditioned pomace was performed using the ESSS vibrating screen separator operated at frequencies between 25 and 45 Hz. The grape pomace was obtained from two Romanian research institutes: ICDVV Valea Călugărească (Prahova County) and INCDBH Ștefănești (Argeș County). Two white grape varieties were selected for the representative application scenario: Riesling and Fetească Regală. The conceptual process flow for grape seed valorization using the NF80 small-scale screw press, from pomace conditioning to the recovery of oil and press cake, is presented in Figure 2.

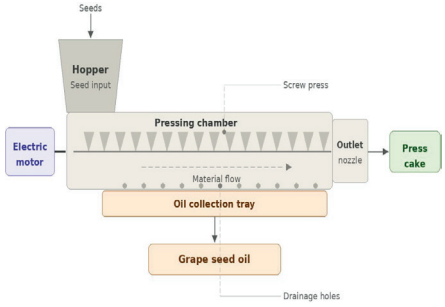

Figure 2. Schematic representation of the main components of the NF80 small-scale screw press: hopper (seed input), pressing chamber with screw press, drainage holes for oil extraction, oil collection tray, outlet nozzle, and press cake discharge.

During the pressing process, the biomass is transported along the screw channel while being progressively compressed. As pressure increases, the oil contained in the seeds is released and collected through small openings in the pressing chamber. The remaining solid fraction, commonly referred to as press cake, is discharged through the outlet of the press. Mechanical extraction methods are often preferred for small-scale operations because they ensure a relatively high oil quality and do not involve chemical solvents that may generate environmental concerns (Kamal-Eldin, 2006).

**Engineering performance indicators**

In order to evaluate the performance of small-scale processing technologies used for the valorization of vineyard by-products, several engineering indicators were considered.

*Processing efficiency* ($\eta_p$) represents the ratio between the mass of valuable product obtained during processing and the mass of biomass introduced into the system.

$$\eta_p = \frac{M_{valuable\ product}}{M_{input\ bionass}} \times 100$$

where: $M_{valuable\ product}$ - mass of recovered product (e.g., grape seed oil), $M_{input\ bionass}$ - mass of processed biomass.

This indicator is commonly used in biomass processing systems to evaluate the efficiency of conversion processes (Laufenberg et al., 2003).

*Specific energy* ($E_s$) consumption represents the amount of energy required to process a unit mass of biomass.

$$E_s = \frac{E_{total}}{M_{processed}}$$

where: $E_{total}$ - total electrical energy consumed during processing, $M_{processed}$- mass of biomass processed.

Energy demand is considered an important engineering parameter for evaluating the sustainability of biomass processing technologies.

*The technological adaptability index* (TAI) evaluates the suitability of the processing technology for decentralized agricultural applications.

$$TAI = \frac{S_c + S_o + S_m}{3}$$

where: $S_c$- equipment complexity score, $S_o$- operational simplicity score, $S_m$- maintenance

requirements score. Each parameter is evaluated on a qualitative scale from 1 to 5.

**Environmental performance indicators**

In addition to engineering parameters, environmental indicators were used to assess the sustainability of vineyard by-product valorization.

The *waste reduction* (WR) rate indicates the proportion of initial biomass converted into valuable products.

$$WR = \frac{M_{initial\,waste} - M_{residual\,waste}}{M_{initial\,waste}} \times 100$$

Waste reduction indicators are frequently used in environmental engineering studies evaluating resource recovery systems (Puglia et al., 2021).

The *resource recovery index* (RRI) reflects the proportion of by-products that can be converted into useful resources.

$$RRI = \frac{M_{recovered\,resources}}{M_{total\,byproducts}}$$

The *circularity coefficient* (CC) expresses the degree to which biomass-derived products are reintegrated into the economic cycle.

$$CC = \frac{M_{reintroduced\,resources}}{M_{total\,biomass}}$$

Such indicators are commonly applied in circular economy assessments related to agricultural residue valorization (Abbate et al., 2025).

The framework indicators defined above were applied to experimental data obtained from the NF80 screw press trials and are discussed in the following section.

## RESULTS AND DISCUSSIONS

**Development of the technical framework**

Based on the engineering and environmental indicators defined in the materials and methods section, a technical framework for the sustainable valorization of vineyard by-products was developed. The framework integrates process-level performance criteria with environmental assessment metrics in order to support decision-making in the selection and implementation of small-scale processing technologies. The overall structure of the proposed framework is presented in Figure 3.

The framework is organized around four interconnected stages. The first stage, *biomass assessment*, involves the identification and characterization of vineyard residues, including quantity estimation, moisture content determination, and compositional analysis. For the representative scenario analyzed in this study, the initial moisture content of Riesling (R) pomace was 56.98% and that of Feteasc Regală (FR) was 62.61%, reduced to 24.12% and 27.35% respectively following a two-stage drying protocol combining natural air-drying and forced convection at 30-40°C (Mushtaq et al., 2020). Physical characterization of the separated seeds revealed mean diameters of 3.65 mm for Riesling (sphericity 0.643) and 3.75 mm for Feteasc Regală (sphericity 0.696), with oil contents of 9.52% and 9.72% respectively - both within the 6-10% optimal moisture range for mechanical pressing (Mushtaq et al., 2020).

The second stage focuses on the *selection of appropriate processing technologies* based on engineering criteria. In this context, small-scale screw pressing was identified as a suitable solution for decentralized applications due to its relatively low energy requirements, absence of chemical solvents, and operational simplicity (Kamal-Eldin, 2006; Passos et al., 2010). The NF80 screw press, evaluated across six configurations, achieved a technological adaptability index (TAI) of 4.0 out of 5, reflecting its simple construction and ease of deployment at farm level.

**Application of the framework to grape seed oil extraction**

The third stage of the framework, *process implementation*, was applied to the grape seed oil extraction scenario using the NF80 screw press. Seed separation from conditioned pomace was performed at 35 Hz using the ESSS vibratory screen separator, recovering 6.52 kg of seeds from 20 kg of Riesling pomace (32.6%) and 6.34 kg from Feteasc Regală pomace (31.7%), exceeding the 18-25% range commonly cited in the literature (Laufenberg et al., 2003). The crude oil yield and extraction efficiency across all six press configurations are presented in Figure 4.

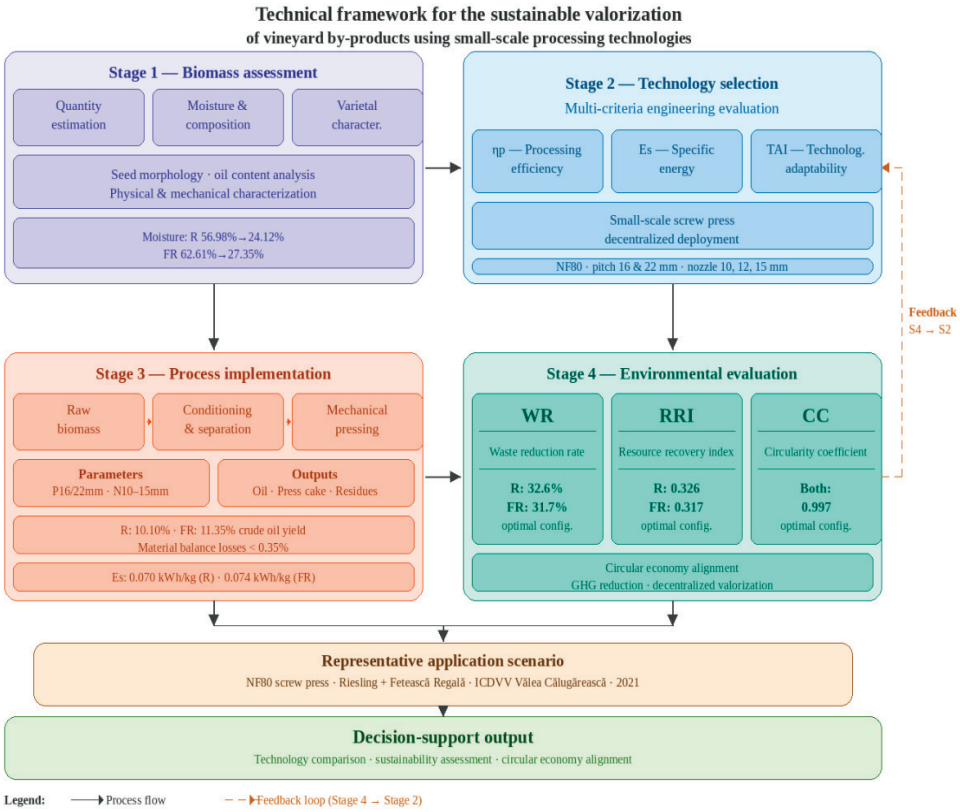

Figure 3. Technical framework for the sustainable valorization of vineyard by-products using small-scale processing technologies, structured around four interconnected stages and integrating engineering and environmental performance indicators

The highest performance was obtained with the pitch (P) 16 mm, nozzle (N) 12 mm, and speed 10 rpm configuration for both varieties, yielding 10.10% crude oil and 83.81% extraction efficiency for Riesling, and 11.35% crude oil with 92.23% extraction efficiency for Fetească Regală. Specific energy consumption was 0.070 kWh/kg and 0.074 kWh/kg respectively - values significantly lower than solvent-based extraction systems and competitive with cold-pressing technologies at comparable scales (Kamal-Eldin, 2006). The pitch 22 mm configurations showed a marked performance decrease, with yields falling to 7.43-8.65%, attributable to the reduced compression ratio and incomplete cell wall rupture (Passos et al., 2010). These results confirm trends reported for cold-pressed grape seed oil, where mechanical pressing yields of 8-12% are typical (Kapcsándi et al., 2021).

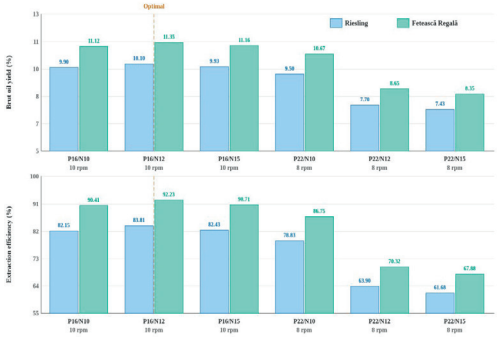

Figure 4. Brut oil yield (top) and extraction efficiency (bottom) across six NF80 press configurations for Riesling and Feteasca Regala (3 kg seed input). P = screw pitch (mm), N = nozzle diameter (mm)

From an energy perspective, the low specific energy consumption confirms the suitability of the NF80 system for decentralized applications

where energy efficiency is a critical operational constraint. The material balance for the complete valorization chain is presented in Figure 5. From a 3 kg seed input, 303 g of crude oil and 2,687 g of press cake were recovered for Riesling (losses 0.33%), and 340 g of crude oil with 2,650 g of press cake for Feteasc Regală (losses 0.32%). The press cake fraction, representing 89.6% and 88.3% of seed input respectively, constitutes a valorizable secondary stream for fertilizer, animal feed, or bioenergy applications (Puglia et al., 2021).

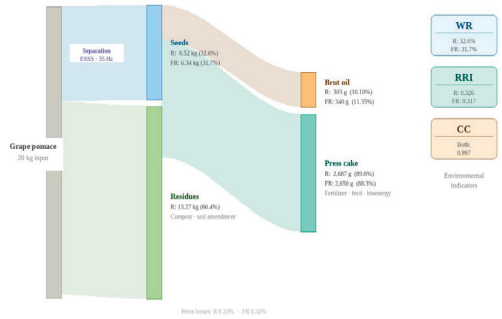

Figure 5. Sankey diagram of the material balance for the grape seed valorization chain: from 20 kg pomace input through seed separation to mechanical pressing. Band width is proportional to mass flow. Environmental indicators (WR, RRI, CC) are presented for Riesling (R) and Feteasc Regală (FR) under the optimal processing configuration

## Environmental performance assessment

The fourth stage of the framework was applied through the calculation of the three *environmental indicators*. The complete set of engineering and environmental performance indicators under the optimal configuration is presented in Table 1, and the comparative performance profiles for both varieties are illustrated in Figure 6.

The waste reduction rate (WR) reached 32.6% for Riesling and 31.7% for Feteasc Regală, reflecting the proportion of pomace input converted into the recoverable seed fraction. These values confirm that approximately one third of the pomace mass can be systematically redirected from the waste stream into a productive valorization chain (Kokkinomagoulos & Kandylis, 2023). The resource recovery index (RRI) was 0.326 and 0.317 respectively.

Table 1. Environmental performance indicators for grape seed valorization under optimal processing configuration

| Indicator | Symbol | Riesling | Feteasc regală | Unit |
|---|---|---|---|---|
| Waste reduction rate | wr | 32.6 | 31.7 | % |
| Resource recovery index | rri | 0.326 | 0.317 | – |
| Circularity coefficient | cc | 0.997 | 0.997 | – |
| Overall circular performance | – | high | high | quali-tative |

The residual pomace fraction retains further valorization potential through composting or anaerobic digestion pathways, contributing to overall system circularity. The circularity coefficient (CC) was 0.997 for both varieties, indicating near-complete reintegration of all biomass-derived fractions, oil and press cake, into productive use pathways, consistent with circular economy objectives for agri-food by-product valorization (Abbate et al., 2025).

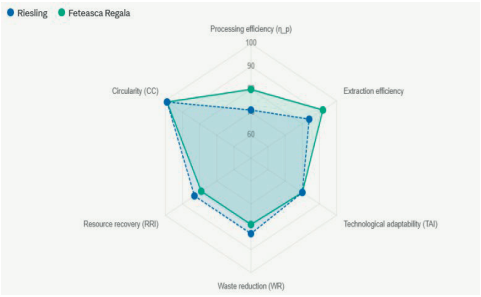

Figure 6. Normalized performance profile (0–100 scale) of all framework indicators for Riesling and Feteasca Regala under optimal configuration (pitch 16 mm, nozzle 12 mm, 10 rpm)

Furthermore, the implementation of small-scale pressing directly at source eliminates the need for transportation of raw pomace to centralized processing facilities, reducing associated greenhouse gas emissions - an aspect particularly relevant in viticultural regions with dispersed farm structures such as Muntenia and Oltenia in Romania.

## Correlation analysis and framework applicability

The relationships between engineering and environmental performance indicators across all

six configurations and both varieties are presented in Figure 7. Processing efficiency ($\eta_p$) shows a strong positive correlation with the circularity coefficient (CC, r = +0.96) and moderate correlations with WR (r = +0.72) and RRI (r = +0.58), confirming that configurations maximizing oil yield simultaneously maximize environmental performance. Conversely, specific energy consumption (E s) shows strong negative correlation with CC (r = −0.89), WR (r = −0.61), and RRI (r = −0.48). The TAI showed no correlation with environmental indicators (r = 0.00), confirming its role as an independent equipment-level criterion in the framework.

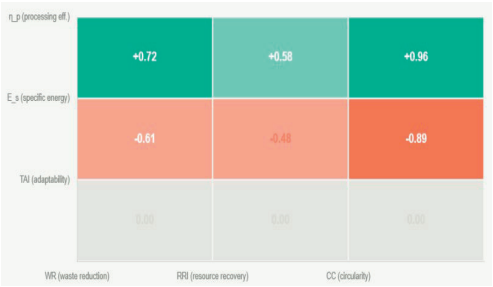

Figure 7. Pearson correlation matrix between engineering and environmental framework indicators across all processing configurations (n = 12). Values range from −1 (strong negative) to +1 (strong positive)

These findings demonstrate a convergence of engineering and environmental optima under the pitch 16 mm configurations, making them simultaneously optimal from both technical and sustainability perspectives. Compared to centralized industrial solutions, the proposed framework applied to small-scale systems offers advantages in flexibility, reduced transport requirements, and improved local resource utilization. Limitations include variability in raw material characteristics across harvest years and the need for future validation through life cycle assessment (LCA) and techno-economic analysis to quantify environmental benefits more precisely across diverse viticultural contexts.

## CONCLUSIONS

The present study proposed and applied a technical framework for the sustainable valorization of vineyard by-products through the integration of engineering and environmental performance indicators. The framework proved to be a structured and effective approach for supporting decision-making in small-scale processing applications, particularly in decentralized viticultural systems.

The results obtained from the representative application scenario demonstrated that grape pomace can be efficiently valorized through mechanical processing, with grape seeds representing a key resource for oil extraction. The application of the NF80 screw press confirmed the technical feasibility of small-scale processing, achieving satisfactory processing efficiency and low specific energy consumption under optimized operating conditions.

From an environmental perspective, the implementation of the proposed framework enabled a significant reduction in waste streams and an efficient recovery of valuable resources. The calculated values of waste reduction rate and resource recovery index indicate that a substantial fraction of vineyard residues can be redirected into productive use, while the high circularity coefficient highlights the potential for reintegrating both oil and press cake into the economic cycle.

The integration of engineering indicators (processing efficiency, specific energy consumption, and technological adaptability) with environmental metrics (waste reduction, resource recovery, and circularity) provides a comprehensive tool for evaluating valorization pathways. This approach allows the identification of optimal processing configurations that simultaneously meet technical and sustainability criteria.

Furthermore, the results emphasize the advantages of small-scale processing technologies in reducing transportation needs, lowering associated emissions, and improving local resource utilization. These aspects are particularly relevant for small and medium-sized vineyards, where access to centralized processing infrastructure is limited.

Although the framework was validated using a representative case study, further research is required to extend its applicability through larger datasets, multi-seasonal analysis, and integration with life cycle assessment and techno-economic evaluation methods. Such

developments would enhance the robustness of the framework and support its implementation across different viticultural regions.

Overall, the proposed technical framework contributes to the advancement of sustainable vineyard by-product management by providing a practical and adaptable model aligned with circular economy principles and environmental engineering objectives.

***Abstract***

*Sustainable societal development requires practical solutions that promote the use of traditional and locally available materials, particularly for vulnerable rural communities. In this context, unfired clay represents an environmentally friendly construction material due to its low embodied energy, recyclability, and local availability. Compared to conventional fired materials, it reduces energy consumption and environmental impact, supporting sustainable construction practices. At the same time, the valorization of plant-based waste generated by agricultural and wood-processing activities represents an effective strategy for improving resource efficiency and reducing environmental pollution. According to the National Institute of Statistics, agriculture accounted for approximately 2.5% of Romania's GDP in 2025 and generated over 50% of total municipal waste as vegetal residues. As consumption increases, the management of such waste becomes increasingly challenging, while its decomposition releases greenhouse gases such as methane, contributing to climate change. The incorporation of plant-based waste into clay-based construction materials represents a promising approach for waste valorization and the development of sustainable building materials. This study investigates the effect of hemp fibers and sawdust on the physical and mechanical properties of unfired clay mixtures.*

***Key words****: hemp fibers, plant-based waste, sawdust, sustainable construction, unfired clay.*

## INTRODUCTION

The development of sustainable construction materials has become a strategic research direction in civil engineering, driven by the urgent need to reduce the environmental impact of the construction sector and to address the growing challenges associated with global climate change (Hegyi et al., 2016). Over the past decades, the construction industry has been identified as a major contributor to global greenhouse gas emissions, both through the industrial processes involved in material production and through the extensive consumption of natural resources required for construction activities.

In particular, the production of conventional construction materials such as cement and fired bricks involves energy-intensive technological processes that generate significant amounts of carbon dioxide emissions. These environmental concerns have stimulated increasing research efforts aimed at identifying alternative construction materials and technologies capable of reducing environmental impact while maintaining adequate structural performance and energy efficiency (Bradu et al., 2025).

Within this context, the use of locally available natural materials has gained considerable attention as part of sustainable construction strategies. Materials such as unfired earth, wood, and other natural resources offer significant advantages in terms of reduced embodied energy and lower carbon footprint during production. Moreover, the use of local materials reduces transportation-related environmental impacts and facilitates the adaptation of buildings to specific climatic and geographical conditions (Walker et al., 2005; Minke, 2012).

Masonry elements produced from natural materials such as clay soil, sand, local aggregates, and plant-based waste represent one of the oldest construction technologies used

worldwide (Hegyi et al., 2023). These materials provide several sustainability-related advantages, including local availability, low energy consumption during processing, recyclability, and environmental compatibility. In addition, unfired clay masonry elements contribute to improved hygrothermal comfort in buildings due to their ability to regulate indoor humidity and their high thermal inertia, which helps stabilize indoor environmental conditions (Houben & Guillaud, 1994; Tomaževič, 1999).

The use of clay soil for masonry construction has a long tradition in Romania, particularly in rural areas where traditional building techniques have been developed according to local climatic conditions and available resources (Petcu et al., 2023). The geological diversity of Romania provides significant reserves of clay soils, sands, and natural aggregates that can be utilized for producing environmentally friendly masonry materials (Calatan et al., 2020).

At the same time, the agricultural sector and the wood-processing industry generate considerable amounts of plant-based waste, including sawdust resulting from timber processing and hemp fibers obtained from the cultivation of this traditional crop (Mircea et al., 2021). The incorporation of these materials into masonry compositions can lead to the development of natural composite materials with improved thermal insulation performance and enhanced mechanical behavior. Furthermore, this approach supports the valorization of renewable resources while reducing the amount of biodegradable waste that could otherwise contribute to greenhouse gas emissions during decomposition (Walker et al., 2005; Ashour et al., 2010).

Hemp is characterized by high ecological adaptability, being able to grow under a wide range of climatic and soil conditions without requiring intensive use of fertilizers or pesticides. Due to its ability to absorb and neutralize certain soil contaminants, hemp cultivation can contribute to reducing soil pollution and improving soil quality. In addition, the deep root system of this plant improves soil structure and promotes aeration, facilitating the development of subsequent agricultural crops (Binici et al., 2007).

Moreover, hemp plays an important role in carbon sequestration, capturing atmospheric carbon dioxide from the early stages of plant growth. Hemp-based products are non-toxic, biodegradable, and renewable, making them particularly attractive for the development of sustainable construction materials (Lachheb et al., 2023).

Historically, Romania was one of the major global producers of industrial hemp. In the 1990s, with a production exceeding 72,000 tons, Romania ranked third worldwide in hemp production. However, increasingly restrictive regulations significantly reduced interest in this crop. In recent years, a gradual revival of hemp cultivation has been observed in Romania, supported by investments in processing facilities, access to European Union funding, and its higher economic potential compared to traditional crops such as cereals and oilseeds (Neacșu, 2022).

In parallel, Romania has a well-developed forestry and wood-processing sector, generating significant quantities of wood residues, particularly sawdust. This type of waste represents an important resource within the framework of the circular economy and is increasingly used in various applications, including energy production, wood-based panel manufacturing, and sustainable construction materials (Bailly et al., 2024). The incorporation of sawdust into construction materials contributes both to the efficient reuse of industrial by-products and to the improvement of certain physical properties such as density reduction and enhanced thermal insulation.

In recent years, increasing research interest has been directed toward the use of sawdust in ecological construction materials. The integration of this by-product into building materials not only facilitates the valorization of wood waste but also improves certain physical and mechanical properties of composite materials. Furthermore, this approach supports the development of locally sourced, low-cost construction materials while promoting environmentally sustainable building solutions, particularly in rural areas (Toader et al., 2025).

Despite the growing interest in plant-based additives for earthen construction materials, limited research has been conducted on the combined use of locally available clay soils with vegetal residues such as sawdust and hemp fibers in masonry elements. In particular, there

is still insufficient experimental data regarding the influence of these additives on the physical and mechanical properties of clay-based composites produced from locally available materials.

Therefore, the present study aims to investigate the influence of plant-based waste additives on the performance of clay masonry materials. A comparative experimental study was conducted on clay-based compositions intended for masonry elements, produced from locally available sustainable materials and modified by the addition of plant-based waste in the form of sawdust and hemp fibers. The main objective of this research is to evaluate the influence of these vegetal additives on the physical and mechanical properties of the resulting composites and to identify sustainable construction solutions based on locally available natural resources.

## MATERIALS AND METHODS

The mixtures used for the production of masonry elements were composed of locally available materials, including clay soil, sand, aggregates, and agricultural waste in the form of sawdust and hemp fibers, together with a natural additive (Figure 1). The formulations of the mixtures are presented in Table 1.

Table 1. Composition of the evaluated clay-based mixtures

| Constituents | Unit | S1 | S2 | H1 | H2 |
|---|---|---|---|---|---|
| Clay soil | g | 10,758 | 10,758 | 10,758 | 10,758 |
| Sand 0-1 mm | g | 220 | 220 | 220 | 220 |
| Sand 0-4 mm | g | 2,289 | 2,289 | 2,289 | 2,289 |
| Aggregate 4-8 mm | g | 2,102 | 2,102 | 2,102 | 2,102 |
| Hemp | g | - | - | 1,537 | 3,074 |
| Sawdust | g | 1,537 | 3,074 | - | - |
| Additive | g | 107.6 | 107.6 | 107.6 | 107.6 |
| Clay/water ratio | - | 0.28 | 0.29 | 0.28 | 0.22 |
| Spread | mm | 108.9 | 106.9 | 110.6 | 105.1 |

The clay soil used as a binder consisted of 52% clay fraction, 44% silt, and 4% sand.

The sand incorporated into the clay mixture was coarse construction sand with particle size distributions of 0-1 mm and 0-4 mm. In addition, natural alluvial aggregates with particle sizes ranging from 4 to 8 mm were used.

The amount of water was determined experimentally for each mixture in order to ensure optimal workability of the fresh material. To obtain smoother and more uniform surfaces of the self-supporting elements and to improve the workability of the mixtures, rabbit glue was used as a natural additive. This additive enhances the elasticity and cohesion of the clay matrix.

Plant-based waste in the form of hemp fibers and sawdust was incorporated into the material composition as additives in order to valorize renewable resources.

a) Hemp fibers

b) Sawdust

c) Rabbit glue

Figure 1. Constituent materials

The incorporation of fibers in a saturated state improves the adhesion between the fibers and the clay matrix. Moistening the fibers helps eliminate entrapped air, reducing the risk of void formation and ensuring a stronger bond between the constituent materials.

The preparation of the clay mixture followed several stages. First, the clay soil and the vegetal waste were mixed in a large container until a homogeneous mixture was obtained. The rehydrated rabbit skin glue was dissolved in the required amount of water and added to the composition, while mixing continued until a uniform consistency was achieved. Finally, sand with particle sizes of 0-1 mm and 0-4 mm, together with aggregates (4-8 mm), were added to the mixture, and mixing was continued until a homogeneous texture was obtained.
The consistency of the fresh clay mixture was determined according to SR EN 1015-3:2001/A2:2007 (Figures 2 and 3).

a) 10% sawdust content

b) 20% sawdust content

Figure 2. Spread of the clay mixture with sawdust addition

The principle of this method is as follows: the conical mold is placed on the circular flow table, using a manual flow table manufactured by MATEST (Italy), and filled with the fresh mixture in two layers. Each layer is compacted using a metal tamper. After removing the mold, 15 drops are applied to the flow table within 15 seconds, after which the average diameter of the spread specimen is measured.

a) 10% hemp fiber content

b) 20% hemp fiber content

Figure 3. Spread of the clay mixture with hemp fiber addition

The mixture was cast into standardized molds, using cubic molds for concrete sample preparation manufactured by UTEST (Turkey), with dimensions of 150 × 150 × 150 mm, intended for compressive strength testing after 28 days. In addition, part of the mixture was cast into molds measuring 300 × 300 × 50 mm for thermal conductivity testing.
The specimens were demolded after 5 days and conditioned at a temperature of 23 ± 5°C. The stages of specimen preparation are illustrated in Figure 4.
The drying time of the specimens varies depending on the mixture composition and environmental conditions. Mixtures containing sawdust or hemp tend to require a longer drying period due to their higher moisture retention capacity.
This time can be reduced by exposing the mixtures to air circulation or controlled temperatures; however, excessive acceleration of the drying process should be avoided in order to prevent cracking.

a) Mixing of the materials

b) Casting of the specimens

c) Conditioning of the specimens

Figure 4. Stages of specimen preparation

The density of the elements was determined in accordance with SR EN 1015-10:2002/A1:2007 - Methods of test for mortar for masonry. Part 10: Determination of the apparent density of hardened mortar.
The density of the hardened material was calculated using Eq. (1):

$$\boldsymbol{D = \frac{m}{V}} \quad (1)$$

where:
$D$ - density of the hardened material, kg/m³;
$m$ - mass of the specimen in saturated state, kg;
$V$ - volume determined by measurement, m³.
The compressive strength was calculated using Eq. (2):

$$\boldsymbol{f_c = \frac{F_c}{A}} \quad (2)$$

where:
$f_c$ - compressive strength, MPa;
$F$ - maximum load at the moment of rupture, N;
$A$ - area of speciment, mm².

The thermal conductivity was determined in accordance with SR EN 12667:2002 - Thermal performance of building materials and products. Determination of thermal resistance by means of guarded hot plate and heat flow meter methods, using a thermal conductivity measuring device (HESTO Lambda Control A 90) manufactured by HESTO Elektronik GmbH (Germany). Products of high and medium thermal resistance. The thermal resistance was calculated using Eq. (3):

$$\boldsymbol{R = \frac{d}{\lambda}} \quad (3)$$

where:
$R$ - thermal resistance, m²K/W;
$d$ - thickness of the layer, mm;
$\lambda$ - thermal conductivity of the material, W/mK.

## RESULTS AND DISCUSSIONS

The determination of the geometric characteristics of unfired clay specimens after the drying process is essential for evaluating the shrinkage behavior of the material and its ability to maintain the initial mold geometry. The dimensional stability of masonry elements plays an important role in ensuring proper placement within masonry structures, contributing to the uniform distribution of vertical loads and adequate contact with the bonding mortar. Significant dimensional deviations may lead to local stress concentrations, crack initiation, and a reduction in the overall structural stability.
The experimental measurements indicated relatively small dimensional deviations compared to the initial nominal dimensions of the specimens, suggesting a good dimensional stability of the studied mixtures. For specimens containing 10% vegetal waste addition, both sawdust and hemp fibers exhibited a maximum shrinkage of 3.5 mm, corresponding to 2.33% of the initial dimension.
For mixtures incorporating 20% sawdust, the measured shrinkage was 3.2 mm, while specimens containing 20% hemp fibers showed

a slightly higher shrinkage value of 4.1 mm. This behavior may be associated with the higher water absorption capacity and greater volumetric variability of hemp fibers compared to sawdust, which can influence the drying process and dimensional stability of the clay matrix (where H represents the specimen height, l the specimen width, L the specimen length, and Δ the longitudinal/transversal shrinkage of the specimen).

The corresponding experimental results are presented in Tables 2 and 3, where samples 1, 2, and 3 represent the three tested specimens for each composition (10% and 20% addition of sawdust or hemp fibers).

Table 2. Geometrical characteristics of the specimens with sawdust addition after 28 days

| Sample no. | Dimensions, mm | | | | |
|---|---|---|---|---|---|
| | 10% sawdust | | | | |
| | H mm | l mm | L mm | % $\Delta_l$ | % $\Delta_L$ |

The determination of the density of clay-based mixtures represents an important indicator in the evaluation of the physical and mechanical performance of construction materials, as it directly influences both the structural behavior and the thermal insulation properties of the material. The analysis of density allows the assessment of the degree of compaction and homogeneity of the mixture, as well as the identification of an optimal balance between mechanical strength and thermal insulation capacity.

An increase in material density is generally associated with a higher degree of compaction of the clay matrix and improved mechanical strength. However, it simultaneously leads to an increase in thermal conductivity, which reduces the material's insulating capacity. From a practical perspective, construction elements with densities exceedingly approximately 1200 kg/m³ become more massive and more difficult to handle and install, potentially requiring additional construction measures to prevent settlement or deformation during construction.

Therefore, optimizing the density of the material represents an important aspect in the design of clay-based mixtures intended for construction applications.

The experimental density results obtained for the four analyzed mixtures indicate a coefficient of variation below 5%, highlighting a relatively high degree of homogeneity of the materials produced under laboratory conditions.

The highest density value was recorded for the sample containing 10% sawdust addition, reaching 1643 kg/m³, with a coefficient of variation of 2.92%. Increasing the amount of sawdust to 20% of the total aggregate mass led to a density reduction of approximately 8%, resulting in a value of 1509 kg/m³.

The specimens produced with 20% hemp fiber addition exhibited the lowest density among all analyzed samples, namely 1383 kg/m³, with a coefficient of variation of 3.43%, representing a 14.3% decrease compared to the values recorded for the specimens containing 10% hemp fibers.

The overall range of experimentally determined densities, illustrated in Figure 5, varies between approximately 1362 and 1642 kg/m³. These values fall within the range characteristic of conventional construction materials, being comparable to the density of solid bricks (approximately 1600-1900 kg/m³) and close to the density range of hollow ceramic blocks (700-1400 kg/m³).

This comparison suggests that the analyzed clay-based materials may present significant

potential for use in construction applications, offering a favorable balance between mechanical performance and thermal insulation properties.

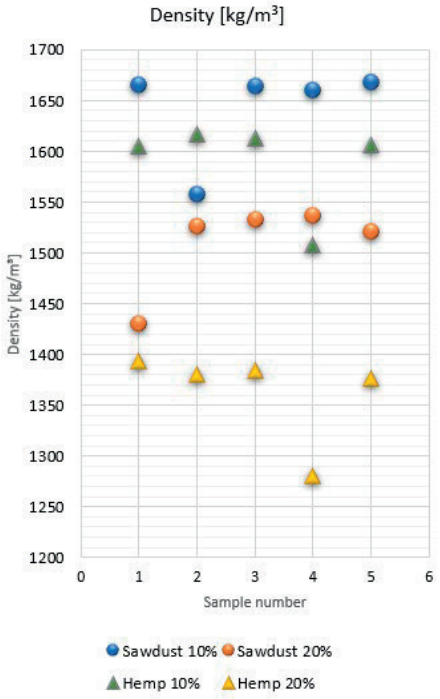

Figure 5. Density of clay-based mixtures

The compressive strength of clay-based elements is influenced by several factors, including the type and quantity of clay, the particle size distribution of the mixture, the preparation technology of the mixture, and the casting process of the specimens. These parameters determine the degree of cohesion of the matrix and the way stresses are transmitted within the material. According to data reported in the literature, the compressive strength of unfired clay materials generally ranges between 0.2 and 5 N/mm², depending on the composition and production conditions of the mixture (Ashour et al., 2011).

The compressive strength values obtained experimentally are presented in Figure 6. The compositions containing sawdust recorded the lowest compressive strength values, particularly in the case of the 20% addition, for which the experimentally determined average value was 1.46 MPa, with a coefficient of variation of 4.02%. The specimens containing 10% sawdust showed an average compressive strength of 1.602 MPa and a coefficient of variation of 8.95%.

Mixtures incorporating hemp fibers exhibited better mechanical behavior, with compressive strength values slightly varying depending on the proportion of fibers added. The compressive strength reached 2.03 N/mm² for the composition containing 10% hemp fibers and 1.912 MPa for the mixture with 20% hemp fiber addition.

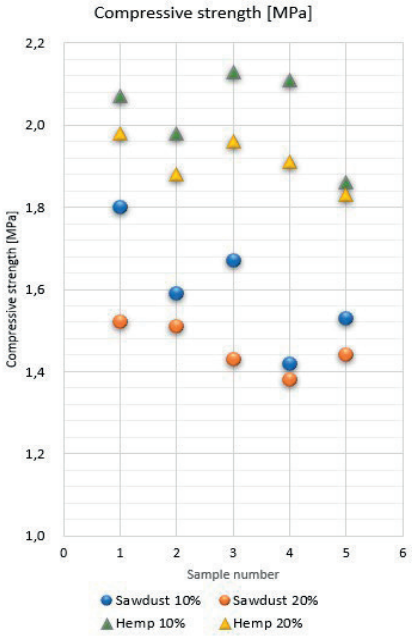

Figure 6. Compressive strength of clay-based mixtures

The comparative analysis of the results reveals a general trend of decreasing compressive strength with the increase in the percentage of vegetal material incorporated into the clay matrix. This behavior can be explained by the reduction in the structural continuity of the clay phase and by the occurrence of discontinuities or additional porosity within the material, which lead to a reduced capacity of the material to uniformly absorb and transmit mechanical stresses.

Following the compressive strength tests, all clay specimens containing vegetal additives exhibited a failure mode characterized by the appearance of vertical cracks distributed over the entire surface of the tested elements, a phenomenon typical for brittle materials subjected to axial compressive loading. This type of cracking indicates the progressive

development of internal stresses and the propagation of cracks in the direction of the applied load until the structural integrity of the specimens is lost.

The failure mode of the specimens subjected to axial compression is illustrated in Figures 7 and 8.

Figure 7. Failure mode of the specimens containing hemp fibers under axial compression

Figure 8. Failure mode of the specimens containing sawdust under axial compression

The determination of the thermal conductivity of materials is essential for the design and efficient use of building products and structures involving heat transfer, ensuring optimal thermal performance, safety, and energy efficiency.

In the construction sector, the evaluation of the thermal conductivity of unfired clay-based materials with fiber additives is particularly important for assessing their thermal insulation performance.

Such materials can contribute to improving the energy efficiency of buildings by reducing heat losses during winter and limiting heat gains during summer.

Consequently, thermal conductivity represents a key parameter in determining indoor thermal comfort and reducing energy consumption associated with heating and cooling.

The experimentally determined values of thermal conductivity and thermal resistance for the analyzed clay-based specimens are presented in Table 4.

Table 4. Experimental values of thermal conductivity and thermal resistance

| Specimen type | Dimensions | Thickness | Thermal conductivity λ | Thermal resistance |
|---|---|---|---|---|
| | [mm] | [mm] | λ[W/mK] | [$m^2$K/W] |
| R1 (10% sawdust) | 280x295 | 26.67 | 0.19099 | 0.140 |
| R2 (20% sawdust) | 290x295 | 31.16 | 0.18369 | 0.169 |
| R3 (10% hemp) | 294x292 | 26.12 | 0.17503 | 0.149 |
| R4 (20% hemp) | 295x260 | 26.39 | 0.17258 | 0.152 |

The data presented in Table 4 indicate that the specimens containing sawdust exhibited higher thermal conductivity values (λ). At the same time, increasing the content of vegetal additives contributed to improved thermal insulation performance of the clay-based composite.

## CONCLUSIONS

The incorporation of vegetal waste into the composition of construction materials influences both the physical behavior and the mechanical and thermal insulation properties of the material. Based on the comparative study of the clay-based mixtures, the following conclusions can be drawn:

- From the perspective of the dimensional stability of the specimens, the relatively small deviations of the geometric characteristics, ranging between 1.98% and 2.6%, indicate a relatively uniform shrinkage during the drying process, suggesting good dimensional stability of the analyzed mixtures.
- The density coefficient of variation below 5% confirms the production of relatively homogeneous materials. The determined density values, ranging between 1362 and 1642 kg/m³, demonstrate that the studied materials fall within the density range characteristic of commonly used construction materials. The results indicate that vegetal additives contribute to reducing the density of the clay matrix, an effect more pronounced in the case of hemp fiber compositions, while the addition of sawdust leads to comparatively higher density values.
- From the perspective of mechanical behavior, a general tendency of decreasing compressive strength was observed with increasing vegetal additive content. This phenomenon can be associated with increased porosity and the presence of discontinuities within the clay matrix structure. Nevertheless, the mixtures containing hemp fibers exhibited slightly higher compressive strength values compared to the specimens containing sawdust. The observed failure mode, characterized by vertical cracks distributed across the surface of the specimens, confirms the typical behavior of brittle materials subjected to axial compressive loading.
- Regarding thermal insulation performance, the experimental results indicate that increasing the vegetal additive content contributes to the reduction of thermal conductivity for both types of vegetal additives, although this improvement is accompanied by a reduction in mechanical performance.

Overall, the experimental data suggest the existence of a trade-off between density, mechanical strength, and thermal conductivity, highlighting the need to optimize the proportion of vegetal additives in order to obtain a clay-based material with balanced properties suitable for construction applications.

***Abstract***

*The objectives of the study were to (i) establish and compare As, Cu, and Zn concentrations in two contrasting soil types under different management and (ii) assess soil pollution of the study area by the mentioned potentially toxic elements. A 40 composite topsoil samples were collected in Middle Dalmatia, Croatia, out of which 20 were from Terra rossa and 20 from Regosols. On each soil type, 10 samples were taken from intensive olive groves (IOG) and 10 from traditional low-input olive groves (TOG). The total concentrations of As, Cu, and Zn were obtained using the pXRF method. The mean As, Cu, and Zn concentrations in Terra rossa were 21.9, 112.7, and 124.5 mg/kg, respectively. In Regosols, mean As, Cu, and Zn concentrations were 6.3, 55.0, and 63.6 mg/kg, respectively. Significantly higher ($p<0.05$) As, Cu, and Zn concentrations were determined in Terra rossa compared to Regosols. Significantly higher ($p<0.05$) Cu concentrations were found in IOG compared to TOG (124.5 and 43.2 mg/kg, respectively). Terra rossa under IOG was polluted with Cu, while the other soils were not. The studied soils were not polluted with As and Zn.*

***Key words****: olive groves, potentially toxic elements, Regosol, soil pollution, Terra rossa.*

## INTRODUCTION

Potentially toxic elements (PTE) represent a threat to soil fertility, quality, health, and security, as recognized in various studies e.g. Kibblewhite et al. (2007), Hou et al. (2020). The PTE distribution in soils is governed by natural conditions and anthropogenic inputs. Among the natural reasons for PTE variability, soil properties, parent material, climate, and geomorphology stand out (Mottese et al., 2020). The most important areas of olive production in Dalmatia, Croatia, are widespread on soils derived from limestones (Terra rossa and Calcocambisols) and flysch deposits (Regosols). These are two contrasting parent materials on which soils with different properties develop. Soils developed over limestones contain elevated levels of PTE (Kabata-Pendias & Pendias, 2001; Halamić & Miko, 2009). Furthermore, high clay content and abundance of Fe and Al oxides contribute to strong adsorption and retention of PTE in the top-soil horizon of Terra rossa (Miloš & Bensa, 2021). PTE concentrations are typically lower in soils formed on flysch sediments, though this varies depending on the nature and sedimentation processes of the rock-derived material (Lovrenčić Mikelić et al., 2013). Also, since these soils contain lower clay and humus content, they retain less PTE. Anthropogenic inputs of PTE in soils involve different types of emissions from the industrial areas, as well as from agricultural activities (Zhang et al., 2019). Fertilizers and plant production products are the primary agricultural sources of PTE in agricultural soils (Pathak et al., 2002; Wyszkowski & Brodowska, 2020). Since the late 19$^{th}$ century, viticulture in Europe extensively used Cu-based fungicides (Komarek et al., 2010). Furthermore, nitrogen and phosphate fertilizers can be significant sources of As and Zn in cultivated soils (Kabata Pendias & Mukherjee, 2007; Sachdeva et al., 2025). Given its impact on food safety, PTE pollution in agricultural soils is especially concerning (Antoniadis et al., 2017; Edelstein & Ben-Hur, 2018) considering negative consequences for all agroecosystems (Kibblewhite et al., 2007). Elevated Cu concentrations in soil diminish microbial growth and biomass (Díaz Raviña et al., 2007) as well as development of plant roots (Ambrosini et al., 2015).

Increased concentrations of Cu are predominantly reported for soils of permanent crops, particularly vineyards (Komarek et al., 2010) and olive groves (Avramidis et al., 2019). Pollution of agricultural soils by As (Jimenez Balesta et al., 2023) and Zn (Fernández-Calviño et al., 2012) was also stated in earlier literature findings. Excessive concentrations of arsenic can induce aberrant plant growth and disturb ecological equilibrium (Kabata-Pendias & Pendias, 2001). Soil organisms such as earthworms (Lev et al., 2010) and bacterial communities (Pan et al., 2020) are negatively affected by high Zn concentrations. We hypothesized that Terra rossa and Regosols differ in PTE concentrations, and that soil management in olive groves affects PTE concentrations in soil. The objectives of this study were (i) to establish and compare As, Cu, and Zn concentrations in two contrasting soil types under different management and (ii) to assess soil pollution of the study area by the mentioned PTE.

## MATERIALS AND METHODS

The study was conducted in Middle Dalmatia, Croatia (Figure 1A), distinguished by a Mediterranean type of climate (Csa), commonly referred to as an "olive climate" (Filipčić, 1998). The western part of the study area is built up of Cretaceous platy and massive limestones with pronounced stratification, while the eastern part consists of Eocene flysch deposits (Figure 1B). The limestones are of Senonian and Turonian age and are characterized by dominant biocalcarenites. Flysch deposits are predominantly classified as calcarenites, breccia-conglomerates, calcirudites, and marls (Marinčić et al., 1967).

This area is characterized by typical karst geomorphology, with the steeper slopes in the northern part and the gentler ones in the southern part. Therefore, the northern part of the area is subject to erosion processes and characterized by shallow soils, while in the southern parts, colluvial processes are present and deeper soils dominate. The dominant soil types on limestones are Terra rossa, while Regosols are developed on Flysch deposits (Figure 1C; Čolak & Martinović, 1974). Terra rossa is a Mediterranean soil distinguished by its red colour, heavy texture and inconstant depth. Regosols on flysch deposits are calcareous silty soils highly susceptible to erosion and characterized by alkaline reaction and low humus content. The correlation analogs of Terra rossa and Regosol are Leptic Chromic Cambisols (Clayic) and Regosols (Calcaric, Siltic/Loamic), respectively (IUSS Working Group of WRB, 2015). This area is under long-term anthropogenic influence, which is evident in the numerous terraces and dry-wall enclosures (Miloš & Bensa, 2021). Olive growing in the study area is characterized by dry farming, encompassing traditional low-input (TOG) and intensified olive growing systems (IOG). The traditional low-input growing system is characterized by periodic soil cultivation, fertilization with low doses of fertilizers, and rare application of pesticides. In a more intensive olive growing system, fertilization and plant protection are more often applied, including larger quantities of fertilizers and pesticides.

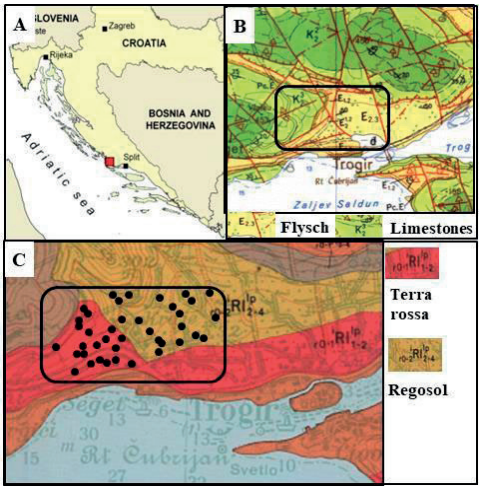

Figure 1. Location of the study area (A), Basic geological map of Croatia at scale 1:100 000 section Split (Marinčić et al., 1967) with indicated study area (B) and Basic soil map of Croatia at scale 1:50 000 section Šibenik 4 (Čolak & Martinović, 1974) with indicated study area and sampling locations (C)

A 40 composite topsoil samples (0-20 cm) were taken in currently productive private olive groves in the study area (Figure 1C). The composite soil samples consisted of 3 sub-samples taken at a distance of 1 m in a cross

arrangement. The 20 samples were taken from Terra rossa and 20 samples from Regosols. On each soil type, 10 samples were taken from traditional low-input olive groves (TOG) and 10 from intensive ones (IOG).

The disturbed soil samples were prepared according to ISO 11464:2006. Soil particle size distribution was analyzed by the pipette method using wet sieving and sedimentation. Soil pH in $H_2O$ and KCl (c=1M) was measured after ISO 10390:2005. A modified volumetric method (ISO 10693:1995) was used for determination of $CaCO_3$ content. Humus content was dteremined using the Tjurin method (JDPZ, 1966) and subsequently converted to soil organic carbon (SOC) by dividing by the Van Bemmelen factor (1.724). The $P_2O_5$ and $K_2O$ concentrations were determined using lactate-acetate as the extraction solution (Egner et al., 1960).

The total concentrations of As, Cu, and Zn were determined using the Vanta handheld XRF analyser C Series (Olympus, Waltham, MA, USA, 2019) according to the loose powder method (Takahashi, 2015). The certified (SRM 2711) and reference soil samples (ISE 989) were used to control accuracy and precision of the analyses. The results of the analyses were acceptable (accuracy: RPD < 5% and recovery 95%-105%; precision: RSD < 5%).

The Ordinance on the protection of agricultural land from pollution (Official Gazette 71/19) was used to evaluate the pollution of the studied soils. When agricultural land contained more PTE than the maximum permissible concentrations (MPC) (mg/kg), it was considered polluted. The MPC of PTE in agricultural soils is prescribed considering $pH_{KCl}$ values (Table 1).

Table 1. Maximum permissible concentrations (MPC) (mg/kg) of selected PTE in agricultural soils in Croatia (Official Gazette 71/19)

| | $pH_{KCl}$ | | |
|---|---|---|---|
| Element | < 5 | 5-6 | >6 |
| As | 15 | 25 | 30 |
| Cu | 60 | 90 | 120 |
| Zn | 60 | 150 | 200 |

Descriptive statistics (minimum, maximum, mean, coefficient of variation, and skewness) were used to process obtained data of basic chemical soil properties and PTE concentrations. A two-way analysis of variance (ANOVA) was carried out for statistical comparison of analysed PTE concentrations. All statistical analysis was performed using MS Excel.

## RESULTS AND DISCUSSIONS

Basic soil properties govern adsorption processes in soils. Adsorption and retention of PTE in soils dominantly depend on soil texture, especially clay minerals (Bradl, 2004; Uddin, 2017; Huang et al., 2020), organic matter content (Kabata-Pendias & Pendias, 2001; Wan et al., 2024), and pH values (Elzahabi & Yong, 2001; Romić et al., 2014).

Particle size analysis has shown differences between the studied soil types (Table 2).

Table 2. Descriptive statistic for particle size distribution of Terra rossa and Regosols

| Soil type | Min. | Max. | Mean | CV | Skew |
|---|---|---|---|---|---|
| | Coarse sand (2.0-0.2 mm) | | | | |
| Terra rossa | 0.1 | 0.7 | 0.3 | 80.7 | 1.08 |
| Regosol | 1.9 | 12.3 | 5.7 | 55.7 | 1.14 |
| | Fine sand (0.2-0.063 mm) | | | | |
| Terra rossa | 1.9 | 3.1 | 2.6 | 14.3 | 0.09 |
| Regosol | 4.8 | 15.7 | 9.2 | 33.4 | 0.66 |
| | Coarse silt (0.063-0.02 mm) | | | | |
| Terra rossa | 15.9 | 22.3 | 19.6 | 9.5 | -0.43 |
| Regosol | 14.3 | 23.8 | 19.2 | 13.89 | -0.18 |
| | Fine silt (0.02-0.002 mm) | | | | |
| Terra rossa | 35.6 | 50.2 | 43.4 | 8.1 | -0.38 |
| Regosol | 31.1 | 51.1 | 42.4 | 13.8 | -0.42 |
| | Clay (< 0.002 mm) | | | | |
| Terra rossa | 27.6 | 46.0 | 34.2 | 14.0 | 1.47 |
| Regosol | 18.2 | 29.1 | 23.5 | 14.6 | 0.04 |

Min. - minimum; Max. - maximum; CV - coefficient of variation; Skew - skewness

Terra rossa soils are composed predominantly of fine silt (mean value 43.4%), followed by clay particles (mean value 34.2%). Sand particles (coarse and fine) form less than 3% on average. In Regosols, fine silt particles also dominate (mean value 42.4%). However, a lower content of clay particles (mean value 23.5%) was observed in comparison to Terra rossa soils. Furthermore, a higher content of sand was recorded in Regosols in comparison to Terra rossa soils (Table 2).

Terra rossa has mainly a silty clayey loamy texture, while Regosols are mainly silty loams, but silty clayey loams also occur (Figure 2). The

determined texture of the studied soils is consistent with literature findings for Terra rossa (Bellanca et al., 1996; Vingiani et al., 2018; Miloš & Bensa, 2021) and soils on flysch deposits (Bogunović et al., 2009; Miloš & Bensa, 2019; Bensa & Jurković Balog, 2023).

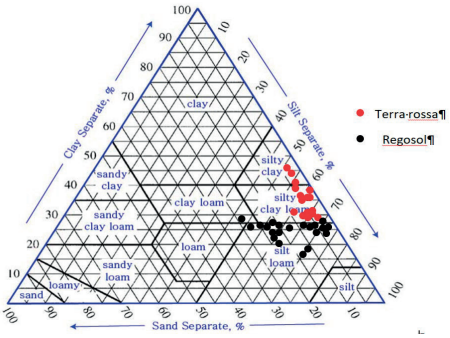

Figure 2. Display of soil samples on texture triangle (FAO/UNESCO, 1990)

Terra rossa soils under both management types have a slightly acidic to neutral reaction and low $CaCO_3$ content (Table 3).

Table 3. Descriptive statistic for basic chemical properties of Terra rossa soils under traditional (TOG) and intensive olive groves (IOG)

| Management type | Soil property | Min. | Max. | Mean | CV | Skew |
|---|---|---|---|---|---|---|
| TOG | pH (KCl) | 6.07 | 6.90 | 6.61 | 4.33 | -1.10 |
| | pH (H2O) | 7.11 | 7.78 | 7.43 | 3.22 | 0.02 |
| | $CaCO_3$ | 1.50 | 3.00 | 1.94 | 23.1 | 1.31 |
| | SOC | 2.52 | 4.45 | 3.44 | 17.4 | 0.08 |
| | $P_2O_5$ | 0.59 | 5.85 | 1.98 | 78.3 | 1.73 |
| | $K_2O$ | 25.5 | 57.3 | 36.4 | 30.2 | 0.72 |
| IOG | pH (KCl) | 5.62 | 7.01 | 6.53 | 6.46 | -1.07 |
| | pH (H2O) | 6.51 | 7.77 | 7.25 | 5.18 | -0.47 |
| | $CaCO_3$ | 1.90 | 4.34 | 2.88 | 24.5 | 0.75 |
| | SOC | 3.31 | 7.20 | 4.59 | 23.5 | 1.38 |
| | $P_2O_5$ | 21.8 | 49.4 | 34.4 | 26.1 | 0.09 |
| | $K_2O$ | 71.3 | 252 | 111.6 | 43.0 | 2.86 |

Min. - minimum; Max. - maximum; CV - coefficient of variation; Skew - skewness

The SOC content in Terra rossa under TOG was in the range of 2.52-4.45% with symmetric data distribution (skew 0.08), while Terra rossa under IOG had higher SOC content (3.31-7.20%), with asymmetric data distribution (skew 1.38). This suggests various organic fertilizations in Terra rossa soils under IOG, as well as different soil tillage systems. Several authors have noted an increase in SOC content after the application of organic amendments (Perez Lomas et al., 2010; Aranda et al., 2015; Mekki et al., 2017; Mbarek et al., 2020). Conversely, soil tillage promotes mineralization and lowers SOC content (Haddaway et al., 2017; Hashimi et al., 2022). In Terra rossa soils under TOG a lower $P_2O_5$ concentrations (0.59-5.85 mg/100 g of soil) were established, compared to soils under IOG (21.8-49.4 mg/100 g of soil). The supply of $K_2O$ was rich and very rich in soils under both management types, although Terra rossa soils under IOG contained much higher $K_2O$ concentrations compared to TOG (mean values 111.6 and 36.4 mg/100 g of soil, respectively) (Table 3).

The Regosols under both management types were highly calcareous and had an alkaline soil reaction with minor differences (mean $pH_{(KCl)}$ values of 7.28 and 7.41, respectively) (Table 4).

Table 4. Descriptive statistic for basic chemical properties of Regosol under traditional (TOG) and intensive olive groves (IOG)

| Management type | Soil property | Min. | Max. | Mean | CV | Skew |
|---|---|---|---|---|---|---|
| TOG | pH (KCl) | 7.19 | 7.40 | 7.28 | 0.90 | 0.62 |
| | pH (H2O) | 7.63 | 7.98 | 7.88 | 1.29 | -1.60 |
| | $CaCO_3$ | 15.0 | 23.0 | 18.3 | 13.9 | 0.14 |
| | SOC | 1.13 | 1.97 | 1.46 | 17.0 | 0.73 |
| | $P_2O_5$ | 0.29 | 1.96 | 1.09 | 47.7 | 0.30 |
| | $K_2O$ | 9.80 | 23.0 | 18.3 | 21.3 | -0.87 |
| IOG | pH (KCl) | 7.23 | 7.58 | 7.41 | 1.77 | -0.07 |
| | pH (H2O) | 7.73 | 8.47 | 8.26 | 2.68 | -1.71 |
| | $CaCO_3$ | 14.3 | 25.0 | 19.0 | 16.7 | 0.19 |
| | SOC | 1.39 | 2.12 | 1.79 | 12.8 | -0.07 |
| | $P_2O_5$ | 4.42 | 13.0 | 7.57 | 38.6 | 0.57 |
| | $K_2O$ | 27.5 | 66.0 | 40.4 | 25.7 | 1.54 |

Min. - minimum; Max. - maximum; CV - coefficient of variation; Skew - skewness

The SOC content was lower in Regosols under TOG compared to IOG (mean values 1.46% and 1.79%, respectively). The Regosols under TOG were poorly supplied with $P_2O_5$, while soils under IOG were moderately supplied (mean values 1.09 and 7.57 mg/100 g of soil, respectively). The $K_2O$ concentrations were also lower in Regosols under TOG than in IOG (mean values 18.3 and 40.4 mg/100 g of soil, respectively) (Table 4).

The obtained results correspond to earlier studies of Terra rossa (Durn, 1999; Vingiani et al., 2018; Miloš & Bensa, 2021) and Regosols on flysch deposits (Bogunović et al., 1999; Miloš & Bensa, 2019). Higher concentrations of $P_2O_5$, $K_2O$ and SOC in soils under IOG, in both soil types, confirmed application of mineral and

organic fertilizers in much higher doses compared to TOG.

Descriptive statistics for PTE (As, Cu, and Zn) in the studied soils are presented in Table 5. A two-way ANOVA has shown the effect of soil type, soil management, and their interaction on PTE concentrations in the studied soils (Table 6).

Table 5. Descriptive statistic for As, Cu and Zn concentrations in Terra rossa and Regosol under traditional (TOG) and intensive olive groves (IOG)

| ST | MT | Element | Min. | Max. | Mean | CV | Skew |
|---|---|---|---|---|---|---|---|
| Terra rossa | TOG | As | 21.7 | 26.6 | 23.4 | 6.6 | 0.73 |
| | | Cu | 33.9 | 85.7 | 48.9 | 30.9 | 1.74 |
| | | Zn | 114.0 | 135.5 | 124.6 | 5.7 | -0.02 |
| | IOG | As | 16.1 | 24.1 | 20.3 | 14.0 | -0.17 |
| | | Cu | 68.7 | 290.8 | 176.4 | 45.2 | 0.11 |
| | | Zn | 42.5 | 165.0 | 124.5 | 33.6 | -1.56 |
| Regosols | TOG | As | 4.50 | 6.52 | 5.58 | 10.8 | -0.18 |
| | | Cu | 19.8 | 63.5 | 37.4 | 40.5 | 0.48 |
| | | Zn | 32.3 | 66.7 | 52.7 | 24.5 | -0.67 |
| | IOG | As | 5.38 | 8.50 | 7.03 | 15.3 | -0.21 |
| | | Cu | 43.4 | 107.1 | 72.6 | 31.4 | 0.15 |
| | | Zn | 55.7 | 95.7 | 74.5 | 16.5 | 0.19 |

ST - soil type; MT - management type; Min. - minimum; Max. - maximum; CV - coefficient of variation; Skew - skewness

Soil type and the interaction effect of soil type and management significantly influenced As concentrations in the studied soils, while soil management had no significant impact (Table 6). Significantly higher As concentrations ($p$<0.05) were detected in Terra rossa soils in comparison to Regosols (16.1-26.6 and 4.50-8.50 mg/kg, respectively) (Table 5).

The As concentrations in Terra rossa soils and Regosols (16.1-26.6 mg/kg and 4.50-8.50 mg/kg, respectively) are analogous to findings from the Geochemical Atlas of Croatia (Halamić & Miko, 2009) which indicated As level over 25 mg/kg in soils derived from limestones and below 12 mg/kg in soils on flysch deposits. Peh et al. (2003) also reported higher As concentrations in Terra rossa soils than in flysch-derived soils in Istria (mean values 20.31 and 7.83 mg/kg, respectively).

The As concentrations in Terra rossa soils in current study are also in accordance with previous findings for a broader study area in Dalmatia (Miko et al., 2001; Bensa et al., 2025). Although As concentrations in soils under different land management types did not differ significantly (Table 6), Regosols under IOG contained higher As concentrations than Regosols under TOG (mean values 7.03 and 5.58 mg/kg, respectively) (Table 5). The increased level of As in agricultural soils may be attributed to the application of mineral fertilizers as emphasized by Kabata Pendias & Mukherjee (2007).

The Cu concentrations in Terra rossa soils and Regosol displayed wide ranges (33.9-290.8 and 19.8-107.1 mg/kg, respectively), (Table 5). Data distributions for Cu concentrations in Regosols under both management types, as well as in Terra rossa soils under IOG were approximately symmetric (skew<0.5). However, Terra rossa soils under TOG revealed positively skewed data distribution (skew 1.74), (Table 5). This can be attributed to the fact that some low-input olive groves were planted on former vineyard soils with accumulated Cu (Miloš & Bensa, 2021), although recent use of Cu-based fungicides is rare or completely absent on these soils. Significantly higher Cu concentrations ($p$<0.05) were established in Terra rossa soils compared to Regosols, as well as in soils under IOG in comparison to TOG (Tables 5 and 6). Significantly higher Cu concentrations in Terra rossa soils than in Regosol can be linked to higher SOC and clay content (Tables 2 and 3). Soil colloids (organic matter and clay minerals) adsorb copper strongly (Parat et al., 2002). Organically complex Cu is particularly firmly bound, inhibiting its mobilization and leading to

Cu accumulation in topsoil (Cerqueira et al., 2011). Additionally, amorphous and crystalline Fe and Al oxides readily adsorb Cu (Romić et al., 2014), leading to increased Cu concentrations in Terra rossa soils. Significantly higher Cu concentrations in soils under IOG compared to TOG can be ascribed to the increased application of Cu-based fungicides. Nevertheless, the Cu concentrations in the current study are lower compared to those reported by Avramidis et al. (2019) for intensive olive groves in Greece (mean value 286.2 mg/kg).

Soil type significantly influenced Zn concentrations in the studied soils, while soil management and the interaction effect of soil type and management did not have a statistically significant impact (Table 6). Significantly higher Zn concentrations ($p$<0.05) were determined in Terra rossa soil than in Regosol (42.5-165.0 and 32.3-95.7 mg/kg, respectively), (Table 5). The obtained results are in line with previous findings for the studied soil types. Peh et al. (2003) also stated lower Zn concentrations in flysch derived soils in comparison to soils on limestones (45-130 and 59-186 mg/kg, respectively).

A similar range of Zn concentrations in a broader study area in Dalmatia was reported for the studied soil types. Miloš & Bensa (2019) established a range of 24.1-105.9 mg/kg in anthropogenic terraced soils on flysch deposits in the Kaštela bay coastal area. A study of former vineyard soils on Terra rossa in Middle Dalmatia under natural vegetation and olive groves revealed Zn mean values similar to the current study (118.1 and 138.0 mg/kg, respectively) (Bensa et al., 2025).

**Soil pollution by PTE**

All studied soils exhibited As concentrations below the maximum permissible concentrations (MPC) of 30 mg/kg (Official Gazette 71/19 (Figure 3). Obtained results are comparable to previous studies of As concentrations in a broader study area in Croatia (Lovrenčić Mikelić et al., 2013; Bensa et al., 2025) which similarly found no evidence of arsenic pollution of agricultural soils. Grattacaso et al. (2025) documented an As concentration range of 5.55-14.6 mg/kg in olive grove soils derived from various parent materials in Italy, which were not contaminated with arsenic.

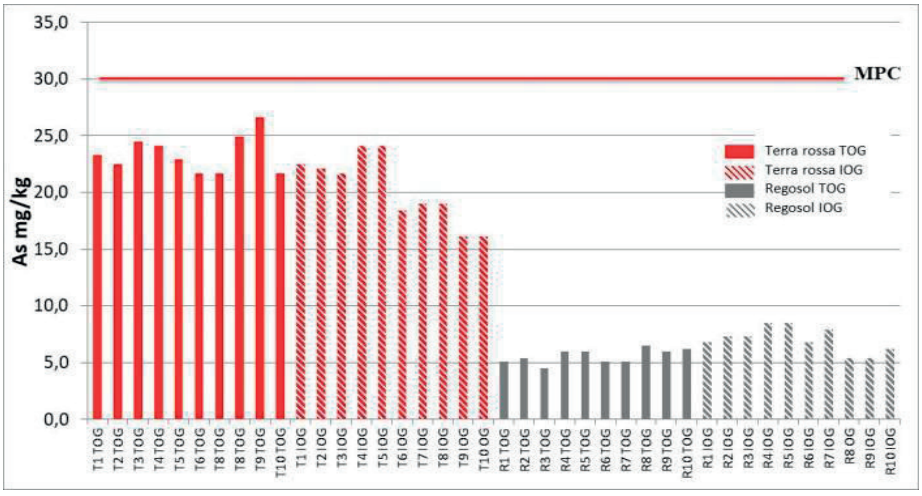

Figure 3. As concentrations in studied soils and MPC (Official Gazette 71/19)

The majority of the studied Terra rossa soils under IOG (70%) exhibited pollution by Cu, but the remaining portion (30%), along with Terra rossa soils under TOG, showed no pollution (Figure 4). The Cu concentrations in Regosols under both management types were below the MPC of 120 mg/kg (Official Gazette 71/19) (Figure 4).

Pollution of olive grove soils by Cu was reported in many studies. Avramidis et al. (2019) reported a range of 58.4 -671.6 mg/kg in various soils of Aetoliko lagoon in Greece developed

over limestones and clastic sediments, out of which 88% of samples were polluted by Cu. Similarly, Bensa et al. (2025) established pollution by Cu in 90% of the samples from Terra rossa soils under olive groves planted on former vineyard soils. However, Miloš & Bensa (2021) reported only 10% of Cu-polluted Terra rossa soils under olive groves in Middle Dalmatia. In olive groves on terraced soils on flysch deposits, Miloš & Bensa (2019) established much lower Cu concentrations (mean value 38.1 mg/kg) far below MPC, that are comparable to the current study.

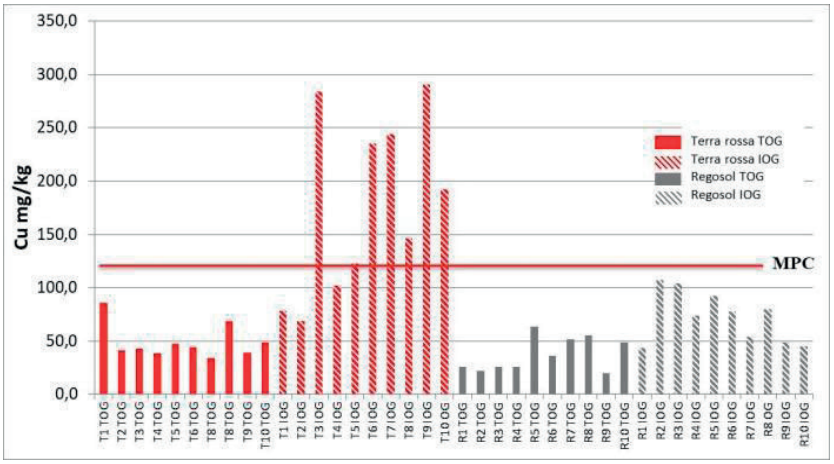

Figure 4. Cu concentrations in studied soils and MPC (Official Gazette 71/19)

The Zn concentrations in Terra rossa soils and Regosol under both management types were below the MPC of 200 mg/kg (Official Gazette 71/19) (Figure 5). Obtained results are in line with previous studies on broader study areas for Terra rosa soils (Miko et al., 2001, Bensa et al., 2025) and Regosols (Miloš & Bensa, 2019). However, previous study of olive grove soils (Doğan & Gülserr, 2020) pointed out higher Zn concentrations, and the authors stated that studied soils can be considered polluted. Additionally, Lovrenčić Mikelić et al. (2013) found elevated Zn concentrations in agricultural soils of the Kaštela Bay coastal area in Dalmatia that may be considered polluted.

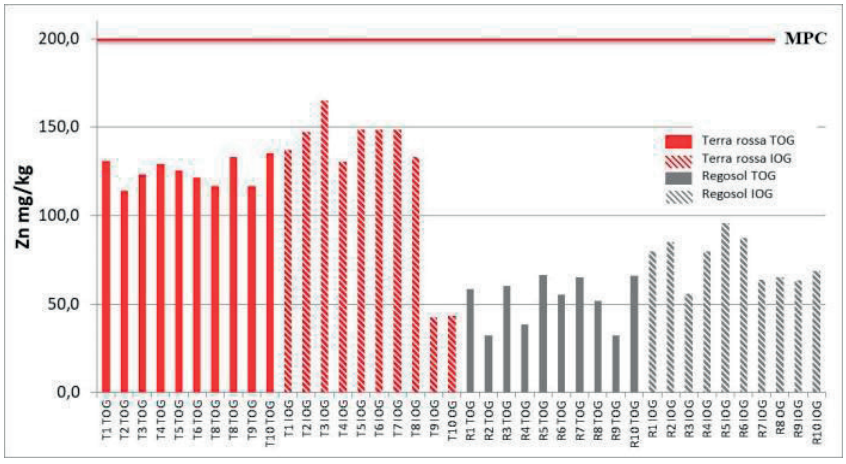

Figure 5. Zn concentrations in studied soils and MPC (Official Gazette 71/19)

## CONCLUSIONS

A study of PTE concentrations in Terra rossa soils and Regosols under traditional low-input and intensive olive groves showed significantly higher As, Cu, and Zn concentrations in Terra rossa soils compared to the Regosols. Furthermore, significantly higher Cu concentrations were found in soils under intensive olive groves than in soils under traditional low-input management. The soil management type did not significantly influence As and Zn concentrations. According to Croatian legislation (Official Gazette 71/19), only Terra rossa soils under intensive olive groves were polluted with Cu, while other studied soils were not polluted with Cu. Likewise, the studied soils were not polluted by As and Zn. The obtained results indicate the need for further, more detailed study on copper in olive grove soils in Dalmatia, especially on Terra rossa soils.

***Abstract***

*Human activities release various pollutants into the atmosphere, many of which directly affect plants. Among these pollutants are carbon dioxide ($CO_2$), which serves as the essential substrate for photosynthesis, and ozone ($O_3$), which acts as a harmful oxidant. With a particular emphasis on photosynthetic parameters, pigment content, volatile organic compound emissions, and biochemical features, this research investigates the responses of Raphanus sativus plants to increased exposure to $CO_2$ and $O_3$, focusing on three different varieties: Johanna, Helga, and Rozaria. To create conditions similar to those in the real world, the plants were grown under varying $CO_2$ concentrations (400, 800, and 1200 ppmv) and subjected to high ozone levels (100 ppb). Photosynthetic parameters were assessed through a gas exchange system, while volatile organic compound (VOC) emissions were analyzed using gas chromatography-mass spectrometry (GC-MS). Additionally, photosynthetic pigments were identified and quantified using the UHPLC-DAD system. Higher $CO_2$ levels initially enhanced net photosynthesis, but ozone severely reduced photosynthesis, leading to partial recovery after 24 hours. Ozone degraded chlorophyll a and b at all $CO_2$ concentrations, whereas zeaxanthin protected the photosynthetic system.*

***Key words****: abiotic stress, climate changes, ozone fumigation, secondary metabolites.*

## INTRODUCTION

Atmospheric carbon dioxide ($CO_2$) levels continue to rise steadily, altering photosynthetic processes, carbon allocation, and physiological responses in terrestrial ecosystems. At the Mauna Loa Observatory, the annual mean $CO_2$ concentration is projected to increase by 2.37 ± 0.55 ppm in 2026 relative to 2025, reaching a record level of 429.4 ± 0.6 ppm.

Numerous studies show that higher $CO_2$ levels stimulate photosynthetic carbon assimilation and can also modify respiration, with robust responses reported in $C_3$ species (Leakey et al., 2006; Zheng et al., 2010; 2019; Ainsworth & Long, 2021; Li et al., 2023). However, the magnitude and persistence of this growth stimulation are highly context-dependent. In particular, plant responses to elevated $CO_2$ vary with nutrient supply, and the fertilization effect often weakens as nutrient availability declines (Menge & Field, 2007; Lenka & Lal, 2012; Pandey et al., 2015). As rising $CO_2$ can increase plant nutrient demand, nutrient limitation may therefore attenuate or even offset $CO_2$-driven gains in growth, especially under low-fertility conditions (Lenka & Lal, 2012; Pandey et al., 2015; Jin et al., 2025).

Tropospheric ozone ($O_3$) is a secondary pollutant formed through sunlight-driven photochemical reactions involving volatile organic compounds (VOCs) and nitrogen oxides ($NO_x$). It has been observed that free-tropospheric ozone levels have risen since the mid-1990s, with reported rates ranging from approximately 2% to 12% per decade, depending on the region. The biggest increases are usually seen in developing and quickly industrialising areas, such as East Asia, the Persian Gulf, India, northern South America, the Gulf of Guinea, and Malaysia/Indonesia. In Europe and North America, on the other hand, trends are usually

weaker and more mixed. The health effects of ozone exposure are most reliably recorded for the respiratory and cardiovascular systems (Kim et al., 2020). However, studies indicate potential links to respiratory mortality, the onset of asthma in children, and heightened respiratory symptoms in individuals with asthma (Kim et al., 2020; Hua et al., 2025).

Ozone primarily impacts above-ground plant tissues through direct leaf uptake, yet some of the earliest detectable responses can occur below ground (Nakadera et al., 2024). Root growth may be suppressed, respiratory costs can increase, and symbiotic interactions (e.g., with mycorrhizae) may be disturbed (Agathokleous et al., 2020; Zhang et al., 2024). With sufficiently high or prolonged exposure, ozone can reduce overall plant growth and alter typical plant-parasite relationships (Duque et al., 2019). Recent open-field enrichment experiments simulating future atmospheric conditions have emphasized the complex interplay between elevated carbon dioxide and tropospheric ozone in determining crop performance. In mustard (*Brassica juncea* L.), a major oilseed crop of economic and nutritional importance, elevated $CO_2$ (550 ppm) has been reported to enhance yield by stimulating photosynthesis and increasing photosynthate accumulation. In contrast, elevated ozone (65 ppb) significantly reduces yield by impairing branching patterns, biomass production, and seed formation. Importantly, when both factors co-occur, $eCO_2$ may partially mitigate ozone-induced yield losses, suggesting a buffering interaction under future climate scenarios characterized by rising atmospheric $CO_2$ and persistent ozone pollution. Moreover, varietal differences in responsiveness indicate that selecting ozone-tolerant and $CO_2$-responsive genotypes could be critical for sustaining mustard productivity under projected climate change conditions (JawaharJothi et al., 2025). Recent studies in wheat (*Triticum aestivum* L.) indicate that stomatal $O_3$ flux - a key determinant of ozone injury - varies substantially across different $O_3$ and $CO_2$ regimes and plays a central role in shaping physiological performance and yield. In two Indian wheat cultivars differing in $O_3$ sensitivity, elevated $CO_2$ reduced stomatal $O_3$ flux and partially mitigated $O_3$-induced yield losses. Notably, the $O_3$-sensitive cultivar exhibited greater yield protection under the combined $eCO_2$ + $eO_3$ treatment, likely due to enhanced allocation of photosynthates to reproductive structures, as reflected in a higher harvest index. Moreover, yield responses were more strongly correlated with stomatal $O_3$ flux in the sensitive cultivar than in the tolerant one, underscoring the importance of flux-based approaches for predicting crop performance under future atmospheric conditions (Mishra et al., 2024).

Given the concurrent rise in atmospheric $CO_2$ and tropospheric ozone under ongoing climate change, understanding their interactive effects on crop physiology is essential. Therefore, the present study aimed to evaluate how elevated $CO_2$ (800 and 1200 ppm) modulates ozone-induced stress (100 ppb) in three radish (*Raphanus sativus* L.) cultivars (Johanna, Helga, and Rozaria). We specifically assessed photosynthetic performance, chlorophyll content, and the accumulation of antioxidant-related secondary metabolites (total phenolics and flavonoids) to determine (i) whether elevated $CO_2$ mitigates ozone-induced physiological impairment and oxidative stress, and (ii) whether genotypic variability influences stress resilience under combined atmospheric conditions.

## MATERIALS AND METHODS

The impact of increased $CO_2$ concentrations and ozone exposure on plant growth was studied by selecting and cultivating seeds from three *Raphanus sativus* (Brassicaceae) varieties. Those varieties included *Raphanus sativus* var. Johanna (Agrosel, Romania), *Raphanus sativus* var. Helga (Agrosel, Câmpia-Turzii, Romania) and *Raphanus sativus* var. Rozaria (Agrosel, Campia-Turzii, Romania).

A combination of commercial garden soil and sand was used to plant the seeds in 0.8-liter plastic containers. The plants were cultivated under artificial light from LED lamps at 800 $\mu mol\ m^{-2}s^{-1}$. We kept the daytime and nighttime temperatures at 25°C and 22°C, respectively, and the relative humidity at 65%. The light and dark cycles were set at 12 hours each. Every two days, the plants were watered until the soil was saturated. An ambient level of 400 ± 20 ppm $CO_2$ was used for plant cultivation, along with two higher levels of 800 and 1200 ppm $CO_2$,

respectively. Ozone gas at 100 ppb was used to fumigate the plants for 5 minutes.
The experiments were conducted on plants at least 4 weeks old, with at least 3 fully formed leaves throughout their growth cycle. The plants were fertilized with foliar fertilizers (Bionat Plus, Panetone SRL, Timisoara, Romania) and root fertilizers (Cropcare 11-11-21, YaraMila, Oslo, Norway).

***Determination of photosynthetic parameters***
A portable gas-exchange system (GFS-3000, Heinz Walz GmbH, Effeltrich, Germany) was employed to assess photosynthetic parameters, including $CO_2$ assimilation rate and stomatal conductance to water vapor. The device features an environment-controlled cuvette with an 8 $cm^2$ aperture and a complete-window leaf-chamber fluorimeter for sample illumination. A 4 $cm^2$ segment of radish leaf was positioned in the chamber for each measurement. All conditions remained constant except for $CO_2$, which was varied at 400, 800, and 1200 ppm during the experiment. The constant parameters were: air flow at 750 µmol $s^{-1}$, incident light at 1000 µmol $m^{-2}$ $s^{-1}$, relative humidity at 65%, and cuvette temperature at 25 °C (Niinemets et al., 2010).

***Chromatographic analysis of photosynthetic pigments***
To identify and quantify photosynthetic pigments, a high-performance liquid chromatography (HPLC) system (NEXERA 8030, Shimadzu, Japan) in conjunction with a diode-array detector (DAD) was utilized following the procedures described in (Opriş et al., 2013).

***Total Phenolic Content Determination***
The extracts were obtained from fresh leaves using static maceration in a methanol-water mixture (60-40%) for 7 days at +4°C. All extracts were filtered using a 0.45 µm PTFE membrane. The total phenolic content of radish leaves, quantified as gallic acid equivalents (GAE), was assessed utilizing the Folin-Ciocalteu method as described (Lupitu et al., 2022).

***Flavonoid Content Analysis***
Total flavonoids were quantified by the $AlCl_3$ colorimetric method as described in our previous work (Copolovici et al., 2021), measuring absorbance at 434 nm and expressing results as rutin equivalents (calibration curve: 0.02-0.4 mg $mL^{-1}$).

***Total Volatile Organic Compounds Determination***
Total VOCs were collected and analyzed by GC–MS according to the protocol described in our previous study (Lupitu et al., 2025). Briefly, VOC emissions were sampled under the experimental treatments and quantified as the sum of identified compounds.

***Statistical Analysis and Data Handling***
All analyses were performed in triplicate, and results are presented as mean ± SD. Statistical significance was assessed by two-way ANOVA followed by Tukey's post hoc test using GraphPad Prism (v. 11.0.1), with $p < 0.05$ considered significant.

## RESULTS AND DISCUSSIONS

***Photosynthetic Parameters under Elevated $CO_2$ and Ozone Exposure***
Figure 1a illustrates the effects of elevated carbon dioxide (800 and 1200 µmol $mol^{-1}$) and ozone exposure on the photosynthetic assimilation rate of the three radish cultivars (Johanna, Helga, and Rozaria). Under control conditions, assimilation rate increased progressively with rising $CO_2$ concentration in all cultivars, with the highest values recorded at 1200 µmol $mol^{-1}$, indicating strong $CO_2$ fertilization (Chen et al., 2022). Ozone exposure significantly reduced assimilation at all $CO_2$ levels, with the strongest inhibition observed at ambient $CO_2$.
However, increasing $CO_2$ partially alleviated ozone-induced suppression, particularly at 800 and 1200 µmol $mol^{-1}$, suggesting a protective interaction between elevated $CO_2$ and ozone stress. The same behaviour has been observed across different Indian mustard cultivars under strong $CO_2$ fertilization (Mishra et al., 2024). Across the three radish cultivars, both $CO_2$ concentration and ozone exposure had a significant effect on stomatal conductance ($g_s$) (Figure 1b).

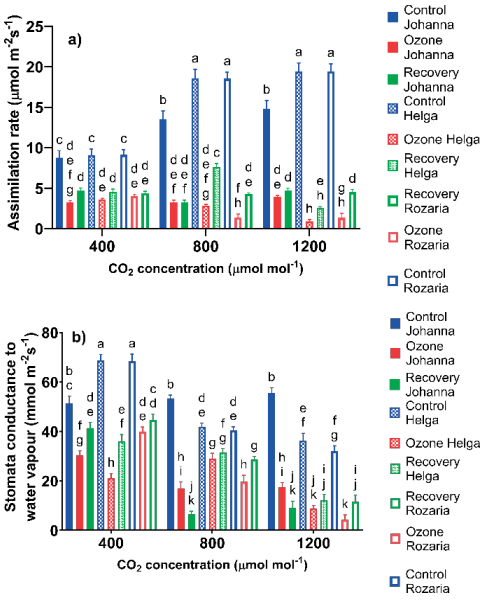

Figure 1. Effects of carbon dioxide (400, 800 and 1200 μmol mol$^{-1}$) and ozone exposure (100 ppb) on the net photosynthetic assimilation rate (μmol m$^{-2}$ s$^{-1}$) (a) and stomatal conductance to water vapour (b) in three radish (*Raphanus sativus* L.) cultivars: Johanna, Helga, and Rozaria. Plants were subjected to control, ozone stress, and recovery treatments under each $CO_2$ concentration. Bars represent mean values ± SD. Different letters indicate statistically significant differences among treatments within each $CO_2$ level ($p < 0.05$)

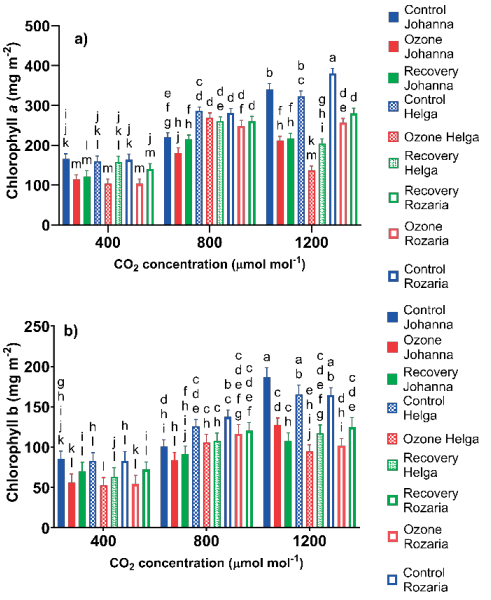

Figure 2. Effects of elevated $CO_2$ (400, 800 and 1200 μmol mol$^{-1}$) and ozone (100 ppb) on chlorophyll *a* (a) and chlorophyll *b* (b) content in three radish (*Raphanus sativus* L.) cultivars (Johanna, Helga, Rozaria). Plants were subjected to control, ozone stress, and recovery treatments under each $CO_2$ level. Bars represent mean ± SD. Different letters indicate significant differences among treatments within each $CO_2$ concentration ($p < 0.05$)

In controlled conditions, $g_s$ decreased progressively with increasing $CO_2$ concentration, indicating partial stomatal closure in response to elevated $CO_2$ levels. A lot of research has shown that similar reactions occur when $CO_2$ levels rise (Ainsworth & Rogers, 2007; Franks et al., 2013; Ainsworth & Long, 2021), as elevated $CO_2$ typically triggers a reduction in stomatal aperture and conductance through both hydraulic and ABA-related signaling, resulting in lower $g_s$ and reduced stomatal diffusion of gases (Xu et al., 2016). At higher $CO_2$ levels, the ozone-induced drops in $g_s$ were less noticeable. It indicates that $CO_2$ enrichment altered stomatal responses and may have limited the amount of ozone they could take in (Bhatia et al., 2021).

***Photosynthetic Pigment Responses***

Chlorophyll content was significantly affected by both $CO_2$ concentration and ozone exposure in all three radish cultivars (Figure 2).

Under control conditions, chlorophyll *a* and chlorophyll *b* increased progressively with rising $CO_2$ levels, indicating enhanced photosynthetic capacity under $CO_2$ enrichment. The increase in chlorophyll content under elevated $CO_2$ may be linked to increased Rubisco carboxylation capacity, suggesting coordinated upregulation of the photosynthetic machinery under $CO_2$ enrichment (Wang et al., 2025).

Both chlorophyll fractions decreased significantly upon ozone exposure, especially at ambient $CO_2$ levels, indicating oxidative damage to the photosynthetic apparatus. However, the ozone-induced decrease in chlorophyll content was lessened under high $CO_2$, suggesting a buffering or protective effect of $CO_2$ enrichment (Férriz et al., 2025).

Among cultivars, Johanna and Helga generally maintained higher chlorophyll levels under combined treatments than Rozaria, which showed a more pronounced decline under ozone stress, especially at lower $CO_2$ concentrations.

Recovery treatments partially restored chlorophyll content, although values did not always reach control levels. It is still not clear whether the higher chlorophyll content is due to structural changes in the photosynthetic apparatus or to slower pigment breakdown. The interaction between increased carbon assimilation and modulation of oxidative stress is likely to affect the stability of photosynthetic pigments under multiple atmospheric stressors (Ainsworth & Rogers, 2007; Ainsworth & Long, 2021).

### *Antioxidant Compounds: Total Phenolics and Flavonoids*

The total phenolic content was significantly influenced by both $CO_2$ concentration and ozone exposure among the three radish cultivars (Figure 3a).

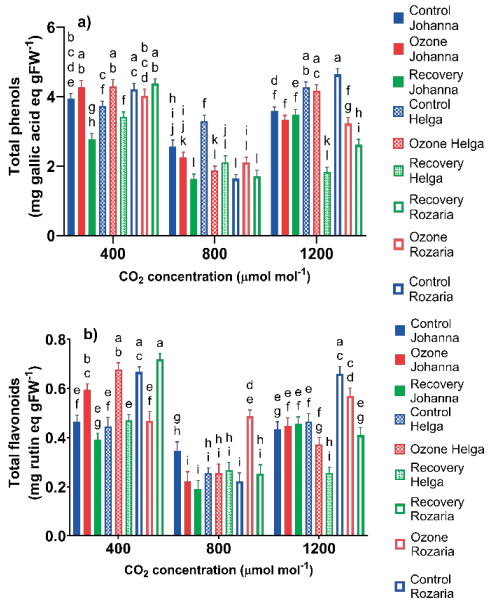

Figure 3. Effects of $CO_2$ concentration (400, 800 and 1200 µmol $mol^{-1}$) and ozone exposure (100 ppb) on (a) total phenolic content and (b) total flavonoid content in three radish (*Raphanus sativus* L.) cultivars (Johanna, Helga and Rozaria) under control, ozone and recovery treatments. Values are means ± SD (n = 3). Different letters indicate significant differences among treatments within each $CO_2$ level (two-way ANOVA followed by Tukey's test, $p < 0.05$)

Ozone treatment typically increased phenolic accumulation relative to control plants, especially under ambient carbon dioxide, suggesting the activation of antioxidant defense mechanisms in response to oxidative stress (Winyard et al., 2005).

Phenolic levels exhibited greater variability among cultivars under elevated $CO_2$ conditions. In some cases, $CO_2$ enrichment alone led to a marginal decrease in phenolic concentration compared to ambient conditions. Conversely, under the combined $eCO_2$ and $eO_3$ treatment, phenolic accumulation was consistently higher than in control plants, yet frequently lower than in conditions with ozone alone. This implies that increased $CO_2$ may partially influence ozone-induced oxidative stress responses (Bhatia et al., 2021). There were clear differences between cultivars. For example, Johanna showed the strongest increase in phenolics under ozone stress, while Rozaria showed a more moderate response.

The increase in total phenolics during ozone exposure indicates the activation of secondary metabolic pathways that are responsible for scavenging reactive oxygen species (ROS) (Jin et al., 2025). Phenolic compounds are important non-enzymatic antioxidants that help protect membranes and maintain the stability of the photosynthetic apparatus under high oxidative stress (Tamaoki, 2008; Piechowiak et al., 2026). The diminished phenolic response in elevated $CO_2$ conditions may indicate reduced oxidative stress, potentially resulting from decreased stomatal ozone absorption and enhanced carbon availability, which facilitate metabolic equilibrium. The interplay between carbon enrichment and ozone stress seems to govern the equilibrium between growth and defense allocation in radish cultivars.

For all three radish cultivars, $CO_2$ concentration and ozone exposure significantly affected total flavonoid content (Figure 3b). Compared with control plants, ozone treatment generally increased flavonoid accumulation, especially under ambient $CO_2$, suggesting that antioxidant defense mechanisms were activated in response to oxidative stress. At elevated $CO_2$ levels, flavonoid levels varied across cultivars. In some instances, $CO_2$ enrichment alone did not significantly enhance flavonoid content relative to ambient conditions; however, under the combined $eCO_2$ + $eO_3$ treatment, flavonoid accumulation persisted at elevated levels,

indicating that secondary metabolism remained active under stress.

Helga had the highest flavonoid levels when exposed to ozone, especially at 400 and 800 µmol mol$^{-1}$ $CO_2$. Rozaria, on the other hand, had lower values when exposed to both stress treatments. Johanna's responses were in the middle. These results indicate that flavonoid biosynthesis represents an important component of the oxidative stress response in radish, and its modulation under elevated $CO_2$ suggests a complex balance between carbon availability and defense allocation. These findings demonstrate that flavonoid biosynthesis is a significant aspect of the oxidative stress response in plants, and its alteration in response to increased $CO_2$ indicates a complex equilibrium between carbon availability and defense distribution (Falcone Ferreyra et al., 2012; Ibrahim & Jaafar, 2012).

### *Volatile organic compound emissions*

Ozone exposure significantly affected total VOC emissions, with clear patterns that depended on cultivar and $CO_2$ levels. Under controlled conditions, VOC emissions remained relatively low across all $CO_2$ levels (Figure 4). Conversely, ozone treatment resulted in a significant increase in total VOCs across all cultivars, consistent with the activation of stress-related volatile emission pathways under oxidative stress.

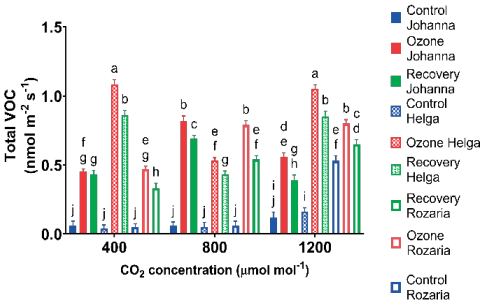

Figure 4. Effects of $CO_2$ concentration (400, 800 and 1200 µmol mol$^{-1}$) and ozone exposure (100 ppb) on total VOC emissions in three radish (*Raphanus sativus* L.) cultivars (Johanna, Helga and Rozaria) under control, ozone and recovery treatments. Values are means ± SD (n = 3). Different letters indicate significant differences among treatments within each $CO_2$ level (two-way ANOVA followed by Tukey's test, $p < 0.05$)

Higher levels of $CO_2$ altered VOC responses to ozone. At 800 and 1200 µmol mol$^{-1}$ $CO_2$, VOC emissions under ozone differed from those under ambient $CO_2$. This suggests that the amount of carbon available and the way stomata function when $CO_2$ levels are high affect volatile release. Recovery treatments showed VOC levels midway between those of plants stressed by ozone, indicating that the plants partially recovered physiological status after the stress was removed, but differences between cultivars persisted. In general, the data show that total VOC emissions are a good indicator of ozone stress and that higher $CO_2$ levels can alter this response, with differences among Johanna, Helga, and Rozaria.

Total VOC emissions increased significantly in the presence of ozone, supporting the idea that $O_3$ is a strong oxidative stressor that triggers the release of stress-related volatiles used for defense and signaling (Li et al., 2017). The modulation of this response under elevated $CO_2$ suggests that the two atmospheric drivers do not exert simply additive effects, but rather interact in a more complex manner. This is in line with evidence that multiple concurrent stresses can significantly alter the size and composition of plant VOC emissions (Holopainen & Gershenzon, 2010). One possible explanation is that $CO_2$-Induced stomatal regulation reduces the amount of $O_3$ that stomata take in, thereby lowering oxidative pressure within the plant and partially blocking ozone-driven volatile signaling. However, changes in carbon availability under elevated $CO_2$ may still allow the formation of *de novo* VOCs (Himanen et al., 2009; Holopainen & Gershenzon, 2010).

## CONCLUSIONS

Higher levels of $CO_2$ improved the physiological performance of radishes by increasing net $CO_2$ assimilation and raising the levels of chlorophyll a and b in all cultivars. This is consistent with a $CO_2$ fertilization response. On the other hand, exposure to 100 ppb of ozone clearly induced oxidative stress, lowering chlorophyll content and assimilation, and altering stomatal conductance. This showed that the photosynthetic machinery was not working properly.

Significantly, increased $CO_2$ levels (800-1200 ppm) partially alleviated ozone damage, as evidenced by a diminished ozone-induced reduction in assimilation, stomatal conductance, and pigment pools relative to ambient $CO_2$, indicating a buffering interaction among concurrent atmospheric change factors. Ozone also triggered secondary metabolism associated with antioxidants, as evidenced by higher levels of total phenolics and flavonoids. The fact that these levels changed when $CO_2$ levels rose suggests that the balance between growth and defence allocation is changing. Total VOC emissions rose sharply when ozone was present, and $CO_2$ levels also affected them. This shows that volatile release is a sensitive indicator of ozone stress, and its strength depends on how $CO_2$ affects stomatal regulation and carbon availability. Lastly, cultivar-specific response patterns (for example, Johanna had a stronger phenolic induction, Helga had a higher flavonoid accumulation, and Rozaria was generally more sensitive under combined stress) show that there is a lot of genotypic variability and support the idea that cultivar selection could help crops do well in the future when $CO_2$ levels are rising.

***Abstract***

*The composition of fish muscle is influenced by environmental factors and can be used to assess the status of the aquatic ecosystems. This study explores the relationship between moisture and lipid content in the muscle tissue of selected freshwater fish species from the Lower Danube River, aiming to evaluate their potential as ecological indicators. Eight edible fish species, asp, vimba bream, perch, wels catfish, zander, pontic shad, common roach, and common carp, were included in the analysis. Moisture content was determined by freeze-drying and total lipid content was assessed on the dry fish using the Soxhlet extraction method. Lipid content was expressed both as dry and wet weight to allow an extensive interpretation in a biological and environmental context. Total mercury concentrations were also determined in fish samples, ranging from 0.15 ± 0.02 mg/kg in pontic shad to 1.04 ± 0.62 mg/kg in wels catfish. The results for moisture content ranged from 73.67 ± 2.52 % to 81.25 ± 1.06%, while lipid content (expressed as wet weight) showed high variability among species (0.4 ± 0.00% to 17.67 ± 5.42%). A strong inverse correlation was observed between moisture and lipid content (r ≈ -0.929), which suggests that fish muscle composition reflects differences in energy storage and environmental conditions. The findings of this study support the use of biochemical parameters as complementary indicators in aquatic environmental assessment, particularly in freshwater systems subject to environmental variability.*

***Key words:*** *Danube River, freshwater fish, freeze-drying, lipids, mercury.*

## INTRODUCTION

Aquatic ecosystems evaluation is based on the integration of physicochemical and biological indicators that show both natural diversity and environmental stresses. This evaluation is closely linked to water quality monitoring, which provides essential information regarding the environmental status and the anthropic pressures, especially for the large rivers like Danube (Iticescu et al., 2014). In addition, environmental monitoring is strongly connected to broader sustainability goals and policy frameworks (Georgescu et al., 2025). Moreover, recent studies emphasize the importance of conventional and emerging pressures on water ecosystems, highlighting their role in supporting water security and the socio-economic development (Goswami & Bisht, 2017; Wang et al., 2024; Zlati et al., 2024; Cadieux, 2026; Moon et al., 2026).

Within this perspective, identifying complementary indicators capable of evaluating the ecosystem regarding the environment quality and trophic dynamics remains a key objective in environmental research and monitoring.

Even though physicochemical characteristics provide an overview of water quality and biological communities are an indicator of long-term responses to ecological changes, biochemical parameters of fish tissues can reflect environmental changes over time and contribute to the assessment of the physiological state of the aquatic organisms. Therefore, fish are considered relevant bioindicators of

ecological condition in water environments due to their sensitivity to environmental pressures and can be complementary to physicochemical and biological monitoring by integrating trophic interactions and environmental quality (Maceda-Veiga & De Sostoa, 2011; Wannas & Mohammed, 2025). The principal constituents of fish muscle are generally water, lipids and proteins, while carbohydrates and ash are present in low levels. Since the protein concentrations tend to vary less than the lipid content, fluctuations in fat content are linked to interchanges between water and lipid fractions. As a consequence, an inverse relationship between moisture and lipid content in fish species was reported, with greater lipid depositions corresponding to lower water content (Naeem & Salam, 2010; Ahmed et al., 2022; Warret Rodrigues et al., 2023). Lipid and moisture content can offer valuable insight about energy storage and other physiological characteristics and may reflect the adaptive response to environmental conditions in freshwater ecosystems like the Lower Danube River (Petricorena, 2014; Martin et al., 2017; Ahmed et al., 2022).

Furthermore, the assessment of total mercury can be included alongside fish muscle composition, as mercury is known for its persistence in the aquatic ecosystems, and for its bio-accumulative and bio-magnification character across the trophic chain (Tolkou et al., 2023; Rock et al., 2025). Therefore, monitoring total mercury in fish from different trophic levels can give additional data on the ecosystem quality (Zillioux, 2015; Bernal-Alviz et al., 2025).

The selected fish species are representative for different trophic positions and feeding habits within the lower Danube River, and permit a more extensive evaluation of the biochemical interspecific variation in fish muscle. The study includes omnivorous species such as common carp (*Cyprinus carpio carpio*) and common roach (*Rutilus rutilus*); benthic-omnivorous vimba bream (*Vimba vimba*); predatory species including perch (*Perca fluviatilis*), pontic shad (*Alosa immaculata*), asp (*Leuciscus aspius*), zander (*Sander lucioperca*), and wels catfish (*Silurus glanis*) (Okgerman et al., 2013; Gerasimov & Strel'nikova, 2016; Mazlum & Akgumus, 2019; Olsson, 2019; Pfauserová et al., 2019; Nahon et al., 2020; Santos et al., 2025).

The aim of the present study was to evaluate the relationship between moisture and lipid content in muscular tissue of selected freshwater fish species from the Lower Danube River and to investigate their potential as indicators of ecological status. Furthermore, mercury concentrations were assessed to provide supplementary information on the extent of metal contamination in the aquatic environment. This work highlights the importance of fish muscle composition in ecological evaluation. It also provides preliminary data for the Lower Danube River, contributing to the relatively limited research regarding the use of simple compositional analysis in freshwater monitoring.

## MATERIALS AND METHODS

Fish samples were collected in spring 2023 from local fishermen in the Lower Danube and Danube Delta regions. The biometric characteristics of the analysed fish were as follows: asp, total length 37.00 cm and body weight 386.00 g (n=1); vimba bream, 44.40 ± 31.89 cm and 265.70 ± 34.02 g (n=3); perch, 22.33 ± 1.51 cm and 169.33 ± 22.05 g (n=3); wels catfish, 74.83 ± 3.67 cm and 2916.67 ± 633.11 g (n=2); zander, 23.35 cm and 151.50 g (n=1); pontic shad, 25.93 ± 1.40 cm and 167.67 ± 21.94 g (n=3); common roach, 30.00 cm and 290.00 g (n=1); common carp, 59.10 ± 4.45 cm and 2800 ± 1255.99 g (n=3). Two of the eight analysed species are represented in Figure 1. All specimens were eviscerated immediately after collection. Muscle samples were collected from the dorsal white muscle. The fish muscles were frozen, and stored at –20°C until analysis.

Ten grams of each muscle sample were first pre-frozen at −80°C for 24 hours, then freeze-dried for 24 hours at a condenser temperature of −80°C and a vacuum pressure of 200 Pa to remove all water content, allowing accurate determination of the moisture level in the fish tissues (Figure 2); the lyophilization was performed on a Table Top Freeze Dryer BK-FD10PT (BioBase, Shandong, China).

Figure 1. Examples of analysed species: perch and Pontic shad

Moisture was calculated by the gravimetric method using the formula:

$$\text{Moisture (\%)} = \frac{wet\ weight - dry\ weight}{wet\ weight} \times 100$$

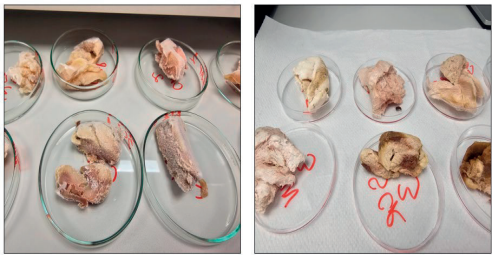

Figure 2. Fish muscle before and after freeze-drying

Subsequently, lipid determination was carried out on the dried samples. The total lipids were analysed by the modified Soxhlet method, with 30 minutes of hot extraction, 60 minutes of rinsing time and 30 minutes of solvent recovery. The samples were extracted with 150 mL n-hexane, with the heating block set to 180°C. The samples were weighed in the cellulose thimble. Each extraction beaker contained 2 boiling stones to ensure constant boiling. The extract was evaporated to dryness, permitting the gravimetric determination of fat content. The total lipid content was determined using a Soxtherm SOX414 (C. Gerhardt Analytical Systems, Königswinter, Germany) fully automated extraction unit. Lipids were expressed on dry weight, using the gravimetric method:

$$\text{Lipids (dry weight, \%)} = \frac{final\ mass - initial\ mass}{sample\ mass} \times 100$$

The results were further used for conversion to wet weight:

$$\text{Lipids (wet weight, \%)} = \text{Lipids (dry weight, \%)} * (1 - \text{Moisture}/100)$$

The data have been statistically processed and interpreted in Python (version 3.12) using the pandas, matplotlib, and SciPy libraries within the Spyder IDE.

Pearson's Correlation analysis was used to evaluate the relationship between lipids content and moisture.

Approximately 50 milligrams of fresh, non-lyophilized muscle was weighed in nickel sample boat and submitted to the analysis using DMA-80 evo Direct Mercury Analyzer (Milestone, Sorisole, Italy). Samples were analysed directly without previous digestion. Total mercury (THg) was assessed by thermal decomposition of the sample, followed by catalytic removal of by-products, gold amalgamation and quantification by atomic absorption spectroscopy (AAS).

One-way statistical analysis (ANOVA) was performed using Data Analysis ToolPak in Microsoft Excel (Microsoft Corporation, WA, USA) to evaluate differences among species regarding total mercury concentrations, lipids content and moisture. Only fish with duplicate or triplicate measurements were included in the analysis. Statistical significance was accepted at $p<0.05$.

## RESULTS AND DISCUSSIONS

Results for moisture and lipid content in freshwater fish from the Danube River are presented in Table 1.

Moisture content was fairly constant among the species, ranging from 73.67 ± 2.52 % to 81.25 ± 1.06 %; these results are in accordance with a study conducted by Xia (2025) on freshwater fish. However, Pontic shad showed lower levels of 65.70 ± 8.00%, consistent with its high lipid content.

One-way ANOVA indicated significant differences in moisture content among fish species ($F = 5.09$; $p = 0.024$).

The differences in total lipid content observed between the analysed fish species can indicate different feeding behaviour, distinct habitats and environmental characteristics in the Lower Danube River ecosystem. Lipids can be used as an indicator of energy storage and fish physiological characteristics and can be

influenced by food resource availability and trophic interactions. Fish species that have increased lipid concentrations have access to more energy-rich food resources, whereas decreased lipid levels can indicate accelerated metabolism or environmental pressures.

Pontic shad showed the highest lipid levels, 17.67 ± 5.42% wet weight (ww), which can reflect energy reserves for migration (Misir et al., 2016). Common carp also showed relatively high lipid concentrations of 7.57 ± 2.34% ww, due to their omnivorous feeding behaviour and efficient accumulation of energy reserves (Ayalew et al., 2025). Lower lipid levels were exhibited by perch (0.4 ± 0.00% ww), zander (0.6% ww) and asp (0.7% ww), which can be explained by their predatory feeding character, intense swimming activity or habitat conditions. These species use most of their energy for locomotion, resulting in lower lipid deposition in their fish muscle tissue. Intermediate lipid values were obtained for common roach, wels catfish and vimba bream (2.1% ww, 2.35 ± 0.35% ww, 3.13 ± 0.91% ww, respectively). These results indicate species-specific feeding behaviour and resource management (Łuczyńska et al., 2020; Simeanu et al., 2022). Lipid levels remained highest in Pontic shad when expressed on a dry weight basis, suggesting that inter-species differences were present even after normalising for moisture content.

These findings suggest that fish muscle composition, especially lipid and moisture content, indicate species-specific adaptive response and can represent useful information on energy usage, availability of food resources, and ecological stress, supporting its use as a bioindicator within the Lower Danube River ecosystem.

One-way ANOVA revealed significant differences in lipid content between fish species ($F = 14.33$; $p = 0.001$).

Table 1. Moisture and lipid content in freshwater fish from the Danube River

| Fish species | Abbreviation | Number of specimens | Moisture (%) | Total lipids (% dry weight) | Total lipids (% wet weight) |
|---|---|---|---|---|---|
| common carp (*Cyprinus carpio carpio*) | CRP | 3 | 73.67 ± 2.52 | 28.77 ± 8.93 | 7.57 ± 2.34 |
| perch (*Perca fluviatilis*) | BIB | 3 | 78.90 ± 1.04 | 1.87 ± 0.15 | 0.4 ± 0.00 |
| vimba bream (*Vimba vimba*) | MOR | 3 | 76.77 ± 2.05 | 13.33 ± 2.95 | 3.13 ± 0.91 |
| pontic shad (*Alosa immaculata*) | SCR | 3 | 65.70 ± 8.00 | 51.03 ± 5.67 | 17.67 ± 5.42 |
| wels catfish (*Silurus glanis*) | SMN | 2 | 81.25 ± 1.06 | 12.65 ± 1.06 | 2.35 ± 0.35 |
| zander (*Sander lucioperca*) | SL | 1 | 79.9 | 3.0 | 0.6 |
| common roach (*Rutilus rutilus*) | BAB | 1 | 77.7 | 9.6 | 2.1 |
| asp (*Leuciscus aspius*) | AVAT | 1 | 78.0 | 3.0 | 0.7 |

The negative correlations between moisture and lipid content across the analysed muscles (wet weight basis; r=-0.929, n=17, $p<0.001$) are represented in Figure 3. The linear regression equation was y=-1.020x+82.550, $R^2$=0.864, indicating a statistically significant inverse relationship. As lipid levels increase, moisture content decreases as a result of intracellular water being replaced by high-energy lipidic deposits (Huss, 1995). The obtained results align with the well-documented moisture-lipid relationship described for muscle (Zhang et al., 2014; Matos et al., 2019; Ahmed et al., 2022).

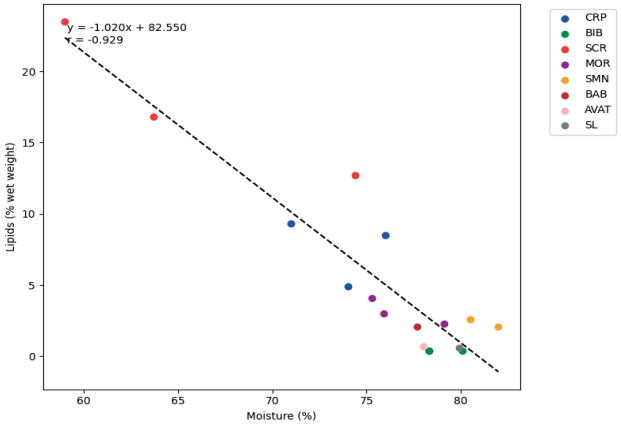

Figure 3. Correlations between lipids content and moisture

Mercury (Hg) is a widespread environmental pollutant that is extremely toxic and bioavailable. It accumulates in aquatic food chains and poses serious health concerns to consumers who eat seafood (Fioravanti et al., 2025). In all fish samples (Figure 4), the total mercury concentration varied between 0.15 ± 0.02 to 1.04 ± 0.62 mg/kg. Catfish recorded the highest concentration of 1.044 ± 0.62 mg/kg and at the opposite pole, the pontic shad determination recorded values of 0.15 ± 0.02 mg/kg.

Catfish from Danube are predator species which can accumulate high mercury levels by consuming other fish species. They are freshwater omnivores and consume substrate that is found at the bottom of water bodies (Cadieux, 2026).

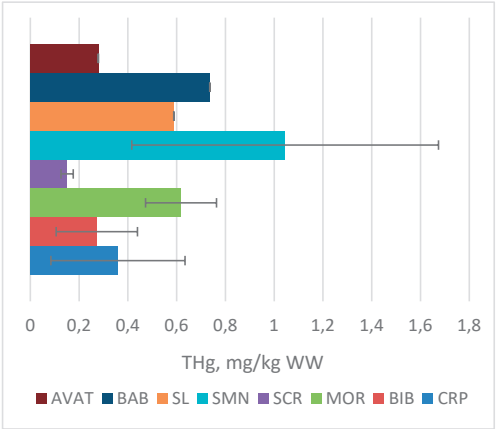

Figure 4. Total mercury (THg) concentrations (mg/kg) in fish muscle

Moreover, they have a potential to bioaccumulate this toxic element in time. Usually, the mercury level within the catfish reflects very well the degree of pollution from that environment. Pontic shad usually feed with smaller plankton, so their position into the food chain is lower and has a much shorter average lifespan compared to catfish. According to Brodziak-Dopierała & Fischer (2023), mercury levels in catfish from river Po ranged from 0.51 to 1.43 mg/kg. The observed levels are similar, which means that support the comparability between studies. Milea (2023) measured the mercury in pontic shad and obtained 0.21 mg/kg DW and Brodziak-Dopierała & Fischer (2023) stated that fish from the Danube, which passes through Croatia, have approximately 0.191 mg/kg (omnivorous species) and 0.441 mgHg/kg (plankton eaters). Regarding the other analysed samples, common roach, vimba bream, and zander exhibited high concentrations of mercury, followed by smaller concentrations in common carp, asp, and perch. Excepting pontic shad, all fish samples presented an increased intra-species variability in terms of mercury concentration. All these differences could be due to specific environmental factors, diet, age, size of each individual fish (Rock et al., 2025). Mercury levels in fish are important because for humans, eating fish is typically the main source of mercury (Dang & Wang, 2012). Additionally, they are indicators for the environmental pollution status (Tolkou et al., 2023).

One-way ANOVA showed a statistically significant difference in total mercury

concentration among fish species at the 0.05 significance threshold ($F = 3.70$; $p = 0.050$).

## CONCLUSIONS

The present study showed interspecific variability for moisture and lipid content in muscle tissue of freshwater fish species from the Lower Danube River. The highest lipid accumulation was observed in Pontic shad and common carp, while perch, zander, and asp exhibited lower lipid reserves, highlighting differences in feeding strategies, metabolic activity, and habitat adaptations.

A strong inverse relationship between moisture and lipid content was identified ($r=-0.929$), confirming that lipid deposition is associated with lower tissue moisture across the investigated samples.

After determining the concentration of mercury in all fish species, it can be concluded that the highest levels were observed in the predatory species, in catfish. The presence of mercury in fish from the Danube highlights the need for continuous monitoring in order to preserve the quality of the aquatic ecosystem, but also to control the possibility of human exposure to contaminated food.

The findings of this study represent baseline data for the Lower Danube River area and reinforce the use of biochemical parameters as ecological indicators in aquatic environmental assessment in freshwater ecosystems. However, sampling was limited to a single season, and annual variations could not be accounted for. Seasonal changes in the lipid reserves and tissue moisture content can influence the mercury bioaccumulation. Future research should include seasonal sampling and the assessment of other pollutants and stressors to better understand the determinants of biochemical variations. These investigations would consolidate the use of these biomarkers in ecological monitoring programs and would contribute to the Water Framework Directive implementation, while contributing to broader freshwater management and sustainability strategies.

***Abstract***

*Heavy metal contamination represents a persistent threat to aquatic ecosystems due to its toxicity and long-term environmental persistence. Among these metals, zinc plays a dual role as an essential micronutrient at low concentrations but becomes toxic when present in excess. The present study evaluates the acute toxicity of zinc on the freshwater crustacean Daphnia magna, a widely used bioindicator species in ecotoxicological assessments. Toxicity experiments were conducted using standardized Daphtoxkit bioassays in which neonates of D. magna were exposed to zinc concentrations ranging from 1.0 to 6.0 mg/L under controlled laboratory conditions. Mortality rates were recorded at four-hour intervals over an exposure period of 36 hours. The results revealed a strong concentration- and time-dependent increase in mortality. At the lowest concentration tested (1.0 mg/L), mortality reached 20% after 16 hours and increased to 60% after 36 hours. In contrast, the highest concentration (6.0 mg/L) induced rapid toxicity, producing 80% mortality within four hours and complete mortality after twelve hours of exposure. These findings highlight the high sensitivity of D. magna to elevated zinc concentrations and confirm its suitability as an effective biological indicator for monitoring heavy metal contamination in freshwater ecosystems. The results contribute to a better understanding of zinc-induced toxicity mechanisms in aquatic invertebrates and provide valuable information for environmental monitoring and risk assessment of metal pollution.*

***Key words****: Daphnia magna, mortality rate, toxicity, zinc.*

## INTRODUCTION

The contamination of aquatic environments with heavy metals represents one of the most persistent environmental challenges associated with industrialization and modern agricultural activities. Due to their chemical stability and limited biodegradability, heavy metals tend to accumulate in aquatic ecosystems and can exert long-term toxic effects on living organisms (Ali et al., 2019; Pandey & Keshavkant, 2021). Their presence in water bodies may disrupt ecological balance and pose risks to aquatic biodiversity as well as to human health through the contamination of water resources.

Among heavy metals, zinc occupies a particular position because it plays a dual role in biological systems. At low concentrations, zinc is considered an essential micronutrient involved in numerous physiological processes, including enzyme activation, gene expression, and protein synthesis (King, 2011). Several studies have highlighted the importance of zinc in maintaining cellular metabolism and proper organismal functioning (Bellido et al., 2022; Paylar et al., 2022; Oprea et al., 2024). However, when present in elevated concentrations, zinc may become toxic and cause adverse effects on aquatic organisms (DeForest & van Genderen, 2012; Clearwater et al., 2002).

The detection and monitoring of aquatic pollution can be effectively achieved using biological indicators, also known as bioindicators. These are living organisms that respond to environmental changes and can provide valuable information about ecosystem health. Bioindicators may include microorganisms, plants, and animals whose physiological responses can signal the presence of pollutants even at low concentrations (Zaghloul et al., 2020; Simionov et al., 2022). Their use is particularly valuable because they can detect the early stages of environmental contamination and provide insights into the biological effects of pollutants (Wang & Guan, 2010; Parmar et al., 2016; Kadim & Risjani, 2022).

Several aquatic organisms have been widely employed in ecotoxicological testing to assess water pollution. Among these are the freshwater crustacean *Thamnocephalus platyurus*, the

rotifer *Brachionus calyciflorus*, the protozoan *Tetrahymena thermophila*, the cladoceran *Ceriodaphnia dubia*, the aquatic plant *Spirodela polyrhiza*, and the microalga *Pseudokirchneriella subcapitata*. While a variety of aquatic organisms are used as bioindicators, they are mentioned here to provide context, with the present study specifically focusing on *Daphnia magna* due to its high sensitivity and established role in standardized ecotoxicological testing.

One of the most widely used organisms in freshwater ecotoxicology is the cladoceran *Daphnia magna*, commonly known as the water flea. This species plays a crucial ecological role in freshwater ecosystems such as ponds and lakes, where it acts as a primary consumer by filtering suspended particles and microorganisms from the water column. Through this filtering activity, *Daphnia magna* contributes significantly to water clarity and nutrient cycling within aquatic ecosystems

Acute toxicity tests involving freshwater daphnids have become internationally recognized tools for evaluating the toxic effects of chemical substances and for monitoring contaminated water and industrial effluents (Persoone et al., 2009; Fekete-Kertész et al., 2016; Sönmez et al., 2022). The extensive use of *Daphnia magna* in ecotoxicological studies is mainly due to its high sensitivity to pollutants, rapid reproduction, short life cycle, and parthenogenetic reproduction (Koivisto, 1995). In addition, it offers practical advantages such as low experimental costs, standardized protocols, and reproducible results within short testing periods (Kim et al., 2003).

Considering the increasing presence of heavy metals in aquatic ecosystems and the potential ecological consequences of their accumulation, it is essential to evaluate their effects on sensitive aquatic organisms. Therefore, the main objective of the present study was to investigate the toxic effects of zinc at different concentrations on *Daphnia magna* and to assess the relationship between pollutant concentration, exposure time, and mortality rate in this bioindicator species.

## MATERIALS AND METHODS

The experimental study was carried out using the *Daphtoxkit F magna toxicity test system,* produced by MicroBioTests Inc. (Belgium, Figure 1). This standardized bioassay kit contains the necessary materials for performing acute toxicity tests on *Daphnia magna*, including concentrated salt solutions used for preparing the test medium, micropipettes, a microsieve, Petri dishes, spirulina owder for feeding the organisms, and dormant ephippial eggs of *Daphnia magna*.

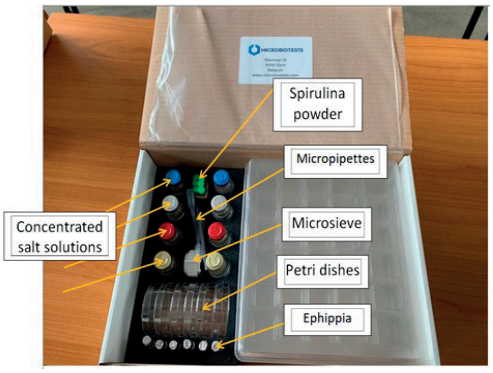

Figure 1. Daphtoxkit *F magna*

### *Preparation of standard freshwater*

A Standard Freshwater solution was prepared according to the protocol described in ISO 6341:2012, which is commonly used in acute toxicity tests involving freshwater crustaceans.

The solution was obtained by adding the following concentrated salt solutions to one liter of distilled water: $NaHCO_3$ with a concentration of 64.75 mg/L (12 mL), $CaCl_2 \cdot 2H_2O$ with a concentration of 294 mg/L, $MgSO_4 \cdot 7H_2O$ with a concentration of 123.25 mg/L, KCl with a concentration of 5.75 mg/L.

After the addition of these components, the solution was diluted with distilled water to obtain a final volume of 2000 mL, and the mixture was thoroughly homogenized to ensure uniform distribution of the salts.

This prepared solution served both as the hatching medium for ephippia and as the dilution medium for preparing pollutant concentrations.

### *Preparation of zinc pollutant solution*

The pollutant solution used in the experiments consisted of zinc sulfate ($ZnSO_4$) dissolved in distilled water. The physicochemical parameters of the test solutions (pH, dissolved oxygen, and conductivity) were maintained within the recommended ranges specified by ISO

6341:2012. A stock solution with a concentration of 104.5184 mg/L $ZnSO_4$ was prepared and subsequently used to obtain the experimental concentrations through serial dilution with Standard Freshwater.

From the stock solution, six working concentrations of zinc sulfate ($ZnSO_4$) were prepared: 1.0 mg/L, 2.0 mg/L, 3.0 mg/L, 4.0 mg/L, 5.0 mg/L, 6.0 mg/L.

Each concentration represented a separate experimental treatment. All experimental variants were performed in four independent replicates in order to ensure reliability and reproducibility of the results.

The prepared solution served both as the hatching medium for ephippia and as the dilution medium for preparing pollutant concentrations.

***Hatching of Daphnia magna ephippia***

Dormant eggs (*ephippia*) of *Daphnia magna* were first rinsed using tap water in order to remove any residues of the storage medium. The ephippia were then placed in a microsieve and transferred into Petri dishes containing 10 mL of pre-aerated Standard Freshwater.

The Petri dishes were covered with lids and incubated for approximately 80 hours at a controlled temperature of 20–22°C under continuous illumination. These conditions allowed the hatching of the ephippial eggs and the emergence of neonate individuals.

***Feeding of Neonates***

After the hatching process was completed, the newly emerged *Daphnia magna* neonates were provided with spirulina powder as a food source. Feeding was performed shortly after hatching in order to ensure the physiological stability of the organisms before the toxicity testing began. Two hours after feeding, the neonates were selected for use in the toxicity experiments (Figure 2).

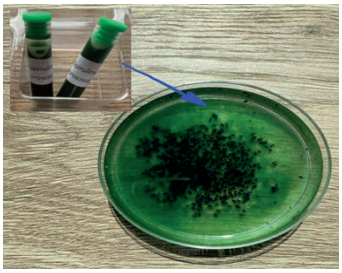

Figure 2. Spirulina feeding

***Toxicity testing procedure***

For each experimental condition, five neonates of *Daphnia magna* were introduced into test plates containing 10 mL of zinc-contaminated Standard Freshwater at the predetermined concentrations. The experimental procedure followed the standardized protocol described in ISO 6341:2012. The use of five neonates per test plate is consistent with Daphtoxkit guidelines and contributes to the reproducibility and reliability of the results. To prevent evaporation of the test solution during the incubation period, the plates were sealed with parafilm strips and covered with a transparent lid.

The experimental plates were then incubated under controlled conditions in darkness at a constant temperature of approximately 22°C (Figure 3).

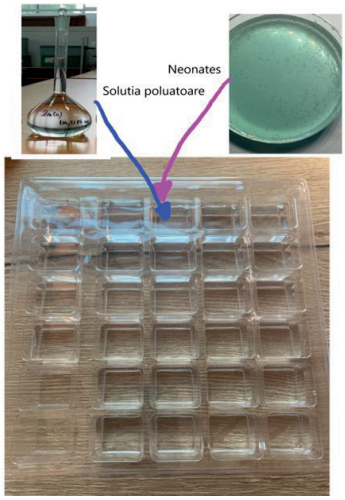

Figure 3. Testing plates

***Monitoring of organism response***

The response of *Daphnia magna* to zinc exposure was monitored throughout the experimental period. Observations were conducted every four hours, during which the number of surviving and dead organisms was recorded.

Mortality was determined based on the absence of movement of the organisms when observed under standard laboratory conditions.

***Calculation of mortality rate***

The mortality rate of the organisms was calculated using the following equation:

$$R_m = \frac{N_i - N_f}{N_i} \cdot 100\ (\%) \quad (1)$$

where:
Rm represents the mortality rate expressed as a percentage (%);
Ni represents the initial number of *Daphnia magna* individuals introduced into the test plate;
Nf represents the number of surviving individuals recorded during observation.
In addition to mortality rate, the inhibitory effect of the pollutant was evaluated by comparing the results obtained in the contaminated samples with those observed in the control group, where the organisms were maintained in uncontaminated Standard Freshwater.

## RESULTS AND DISCUSSIONS

### *Effects of zinc exposure on the survival of Daphnia magna*

After the hatching period and the initial feeding stage, the newly emerged *Daphnia magna* neonates were transferred to freshwater containing different concentrations of zinc (Figure 4).

Figure 4. *Daphnia magna* (water fleas)

During the experimental exposure period, the organisms were not provided with additional food. The survival of the water fleas was monitored throughout the experiment in order to evaluate the influence of zinc concentration and exposure time on organism mortality.
The observations revealed that *Daphnia magna* individuals were able to survive in zinc-contaminated freshwater for a maximum exposure period of approximately 36 hours. However, their number progressively decreased as both the zinc concentration and exposure duration increased.
The experimental results, summarized in Table 1, indicate a clear concentration-dependent reduction in the number of surviving organisms. The values presented represent mean results obtained from four independent replicates for each concentration and exposure time.

Table 1. Zinc toxicity on *Daphnia magna*

| Concentration (mg/L) | Number of *Daphnia magna* in test plates | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | Day 1 | | | | | Day 2 | | | |
| | Hour | | | | | Hour | | | |
| | 8 h | 12 h | 16 h | 20 h | 24 h | 4 h | 8 h | 12 h | 16 h |
| 1.0 | 5 | 5 | 5 | 4 | 4 | 4 | 4 | 3 | 2 |
| 2.0 | 5 | 5 | 4 | 4 | 3 | 2 | 2 | 1 | 0 |
| 3.0 | 3 | 3 | 2 | 2 | 2 | 1 | 1 | 1 | 0 |
| 4.0 | 2 | 2 | 2 | 1 | 1 | 1 | 0 | 0 | 0 |
| 5.0 | 2 | 1 | 1 | 0 | 0 | 0 | 0 | 0 | 0 |
| 6.0 | 1 | 1 | 0 | 0 | 0 | 0 | 0 | 0 | 0 |

For example, at the lowest tested concentration (1.0 mg/L Zn), all five individuals survived during the first 12 hours of exposure. After 16 hours, the number of surviving organisms decreased to four individuals, and after 36 hours, only two organisms remained alive.
At a zinc concentration of 2.0 mg/L, the number of surviving individuals began to decrease earlier. While five organisms were initially present, survival declined progressively to zero by the end of the exposure period.
At 3.0 mg/L, the toxic effects became more pronounced. Only three individuals remained alive after the initial exposure period, and the population gradually declined until complete mortality occurred by the end of the experiment.
Higher zinc concentrations caused even faster reductions in survival. At 4.0 mg/L, only two organisms remained alive after the first observation interval, and the entire population was eliminated within the experimental timeframe.
Similarly, at 5.0 mg/L, mortality increased rapidly, with only one organism surviving after the early observation intervals and complete mortality occurring shortly afterward.
The most severe toxic effects were observed at the highest concentration tested (6.0 mg/L). In this case, only one individual survived during the initial observation period, and all organisms died within a few hours of exposure.

These results clearly demonstrate that zinc toxicity in *Daphnia magna* increases significantly with increasing pollutant concentration.

***Mortality rate of water fleas***

The mortality rate of the water fleas was calculated based on the recorded number of surviving individuals at each observation interval. The results are illustrated in Figures 5 and 6, which show the mortality rates recorded after the first and second days of exposure.

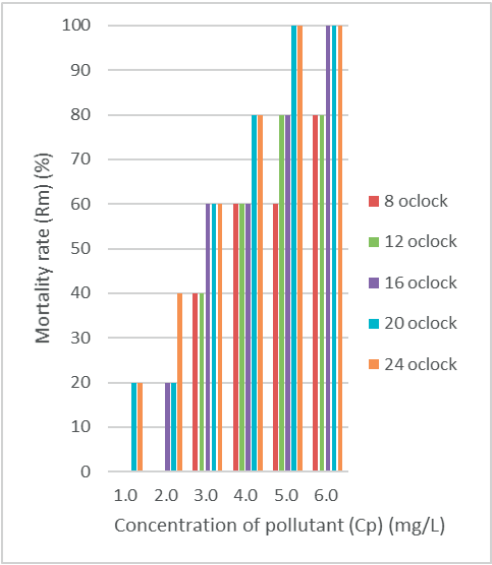

Figure 5. Mortality rate of water fleas after Day 1 of exposure to the pollutant

During the first day of exposure, the mortality rate remained relatively low at the lower zinc concentrations. At concentrations of 1.0 mg/L and 2.0 mg/L, mortality reached approximately 20% only after 16 hours and 12 hours of exposure, respectively.

In contrast, the mortality rate increased substantially at higher zinc concentrations. At the maximum concentration tested (6.0 mg/L), mortality reached approximately 80% after only four hours of exposure and increased to 100% after twelve hours.

The results also indicate that mortality increased significantly during the second day of exposure (Figure 6). After 36 hours, the mortality rate reached 60% at the lowest tested concentration (1.0 mg/L), while at all higher concentrations complete mortality (100%) was observed.

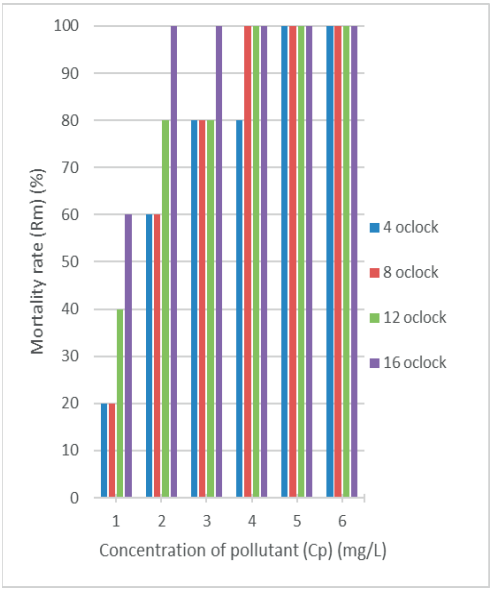

Figure 6. Mortality rate of water fleas after Day 2 of exposure to the pollutant

These findings demonstrate that both exposure time and zinc concentration strongly influence the survival of *Daphnia magna*.

After calculating the mortality rate of water fleas, the $LC_{50}$ (lethal concentration for 50% of organisms) was determined, a standard toxicology indicator used to measure the acute toxicity of a substance. $LC_{50}$ is calculated using statistical methods and is used to compare toxicity and assess ecological and human risks. A lower $LC_{50}$ value indicates higher toxicity.

To calculate the $LC_{50}$ value, the logarithmic method was applied. Using the AAT Bioquest $LC_{50}$ calculator, the concentrations (X values) and the corresponding responses expressed as percentage mortality (Y values) were entered to obtain the equations required for determining the $LC_{50}$ for Zn exposure on Day 1 and Day 2. The resulting equations and $LC_{50}$ values are presented in Table 2.

Table 2. The $LC_{50}$ values for Zn pollution used in the experiment

| Type of Pollutant | Equation | | $LC_{50}$ | |
|---|---|---|---|---|
| $Zn^{2+}$ | *Day 1* | *Day 2* | *Day 1* | *Day 2* |
| | $Y = 0.034 + \frac{1.019 - 0.034}{1 + \left(\frac{X}{2.96}\right)^{4.623}}$ | $Y = -0.053 + \frac{4.969 + 0.053}{1 + \left(\frac{X}{0.434}\right)^{1.596}}$ | 2.969±0.032 | 0.434±0.063 |

All values are mean values of repetitions ± S.D.

***Relationship between zinc concentration and population inhibition***

In addition to mortality rate, the inhibitory effect of zinc exposure on *Daphnia magna* populations was also evaluated by comparing the survival of organisms in contaminated water with that observed in the control sample maintained in uncontaminated freshwater.

Graphical analysis of the relationship between pollutant concentration and inhibition of the organisms revealed a clear correlation between increasing zinc concentration and increasing levels of inhibition. This relationship is illustrated in Figures 7, 8, and 9, which show the correlation between pollutant concentration (Cp) and the inhibition of *Daphnia magna* (I) after 12 hours, 24 hours, and 36 hours of exposure, respectively.

The results indicate that inhibition increased with both zinc concentration and exposure time.

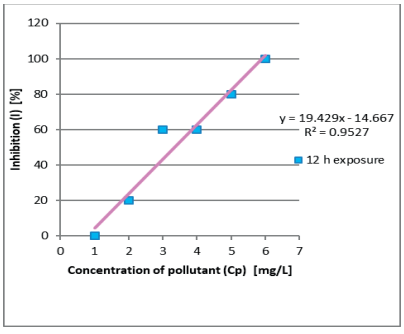

Figure 7. Correlation between the concentration of pollutant (Cp) and inhibition (I) of *Daphnia magna* under the influence of water pollution with Zn after 12 hours of exposure

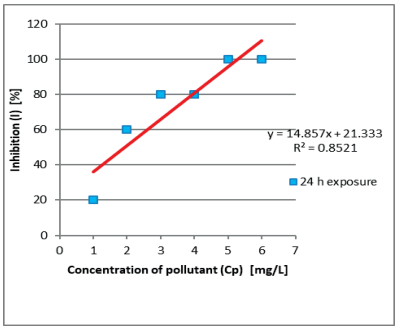

Figure 8. Correlation between the concentration of pollutant (Cp) and inhibition (I) of *Daphnia magna* under the influence of water pollution with Zn after 24 hours of exposure

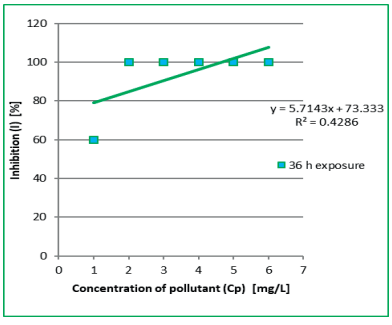

Figure 9. Correlation between the concentration of pollutant (Cp) and inhibition (I) of *Daphnia magna* under the influence of water pollution with Zn after 36 hours of exposure

The relationship between pollutant concentration and inhibition was quantified using the correlation coefficient ($R^2$), which showed a decreasing trend over time, with values of 0.9527 after 12 hours, 0.8521 after 24 hours, and 0.4286 after 36 hours. This decline suggests that, at longer exposure times, the strength of the correlation weakened due to the high mortality observed, with surviving organisms recorded only at the lowest zinc concentration tested (1.0 mg/L).

***Toxicological interpretation***

Zinc is widely recognized as a metal that can exert both beneficial and harmful effects on aquatic organisms depending on its concentration in the environment. At low concentrations, zinc functions as an essential

trace element and plays an important role in enzymatic activity and metabolic regulation.
However, when present in elevated concentrations, zinc may become toxic and disrupt important biological processes in aquatic organisms.
From an ecological perspective, increased mortality of *Daphnia magna* may disrupt trophic interactions, as this species represents a key link between primary producers and higher trophic levels. A decline in its population could lead to algal overgrowth and reduced water quality. Prolonged exposure to high zinc concentrations can affect growth, reproduction, and overall physiological functioning. Toxic accumulation of the metal may interfere with essential biological processes such as cellular respiration, ionic balance, and metabolic regulation, ultimately leading to organism mortality.
The results obtained in the present study are consistent with those reported by De Schamphelaere et al. (2004), who demonstrated that excessive zinc exposure can negatively affect the development and reproduction of *Daphnia magna* due to metal accumulation within the organism.
Furthermore, previous research conducted by Simionov et al. (2022) suggests that the toxicity of zinc in aquatic environments can be influenced by environmental parameters such as water alkalinity and salinity, which affect the bioavailability and uptake of metals by aquatic organisms.
The findings of the present study confirm that *Daphnia magna* populations are highly sensitive to zinc exposure. A significant reduction in organism survival was observed as zinc concentrations increased. After 32 hours of exposure, the population decreased by approximately 40% at the lowest concentration (1.0 mg/L), while reductions of approximately 80% were observed at concentrations of 2.0 mg/L and 3.0 mg/L.
At 4.0 mg/L, the population was completely eliminated, resulting in 100% mortality. At the highest concentration tested (6.0 mg/L), toxicity reached its maximum level within only 12 hours of exposure, indicating a rapid and severe toxic effect on the organisms.

## CONCLUSIONS

The present study demonstrates that *Daphnia magna* exhibits a pronounced sensitivity to zinc contamination, reinforcing its relevance as a reliable bioindicator for evaluating heavy metal pollution in freshwater environments. Experimental results clearly show that both exposure duration and zinc concentration significantly influence mortality rates in *D. magna*. Even relatively low concentrations of zinc (1.0 mg/L) produced measurable toxic effects within a short exposure period, while higher concentrations caused rapid and complete mortality.
The observed concentration-dependent toxicity confirms that zinc, although biologically essential in trace amounts, can severely disrupt physiological processes when present in elevated concentrations. The observed toxicity could be related to potential disruptions in physiological processes such as ion regulation and metabolic activity; however, these mechanisms were not directly measured and therefore remain speculative. These findings are consistent with previous ecotoxicological studies demonstrating that metal bioavailability and exposure time are critical determinants of toxic responses in aquatic invertebrates.
From an environmental perspective, the results underline the importance of monitoring zinc levels in freshwater systems, particularly in areas influenced by industrial activities, mining operations, or urban wastewater discharges. The rapid toxic response observed in *D. magna* suggests that this organism can serve as an early warning indicator of metal contamination in aquatic ecosystems.
Future research should focus on evaluating the influence of environmental parameters such as water hardness, pH, temperature, and dissolved organic matter on zinc toxicity. These factors may significantly affect metal bioavailability and consequently modify toxic responses in aquatic organisms. Additionally, further studies involving sublethal endpoints such as reproduction, growth, and behavioral changes could provide a more comprehensive understanding of long-term ecological impacts.

Overall, the findings contribute to the growing body of knowledge on metal toxicity in freshwater organisms and support the use of *Daphnia magna* in ecotoxicological monitoring and environmental risk assessment programs.

***Abstract***

*In the context of expanding environmental degradation processes, degraded lands represent potential areas for forest plantations that help reduce soil erosion, increase carbon storage and biodiversity. Research conducted in 2025 aimed to determine the carbon stock (in soil, litter, forest biomass and deadwood) and the annual carbon sequestration capacity in forest stands established on degraded lands in the Curvature Subcarpathians region. The results indicate that soil and living biomass are essential components for storing organic carbon. Soil carbon stock is relatively stable (between 70 and 120 t/ha), while carbon in living biomass shows greater variation (between 45.78 and 258.24 t/ha). The distribution of carbon in soil, litter, forest biomass and deadwood reflects the influence of environmental conditions and stand structure on carbon storage dynamics. The results demonstrate that forest plantations on degraded lands represent an effective tool for carbon storage and for mitigating the effects of climate change, capable of providing significant ecosystem and socio-economic services.*

***Key words****: carbon storage, degraded lands, forest biomass, stands.*

## INTRODUCTION

Beyond their traditional production and protective roles, forests play an important part in carbon storage and mitigation of greenhouse gas (GHG) concentrations, functions that have gained particular importance in Romania following its accession to the Kyoto Protocol (1997). In recent years, the role of forests in carbon storage and the mitigation of greenhouse gas emissions (GHG) has emerged as a global priority, as emphasized in the EU Green Book on forest protection and information (European Commission, 2010). The report highlights that European forests have the capacity to act as efficient absorbers for gases such as $CO_2$, $NH_3$ and $NO_x$ but this is not yet fully understood.. Given that substantial reductions in GHG emissions are difficult to achieve in the short term, carbon sequestration is increasingly considered as a viable long-term solution.

Forests represent the most important terrestrial ecosystem in the carbon (C) cycle and also play a key role in carbon storage (Schulze et al., 2010; Konôpka et al., 2025). Phytomass, or tree biomass, by definition, refers to the organic mass of trees (Koch, 2010), and carbon storage in tree biomass has become an effective measure for mitigating climate change (Somogyi et al., 2007). More than 80% of aboveground biomass is stored in forest ecosystems and also accounts for over 70% of the carbon present in soils (Jandl et al., 2007).

Therefore, in addition to their traditional production and protection roles, forest ecosystems contribute significantly to carbon sequestration by functioning as important carbon pools.

In the context of ongoing climate change conditions and increasing environmental degradation processes, degraded lands represent potential sites for establishing tree plantations (Constandache et al., 2023). Afforesting degraded lands can provide multiple benefits, such as biodiversity, strengthening ecosystem stability, preventing soil erosion, offering recreational opportunities, and enhancing carbon storage (Maestre & Cortina, 2004; Semwal et al., 2013; Moscatelli et al., 2017; Oprică et al., 2022). Soil organic carbon dynamics have been widely investigated across different forest ecosystems, with particular attention given to pines species (*Pinus* spp.) due to their significant ecological and economic importance (Dincă et al., 2015; Torres et al., 2021).

Pine species have often been studied both in monocultures and in mixture with other forest

species, offering valuable information on their carbon sequestration potential (Tudor et al., 2025). Studies comparing pure pine stands with mixed-species forests suggest that, while pine stands accumulate substantial amounts of carbon in their aboveground biomass, mixed forests may provide a more even distribution of carbon between belowground and aboveground components (Rodríguez de Prado et al., 2023).

Soil organic carbon is a fundamental component of forest ecosystems (Nadelhoffer, 2004; Batjes, 2014). On a global scale, soils store almost three times more carbon than the atmosphere and about 4.5 times more than the total terrestrial carbon pool in the biosphere (Lajtha et al., 2014), surpassing the combined carbon found in both the atmosphere and vegetation (Jobbágy et al., 2000). Forest soils have significant role in the global carbon cycle, containing roughly 1.5 times more carbon than the biomass of isolated standing trees (Baritz et al., 2010).

Soil carbon also representing a critical factor in the balance of greenhouse gases (GHGs), contributing to the mitigation of rising GHG emissions (Janssens et al., 2003; Jandl et al., 2007; Baritz et al., 2010). However, measuring soil organic carbon stocks over time and space is challenging due to specific local conditions and the differing results obtained in various studies, which makes harmonization of data being difficult for the development of predictive models (Grüneberg et al., 2014; Dincă et al., 2015).

Data from the National Greenhouse Gas Inventory, compiled under the United Nations Framework Convention on Climate Change (UNFCCC), indicate that Romanian forest lands absorbed an average of around 25 million tons of $CO_2$ equivalent over the last 10 years (2011-2020), accounting about 25% of the total national greenhouse gas emissions (Dragostin et al., 2022).

Given the importance of quantifying carbon dioxide fluxes from forests for greenhouse gas (GHG) inventory reporting (Braga, 2018), and considering that this represents a novel research direction in Romania, it was deemed appropriate to carry out a study focusing on degraded lands as well. The results obtained can provide an initial basis for evaluating the annual carbon dioxide pools from plantations established on degraded lands within the country.

The aim of the research was to quantify the total carbon stored in the soil, litter, aboveground biomass, and deadwood of forest plantations established on degraded lands in the Curvature Subcarpathians region.

## MATERIALS AND METHODS

The research was carried out in permanent experimental plots (PEP), located in representative situations of stands on degraded lands in three experimental perimeters (EP) in the Subcarpathian Curvature area (Figure 1): Caciu-Bârseşti (CB), Pârâul Sărat-Valea Sării (PS) located from a phytoclimatic point of view in the hilly storey of sessile oak, beech and sessile oak-beech codified as $FD_3$ and Livada-Râmnicu Sărat (LV), located in internal forest-steppe site codified as Ssd (Table 1).

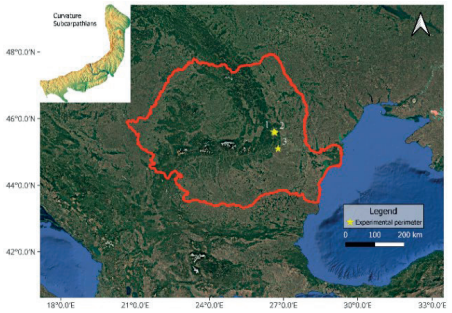

Figure 1. Location of the study (marked on the map with yellow stars: 1 - EP Caciu-Bârseşti; 2 - EP Pârâul Sărat-Valea Sării; 3 - EP Livada-Râmnicu Sărat)

The researches consisted in observations, measurements, field data collection, processing and interpretation regarding the determination of carbon stored in the soil, litter, living biomass and deadwood.

In the laboratory, soil samples were collected from soil profiles at depths of 0-10 cm, 11-20 cm, and 21-40 cm to determine organic carbon (%) and bulk density (BD, g/cm³). Litter samples consisting of dried leaves, fruits, plant residues, and twigs, were collected from each research plot over an area of 1 m² to determine organic carbon content (C%) and mass (g/m²).

To determine the amount of carbon (C) accumulated at different soil depths, the following formula was used:

$$C = SOC\ \% * BD * d * CFst$$

where: C - soil carbon stock (kg/m² × 10 = t/ha); SOC % - soil organic carbon concentration determined in the laboratory (%); BD - bulk density of the soil (kg/dm³);
d - depth or thickness of the analyzed horizon (cm); CFst - correction factor for skeletal fraction (= 1).

The organic carbon in litter (OC_L) stock was calculated as the product of litter mass and the carbon percentage (C %) determined in the laboratory.
Data collection for trees and deadwood to determine the organic carbon stored in wood, involved inventories of tree numbers by species, dendrometric characteristics of trees (DBH-diameter at the breast height, H- height) or deadwood (DBH, length and so on) and sampling of wood samples using a "Pressler" increment borer to determine wood density.
The organic carbon stored in wood (CW) was calculated by first estimating tree volume (m³) using allometric equations. To convert tree volume (m³) into biomass (t), species-specific wood density (WD) values were used, determined gravimetrically (Chave et al., 2006) based on analyses of wood samples extracted from trees of each species. The carbon stock (C, t/ha) corresponding to aboveground biomass (AGB) and deadwood biomass (DWB) was calculated according to standard recommendations (IPCC, 2003; Penman et al., 2003; Eggleston, 2006; IPCC, 2006). Depending on the species, the carbon content in wood ranges between 46% and 59% of the tree biomass (Thomas & Malczewski, 2007). The carbon content in wood (CW), whether living or dead (C_DW), was assumed to be 50% of the biomass (Innes, 2004) and was obtained by multiplying the total biomass by 0.5.

## RESULTS AND DISCUSSIONS

### Soil carbon stock

Based on the research data obtained (Table 2), it was found that the highest soil organic carbon stocks at a depth of 0-40 (20) cm ranged between 99.57-120 t/ha. In some cases, particularly on degraded lands, the total soil depth was only 20 cm. These values were recorded in Scots pine plantations mixed with black pine, aged 50-51 years, on very strongly eroded lands. The lowest values (70.96-71.76 t/ha) were recorded in deciduous plantations or in mixed pine (Scots and black pine) and deciduous stands, aged 71-73 years, on moderately to strongly eroded lands.

In the soil profile, the highest carbon content values were generally recorded in the upper 10 cm (Figure 2).

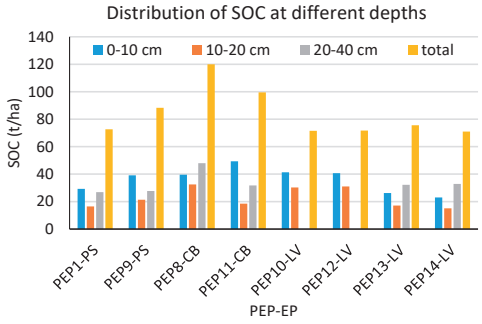

Figure 2. Distribution of soil organic carbon (SOC) stock

In the first 10 cm of the soil profile, carbon stock values ranged between 23.04 t/ha and 49.39 t/ha, whereas in the 10-20 cm layer they ranged from 15.09 t/ha to 32.48 t/ha. The minimum and maximum values by soil horizon were recorded in the same plots/stands as for total carbon stock. In a previous study conducted on eutricambosol soils (Dincă et al., 2012), the following organic carbon stocks were determined by geometric horizons: 42 t/ha (0-10 cm), 26 t/ha (10-20 cm), 33 t/ha (20-40 cm), and 40 t/ha (>40 cm), giving a total of 140 t/ha. For soils in Germany of the cambisol class, Grüneberg et al. (2014) compared periodic values of carbon stock in the mineral layer at a depth of 30 cm, finding 68.3 ± 2.2 t/ha, which is lower than the average value determined in Romania. Batjes (2002) reported that cambisol soils in central and southern Europe have a carbon stock of 69 t/ha for the first 30 cm and 118 t/ha at 100 cm depth. The same author (Batjes, 2014) determined a global carbon stock of 88 t/ha in eutricambosol soils for the first 100 cm.

Compared with values reported by the aforementioned authors, the average carbon stock in soils on degraded lands in the studied plots was 36 t/ha (0-10 cm), 23 t/ha (10-20 cm), and 33 t/ha (20-40 cm), which is lower (in the first 20 cm) or similar (20-40 cm) to those determined for eutricambosols.

According to the guidelines elaborated by ICPA (Dumitru et al., 2011), in the soils analyzed on degraded lands, carbon content in the upper 20 cm is considered good to very good (3.65-6.41%) in all pine-containing stands, and medium (3.11-3.52%) in deciduous stands (oaks). The total carbon stock (throughout the entire soil depth) is generally classified as medium in most of the analyzed cases.

## Litter carbon stock

Litter represents the organic matter on the soil surface, which, due to its characteristics, is an ecologically important component.

The determination of the total litter quantity, such as the organic carbon stock in litter for the analyzed research plots, revealed differences between plots depending on stand composition, age, and the degree of land degradation. According to the summary data (Table 3), the highest litter carbon stock (OC_L) values (12.24-13.04 t/ha) were recorded in pine stands (Scots pine or black pine) mixed with deciduous species, aged 71-73 years, on moderately to strongly eroded lands. Lower values were found in deciduous stands (4.99-7.9 t/ha) and in pine stands on very strongly to excessively eroded lands (4.72-8.60 t/ha), (Table 3).

Table 3. Organic carbon stock in litter (OC_L)

## Carbon Stock in Tree Biomass

Research indicates that carbon stock in biomass on degraded lands varies depending on stand age, species composition, stand structure, and the type of degradation. It is determined by the accumulated wood volume of the different

species, as well as by the wood density or specific gravity. For the studied plots (Table 4), in pine-containing stands, carbon stock in biomass ranged from 45.78 t/ha in a Scots pine plantation mixed with black pine, aged 50 years, on very strongly to excessively eroded land, up to 213.45 t/ha in a predominantly black pine plantation mixed with Scots pine, aged 70 years, on moderately eroded land.

In deciduous stands, biomass carbon stock was 135.44 t/ha in a late pedunculate oak (*Quercus pedunculiflora*) stand and 258.24 t/ha in a red oak (*Quercus rubra*) stand, both aged 73 years and located on moderately eroded land.

Table 4. Carbon stock in tree biomass (CW)

| | St | 669.12 | 0.67 | 4.84 | 3.24 | 1.62 |
| | **total** | | | **499.30** | **226.97** | **113.48** |
| PEP13 - LV | St.r | 600.52 | 0.60 | **860.06** | **516.48** | **258.24** |
| PEP14 - LV | St.b +Dt | 669.12 | 0.67 | **404.83** | **270.88** | **135.44** |

**Legend:** PEP - Permanent Experimental Plot; EP - Experimental Perimeter; SP - species; WD - wood density; V - volume per hectare; AGB- aboveground biomass; CW - carbon stock for living biomass of the tree; Pi - Scots pine; Pi.n - black pine; Dt - diverse hardwood species; St - common oak; St.r- red oak; St.b - greyish oak.

The results indicate that the rate of carbon accumulation in living biomass of the tree increases proportionally with wood density (WD) and unit volume (V). The exponential model used captures the nonlinear nature of carbon stock growth (Figure 3), suggesting that substantial amounts of carbon can be accumulated as tree diameter increases. Moreover, the model parameters allow efficient estimation of the carbon accumulation rate in relation to both tree diameter and species.

In comparison, in the internal forest-steppe site (EP Livada - Râmnicu Sărat), deciduous species (greyish oak - St.b; red oak - St.r) exhibit higher carbon accumulation than conifers (Scots pine - Pi; black pine - Pi.n), due to higher wood density (WD) and favorable dimensional characteristics (DBH, H), which promote greater biomass growth (Figure 3).

Distribution of soil organic carbon stock in relation to diameter at breast height (DBH) for the main species within the experimental perimeter: **a** - EP Caciu Bârseşti and EP Pârâul Sărat-Valea Sării; **b** - EP Livada-Râmnicu Sărat (**Legend**: Pi - Scots pine; Pi.n - Black pine; St.b - greyish oak; St.r - red oak)

## Carbon Stock in Deadwood

To evaluate the biomass derived from deadwood (DWB), the volume of deadwood in the analyzed plots was considered, determined according to the dimensions of the identified pieces by species, along with the average values of deadwood density ($WD_m$) determined for different decay classes (Weggler et al., 2012). These values range from 315.42 to 481.04 kg/m³ for pine species and 534.24-558.55 kg/m³ for manna ash (*Fraxinus ornus*). Scots pine (*Pinus sylvestris*) shows higher wood density and slower decay compared to black pine (*Pinus nigra*), which has lower wood densities and faster decay across the classes.

The carbon stock in deadwood (C_DW) ranges from 17-18 t/ha (Table 5), representing 16-17% of the carbon stock in living tree biomass in the analyzed plots. This is explained by the high proportion of damage (such as drying and

breakage) in pines caused by abiotic stress factors, including drought and wind.

In the analyzed experimental plots where deadwood was identified (Table 5), coniferous species (Scots pine and black pine) represent the main source of deadwood biomass, while the contribution of deciduous species (manna ash) is low, representing less than 5% of the total. This distribution reflects a forest structure dominated by pines, with deadwood accumulation primarily from these species.

The differences observed between the two analyzed plots are associated with stand composition, stand density, the history of ecosystem disturbances and the decay stage of the wood, with slightly higher carbon storage in deadwood from stands dominated by black pine.

Table 5. Carbon stock per hectare in deadwood

| PEP - EP | SP | DWB (t/ha) | C_DW (t/ha) |
|---|---|---|---|
| PEP10 - LV | Pi | 32.38 | 16.19 |
| | Mj | 1.68 | 0.84 |
| | **Total** | **34.06** | **17.03** |
| PEP12 - LV | Pi.n | 35.47 | 17.74 |
| | Mj | 0.17 | 0.09 |
| | **Total** | **35.64** | **17.83** |

**Legend**: PEP- Permanent Experimental Plot; EP -Experimental Perimeter; DWB - deadwood biomass; C_DW - Carbon stock in deadwood; Pi - Scots pine; Pi.n - black pine; Mj - manna ash.

**Total Organic Carbon Stock (Soil, Litter, Living and Dead Biomass)**

The data summarized in Figure 4 reveal considerable variations in carbon stocks across the permanent experimental plots (PEPs).

Higher total carbon values were recorded in PEPs dominated by species with high productive potential relative to environmental conditions (land degradation), such as black pine and xerophytic oaks. These results are consistent with accumulated living biomass, stand age, forest structure and vegetation conditions.

The contribution of soil carbon remains relatively stable, ranging between 70 and 120 t/ha, whereas litter carbon exhibits greater variability. The highest litter carbon stock (13.04 t/ha) was observed in well-balanced pine with deciduous mixtures of older age (PEP10-LV), likely due to more substantial accumulation of organic matter.

Experimental plots with pine stands (PEP10 and PEP12-LV) in the internal forest-steppe site (Ssd) are notable for the presence of a significant deadwood component (~17.00 t/ha), which further contributes to total carbon stock. In contrast, in other plots, deadwood is absent or insignificant, indicating either low tree mortality dynamics or rapid decomposition of deadwood.

Overall, total carbon stock is primarily determined by living biomass and soil carbon, highlighting the influence of stand composition and structure (depending on pedological conditions) on carbon storage capacity.

From the graphical analysis (Figure 4), the following characteristics emerge:

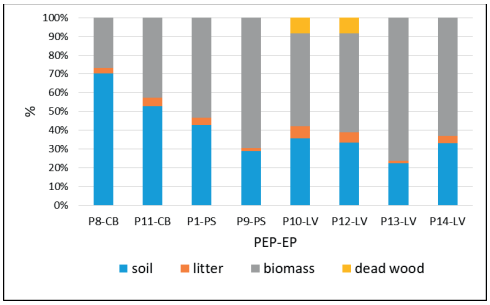

Figure 4. Carbon Stock Structure (%) by component (soil, litter, biomass, deadwood) for different experimental plots

- Pine stands store more carbon in the soil than deciduous (quercine) stands. Conversely, deciduous stands accumulate more carbon in the aboveground living biomass;
- Stands from internal forest-steppe site (Ssd), particularly pine stands, accumulate more carbon in litter and deadwood compared to stands from the hilly storey of sessile oak, beech and sessile oak-beech ($FD_3$) phytoclimatic level;
- Pines on very strongly eroded lands in the $FD_3$ level accumulate less carbon in the aboveground living biomass, with a greater proportion stored in the soil. In contrast, pine stands in internal forest-steppe site (Ssd) on moderately eroded lands accumulate more carbon in the aboveground living biomass.

## CONCLUSIONS

The determination of organic carbon stock in forest plantations on degraded lands involved quantifying carbon accumulated in the main storage compartments of forest ecosystems: soil, litter, living tree biomass and deadwood.

Higher values of soil carbon stock were determined in younger pine stands on very heavily

eroded lands, compared to older deciduous stands on moderately eroded lands. In the litter, the largest amount of carbon was accumulated by mixed pine and deciduous trees of older ages, on moderately-severely eroded lands.

The carbon stock in tree biomass varies depending on the age, composition, structure of the stands and the degree of soil degradation, being almost 5 times lower in younger stands on heavily eroded lands (45.78 t/ha) compared to those of older age and on moderately eroded lands (>200 t/ha).

The carbon stock in dead wood differs according to species and phytoclimatic zone, with higher values being recorded in pine stands in the forest-steppe zone, as a result of damage caused by abiotic factors.

Total carbon stock is generally given by living biomass and soil carbon. The proportion of carbon stored in dead wood and litter becomes significant only in certain ecological contexts, such as the case of stands in the hilly forest-steppe area.

The complexity represented by environmental conditions revealed differences between the analyzed areas, highlighting the role of stand structure and composition in carbon storage. These results highlight the importance of species diversity and forest structure for the carbon sequestration capacity of forest ecosystems.

The aim of the study to know the total carbon stock in stands on degraded lands was achieved, this being limited to stands in the Curvature Subcarpathian area with the possibility of being used in similar situations. The results obtained make an important contribution to the assessment of the carbon stock in forests and the monetization of their ecosystem services, reflecting the importance of forest ecosystems in carbon sequestration and climate change mitigation.

In the next stage, new research is needed to determine the annual carbon flux, which is a dynamic, variable and complex process in relation to the characteristics of the stands, the silvicultural works applied, the impact of damaging abiotic factors, etc.

## ACKNOWLEDGEMENTS

This research was conducted as part of the NUCLEU Research Program, Project PN 23090203, funded by the Ministry of Education and Research and implemented by the ”Marin Drăcea” National Institute for Research and Development in Forestry (INCDS).

***Abstract***

*Fine and ultrafine particulate matter (PM) is a major environmental and public health issue, particularly in densely populated urban areas exposed to significant anthropogenic emissions. This study presents an analysis of PM concentrations based on size in a high-traffic area of Galați, Romania, using the REXDAN Research Center monitoring system and the RAPID-E real-time analyzer. The continuous measurements were carried out between December 31, 2023 (10:00 p.m.) and December 31, 2025 (10:00 p.m.), covering the particle size fractions of 0.3, 0.5, 1 and 5 µm. In addition to an earlier study of daily and weekly variations, this work examines seasonal variability as well as diurnal (day/night) contrasts. Statistical and temporal analyses were used to characterize fluctuations in PM concentrations and to identify trends related to weather conditions and anthropogenic activities. The results improve the understanding of particulate dynamics in urban settings and support the development of effective air quality management strategies.*

***Key words:*** *diurnal variation, particulate matter (PM), RAPID-E monitoring system, seasonal variability, urban air quality.*

## INTRODUCTION

Atmospheric pollutants, such as particulate matter (PM), $NO_2$, $SO_2$, $CO_2$, CO and $O_3$, have a significant influence on air quality and originate from a wide range of sources and processes, including atmospheric and chemical reactions, mechanical resuspension, biological activity, industrial emissions, agricultural activities and other pollution-generating processes (Manisalidis et al., 2020; World Health Organization, 2021; European Environment Agency, 2024).

These pollutants require continuous monitoring and control due to their effects on the environment, ecosystems and, most importantly, public health. Among them, particulate matter is considered one of the most harmful air pollutants, as it can directly or indirectly affect multiple internal organs. Fine and ultrafine particles, particularly those with diameters below 1 µm, may penetrate deep into the respiratory system, enter the bloodstream and reach sensitive organs such as the heart and brain, potentially causing severe and long-term health effects (Ngoc et al., 2017; Yang et al., 2021; Garcia et al., 2023). The most vulnerable population groups include elderly people, children and individuals with pre-existing health conditions, for whom exposure to particulate matter may act as an aggravating factor (Kirešová et al., 2023; Hamanaka & Mutlu, 2025).

In urban areas, the main sources of pollutants such as $NO_2$, $SO_2$ and particulate matter are fossil fuel combustion, road traffic and industrial activities (Karagulian et al., 2015; Roșu et al., 2020; World Health Organization, 2021). However, atmospheric particles may also originate from natural sources, including desert dust, volcanic eruptions and sea salt aerosols, which are difficult or impossible to control directly (Lonati & Giugliano, 2006; Ramgolam et al., 2008; Baldacchini et al., 2019). Atmospheric particles can occur in different physical states: some are entirely liquid, others are solid, while certain particles consist of a solid core surrounded by a liquid layer. Their

chemical composition is complex and may include inorganic ions, metallic compounds, elemental carbon, organic substances and crustal materials (Wilson et al., 2002; Mugica et al., 2009; Tao et al., 2017). In addition, many atmospheric particles are hygroscopic, meaning that they can absorb atmospheric moisture and retain water within their structure.

At the European level, air quality limit values are already established for $PM_{10}$ and $PM_{2.5}$, requiring continuous monitoring and data collection. However, as previously mentioned, particles with diameters below 1 μm may have particularly important health implications. To address the need for high-resolution monitoring of fine and ultrafine airborne particles, the Rapid-E+ device, developed as an advanced version of the Rapid-E system, has become a valuable tool for monitoring airborne particles such as pollen, fungal spores and bacteria (Sikoparija et al., 2024; Bruffaerts et al., 2025). This device employs optical detection technology combined with laser illumination to measure particles within the 0.3-100 μm size range with high accuracy. Therefore, Rapid-E+ provides a rapid and reliable method for the continuous monitoring of airborne particles (Šauliene et al., 2019).

The present article represents a continuation of a previous study that investigated the variation of particulate matter during weekdays and weekends (Cristea et al., 2025). In addition to the earlier analysis of daily and weekly variability, the present work investigates seasonal variability and differences between diurnal and nocturnal intervals. Statistical and temporal analyses were applied to characterize fluctuations in suspended particle concentrations and to identify trends associated with meteorological conditions and anthropogenic activities. The results contribute to a better understanding of atmospheric particle dynamics in urban environments and provide support for the development of effective air quality monitoring and management strategies.

## MATERIALS AND METHODS

### Study area and localization

For this study, continuous measurements of suspended particle concentrations were carried out in the municipality of Galați, one of the most important urban centers in north-eastern Romania. The monitoring campaign was conducted over a two-year period, from December 31, 2023, to December 31, 2025. The measurements were performed at the REXDAN Research Infrastructure (REXDAN RI), located on George Coșbuc Boulevard no. 98, Galați, Romania (45°26'6.66"N, 28°2'14.02"E).

The monitoring site was selected because it is in an urban area characterized by intense road traffic and active urban dynamics, both of which may influence local particulate matter concentrations. In addition, the location provided suitable conditions for the simultaneous operation of the aerosol monitoring system and the meteorological station within the same research infrastructure.

To obtain relevant data on atmospheric particle concentrations and local meteorological conditions, two complementary monitoring systems were used: the Rapid-E+ aerosol monitoring device and the ACTRIS RADO Galați meteorological station. The Rapid-E+ device was installed in the courtyard of the REXDAN RI, while the meteorological station was located on the rooftop of the same facility. This configuration allowed the continuous acquisition of particle concentration data together with meteorological parameters representative of the local urban environment from Galati city. The location of the Rapid-E+ device was previously presented in Cristea et al. (2025).

The main objective of this study was to assess the temporal variability of suspended particles in an urban environment and to investigate their relationship with local atmospheric parameters.

### Equipment and data used

The particulate matter measurements were performed using the Rapid-E+ system, an advanced real-time bioaerosol sensor developed for the detection, characterization and classification of individual airborne particles. During the two-year monitoring period, the Rapid-E+ system and the ACTRIS RADO Galați meteorological station operated simultaneously, enabling the direct comparison and correlation of particle concentration data with local meteorological parameters.

The instrument uses proprietary laser-based optical technology, combining scattered light pattern analysis with fluorescence spectroscopy,

which allows the characterization of aerosols in complex atmospheric environments (Plair SA, 2025a; 2025b). The integration of GPU-based processing improves the speed of data acquisition and processing, enabling efficient real-time monitoring of ambient air (Plair SA, 2025b).

The Rapid-E+ sensor continuously detects and characterizes airborne particles with diameters ranging from 0.3 to 100 µm (Plair SA, 2025a). The raw particle counts provided by the instrument are cumulative and correspond to particles above specific size thresholds. Thus, the 0.3 µm channel represents particles between 0.3 and 100 µm, the 0.5 µm channel corresponds to particles between 0.5 and 100 µm, the 1 µm channel includes particles between 1 and 100 µm, and the 5 µm channel represents particles between 5 and 100 µm (Plair SA, 2025b). These cumulative data were subsequently used to derive size-resolved particle fractions for further analysis.

The device can operate autonomously and remotely, allowing continuous data acquisition and access to measurements from any location. Rapid-E+ is designed for the real-time monitoring of airborne biological and non-biological particles, including pollen, fungal spores and bacteria, and is therefore suitable for applications in air quality assessment, biological risk monitoring, public health studies and environmental research (Plair SA, 2025b). The main technical specifications and operational features of the instrument are described in the previous study by Cristea et al. (2025) and on the official Rapid-E+ webpage (Plair SA, 2025a).

Figure 1 shows the Rapid-E+ system installed at the REXDAN RI. The instrument is placed inside a climate-controlled protective enclosure, which reduces direct exposure to external environmental factors, while the air intake tube is positioned externally to ensure continuous sampling of ambient air.

The ACTRIS RADO Galati meteorological station was used to continuously monitor local atmospheric conditions during the study period. The station recorded meteorological data at a temporal resolution of 5 minutes, providing detailed information on short-term atmospheric variability. The monitored parameters included air temperature, relative humidity, atmospheric pressure, visibility, wind speed and wind direction.

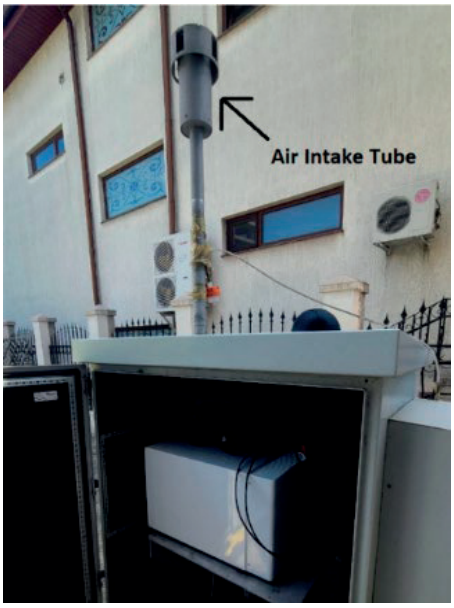

Figure 1. Rapid-E+ equipment installed at the REXDAN RI, showing the protective enclosure and the external air intake tube used for ambient air sampling of PM during 2024-2025 measurements

The meteorological data were used to evaluate the influence of local atmospheric conditions on airborne particle concentrations and size distribution. Continuous monitoring allowed the identification of temporal variations and supported the analysis of possible relationships between meteorological parameters and aerosol concentrations. The collected meteorological datasets were further used for comparison and correlation analyses with the Rapid-E+ measurements in order to assess the influence of atmospheric conditions on urban particle dynamics.

Figure 2 presents the ACTRIS RADO Galați meteorological station installed on the rooftop of the REXDAN RI. More technical specifications of the meteorological sensors can be found in the corresponding ACTRIS and Cloudnet instrument database entries (DJUG CS106, 2026; DJUG Ultrasonic Anemometer 2D, 2026; DJUG Weather Station, 2026).

Figure 2. ACTRIS RADO Galați meteorological station installed on the rooftop of the REXDAN RI used for continuous records of local atmospheric parameters for the 2024-2025 measurements

The Rapid-E+ system and the ACTRIS RADO Galați meteorological station operated simultaneously, enabling the direct comparison and correlation of particle concentration data with local meteorological parameters.

**Data processing and statistical analysis**

The analysis was based on particle number concentrations measured by the Rapid-E+ system within the 0.3-100 µm size range and on meteorological data recorded by the ACTRIS RADO Galați meteorological station. Since the Rapid-E+ instrument provides cumulative particle counts above specific diameter thresholds, a subtraction method was applied between consecutive cumulative channels to obtain size-resolved particle fractions.

Therefore, the broad measurement range was divided into four distinct size intervals: 0.3-0.5 µm, 0.5-1 µm, 1-5 µm and 5-100 µm. Each interval represents the isolated contribution of particles within the corresponding diameter range. If the instrument provides cumulative counts above each size threshold, namely $N_{\geq 0.3}$, $N_{\geq 0.5}$, $N_{\geq 1}$and $N_{\geq 5}$, the size-resolved fractions were calculated as follows:

$$N_{0.3-0.5} = N_{\geq 0.3} - N_{\geq 0.5} \quad (1)$$

$$N_{0.5-1} = N_{\geq 0.5} - N_{\geq 1} \quad (2)$$

$$N_{1-5} = N_{\geq 1} - N_{\geq 5} \quad (3)$$

$$N_{5-100} = N_{\geq 5} \quad (4)$$

where $N_{(\geq x)}$ represents the cumulative particle number concentration measured for particles with diameters greater than or equal to $x$ µm, while $N_{a-b}$ represents the particle number concentration calculated for the size interval between $a$ and $b$ µm.

All meteorological datasets were filtered and averaged to hourly values to ensure temporal compatibility with the particulate matter dataset. Pearson correlation analysis was then applied to evaluate the relationships between meteorological parameters and particle concentrations for each size fraction. The resulting correlation coefficients were represented as heatmaps to visualize the strength and direction of the relationships. The strength of the Pearson correlations was interpreted based on the absolute value of the correlation coefficient: weak correlations were considered for $|r| < 0.30$, moderate correlations for $0.30 \leq |r| < 0.50$, and strong correlations for $|r| \geq 0.50$. Positive values indicate that particle concentrations increase with the corresponding meteorological parameter, whereas negative values indicate an inverse relationship. Although statistical significance was assessed using $p$-values, only moderate and strong correlations were considered relevant for physical interpretation. Very weak correlations, even when statistically significant, were not interpreted as physically meaningful.

To assess the statistical significance of the observed correlations, a $p$-value analysis was performed for the Pearson correlation coefficients. This allowed the identification of statistically significant relationships and helped determine whether the observed correlations were unlikely to have occurred due to random variation in the dataset. Statistical significance was indicated directly on the Pearson correlation heatmaps using asterisks: $p < 0.05$, $p < 0.01$, and $p < 0.005$. Only moderate and strong correlations were considered relevant for physical interpretation.

## RESULTS AND DISCUSSIONS

The results are presented in three complementary stages to evaluate the relationships between meteorological parameters and size-resolved particulate matter fractions. First, the overall Pearson correlation

patterns were analyzed for the entire 2024-2025 monitoring period, as shown in Figure 3. Second, the dataset was divided by season to identify seasonal differences in the strength and direction of the correlations. Finally, daytime and nighttime conditions were analyzed separately to assess whether diurnal atmospheric variability influenced the relationships between meteorological parameters and particle concentrations. For each condition an explanation attempt is done based on the recorded data for weather (meteorological parameters) corellated with the PM classes. Figure 3 summarizes the overall correlations between local meteorological parameters and the size-resolved particulate matter fractions derived from the Rapid-E+ measurements. Positive correlation coefficients indicate that particle concentrations tend to increase with increasing values of the corresponding meteorological parameter, whereas negative coefficients indicate an inverse relationship.

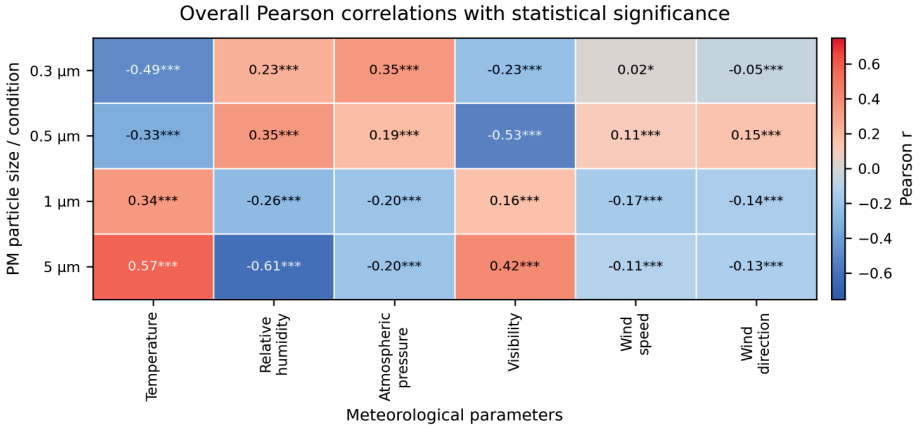

Figure 3. Overall Pearson correlation heatmap between meteorological parameters and size-resolved particulate matter fractions during the 2024-2025 monitoring period in Galați, Romania. Asterisks indicate statistical significance: ***$p < 0.005$, *$p < 0.01$, $p < 0.05$

Figure 3 shows the overall Pearson correlations between meteorological parameters and particle size fractions for the entire 2024-2025 monitoring period. The strongest negative correlation was observed between relative humidity and the 5 µm fraction (r = −0.61), suggesting that higher humidity was generally associated with lower concentrations of coarse particles, possibly due to particle removal, deposition or hygroscopic growth effects. A strong positive correlation was observed between temperature and the 5 µm fraction (r = 0.57), while visibility was negatively correlated with the 0.5 µm fraction (r = −0.53), indicating that fine particles may contribute to reduced atmospheric visibility. The 0.3 µm and 0.5 µm fractions generally showed correlation patterns opposite to those of the 1 µm and 5 µm fractions, especially for temperature, relative humidity, pressure and visibility. In contrast, wind speed and wind direction showed weak correlations with all particle fractions, suggesting a limited influence on the overall dataset. Most correlations were statistically significant, with *p*-values generally below 0.005 as presented in Figure 3 with asterisks that indicate the statistical significance: ***$p < 0.005$, *$p < 0.01$, $p < 0.05$. Similar approach was conducted for the other correlation heat maps presented in below figures.

Figure 4 highlights the seasonal variability of the relationships between meteorological parameters and particle size fractions. Stronger correlations were generally observed during winter, spring and autumn, while summer showed weaker and more variable associations, indicating that the influence of meteorological conditions on particulate matter is season dependent.

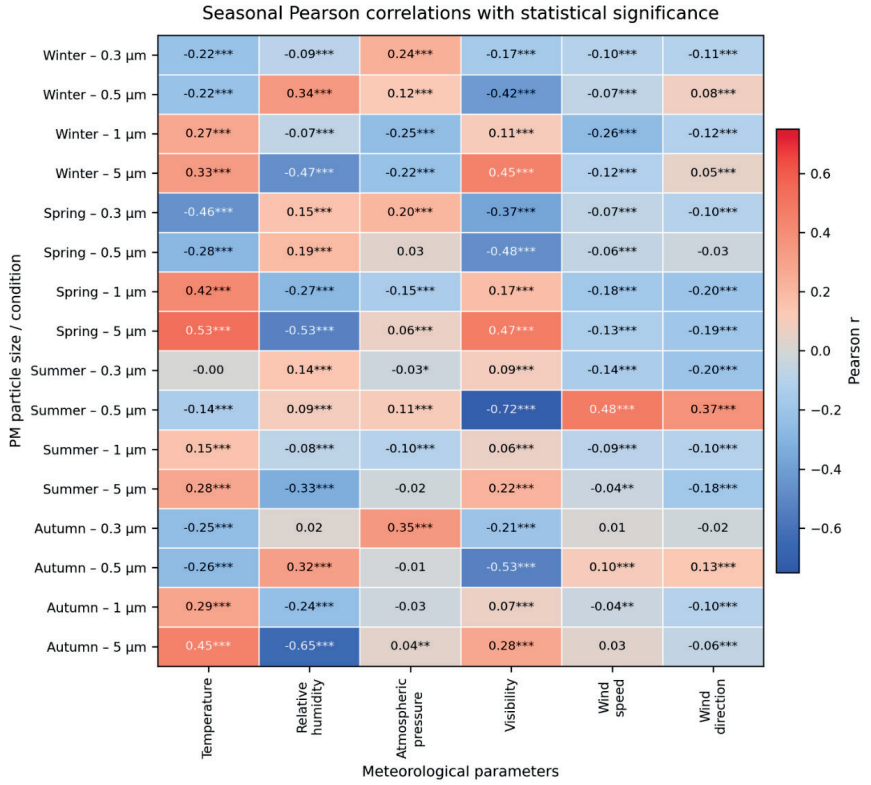

Figure 4. Seasonal variability of Pearson correlations between meteorological parameters and size-resolved particulate matter fractions during the 2024-2025 monitoring period in Galați, Romania. Asterisks indicate statistical significance: ***$p < 0.005$, *$p < 0.01$, $p < 0.05$

In winter, the 5 µm fraction showed a moderate positive correlation with visibility (r = 0.45) and a moderate negative correlation with relative humidity (r = −0.47). In spring, the strongest positive correlation was observed between temperature and the 5 µm fraction (r = 0.53), suggesting that warmer and drier conditions may favor coarse particle resuspension. During summer, most correlations were weak, except for the strong negative relationship between visibility and the 0.5 µm fraction (r = −0.72), indicating a strong optical effect of fine particles. In autumn, the 5 µm fraction was positively correlated with temperature (r = 0.45) and strongly negatively correlated with relative humidity (r = −0.65), again suggesting the sensitivity of coarse particles to humidity-related processes. The *p*-value analysis presented in Figure 4 (asterisks) indicated that most seasonal correlations were statistically significant, although weaker relationships involving pressure, wind speed and wind direction should be interpreted with caution.

Figure 5 presents the seasonal Pearson correlations calculated for daytime conditions. In winter, the 5 µm fraction showed a strong positive relationship with visibility (r = 0.52) and a moderate negative relationship with relative humidity (r = −0.43). This pattern suggests that coarse particles were less abundant under more humid daytime conditions, possibly due to humidity-related removal processes, while clearer atmospheric conditions were associated with higher coarse particle concentrations. In spring, the 5 µm fraction was moderately correlated with temperature (r = 0.48) and visibility (r = 0.45), indicating that warmer and clearer conditions may favor the presence or resuspension of coarse particles.

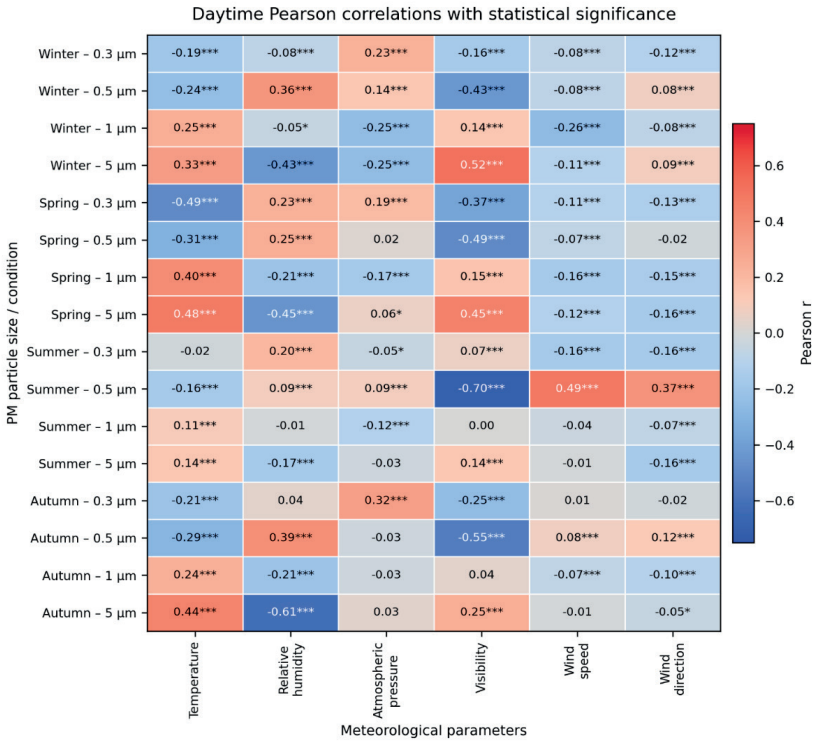

Figure 5. Daytime seasonal variability of Pearson correlations between meteorological parameters and size-resolved particulate matter fractions during the 2024–2025 monitoring period in Galați, Romania. Asterisks indicate statistical significance: ***$p < 0.005$, *$p < 0.01$, $p < 0.05$

During summer, most correlations were weak, except for the strong negative relationship between visibility and the 0.5 µm fraction (r = −0.70), suggesting that fine particles had an important role in reducing atmospheric visibility through light scattering. Moderate positive correlations were also observed between the 0.5 µm fraction and wind speed (r = 0.49), as well as wind direction (r = 0.37), which may indicate the influence of local transport processes. In autumn, the 5 µm fractions showed a moderate positive correlation with temperature (r = 0.44) and a strong negative correlation with relative humidity (r = −0.61), again indicating the sensitivity of coarse particles to humidity-related atmospheric processes.

Figure 6 shows the seasonal Pearson correlations calculated for nighttime conditions. In winter, the 5 µm fraction was moderately positively correlated with visibility (r = 0.41) and moderately negatively correlated with relative humidity (r = −0.48), showing a pattern like that observed during daytime. In spring, the 5 µm fractions showed a strong positive correlation with temperature (r = 0.53) and a strong negative correlation with relative humidity (r = −0.56), suggesting that warmer and drier nighttime conditions may favor the persistence of coarse particles.

During summer, the strongest nighttime relationship was observed between visibility and the 0.5 µm fraction (r = −0.74), indicating a strong influence of fine particles on visibility reduction. In autumn, the 5 µm fraction was strongly negatively correlated with relative humidity (r = −0.65), while temperature remained moderately positively correlated with the same fraction (r = 0.36). These results suggest that nighttime particle dynamics are strongly influenced by humidity and atmospheric stability, which may reduce vertical mixing and favor particle accumulation near the surface.

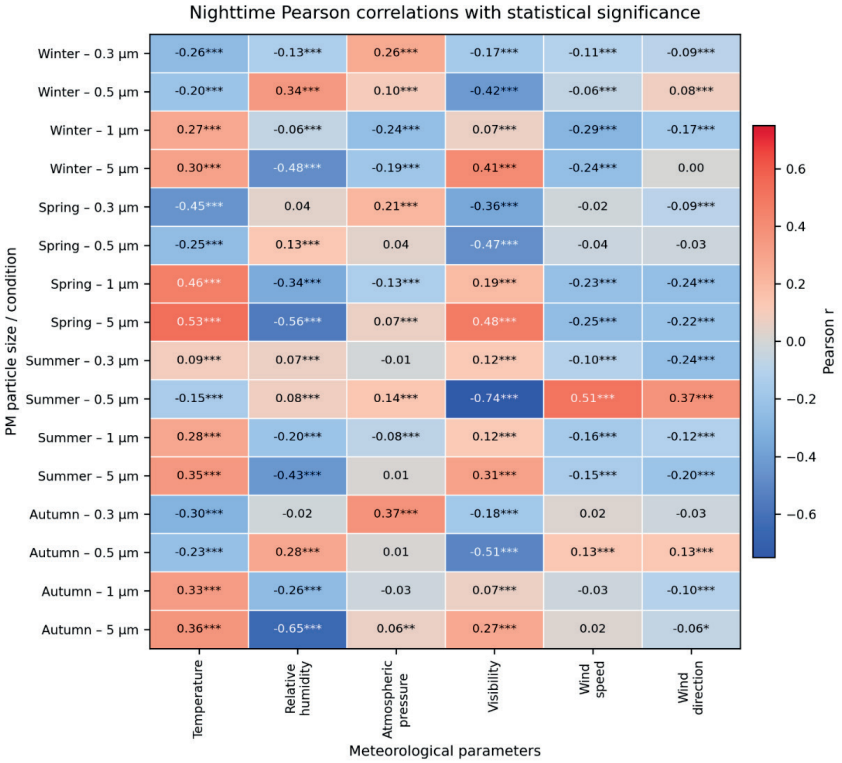

Figure 6. Nighttime seasonal variability of Pearson correlations between meteorological parameters and size-resolved particulate matter fractions during the 2024-2025 monitoring period in Galați, Romania. Asterisks indicate statistical significance: ***$p < 0.005$, *$p < 0.01$, $p < 0.05$

Overall, the daytime and nighttime patterns were broadly similar, but several correlations were slightly stronger during nighttime, particularly those involving relative humidity, visibility and the 5 µm fractions.

This may reflect more stable nocturnal atmospheric conditions, reduced dispersion and enhanced particle accumulation.

The *p*-value analysis presented in Figure 6 (asterisks) indicated that several correlations were statistically significant, especially those involving temperature, relative humidity and visibility, whereas weaker correlations involving atmospheric pressure, wind speed and wind direction should be interpreted with caution.

As shown in Table 1, most moderate and strong correlations were statistically significant, with *p*-values below 0.005.

Table 1. Main statistically significant moderate and strong correlations identified during the 2024-2025 monitoring period

| An. | Cond. | PM | Par. | r | *p*-value |
|---|---|---|---|---|---|
| Ov. | Full | 5 µm | RH | −0.61 | <0.005 |
| Ov. | Full | 5 µm | T | 0.57 | <0.005 |
| Ov. | Full | 0.5 µm | Vis. | −0.53 | <0.005 |
| Seas. | Sum. | 0.5 µm | Vis. | −0.72 | <0.005 |
| Seas. | Aut. | 5 µm | RH | −0.65 | <0.005 |
| Day | Sum. | 0.5 µm | Vis. | −0.70 | <0.005 |
| Night | Sum. | 0.5 µm | Vis. | −0.74 | <0.005 |
| Night | Spr. | 5 µm | T | 0.53 | <0.005 |
| Night | Spr. | 5 µm | RH | −0.56 | <0.005 |
| Night | Aut. | 5 µm | RH | −0.65 | <0.005 |

**Note.** An. = analysis; Cond. = condition; Ov. = overall analysis; Seas. = seasonal analysis; Day = daytime; Night = nighttime; Full = full monitoring period; Spr. = spring; Sum. = summer; Aut. = autumn; PM = particulate matter fraction; Par. = meteorological parameter; T = temperature; RH = relative humidity; Vis. = visibility. The table includes only strong correlations, defined as $|r| \geq 0.50$. The sign of r indicates the direction of the relationship.

The strongest and most consistent relationships were observed for relative humidity, temperature and visibility, especially in relation to the 0.5 µm and 5 µm particle fractions.

## CONCLUSIONS

The results of this study highlight the influence of local meteorological conditions on size-resolved particulate matter dynamics in the urban area of Galați during the 2024-2025 monitoring period. The strongest relationships were observed for temperature, relative humidity and visibility, particularly in relation to the 0.5 µm and 5 µm particle fractions. The 5 µm fraction showed strong sensitivity to humidity-related processes, with negative correlations with relative humidity, while its positive correlations with temperature suggest that warmer and drier conditions may favor the persistence or resuspension of coarse particles.

The negative correlations between visibility and the 0.5 µm fraction, especially during summer and nighttime conditions, indicate that fine particles may play an important role in reducing atmospheric visibility through light scattering. Seasonal analysis showed that the relationships between meteorological parameters and particulate matter were not constant throughout the year, with stronger correlations generally observed during winter, spring and autumn, and weaker or more variable associations during summer.

The comparison between daytime and nighttime conditions indicated broadly similar patterns, but several correlations were slightly stronger during nighttime. This suggests that more stable nocturnal atmospheric conditions, reduced vertical mixing and lower dispersion may contribute to particle accumulation near the surface. In contrast, atmospheric pressure, wind speed and wind direction showed weaker and less consistent relationships with particle concentrations and should therefore be interpreted with caution.

Overall, the combined use of the Rapid-E+ monitoring system and the ACTRIS RADO Galați meteorological station proved suitable for continuous, high-resolution investigation of urban aerosol dynamics. The results provide useful insight into the interaction between meteorological variability and particle size distribution and support the use of integrated monitoring systems for urban air quality assessment.

***Abstract***

*In recent years, a global strategy to replace petroleum-based polymers has been the development of durable, innovative and sustainable alternatives, namely biodegradable materials. This review provides a narrative synthesis of studies published between 2009 and 2026 investigating the interactions between biodegradable polymers and bacterial microbiota from aquatic environments. It focuses on major classes of biodegradable materials, including PLA, PHA, starch-based polymers and commercial blends and examines their behaviour in freshwater and marine environments. Current literature highlights that environmental conditions strongly influence biodegradation rates and microbial colonization patterns, yet the relationships between biodegradable materials and aquatic microbiomes remain insufficiently characterized. According to published studies, biodegradable polymers generally support more extensive bacterial colonization than conventional plastics, promoting higher microbial diversity and facilitating polymer breakdown into final metabolic products. This review identifies key knowledge gaps regarding the long-term environmental fate of biodegradable materials, synthesizes evidence on microbial drivers of biodegradation, and outlines implications for future research priorities, environmental monitoring strategies and the design of next-generation biomaterials.*

***Key words****: aquatic ecosystem, bacterial microbiota, biodegradable materials, biodegradation, environmental risk.*

## INTRODUCTION

Nowadays, one of the biggest global challenges is represented by plastic pollution with a negative impact on the aquatic environment and on the development of natural biological processes. Waste that reaches the environment interacts with it, leading to the release of harmful substances or altering the composition and structure of existing microbial communities, which can contribute to the reduction of water quality and increase the risk of toxicity for humans and the environment (Zlati et al., 2023). The advantages of petroleum-based plastics are represented by lower costs and better mechanical properties, but the disadvantage is their slow degradation capacity and persistence in the environment, which leads to the accumulation of pollutants (Wang et al., 2026). Specialists' forecasts estimate that by 2050, approximately 12 billion tons of plastic waste will be released into natural environments, having a negative effect on the balance of aquatic ecosystems (Amelia et al., 2025).

The solution that arouses interest and comes to meet this problem of excessive plastic use is represented by its replacement with new biodegradable materials. Materials that can be bio-based, biodegradable or can meet both characteristics at the same time are called bioplastics and are considered to be durable and sustainable substitutes that can replace conventional polymers (Lavagnolo et al., 2024). It is worth noting that the biodegradability of a material is not a universally valid characteristic for all polymers obtained from biological

sources, and not all plastic materials derived from fossil sources are non-biodegradable (Ahsan et al., 2023). For example, recent analyses confirm that bio-based polyethylene (bio-PE) remains chemically identical to conventional polyethylene and therefore non-biodegradable (Burelo et al., 2023), whereas fossil-derived polycaprolactone (PCL) continues to be recognized as a clearly biodegradable polyester in natural environments (Ntrivala et al., 2025).

Biodegradable materials are numerous and among the most commonly used are polylactic acid (PLA), polyhydroxy-alkanoates (PHA/PHB), polybutylene adipate terephthalate (PBAT) and polybutylene succinate (PBS), which are most widely used in the packaging industry due to their remarkable properties (Meyer-Cifuentes et al., 2020; Chen, 2022; Ahsan et al., 2023; Amelia et al., 2025).

However, despite their promise as sustainable alternatives, recent evidence indicates that biodegradable materials may also exhibit incomplete degradation, environmental persistence and ecological risks under natural aquatic conditions.

The biodegradation process of materials that reach the aquatic environment is usually not complete, being influenced by the bacterial communities present and their degradation capacity. An important role is also played by environmental, biological, physical and chemical factors such as water temperature, salinity, pH, dissolved oxygen concentration, ultraviolet radiation and the presence of nutrients, on which the dynamics of material degradation in the aquatic environment depend (Eronen-Rasimus et al., 2022; Jiao et al., 2026; Velayudhan et al., 2026). These environmental parameters not only influence polymer degradation rates but also shape the composition and activity of microbial taxa colonizing biodegradable materials, with certain genera becoming dominant under specific physicochemical conditions.

The microbial community of the aquatic environment has the property of colonizing biodegradable materials from the moment they are released into the aquatic environment (Amaral-Zettler et al., 2020). Microorganisms such as species belonging to the genera *Pseudomonas*, *Bacillus*, *Rhodococcus*, *Variovorax* or the families *Comamonadaceae* and *Xanthobacteraceae* have a remarkable role in the biodegradation process of biodegradable materials through the secretion of extracellular enzymes capable of cleaving polymer chains into low molecular weight compounds (Peng et al., 2022; Ahsan et al., 2023). Recent findings show that the incomplete degradation of biodegradable materials under natural conditions of aquatic ecosystems leads to their prolonged persistence and the potential emergence of unwanted ecological impacts (Zhang et al., 2025).

In this context, understanding the interactions between bacterial microbiota and biodegradable materials becomes essential for assessing the ecological impact and behaviour of these materials in the natural environment. This review synthesizes current information on the impact of aquatic bacterial communities on the degradation of biodegradable materials in both freshwater and marine environments, the dynamics of the plastisphere, a distinct microhabitat, in where bacteria, fungi and other microorganisms adhere to the surface of polymers and actively participate in biodegradation processes. This biofilm provides protection primarily for the microorganisms themselves, offering a stable micro-environment that shields them from environmental stressors while enabling enzymatic activity on the polymer surface (Amaral-Zettler et al., 2020).

The successional colonization pattern of the plastisphere - comprising early, intermediate and advanced stages - has been described in detail by Šerá et al. (2026), and is broadly consistent with observations from other studies reporting shifts from early colonizers consisting of fast-growing, surface-attaching microorganisms, including species of *Pseudomonas*, *Vibrio* and *Alteromonas* to mature biofilms enriched in taxa like *Burkholderiaceae*, *Comamonadaceae* and *Rhodococcus* (Zettler et al., 2013; Danso et al., 2019; Amaral-Zettler et al., 2020).

Although microbial colonization follows a predictable successional trajectory, the extent of biofilm development and the composition of the resulting microbial community depend strongly on the type of polymer. Compared to conventional plastics, biodegradable materials favor higher microbial diversity and biomass and more intense enzymatic activity than that formed on conventional materials such as polyethylene, polypropylene and polystyrene

(PE, PP and PS) due to their hydrophilic properties and the release of low molecular weight organic compounds (Zheng et al., 2025). Studies have shown that the average microbial biofilm biomass on biodegradable materials such as PHA and PLA was consistently, although modestly, higher (1.08-1.26 fold) than that on non-biodegradable plastics (PE, PP and PS), indicating an enhanced potential for microbial colonization and biodegradation (Peng et al., 2022; Zhang et al., 2025).

## BIODEGRADABLE MATERIALS IN AQUATIC ENVIRONMENTS

Biodegradability is defined as the ability of a material to be decomposed by microorganisms into $CO_2$, water and biomass under aerobic conditions, or into $CO_2$, $CH_4$ and biomass under anaerobic conditions. The biodegradation process generally involves three sequential stages: biodeterioration, biofragmentation and microbial assimilation, culminating in the mineralization of polymer-derived compounds (Ahsan et al., 2023; Cerbule et al., 2023).

Figure 1 shows the disintegration process of biodegradable materials, under the action of external environmental factors of degradation but also through internal mechanisms such as enzymatic cleavage.

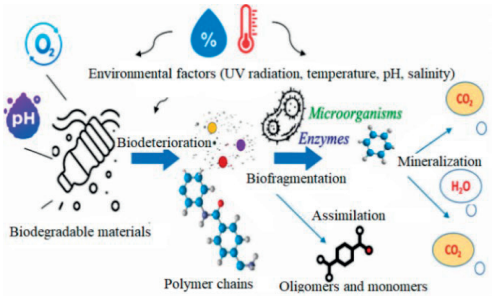

Figure 1. Schematic representation of the biodegradation process of biodegradable polymers, illustrating the sequential stages of biodeterioration, biofragmentation, microbial assimilation and final mineralization (adapted from Amelia et al., 2025)

During the biodeterioration stage, abiotic factors, including UV radiation, oxidation and temperature fluctuations, together with microbial colonization, alter the surface properties of the polymer, facilitating subsequent degradation. In the biofragmentation stage, extracellular enzymes degrade polymer chains into oligomers and monomers that can subsequently be assimilated by microorganisms. Polyesters such as PLA, PBAT and PHA are mainly hydrolysed by esterases, lipases and cutinases, whereas starch-based materials are primarily degraded by amylases. During the assimilation stage, these degradation products are utilized as carbon and energy sources and are ultimately converted into biomass and inorganic products through mineralization (Amelia et al., 2025).

Although the fundamental mechanisms of biodegradation are similar across environments, degradation generally proceeds more slowly in aquatic ecosystems than in terrestrial or industrial composting environments because of lower temperatures, reduced nutrient availability, lower microbial abundance and other environmental constraints that limit microbial activity and enzymatic degradation (Ahsan et al., 2023; Tantawi et al., 2025).

The biodegradability of different polymers therefore depends not only on environmental conditions but also on their chemical composition and physicochemical properties.

Due to their chemical composition, biodegradable materials are more hydrophilic and more susceptible to hydrolysis, which generates oligomers and monomers that can be utilized as carbon and energy sources by microorganisms (Zhang et al., 2025).

Compared with conventional polyolefins such as polyethylene (PE) and polypropylene (PP), biodegradable polyesters including PLA and PBAT exhibit greater biodegradation potential. However, their degradation rates differ substantially depending on environmental conditions, with PLA generally degrading efficiently under industrial composting conditions but much more slowly in natural freshwater and marine environments (Chen, 2022; Ahsan et al., 2023). PHB and PHA are considered among the most biodegradable materials in aquatic environments, both in freshwater and marine systems (Chen, 2022).

Starch-based materials also exhibit high biodegradation potential; however, their degradation rates vary considerably depending on starch content, polymer blending ratio, plasticizer composition, crystallinity and environmental moisture, all of which influence

microbial accessibility and enzymatic hydrolysis (Ahsan et al., 2023).

## ENVIRONMENTAL FACTORS INFLUENCING BIODEGRADATION

Biodegradation of materials in aquatic ecosystems is influenced by the complex interaction of physical, chemical and biological factors, which control both the activity of microorganisms and the properties of polymers. Indicators of biodegradation include mass loss, surface erosion, changes in molecular weight and chemical modifications of the polymer. In particular, oxidative processes generate carbonyl-containing functional groups, which increase surface polarity and consequently reduce hydrophobicity, thereby promoting microbial colonization and further biodegradation (Amelia et al., 2025).
Temperature is one of the most important factors, as low temperatures slow down microbial metabolic activity. For this reason, materials such as PLA exhibit efficient degradation under industrial composting conditions, but much slower degradation under natural conditions of aquatic ecosystems (Ahsan et al., 2023).
Oxygen levels also influence aerobic and anaerobic biodegradation processes. Under aerobic conditions, degradation mainly leads to the formation of $CO_2$, water and biomass, while anaerobic conditions favour fermentative processes and methane production. Aquatic sediments and the water-sediment interface represent areas of intense microbial activity, which favour depolymerization and mineralization processes (Amelia et al., 2025). Ultraviolet radiation promotes surface modification of polymers and increases their susceptibility to microbial colonization. Salinity, pH, and nutrient availability shape the composition of bacterial communities and the microbial succession within the plastisphere, indirectly influencing the efficiency of biodegradation (Eronen-Rasimus et al., 2022). Physico-chemical and biological parameters determine the integrity of the aquatic ecosystem, and an integrated approach to these parameters is essential for managing surface and groundwater used in agriculture, industry, and daily life (Iticescu et al., 2014).
Recent studies suggest that the variability of environmental conditions represents one of the main reasons why the biodegradation of materials labelled as “biodegradable” often remains incomplete in natural ecosystems.

## BACTERIAL COMMUNITIES IN BIODEGRADATION PROCESSES

Among the most frequently reported bacterial genera involved in the degradation of biodegradable materials in aquatic environments are *Pseudomonas*, *Bacillus*, *Rhodococcus*, *Variovorax*, *Alcaligenes*, *Comamonas*, *Shewanella*, and *Vibrio*. These microorganisms adhere to polymer surfaces and secrete extracellular enzymes capable of hydrolyzing polymer chains into oligomers and monomers that are subsequently assimilated and mineralized by the microbial community (Danso et al., 2019; Ru et al., 2020; Amelia et al., 2025).
The biodegradability of biodegradable polymers differs considerably according to polymer chemistry and environmental conditions. Polyhydroxyalkanoates (PHA), including polyhydroxybutyrate (PHB), are consistently reported among the most readily biodegradable biopolymers in aquatic environments, whereas materials such as poly(butylene succinate) (PBS) may exhibit very high degradation rates under specific sediment conditions. For example, Amelia et al. (2025) reported degradation rates approaching 100% for PBS and approximately 70% for PHB in aquatic sediments; however, these values should be interpreted as study-specific rather than universal rankings, as biodegradation strongly depends on environmental conditions, exposure time and experimental design.
The degradation of PLA has been associated with shifts in microbial community composition, including the enrichment of denitrifying bacteria that utilize lactic acid released during polymer hydrolysis as a carbon source and electron donor. Changes in the abundance of anammox bacteria have also been reported during PLA degradation, although their role appears to be linked to nitrogen cycling rather than the direct metabolism of lactic acid (Chen, 2022; Nie et al., 2022). According to studies, among bio-based materials, PHB was the most readily biodegradable, both in freshwater and in seawater (Chen, 2022). Biodegradable starch-based materials also

exhibit a significant degree of biodegradation in seawater; however, the process shows high variability, being influenced by factors such as material properties and environmental conditions (Chen, 2022; Ahsan et al., 2023).
Table 1 summarizes the principal biodegradable polymers investigated in aquatic environments, the dominant bacterial taxa associated with their degradation, the enzymes involved and the reported biodegradation outcomes, based on data compiled from the scientific literature.

Table 1. Biodegradable Materials (BM) in Aquatic Systems - Processes and Mechanisms of Their Degradation Under the Influence of the Plastisphere

| BM | Plastisphere | Effects | Reference |
|---|---|---|---|
| PLA | *Vibrionaceae*<br>*Actinomycetaceae*<br>*Flavobacteriaceae*<br>*Flavobacteriales*<br>*Planctomycetaceae* | Slow biodegradation; mass loss detected; no consistent % reported. | (Peng et al., 2022; Amelia et al., 2025) |
| PHA | *Actinomyces*<br>*Acinetobacter*<br>*Arthrobacter*<br>*Aspergillus*<br>*Bacillus*<br>*Clostridium*<br>*Comamonas*<br>*Enterobacter*<br>*Klebsiella*<br>*Variovorax*<br>*Mycobacterium*<br>*Streptomyces*<br>*Pseudomonas,*<br>*Rhodococcus* | Degradation in multiple aquatic conditions, including extreme habitats. | (Du et al., 2022; Amelia et al., 2025) |
| PHB | *Pseudomonas*<br>*Bacillus*<br>*Rhodococcus*<br>*Variovorax*<br>*Comamonas*<br>*Alcaligenes*<br>*Xanthomonas*<br>*Klebsiella*<br>*Streptomyces* | Very high; up to ~100% in sediments ~8.5% mass loss in 365 days at 25ºC. | (Du et al., 2022; Ahsan et al., 2023; Šerá et al., 2026) |
| PBS | *Actinomicete*<br>*Proteobacteria*<br>*Maribus*<br>*Neptunibacter*<br>*Bacillus* | Microbial degradation in the aquatic environment. | (Brakstad et al., 2022; Peng et al., 2022) |
| PHBH | *Acidovorax,*<br>*Undibacterium*<br>*Chitinimonas* | Signs of deterioration are visible after two weeks. | (Peng et al., 2022; Šerá et al., 2026) |
| Corn starch | *Capitella capitata* | 1.5% mass loss in 90 days at 25°C; up to 69% mass loss in 236 days. | (Ahsan et al., 2023) |

PLA - polylactic acid, PHA - polyhydroxyalkanoate, PHB - poli-3-hidroxibutirat, PHBV - poly(3-hydroxybutyrate-co-3-hydroxyvalerate), PHBH - poly(3-hydroxybutyrate-co-3-hydroxyhexanoate), PBS - poly (butylene Succinate).

Although numerous bacterial and fungal taxa have been identified on the surface of biodegradable materials, their actual contribution to polymer degradation in natural aquatic environments remains poorly understood. The presence of a microorganism in the plastisphere does not necessarily demonstrate that it actively participates in polymer depolymerization, as many taxa may simply exploit degradation products released by other microorganisms or colonize the biofilm without directly degrading the polymer. Consequently, most studies describe the composition of the microbial community rather than experimentally confirming the biodegradation potential of individual taxa under environmentally relevant conditions. This lack of functional validation represents one of the main knowledge gaps in understanding the fate of biodegradable plastics in aquatic ecosystems and highlights the need for field studies that combine microbial community analyses with measurements of enzymatic activity and polymer degradation (Peng et al., 2022).

## ECOLOGICAL LIMITATIONS AND RISKS IN NATURAL BIODEGRADATION

Although biodegradable materials represent promising alternatives to conventional polymers, they may also generate undesirable ecological effects.
Incomplete biodegradation can lead to the formation of biodegradable fragments that persist in aquatic ecosystems and interact with pollutants and living organisms (Amelia et al., 2025). These fragments can adsorb organic pollutants and trace metals from surrounding waters and subsequently release them after ingestion by aquatic organisms, thereby acting as vectors that increase contaminant transport and bioavailability within aquatic food webs (Catarci Carteny et al., 2023; Lu et al., 2024).
The plastisphere developing on biodegradable materials may also provide a favourable habitat for opportunistic and potentially pathogenic microorganisms. The close spatial organization of microbial cells within biofilms facilitates cell-to-cell interactions and horizontal gene transfer, thereby promoting the dissemination of antibiotic resistance genes (ARGs) and other mobile genetic elements.

Several opportunistic and potentially pathogenic bacteria have been reported in plastisphere biofilms associated with biodegradable materials (Amaral-Zettler et al., 2020; Zhang et al., 2023). Their occurrence and ecological significance are discussed in the following section.

These issues demonstrate that the environmental benefits of biodegradable materials cannot be assessed solely based on their biodegradation potential. A comprehensive assessment should also consider the persistence of degradation products, their interactions with contaminants and microorganisms, and their long-term ecological effects under natural environmental conditions. Addressing these knowledge gaps through long-term field studies will be essential for accurately assessing the environmental sustainability of biodegradable polymers in aquatic ecosystems.

## SUSTAINABLE WATER PURIFICATION IN AQUACULTURE

Aquaculture systems represent an increasingly important source of plastic and biodegradable polymer inputs into aquatic environments. Operational materials such as nets, ropes, feed bags, and filtration components introduce both conventional plastics and emerging biopolymers into surrounding waters, where they rapidly become colonized by microbial communities. These biofilm-covered surfaces form localized plastisphere niches, influencing nutrient cycling, pathogen proliferation, and antibiotic-resistance dynamics- all central themes of this review.

At the same time, aquaculture wastewater itself contains high nitrogen and phosphorus loads, suspended organic matter, pathogenic bacteria, antibiotic-resistant strains, and mobile resistance genes (Sun et al., 2025). These pollutants interact with plastic debris present in the system, creating complex microbial consortia that affect both water quality and the degradation pathways of plastic and biodegradable materials. For this reason, sustainable purification strategies are increasingly exploring biodegradable materials as filtration media, microbial carriers, or components of circular-economy remediation technologies.

The link between pollutant accumulation and insufficient recycling or reuse practices is well documented, particularly in systems where circular-economy principles are not implemented (Georgescu et al., 2025). As aquaculture expands, untreated wastewater discharge intensifies environmental pressures (Raza et al., 2025), reinforcing the need for purification methods that align with biodegradation processes and reduce plastisphere-associated risks.

To illustrate current directions in sustainable aquaculture remediation - including microbial consortia, advanced material-based treatments, and energy-efficient systems - Table 2 summarizes several high-efficiency purification methods and highlights their relevance for biodegradable-material applications, plastisphere management, and circular-economy integration.

Table 2. Sustainable aquaculture purification solutions with relevance to biodegradable materials and plastisphere dynamics

| Solution | Description | Effect | Relevance to biodegradable materials & plastisphere | Reference |
|---|---|---|---|---|
| Symbiotic bacteria-algae system | Nitrogen-fixing bacteria isolated from *Penaeus albus* used synergistically with *Tetraselmis suecica* microalgae to remove nutrients and suppress pathogens. | Removes >93% ammonia; reduces total N and P by 67-95% in 4 days; suppresses *Vibrio* and *Aeromonas* by 97-99%; reduces ARGs by 57.9%. | Supports microbial consortia similar to plastisphere communities, offering a model for biofilm-mediated degradation on biodegradable polymer surfaces; algae-bacteria systems can be immobilized on biopolymer carriers for circular-economy wastewater treatment. | (Sun et al., 2025) |
| Ag-ZnO/graphene composite | Photocatalytic and antimicrobial composite designed for antibiotic removal and inactivation of resistant bacteria. | Inactivates 99% *A. baumannii* and 97% *S. aureus* within 24 h; rapid antibiotic degradation and ARG reduction in both ultrapure and real wastewater. | Demonstrates how advanced materials can be integrated with biodegradable polymer matrices to create hybrid purification media; reduces microbial pressures that shape plastisphere biofilms and influence biodegradation kinetics. | (Li et al., 2025) |

| Solution | Description | Effect | Relevance to biodegradable materials & plastisphere | Reference |
|---|---|---|---|---|
| Energy-efficient electrochemical system | Floating ecological bed combined with a closed-loop microbial electrochemical system. | Enriches functional taxa (*Aeromonas*, *Stenotrophomonas*, *Dechloromonas*, *Thioalkalivibrio*, *Clostridium*, *Thermodesulfovibrio*, *Desulfobulbus*) supporting carbon and nitrogen removal and electron transfer. | Electroactive microbial communities resemble those colonizing biodegradable plastics, offering insights into electron-transfer-driven polymer degradation; floating beds can incorporate biopolymer substrates to reduce plastic pollution in aquaculture. | (Liao et al., 2025) |
| Microalgae-based purification | Microalgae added to aquaculture systems for nutrient assimilation and biomass production. | Efficient assimilation of dissolved inorganic carbon, nitrogen, and phosphorus; reduces eutrophication potential. | Microalgal biomass can be used to produce biodegradable bioplastics, linking aquaculture purification to circular-economy material loops; microalgae also colonize plastic surfaces, influencing plastisphere succession. | (Raza et al., 2025) |

## ANTIBIOTIC EFFECTS ON AQUATIC BACTERIAL COMMUNITIES AND THEIR ROLE IN PLASTISPHERE DYNAMICS

Antibiotics are widely used in aquaculture to manage bacterial infections in fish and shellfish. While they provide short-term health benefits, their excessive or prophylactic use has accelerated the emergence of antibiotic-resistant bacteria, disrupting the ecological balance of aquatic systems (Haque et al., 2024). Multiple antibiotic classes, including sulphonamides, fluoroquinolones, and macrolides, are routinely detected in effluents from livestock farms, medical facilities, and wastewater treatment plants. Their presence in aquatic environments alters the structure of bacterial communities, often promoting shifts toward resistant taxa (Zhang et al., 2023).

Freshwater case studies illustrate the scale of this issue: in the upper Danube River, approximately one-third of microorganisms sampled were resistant to one or two antibiotic classes, and over 10% exhibited multi-resistance. Similarly, Swedish data show that *E. coli* populations in rivers and clinical settings share comparable resistance profiles (Leopold et al., 2024). Although these examples come from European freshwater systems, they reflect broader global patterns observed across marine, estuarine, and freshwater environments, where antibiotic contamination shapes microbial community composition and resistance dynamics.

A critical connection to the present review is the role of antibiotics in plastisphere formation. Both conventional plastics and biodegradable materials rapidly develop biofilms when submerged in aquatic environments. Antibiotic exposure influences these biofilms by selecting for resistant strains, modifying microbial succession, and enhancing horizontal gene transfer. As a result, plastisphere biofilms can act as reservoirs and vectors for ARGs, facilitating their spread across ecosystems. This has direct implications for the environmental safety of biodegradable materials, whose degradation depends on microbial activity that may be altered by antibiotic pressure.

In modern aquaculture, intensive antibiotic use also promotes the formation of persistent biofilms. These three-dimensional microbial structures, embedded in an extracellular matrix, exhibit elevated tolerance to antibiotics, disinfectants, and environmental stressors (Haque et al., 2024).

Because plastics and bioplastics serve as ideal substrates for biofilm attachment, antibiotic-selected communities can colonize polymer surfaces, influencing biodegradation rates, polymer fragmentation, and the ecological behaviour of biodegradable materials.

Certain taxa, such as ε-proteobacteria, are frequently associated with environments experiencing high contaminant pressure. Their correlation with antibiotic resistance arises from metabolic versatility, stress-response pathways, and efficient horizontal gene transfer mechanisms (Barra Caracciolo et al., 2019). These traits also make ε-proteobacteria relevant to plastisphere studies, where biofilm-associated microbes encounter complex mixtures of

pollutants, including antibiotics, microplastics, and biodegradable polymer fragments.

The spread of antibiotic resistance in water bodies is largely driven by anthropogenic pollution-wastewater discharges, agricultural runoff, manure applications, and hospital effluents (Callejas et al., 2024). These same pressures influence plastisphere formation and microbial colonization on biodegradable materials.

Understanding antibiotic impacts is therefore essential for evaluating how biodegradable polymers interact with microbial communities, how ARGs propagate within plastisphere biofilms, and how environmental contamination affects biodegradation efficiency and ecological risk.

## PATHOGENIC BACTERIA AND AQUATIC BACTERIAL COMMUNITIES

While previous sections discussed the role of bacterial communities in biodegradation and the ecological risks associated with plastisphere formation, it is equally important to consider the occurrence of pathogenic bacteria within these microbial assemblages. Beyond their contribution to polymer degradation, plastisphere-associated biofilms may provide suitable habitats for opportunistic pathogens, with potential consequences for aquatic ecosystem functioning, aquaculture and public health.

Therefore, this section focuses on representative pathogenic bacteria found in aquatic environments and discusses how their interactions with native bacterial communities and biodegradable-material associated biofilms may influence their persistence and dissemination.

Although bacteria play a major role in maintaining the stability of aquatic environments, the evolution of pathogens has become a threat to the aquatic environment, causing infections if they reach the human body. In aquatic environments, fecal indicator bacteria, particularly *Escherichia coli* and intestinal enterococci, are widely used to assess fecal contamination and associated public health risks. These microorganisms are routinely monitored because their presence reflects recent fecal pollution and the potential occurrence of enteric pathogens. In the context of biodegradable materials, monitoring these indicator bacteria is also relevant for evaluating whether plastisphere biofilms associated with biodegradable polymers provide suitable habitats for fecal-associated microorganisms and other opportunistic pathogens (Li et al., 2021; Schneier et al., 2024).

Besides serving as indicators of fecal contamination, the presence of fecal indicator bacteria on the surfaces of biodegradable materials can give valuable information about the potential of these materials to act as carriers for fecal-associated microorganisms.

Another relevant pathogen is *Salmonella enterica* which can enter aquatic environment through sewage discharges, urban and agricultural runoff and animal waste. Once introduced, it can persist for extended periods in soil and surface water contributing to diseases such as typhoid fever and gastroenteritis. At the same time, these pathogens also interact with the bacterial community, often competing for resources. High bacterial diversity generally inhibits pathogenic species through competitive exclusion, whereas depleted bacterial communities weaken this antagonistic effect, facilitating pathogen spread (Díaz et al., 2024).

Studies have identified various potential pathogens, including *Vibrio*, *Acinetobacter*, *Aeromonas*, *Klebsiella*, *Legionella*, *Arcobacter*, and members of the Campylobacteraceae, colonizing plastisphere biofilms on plastic materials, including biodegradable polymers, in marine and freshwater ecosystems worldwide.

Among these, *Vibrio* species are of particular concern because they can cause diseases in aquatic organisms and humans (Amaral-Zettler et al., 2020; Zhang et al., 2023).

Lactococcosis is caused by *Lactococcus garvieae*, an emerging disease that affects many fish species and causes large economic losses in both marine and freshwater aquaculture particularly in summer, when temperatures above approximately 15-18°C favor bacterial proliferation and disease transmission (Callejas et al., 2024; Khalil et al., 2024; Vendrell et al., 2006). Higher temperatures boost microbial growth and biofilm formation on submerged polymers surfaces showing why it's important to study plastisphere-related microbial communities in conditions that match the

environment. *Bacillus cereus* has a wide spectrum of phenotypic traits, can be a source of contamination in food processing chains, representing a severe risk to human health (Callejas et al., 2024).

As discussed in earlier sections on antibiotic effects and aquaculture wastewater, antibiotic contamination, nutrient loads, and pollutant stressors further shape plastisphere communities, often selecting resistant or opportunistic pathogens. Biodegradable materials, while designed to reduce long-term pollution, also undergo biofilm-mediated degradation, meaning their ecological behavior is tightly coupled to the composition and stability of surrounding microbial communities. Therefore, interactions between pathogens and aquatic bacterial communities highlight the need for approaches that minimize the risks of contaminants in water while preserving the native microbial diversity that supports stability of aquatic ecosystems.

Understanding these relationships is imperative because diverse and functionally balanced microbial communities provide an important ecological barrier against pathogen establishment, whereas disturbances in community structure may facilitate pathogen persistence and the dissemination of antibiotic resistance genes.

In this context, biodegradable materials should not be evaluated solely according to their degradation rates, but also according to their influence on plastisphere development and microbial community assembly. Determining whether plastisphere formation supports native microbial functions or promotes the enrichment of opportunistic and pathogenic microorganisms remains a major research challenge that requires long-term investigations under environmentally relevant conditions.

## KNOWLEDGE GAPS AND FUTURE DIRECTIONS

The dynamics of the plastisphere and the succession of microbial communities associated with biodegradable materials remain insufficiently investigated, even though numerous studies have identified dominant bacterial taxa involved in polymer colonization and degradation (Peng et al., 2022). As discussed throughout this review, particularly in the sections addressing microbial colonization, bacterial biodegradation processes and ecological risks, understanding the functional role of these microbial communities under natural environmental conditions remains one of the major challenges for predicting the environmental fate of biodegradable materials.

### Methodological gaps

Research efforts are directed toward improving the end-of-life biodegradation capacity of commercially available biomass-derived materials such as polylactic acid, polybutylene succinate, and polyhydroxyalkanoates. Although interest in biodegradable materials is steadily increasing, many aspects of their long-term behaviour remain poorly understood, as most studies are conducted under controlled laboratory conditions, using constant temperatures, simplified microbial communities, and relatively short experimental periods that do not reflect the complexity of natural ecosystems (Amaral-Zettler et al., 2020). This results in biodegradation rates that vary considerably between studies and are difficult to compare.

### Climate change and environmental variability

Climate change is expected to modify several environmental drivers that regulate biodegradation processes, including increasing water temperature, altered salinity caused by droughts or extreme precipitation, antibiotic-resistant profile and changes in nutrient availability (Banciu et al., 2021). Rising temperatures speed up microbial metabolism, but they can lower oxygen levels and change how biodegradation happens.

The behaviour and resistance of pollutants, interactions with the biological environment and biodegradation processes are affected by climate change phenomena and the studies carried out must consider these aspects (Georgescu et al., 2025).

**Future research priorities**

Recent studies demonstrate that the biodegradation of biodegradable materials does not necessarily eliminate ecological risks. Incomplete degradation may result in persistent polymer fragments that interact with contaminants, support plastisphere development and provide suitable habitats for opportunistic microorganisms, including bacteria carrying antibiotic resistance genes. Although biodegradable materials represent a promising alternative to conventional plastics, future research should prioritize the development of formulations with improved biodegradation performance under environmentally relevant conditions while minimizing unintended ecological effects. In parallel, advances in waste management systems and standardized environmental biodegradation assessment protocols will be essential to ensure their sustainable application (Dorofte et al., 2025).

In addition, future studies should focus on prioritize long-term field experiments on natural aquatic environments, standardized biodegradation protocols across freshwater, estuarine and marine ecosystems, and the integration of molecular techniques with measurements of enzymatic activity and polymer mineralization. Attention should be given to identifying the functional roles of dominant plastisphere microorganisms, evaluating their biodegradation potential under natural conditions and assessing the long-term ecological consequences of biodegradable polymer degradation.

These aspects highlight the need to evaluate biodegradability not only from the perspective of physical material breakdown but also in terms of the long-term ecological impact on microbiota and the functioning of aquatic ecosystems.

## CONCLUSIONS

Given their increasing use, understanding the biodegradation pathways and environmental fate of biodegradable materials in aquatic systems is essential for developing effective waste-management strategies and minimizing ecological impacts.

Although biodegradable materials represent promising alternatives to petroleum-based polymers, their behaviour in aquatic environments is considerably more complex than their performance under controlled laboratory conditions. Consequently, biodegradability must be evaluated not only through physical disintegration but also through long-term ecological and microbiological effects.

Current evidence indicates that biodegradation efficiency is strongly shaped by microbial community structure and by the physicochemical characteristics of aquatic habitats.

This review highlights that the biodegradation of these materials is primarily governed by the composition, succession and functional activity of plastisphere-associated microbial communities. While most microorganisms contribute to polymer colonization and degradation, plastisphere development may also facilitate the persistence of opportunistic pathogens and antibiotic resistance genes under specific environmental conditions, emphasizing the need to evaluate both biodegradation efficiency and ecological safety.

The succession of plastisphere communities represents one of the key mechanisms controlling the environmental fate of biodegradable materials. Early colonizers initiate biofilm formation, whereas later microbial communities contribute to polymer depolymerization, mineralization and nutrient cycling. Understanding these microbial successions is therefore essential for predicting biodegradation efficiency under natural aquatic conditions.

Furthermore, the increasing leakage of biodegradable materials into natural environments, combined with anthropogenic pollution and antibiotic residues, contributes to shifts in microbial communities and the spread of antibiotic resistance.

Overall, these findings underscore the need for integrated assessments that consider microbial dynamics, environmental conditions, and pollutant interactions to accurately evaluate the real-world biodegradation of these materials in aquatic ecosystems.

In conclusion, biodegradable materials should not be evaluated solely according to their physical disintegration or laboratory-derived biodegradation rates. Their environmental

performance depends on complex interactions between polymer properties, plastisphere succession, microbial community composition and environmental conditions. Consequently, assessing the sustainability of biodegradable materials requires integrating biodegradation efficiency with long-term ecological effects on microbial diversity, ecosystem functioning and the potential development of ecological risks under natural aquatic conditions.

***Abstract***

*Anthropogenic pollution is becoming increasingly widespread in ecosystems worldwide. In recent years, we have observed negative consequences for many species, particularly birds. This review focuses on the impacts of common anthropogenic pollutants on aquatic birds, detailing a range of effects from direct mortality to sublethal impacts, including reduced fitness. There are interactions between these pollutants that can amplify their effects beyond those of each pollutant individually. Despite this, research on these interactions is still limited and requires more targeted investigation. As threats to avian species and anthropogenic pollution continue to rise, implementing mitigation measures is crucial for the preservation of these birds. This paper aims to evaluate specialized scientific articles, highlight, and understand the threats that bird species face.*

***Key words****: environmental contamination, pollutants interactions, toxic effects, wild bird.*

## INTRODUCTION

Biodiversity is at a critically declining level and its current rates are much more frequent than the average natural extinction rate (Barnosky et al., 2011; Tittensor et al., 2014). We have seen the shocking loss of two-thirds of global mammals, birds, fish, reptiles, and insects (Hoffmann et al., 2010), and this severe drop in biodiversity can be attributed to extreme human activity that stresses the species (Hallmann et al., 2017). Waterfowl occupy significant spaces in freshwater and marine ecosystems and serve as sentinels of environmental wellbeing but have been under unprecedented threat from anthropogenic pollution (Degernes, 2008). These avian species are totally reliant on aquatic environments for survival, reproduction and migration, thus their populations and functioning within ecosystems are subject to many environmental stressors (Zhang & Ma, 2011). Numerous studies show that waterbirds serve as valuable bioindicators of the health of aquatic ecosystems, where population dynamics and physiological conditions may serve as biomarkers of the quality of habitats (Arya et al., 2025). The accelerated rate of industrialization, urbanization, and increasing crop cultivation has caused the pollution of water bodies with pollutants such as heavy metals, organic micropollutants, persistent organic pollutants (POPs), microplastics and pharmaceutical substances (Liu et al., 2024; Swarup & Patra 2005). These pollutants do not occur in isolation, but work synergistically to create intricate ecotoxicological systems that challenge the adaptations of waterbird populations at a global scale (Liu et al., 2024). But rising environmental pollutants in aquatic environments are causing serious risks to their health, behavior, and survival. Pollutants, heavy metals, oil spills, plastics, pesticides and industrial waste can accumulate and they enter the food chain, and in the process, they reach birds at the top. Such contaminants interfere with the biologic systems, limit reproduction and disturb the physical and adaptive behaviour of aquatic birds (Shahid et al., 2021). The effects of these pollutants are crucial for the design of conservation measures as well as biodiversity conservation in aquatic regions (Pandiyan et al., 2023; Arya et al., 2025). It is an alarming decline in bird populations associated with environmental pollution, and

these include climate change, loss of habitat fragmentation, invasive species' invasion, spread of pathogenic agents and quality compromise due to pollution. We must raise awareness of these problems to safeguard our avian wildlife and the fragile environment we live (Maxwell et al., 2016; Ceballos et al., 2017). Thanks to their mobility, as well as important roles in many interrelated ecosystem processes, birds are vital to ecosystem functioning and resilience (Whelan et al., 2008; Wenny et al., 2011). They are able to supply all four kinds of ecosystem services: provisioning, regulating, cultural, and supporting (Whelan et al., 2008). Unfortunately, one of the crucial contributions that birds represent to ecosystem health is overlooked. The benefits we gain from bird populations are often at least indirect and may support and manage other processes that promote human health in general (e.g. seed transfer, nutrient cycling, pest control, regulation, ecosystem engineers). Some birds even aid in plant pollination (Wenny et al., 2011). Even though some bird species may not seem particularly charming, they still provide vital ecosystem services. Birds provide various services that benefit human health and well-being. They are a source of nutrition, and their feathers have historically been used for insulation and bedding (FAOSTAT, 2019). Numerous bird species hold significant cultural importance, reflected in the rapidly growing industries of birdwatching and hunting, which play a vital role in the economies of various regions (Mustin et al., 2011; Carver, 2013; Ma et al., 2013; Kronenberg, 2014; Richard et al., 2021).

## MATERIALS AND METHODS

This paper offers a brief review of the literature on the effects of common anthropogenic pollutants on aquatic birds, focusing on stress and pollution-related impacts, the search was conducted using the Web of Science database, Research Gate. Research papers that were freely accessible were utilized; for those that were not available for free, requests were made directly to the authors to obtain their work. The methodology involved a critical analysis of the existing literature and was conducted on 12 January 2026. The search query included specific keywords or a combination of terms related to birds and particular types of pollutants found in the title or abstract (pollutants, wild bird, toxic effects, water pollutants, etc). This initial search yielded over 80 records; after the screening process, studies that did not align with the objectives of the present research were excluded.

## RESULTS AND DISCUSSIONS

Pollutants are those substances introduced into the environment that might lead to damages or disruptions in the natural balance of ecosystems, human health and nature. These chemicals can be natural (such as volcanic ash) or man-made (like pollution from industry, plastics, or pesticides) (Manisalidis et al., 2020). The pollution issue is one of the more prevalent worldwide problems, however, over the last century more industrialisation, urbanisation and unsustainable consumption habits made it very high due to which it is one of the most urgent global issues (Borah et al., 2020). Ecologically, it involves pollutants disrupting ecosystems, devastating biodiversity and causing acid rain, eutrophication and warming world-wide (EEA, 2021). Many birds have exposure to various pollutants simultaneously, and each pollutant category, e.g., various chemicals can contain various compounds contaminated, as well as natural stressors driving multi-component interactions (Grace et al., 2024; Wang et al., 2024). Collectively and separately, these pollutants are likely to be contributing to the population decline. There is still a lack of understanding on how species could vary in their susceptibility, and combined pollution overall effects. It is important to examine the additive effects of pollutants which often coexist in the same place and period (Wang et al., 2024). To increase our understanding of environment effects, we need to assess joint effects of pollutants of the same dimensions with comparable spatial and temporal scales. Moreover, by taking the time complexity of a lot of pollutants in realistic asynchronous scenarios into account, we can provide even better estimates for their cumulative effects (Roşu et al., 2024). It is critical to establish clear insights for the effective pollution

management and policy formulation (Jackson et al., 2021). Pollutants are categorized by the medium they contaminate - air, water, soil - or by their nature, like chemical, biological or physical agents. The most researched and dangerous are air pollutants (e.g., particulate matter, nitrogen oxides, sulphur dioxide, ozone), water pollutants (e.g., heavy metals, nitrates, phosphates, organic compounds), and soil pollutants (e.g., pesticides, persistent organic pollutants, industrial waste). Other categories in this sense are noise, light, and thermal (World Health Organization, 2024). Air pollutants result from burning fossil fuels (for vehicles, power plants, industrial processes), burning biomass, burning waste as if it were human activity, and also the burning of natural sources such as volcanic eruptions or forest fires. The main air pollutants with global health implications include $PM_{25}$ (fine particles), nitrogen dioxide ($NO_2$), sulphur dioxide ($SO_2$), carbon monoxide (CO), and ozone ($O_3$) (World Health Organization, 2023; Nathanson, 2025). In addition, indoor air pollution is of utmost importance, particularly in developing countries where solid biomass or coal are employed as a cooking & heating equipment in poorly ventilated areas (Bilal et al., 2021). Water contamination from either point sources (industrial effluents, wastewater discharges) or non-point sources (agricultural runoff carrying fertilizers, pesticides, and sediments). Heavy metals including lead, mercury, and arsenic, and organic pollutants, such as polychlorinated biphenyls (PCBs) and pharmaceuticals, provide long-term threats to aquatic ecosystems. Soil pollution via deposition of air pollutants, industrial or mining waste runoff, persistent pesticide use, heavy metals accumulation (Johnson et al., 2021). Noise pollution (non-chemical) is a pollutant in that it interferes with human well-being, wildlife behaviour, and ecosystem function. Sources can be traffic and commerce, construction, and urban infrastructures (Goines et al., 2007). Pollutants can affect air quality, biodiversity, ecosystem services and biogeochemical cycles. Acid rain (from $SO_2$ and $NO_x$) can, for instance, degrade forest soils and aquatic ecosystems. Eutrophication in lakes and coastal areas caused by nutrient runoff with nitrogen and phosphorus is one of the most common causes of eutrophication, which also leads to algal blooms, oxygen depletion and mass mortality of fish. Organics and heavy metals accumulate and bioaccumulate in food webs, becoming bio-challenging for both top predators and humans (Lovett et al., 2009; Richard et al., 2021). Common pollutants and ways to be exposed. Bioaccumulation / biomagnification. Aquatic pollution among species represents a serious global biodiversity threat, with waterbirds being one of the organisms most vulnerable to the effects of the compounded impact of chemical pollutants. Birds are key indicators of ecosystem health and pollution levels that capture their ecosystem functioning through their position in food chains, feeding behaviour, and close relationship with aquatic ecosystems (Burger & Gochfeld, 2004; Egwumah et al., 2017). Bioaccumulation and biomagnification are two important concepts in defining the impact of pollutants toward these organisms (Richard et al., 2021). Bioaccumulation is the gradual accumulation of toxins within an individual's body via the ingestion of water, food or direct contact with chronic chemicals. Biomagnification, in contrast, is the upward trend in the concentrations of pollutants as they are transmitted from one trophic level to another, resulting in elevated concentrations of pollutants in predators often birds that are piscivorous or omnivorous (Richard et al., 2021). The bioaccumulation process is influenced by the chemical characteristics of the pollutants, the physiology of the organisms and the environment. Substances with high persistence (POP - persistent organic pollutants) and low solubility in water, combined with that they are highly lipophilic tend to be most preferentially deposited in the tissues of organisms (Elliott & Bishop, 2011). Biomagnification is the process whereby pollutants increase in concentration from trophic level to trophic level. In this way, a contaminant may be found in low concentrations in water or phytoplankton but reach toxic levels in organisms at the top of the food chain, such as piscivorous waterfowl (e.g., gulls, cormorants, pelicans, or fish-eating birds of prey) (Furness, 1993). Bioaccumulation and biomagnification are essential processes in understanding pollutants' effect on aquatic

birds. At the top of food chains, these birds accumulate toxins in concentrations that are highly toxic and contribute to severe health conditions, declining populations as well as ecological chaos. Historical examples, as those from DDT or PCBs, illustrate both the weak point in aquatic ecosystems and their ability to rejuvenate with the control of pollution sources. Long term impact of emerging pollutants on biodiversity requires effective monitoring, stringent environmental policies, and active community participation (Anderson et al., 1975). Waterbirds are extremely susceptible to being contaminated because they depend on water resources and wetlands, according to researchers. Bottom-feeding and consuming sediment expose them to pollutants (Beyer et al., 2008; Veríssimo et al., 2025). Sediments from aqueous sources collect heavy metals, organic pollutants, and debris that can also persist in the digestive tracts of waterbirds for extended periods (Beyer et al., 2008; Veríssimo et al., 2025). Diverse bioavailability of these contaminants is influenced by sediment chemistry and pH. Exposure of bioaccumulate sediments may influence physiology, reproductive fitness, behaviour and population dynamics (Elliott & Bishop, 2011). Sources of pollution in water and soil include industrial effluents such as heavy metals (Hg, Pb, Cd), petroleum hydrocarbons, persistent organic pollutants (POPs), and industrial solvents. These pollutants arise from various activities related to industrialization, leading to significant impacts on both water and soil quality. Accidental leaks and overflows can result in irreversible contamination, which can have lasting effects on aquatic organisms that depend on these environments (Ding, 2025). Ascensive farming practices lead to diffuse pollution from excessive use of fertilizers and pesticides. Chemicals such as neonicotinoids, glyphosate, and nitrogen compounds are washed into wetlands by rainfall, disrupting ecosystem processes (Wania & Mackay, 1996). Poorly upgraded treatment plants release toxic substances from rivers to the environment as microplastics, pharmaceuticals, and detergents. These chemicals cause ecological stress and negatively impact those organisms that are exposed to the contaminants (EPA, 2019). Oceans transport sector, oil pollution and waterfowl impacts are negative and affect water birds via water pollution, changes in plumage and functional impairment (Burger & Elbin, 2015). In recent years, human pollution has seriously compromised waterfowl populations, with some species being threatened by extinction. Past DDT-induced eggshell thinning has been preventing reproduction, though populations started bouncing back after the pesticide was banned. In order to save waterfowl, we need to limit pollution and minimize toxic chemicals, recycle well, minimize oil spills, and protect wetlands. Environmental education is an essential element in creating sustainable and responsible living in nature (Anderson et al, 1975; Heinz & Hoffman, 2003; Burger & Elbin, 2015). Pollution negatively affects waterbird populations, leading to declines in most species found in polluted estuaries, rivers, and coastal areas (Luo et al., 2024). Migratory waterbird declines are associated with polluted staging habitats, indicating that pollution in specific habitats can impact species that have wide geographic ranges (Luo et al., 2024). Protected areas can provide conservation benefits, yet their effectiveness at protecting waterbirds from pollution is variable and frequently inadequate. Well-managed areas with habitat restoration and pollution control can enhance waterbird populations, however, few have proper infrastructure to monitor and remedy pollution (Gaget et al., 2021). Long-term monitoring, using combined conventional biomonitoring and advanced methods such as biomarker analysis, is vital to detect pollution effects on populations at an early stage (Gaget et al., 2021). In order to make relevant comparison by region and time, standardized methods for contaminant analysis and effects-based monitoring are required. Although pollutant concentrations of conventional pollutants decrease, recovery of waterfowl populations is incomplete. There are instances in which some populations have become better stabilized, although researchers attribute partial recovery to changes to ecosystem structure (i.e., changes in prey fish composition), invasive species, climate change and interactions with recovering predator populations. These findings reaffirm that without other anthropogenic stressors, pollution

abatement alone is insufficient to restore population levels to historical levels or ecosystem function (Breton et al., 2008).

## CONCLUSIONS

The research reviewed here conclusively demonstrates that environmental pollutants pose major threats to waterfowl populations globally. Lead, mercury, organochlorine pesticides, PCBs, dioxin-like compounds, PFASs, and plastic debris all have documented adverse effects on species reproduction, immune function, behaviour, and survival. These effects have caused severe population declines in some species and geographic regions, particularly in areas with traditional contamination or continuing high levels of pollution. The coming decades present both challenges and opportunities for waterfowl conservation in the context of pollution. On the one hand, emerging pollutants, including PFASs and microplastics, threaten to create new waves of environmental contamination that require regulatory response and remediation efforts. On the other hand, the growing scientific understanding of pollutant toxicology and mechanisms of action allows for the development of increasingly sophisticated strategies for pollution prevention, remediation, and biomonitoring.

Future research should utilize integrative approaches that examine multiple stressors simultaneously, assess the effects of mixtures of pollutants rather than the toxicity of a single compound, and link molecular and physiological biomarkers to population-level outcomes. In addition, because water birds are inherently adaptable and evolving species, research should investigate the potential for rapid genetic and phenotypic adaptation to polluted environments, taking into account the adaptive costs of such adaptation. Only through continued scientific investigation, coupled with aggressive pollution prevention and remediation efforts, can waterfowl populations be recovered and conserved.

***Abstract***

*The classic transfer factor formula, widely used in studies dedicated to heavy metal mobility in the soil-plant system, represents a direct ratio between the metal concentration in the plant and that in the soil. Although valuable for general comparisons and for describing their behaviour in the environment, this formula does not allow for an adequate separation between the actual forms of mobility, the toxicological characteristics of each metal, and strict reporting to the limits regulated by the Codex Alimentarius. In this context, the paper proposes the Assimilated Mobility Transfer Factor (AMTF), an extended, integrative formula that includes the toxicity coefficient, the mobile fraction in the soil, the actual level of accumulation in fruit, and the food regulations in force. Applying the AMTF to data sets from historically polluted areas, such as the Baia Mare Mining Basin, highlights consistent differences between the mobility of heavy metals and their actual accumulation in fruit, discrepancies that the classic ratio cannot capture. The new formula proposed for the AMTF provides an adequate, modern tool for current food safety and ecotoxicological risk studies.*

***Key words****: food safety, heavy metals, mobile fraction, soil-plant transfer, toxicity coefficient.*

## INTRODUCTION

Heavy metals represent a group of elements exhibiting relatively high density and marked toxicity even at low concentrations, including lead (Pb), cadmium (Cd), mercury (Hg), chromium (Cr), and other substances widely recognized as major environmental pollutants. Their presence in natural ecosystems is closely linked to anthropogenic activities, particularly mining and metallurgical operations, industrial discharges, urban waste disposal, and certain agricultural practices such as the application of fertilizers, pesticides, or sewage sludge (Singh et al., 2011; Boros et al., 2015; Roba et al., 2016; Sur et al., 2017; Rusu et al., 2023).

A defining feature of heavy metals is their persistence in the environment, as they are not subject to biological or chemical degradation processes. This stability promotes their accumulation in soils and sediments and facilitates transfer to living organisms, enabling their movement along trophic chains. Their non-biodegradable character, combined with their potential for bioaccumulation and mobility governed by physicochemical conditions, confers major relevance from the perspective of ecosystem protection and human health, underscoring the need for integrated assessments that simultaneously capture their behavior in soil-plant systems and their toxicological implications (Bizo et al., 2014; Minkina et al., 2017; Moț et al., 2019; Moț et al., 2021; Sabir et al., 2022; Filip & Coman, 2025).

The toxicity of heavy metals to human health is extensively documented in scientific literature and is associated with complex molecular mechanisms involving direct interactions with proteins and nucleic acids, induction of oxidative stress, and disruption of cellular homeostasis. Through these processes, they can impair the normal functioning of biological systems, while the severity of toxic effects depends on the nature of the element, the level and duration of exposure, and individual susceptibility (Jaishankar et al., 2014; Mitra et al., 2022; Kotnala et al., 2025; Jomova et al., 2025). Among these elements, lead (Pb) is recognized for its neurotoxic potential, with chronic exposure being linked to cognitive deficits and developmental disorders in children, as well as elevated blood pressure and impaired renal function in adults. Moreover, long-term accumulation of Pb may result in

anemia, reproductive dysfunctions, and other severe systemic manifestations (Oros et al., 2011; Balali-Mood et al., 2021; Ortega et al., 2021). Cadmium (Cd), characterized by high toxicity even at low concentrations, is predominantly associated with renal impairment and bone demineralization processes that may progress to severe conditions such as Itai-itai disease. In addition, Cd is classified as a human carcinogen and has been implicated in the development of lung and prostate cancers, further emphasizing the importance of assessing its mobility in soil-plant systems (Waalkes, 2003; Davidova et al., 2024; Sasaki et al., 2024.)
The aim of this study was to establish the current level of Pb and Cd contamination in soil and fruit within soil-plant system, as well as to evaluate the potential of the AMTF ecotoxicological indicator for the mathematical modeling of the transfer factor.

## MATERIALS AND METHODS

This study employed an experimental design structured to provide an integrated evaluation of Pb and Cd behavior within the soil–plant–fruit system by investigating contamination levels, bioaccumulation processes, and transfer dynamics in an area known for historical pollution associated with mining and metallurgical activities. The experimental framework consisted of three major analytical components:

a) Regarding heavy metal content in soil;
b) Regarding heavy metal content in fruits;
c) Regarding the transfer factor.

The mathematical modeling of heavy metal pollutant transfer was performed using the AMTF ecotoxicological indicator, which integrates the total and mobile forms of metals in soil, the concentration identified in fruit, and the relation to the maximum permissible limit, allowing classification into transfer classes and the integrated characterization of Pb and Cd heavy metal pollutant behavior within the soil–plant system.
The area of interest covers approximately 588.8 km$^2$ within the Baia Mare Depression and was evaluated in comparison with a less impacted reference area of about 111 km$^2$ located in the Maramureș Depression, namely the Sighetu Marmației. Within these perimeters, soil samples were collected at several sampling depths in accordance with Order No. 184/1997, while plum samples were obtained following the provisions of Order No. 1048/2003.
The Baia Mare Depression (Figure 1) represents a geomorphological contact zone between the Someșan Plateau and the Eastern Carpathians, developed along the southern flank of the Gutâi-Țibleș Neogene mountain units.

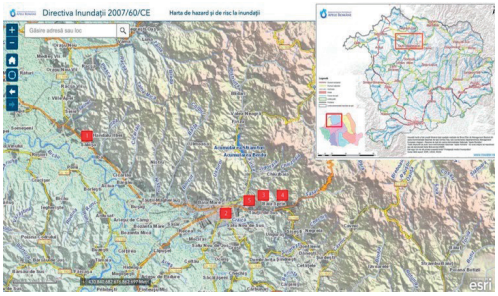

Figure 1. Sampling points

From an altimetric perspective, the base level of the depression ranges between 150-350 m, whereas morphologically it exhibits a basin-shaped configuration. The relief is heterogeneous, and the present study focuses on the Seini-Baia Mare-Baia Sprie piedmont glacis and contact piedmont sectors, extending toward the southern foothills of the Igniș-Gutâi Mountains, which constitute the main investigated zone, while the Sighetu Marmației sector served as the reference area (Coman, 2006; Coman et al., 2010; Ștefan et al., 2012; Marian et al., 2016; Manoiu & Spiridon, 2017).

### Working Method

**a) Regarding heavy metal content in soil**
Soil sampling was conducted in accordance with the existing methodological regulations and standards stipulated in Order No. 184/1997. Samples were collected from the Baia Mare Depression, specifically from the piedmont glacis and contact piedmont sectors, as well as from the Sighetu Marmației sector located in the Maramureș Depression, which served as the reference area. For each sampling point, the soil profile was opened, and samples were obtained from four different depths, namely 5, 30, 50, and

100 cm, to capture the vertical distribution of the investigated elements.
Following field collection, physicochemical analyses were carried out in an accredited laboratory, namely INCDO ICIA Cluj-Napoca, in accordance with the following international standards: SR ISO 11464:1994, SR ISO 11047:1999-PIS-03, and SR EN ISO 1185:2009. The analytical results were subsequently evaluated in relation to the regulatory thresholds in force at the national level (Order No. 756/1997), at the European level (European Council Directive 86/278/EEC 1986), and at international level (US EPA, 2002 after He et al., 2015).

**b) Regarding heavy metal content in fruit**
The sampling plan overlaps perfectly with that of the soils, including for the control sample.
Fruit samples (plums) were collected annually from privately owned orchards in August 2023, 2024, and 2025. The Pb and Cd content in the fruit was determined. The results were interpreted in accordance with the legislation in force, namely Order 975/1998 at national level, EU Directive 2023/915 at European Union level, and Codex Alimentarius, 1995 at international level.

**c) Regarding the transfer factor**
The transfer factor (TF), also known in the literature as the bioaccumulation factor (BAF), biological accumulation factor (BCF), or bioconcentration factor (BCFT), represents the ratio between the content in plants and the content in soil. This factor has been studied nationally and internationally (Olănescu, 2007; Ivasuc & Rusu, 2011; Big et al., 2012; Jolly et al., 2013; Aladesanmi et al., 2019; Jakubus et al., 2019; Nițu et al., 2019; Pehoiu et al., 2020; Noman et al., 2022; Pruteanu et al., 2022; Tong et al., 2022).
The calculation assumes that the transfer of heavy metal pollutants into the soil-plant system is not determined exclusively by the total form, but by the interaction between the mobile fraction, the level of accumulation in the fruit, and the maximum permissible limit.

$$AMTF = (C_{mobile}/C_{mobile}+1) \times \log(C_{total} + 1) \times (C_{fruit}/Standard) \times \delta$$

where:
$\delta$ = metal-specific toxicity coefficient ($\delta_{Cd} = 1$, $\delta_{Pb} = 2$);
$C_{mobile}$ = mobile concentration of the metal in the soil (mg/kg);
$C_{total}$ = total concentration of the metal in the soil (mg/kg);
$C_{fruit}$ = concentration of the metal in the fruit (mg/kg);
Standard = maximum permitted limit in fruit (mg/kg wet substance).

In this calculation formula, the coefficient $\delta$ was introduced as a toxicological weighting factor to reflect the differences in hazard associated with the metals analyzed. $\delta$ was established based on the IARC classification of carcinogenicity:

- ⇒ Cd and its compounds are classified in Group 1,
- ⇒ Pb compounds in Group 2A (EFSA, 2010).

Thus, discrete weights corresponding to these groups were used ($\delta Cd = 1$, $\delta Pb = 2$).

To interpret the AMTF indicator values (Table 1), a transfer class classification system was used, established based on the distribution of the values obtained, the reporting of the accepted normative limits, and a non-linear progression inspired by the Fibonacci sequence ($\Phi$=1.6818).

The application of the logarithmic function attenuates the influence of very high total concentrations and improves the stability of the indicator. Thus, very large differences in the total fraction do not monopolize the result.

Table 1. AMTF ranges

| No. crt. | AMTF values range | Interpretation | Chromatic scale of transfer |
|---|---|---|---|
| 1 | <0.1 | Very low transfer | |
| 2 | 0.10-0.21 | Low transfer | |
| 3 | 0.21-0.55 | Medium transfer | |
| 4 | 0.55-0.89 | High transfer | |
| 5 | 0.89-1.44 | Very high transfer | |
| 6 | ≥1.44 | Extreme transfer | |

## RESULTS AND DISCUSSIONS

### *a) Soil sampling*

The results for total and mobile Pb content are presented in Table 2.

MAL-maximum allowed limit, RO-Romania, EU-Europe INT-International, a - Order No. 756/1997, b - Council Directive 86/278/CEE 1986; c - US EPA, 2002 after He et al., 2015.

*Sampling points* - Pb

In Săbișa, the Pb content in total form is below the maximum permissible limit at all depths analyzed. The maximum value determined, 42.7 mg/kg at a depth of 30 cm, is 15% lower than the maximum permissible limit, with no exceedances of the legal threshold recorded. The Pb content in mobile form is below 0.10 mg/kg, with no legislative reference framework.

In Baia Mare, Pb content in total form is below the maximum permissible limit in the surface horizon, but in the intermediate and deep horizons there are significant exceedances of this limit. At 30 cm, the concentration of 385 mg/kg exceeds the maximum permissible limit by 7.7 times, at 50 cm by 4.76 times, and at 100 cm it reaches a maximum of 9.6 times, highlighting a marked accumulation and historical migration of Pb in the soil profile, specific to areas affected by mining and metallurgical activities. The content of Pb in mobile form remains below 0.02 mg/kg throughout the analyzed profile, with no legislative reference framework.

At Baia Sprie I, the total Pb content exceeds the maximum permissible limit in the surface horizon, where the value of 211 mg/kg represents an exceedance of 4.22 times, as well as in the intermediate horizon, with an exceedance of 1.77 times, while in the deep horizon the concentrations determined are below the maximum permissible limit. The Pb content in mobile decreases with depth.

At Baia Sprie II, the total Pb content exceeds the maximum permissible limit in the surface horizon, where the value of 261 mg/kg represents an exceedance of 5.22 times, while in the intermediate horizon and in the depth horizon the concentrations determined are below the maximum permissible limit. The Pb content in mobile form recording maximum values in the surface horizon and a progressive decrease towards the deep horizon.

In Tăuții de Sus, the total Pb content records the highest values in the analyzed reference area, with a concentration of 890 mg/kg in the surface horizon, corresponding to a 17.8-fold exceedance of the maximum permissible limit, with exceedances also occurring in the intermediate horizon, where the value of 141 mg/kg represents a 2.82-fold exceedance. In the deep horizon, the concentrations determined are below the maximum permissible limit. The Pb content in mobile form varies between 0.087 and 1.20 mg/kg on the analyzed profile, with maximum values in the intermediate horizon and a decrease towards the deep horizon. These values cannot be evaluated comparatively from a regulatory point of view, as there is no legislative framework in force for the mobile form.

In Sighetu Marmației (the control), the total Pb content is below the maximum permissible limit in all horizons analyzed. The Pb content in the mobile form is below 0.02 mg/kg across the entire soil profile.

Therefore, the control site can be considered uncontaminated, confirming the absence of Pb contamination and validating the use of this point as a reference area for the comparative interpretation of the results obtained in areas affected by anthropogenic activities.

*Sampling points* -Cd

The results for total and mobile Cd content are presented in Table 3.

Table 3. Cd content in soil

| No. crt. | Sampling point | Depth (cm) | Cd content (mg/kg) | |

| 7. | MAL RO[a] | - | 3 | - |
| 8. | MAL EU[b] | - | 1-3 | - |
| 9. | MAL INT[c] | - | 0.48 | - |

MAL-maximum allowed limit, RO-Romania, EU-Europe INT-International, a - Order No. 756/1997, b - Council Directive 86/278/CEE 1986; c- US EPA, 2002 after He et al., 2015.

In Săbișa, the total Cd content is below the maximum permissible limit in all analyzed horizons, with the determined values being below the maximum permissible limit. These results indicate the absence of Cd contamination. The Cd content in mobile form is below 0.02 mg/kg across the entire soil profile, and these values cannot be evaluated comparatively from a regulatory point of view, as there is no legislative framework in force for mobile form.

In Baia Mare, the Cd content in total form is below the maximum permissible limit in the surface horizon, but in the intermediate and deep horizons, it exceeds this limit. At 30 cm, the value of 3.47 mg/kg exceeds the maximum permissible limit by 1.16 times, and in the deep horizon, the concentration of 4.00 mg/kg corresponds to an exceedance of 1.33 times, highlighting persistent contamination associated with historical pollution, while at 50 cm, the concentration of 0.83 mg/kg remains below the maximum permissible limit. The Cd content in mobile form shows low values across the entire analyzed profile and cannot be evaluated comparatively from a regulatory point of view, as there is no legislative framework in force for mobile form.

At Baia Sprie I, the total Cd content remains below the maximum permissible limit in all analyzed horizons. The maximum value is recorded in the surface horizon, being 17% lower than the maximum permissible limit. Concentrations decrease progressively in the intermediate horizon and in the deep horizon. The Cd content in mobile form shows values below 0.05 mg/kg across the entire soil profile and cannot be evaluated comparatively from a regulatory point of view, as there is no legislative framework of reference for the mobile form.

At Baia Sprie II, the total Cd content is below the maximum permissible limit in all analyzed horizons. The maximum value, recorded in the surface horizon (2.57 mg/kg), is 14% lower than the maximum permissible limit. The concentrations determined in the intermediate horizon and in the depth, horizon show low variations. The Cd content in mobile form is below 0.05 mg/kg across the entire analyzed profile and cannot be evaluated comparatively from a regulatory point of view, as there is no legislative framework in force for mobile form.

In Tăuții de Sus, Cd content in total form shows the highest values in the reference area analyzed. In the surface horizon, the concentration of 8.80 mg/kg exceeds the maximum permissible limit by 2.93 times, while in the intermediate horizon and in the deep horizon, the values determined are below the maximum permissible limit. The Cd content in mobile form remains below 0.05 mg/kg throughout the soil profile, and these values cannot be evaluated comparatively from a regulatory point of view, as there is no legislative framework in force for mobile forms.

In Sighetu Marmației (the control), the total Cd content is below the maximum permissible limit in all horizons analyzed, indicating the absence

of Cd contamination. The Cd content in the mobile form is below 0.02 mg/kg across the entire soil profile, and these values cannot be evaluated comparatively from a regulatory point of view, as there is no legislative framework in force for the mobile form.

***b) Fruit samples***

The results on the total form of the chemical element Pb in fruits (mg/kg) for 2023, 2024 and 2025 are represented in Table 4.

Table 4. Pb content in fruits

| No. crt | Sampling point | Pb content in 2023 | Pb content in 2024 | Pb content in 2025 |
|---|---|---|---|---|
| 1 | Săbișa | <0.04 | **<0.15** | <0.10 |
| 2 | Baia Mare | <0.04 | **<0.15** | <0.10 |
| 3 | Baia Sprie I | <0.04 | **<0.15** | <0.10 |
| 4 | Baia Sprie II | <0.04 | **<0.15** | <0.10 |
| 5 | Tăuții de Sus | <0.04 | **<0.15** | <0.10 |
| 6 | Sighetu Marmației (the control) | <0.04 | **<0.15** | <0.10 |
| 7 | MAL RO[a] | 0.50 | | |
| 8 | MAL EU[b] | 0.10 | | |
| 9 | MAL INT[c] | 0.10 | | |

MAL-maximum allowed limit, RO-Romania, EU-Europe INT-International, a - Order no. 975/1998; b - Commission Regulation (EU) 2023/915; c - Codex Alimentarius, 1995.

Figure 2 shows, for 2023, the concentrations of Pb in fruit determined at all sampling points were very low and fell entirely within the maximum limits permitted at national, European, and international level. These results indicate an insignificant accumulation of Pb in fruit in the reference area analyzed.

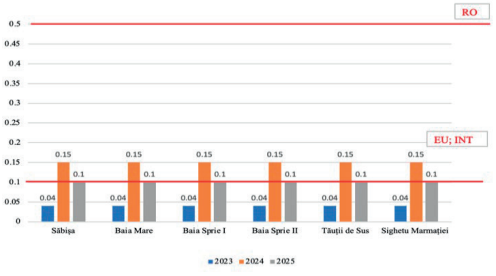

Figure 2. Pb content in fruits

For 2024, Pb concentrations in fruit, determined at all sampling points, showed a sharp increase compared to the previous year, of approximately 275%. The values obtained exceeded the maximum limits allowed at European level but remained below the maximum limits allowed at national level and within the range allowed at international level, as established by the Codex Alimentarius. This development indicates a temporary increase in Pb accumulation in fruit in the reference area analyzed, without generating non-compliance with the national regulatory framework.

For 2025, Pb concentrations in fruit determined at all sampling points decreased by 33.3% compared to the previous year. The values obtained were at the maximum levels allowed at European level and within the maximum levels allowed at national and international level. The trend indicates a partial reduction in Pb accumulation in fruit, following the sharp increase observed for 2024.

In summary, Pb concentrations in fruit were within the maximum limits permitted at national level and within the ranges established by Codex Alimentarius, although a slight exceedance of the European threshold was found for 2024. This behaviour reflects interannual variations in the level of accumulation, without leading to non-compliance with national and international regulatory frameworks.

The results on the total form of the chemical element Cd in fruits (mg/kg) for the year 2023, 2024 and 2025 are represented in Table 5.

Table 5. Cd content in fruits

| No. crt | Sampling point | Cd content in 2023 | Cd content in 2024 | Cd content in 2025 |
|---|---|---|---|---|
| 1 | Săbișa | <0.04 | **<0.15** | <0.10 |
| 2 | Baia Mare | <0.04 | **<0.15** | <0.10 |
| 3 | Baia Sprie I | <0.04 | **<0.15** | <0.10 |
| 4 | Baia Sprie II | <0.04 | **<0.15** | <0.10 |
| 5 | Tăuții de Sus | <0.04 | **<0.15** | <0.10 |

| 9 | MAL INT[c] | 0.05 | | |

MAL-maximum allowed limit, RO-Romania, EU-Europe INT-International, a - Order no. 975/1998; b - Commission Regulation (EU) 2023/915; c - Codex Alimentarius, 1995.

Figure 3 shows, for 2023, the values determined for all sampling points (0.04 mg/kg wet weight) indicate levels below the maximum permissible limit set at national, European, and Codex Alimentarius levels, reflecting a low accumulation of Cd in fruit in the reference area analyzed.

For 2024, Cd concentrations in fruit exceed the maximum permissible limit by approximately 60%, suggesting a temporary intensification of Cd transfer from soil to fruit.

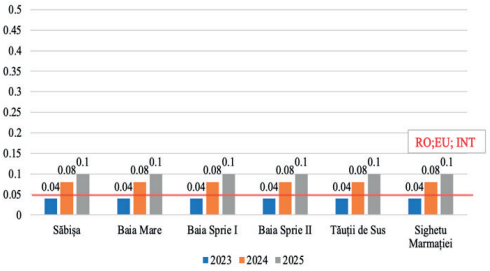

Figure 3. Cd content in fruits

For 2025, the values recorded are significantly higher than the maximum permissible limit set at national, European, and Codex Alimentarius levels, being twice the maximum permissible limit.

The pronounced rainfall deficit characteristic of 2025 can be correlated with the increase in the mobile fraction of Cd and the intensification of root absorption, mechanisms that support, from a pedological and physiological point of view, the high values determined in fruits.

Interpretation of the results in relation to the legislative framework highlights important differences between lead and cadmium in terms of regulatory requirements. In the case of Pb, the maximum limit allowed by national legislation (0.50 mg/kg) is significantly more permissive than the threshold set by Regulation (EU) 2023/915 and Codex Alimentarius (0.10 mg/kg). This fivefold difference between standards reflects a less restrictive regulatory approach at national level, which may lead to situations where the values determined are compliant internally but may generate non-compliance with European requirements. From this perspective, the interpretation of compliance depends directly on the legislative reference level used.

In contrast, for Cd, the maximum permissible limit is uniformly set at 0.05 mg/kg at all legislative levels analyzed. The harmonization of thresholds indicates international recognition of the high toxic potential of this element and a uniform regulatory approach that is more restrictive than that applicable to Pb. Consequently, any exceedance of the threshold for Cd automatically leads to simultaneous non-compliance at national, European, and international levels.

Thus, from a legislative point of view, Cd presents a higher regulatory risk, as the threshold is lower and does not allow for differences in interpretation between regulatory levels, while for Pb there is a wider margin of tolerance within the national framework. This aspect must be considered in the food risk assessment and in the formulation of conclusions on the safety of the product analyzed.

**c) *Transfer factor***

Table 6 shows the results for the assimilated mobility transfer factor (AMTF) for the pollutant -Pb.

The analysis of AMTF-Pb values for the period 2023-2025 shows a clear spatial and vertical differentiation of transfer intensity in the soil-plant-fruit system. Overall, the indicator falls predominantly into the very low transfer (AMTF < 0.10) and low transfer (0.10-0.21) classes, with occasional occurrences in the medium transfer (0.21-0.55) and high transfer (0.55-0.89) classes, without reaching the higher

classes of very high transfer (0.89-1.44) or extreme transfer (≥1.44).

At the surface horizon level, AMTF values reflect the direct influence of historical contamination and the mobile surface fraction, but the distribution is relatively heterogeneous, with variations controlled mainly by the local specifics of contamination. In contrast, the analysis becomes more relevant from a procedural point of view at depths of 30 and 50 cm, where the vertical dynamics of transfer are more clearly outlined.

At 30 cm, the most pronounced variability of the indicator is observed. For Săbișa, Baia Mare, and Sighetu Marmației, the values remain constant in the very low or low transfer class, suggesting effective control of mobility and reduced availability for plant uptake, even in the presence of high total concentrations in certain profiles. In contrast, at the Baia Sprie I and Tăuții de Sus sites, 2024 marks a clear intensification of mobilization processes, with values falling within the high transfer class (0.55-0.89). The maximum value of the entire data set, recorded at 30 cm at Tăuții de Sus (AMTF=0.704), confirms that this horizon represents the level at which the interaction between the mobile fraction, total concentration, and accumulation in fruit becomes maximum. The return to the medium transfer class (0.21-0.55) in 2025 indicates a transitional nature of the intensification in 2024.

At 50 cm, AMTF values are systematically lower than those at 30 cm, falling mainly into the very low and low transfer classes, with limited occurrences in the medium transfer class in 2024. This decrease suggests a progressive reduction in effective mobility with depth, associated with the processes of adsorption and stabilization of Pb in the soil matrix. The absence of values in the higher classes at this depth confirms that, although historical contamination is present in the profile, the actual availability to the active root system decreases with depth.

The depth horizon (100 cm), generally shows low AMTF values, falling within the lower transfer classes, which indicates a limited contribution of this level to the accumulation process in the fruit.

From a temporal perspective, the year 2024 is distinguished by systematically higher AMTF values at 30 cm and, to a lesser extent, at 50 cm, suggesting a temporary intensification of Pb mobilization and availability processes in the intermediate zone of the profile. In 2025, a reduction in transfer intensity is observed, without however changing the overall vertical pattern.

Table 7 shows the results for the assimilated mobility transfer factor (AMTF) for the pollutant -Cd.

| | | 100 | 0.002 | 0.004 | 0.005 |

The analysis of AMTF-Cd values for the period 2023-2025 shows a distribution that is clearly different from that of Pb, characterized by low values and moderate vertical variability. Across the entire dataset, the indicator falls exclusively into the very low transfer class (AMTF < 0.10), without reaching the higher classes (low, medium, high, very high, or extreme). The range of variation, between 0.002 and 0.094, confirms a limited overall transfer of Cd in the soil–plant–fruit system, from the integrative perspective of the AMTF indicator.

At the surface horizon, the values are higher than those at depth, especially at the Tăuții de Sus site, where the maximum value of the set

(AMTF=0.094) is reached in 2025, but still within the very low transfer class. This distribution reflects the direct influence of the mobile surface fraction and accumulation in the fruit, but without exceeding the threshold of 0.10 that would mark the transition to the low transfer class.

At 30 cm, the AMTF-Cd values show relative uniformity between points, ranging between 0.002 and 0.041. In Baia Mare, Baia Sprie I, Baia Sprie II, and Tăuții de Sus, the year 2025 shows slightly higher values compared to 2023 and 2024, but all remain in the very low transfer class. This stability indicates that, although Cd exceeded the legislative threshold in fruit in 2024 and 2025, the integration of the mobile fraction and total concentration through AMTF mitigates the numerical impact, suggesting that the actual intensity of transfer on the intermediate profile remains low.

At 50 cm, the values are comparable or slightly lower than those at 30 cm, confirming a discrete vertical gradient of transfer. The range of 0.002–0.037 indicates limited effective mobility at this depth, with no major differences between the years analyzed. The fact that the values do not increase significantly in 2024 and 2025 at 50 cm suggests that the intensified mobilization processes in these years were concentrated predominantly in the upper root zone, without a marked propagation in depth.

At the depth horizon, the indicator maintains values like those at 50 cm or slightly lower, confirming a minimal contribution of the deep horizon to the accumulation process in the fruit.

From a temporal perspective, there is a progressive increase in AMTF-Cd values from 2023 to 2025 at most points, but this increase does not change the transfer class. Thus, although the legislative analysis indicated exceedances of the 0.05 mg/kg threshold in fruit in 2024 and 2025, the AMTF-based classification keeps Cd in the very low transfer category, highlighting the difference between the specific regulatory non-compliance and the integrated intensity of the transfer process in the soil profile.

In a comparative approach, the analysis of AMTF-Pb and AMTF-Cd values highlights consistent differences between the two elements in terms of the intensity and significance of transfer in the soil–plant–fruit system. For Pb, spatial and vertical variability is more pronounced, with occasional occurrences in the high transfer class (0.55-0.89), especially at a depth of 30 cm in 2024, in areas with significant historical contamination. This behavior indicates local episodes of intensified mobilization, without reaching the very high or extreme transfer classes, suggesting the existence of effective soil immobilization mechanisms that limit the actual transfer to the fruit.

A different pattern is observed for Cd, AMTF values remain consistently in the very low transfer class (AMTF < 0.10), with a uniform distribution across the profile and moderate interannual variations. Although fruit concentrations exceeded the legislative threshold in 2024 and 2025, the integrative indicator did not show a structural intensification of transfer, indicating a dissociation between normative pressure and the procedural intensity of mobilization in the soil.

Thus, comparatively, Pb reflects a more pronounced edaphic pressure and greater variability in transfer, while Cd exhibits high process stability but increased normative vulnerability, determined by the low legislative threshold. This differentiation confirms the ability of the AMTF indicator to integrate mobility, accumulation in fruit, and normative reference into a coherent assessment of the intensity of metal transfer in the investigated fruit tree ecosystems.

## CONCLUSIONS

***Heavy metal content in soil.*** The results obtained highlight the persistence of historical contamination with Pb and, to a lesser extent, with Cd in the soils of the investigated area. For Pb, exceedances of the maximum permissible limit were frequent and distributed over several depths (30–100 cm in Baia Mare; 5–30 cm in Tăuții de Sus), confirming both surface accumulation and migration in the profile. In the case of Cd, exceedances were less numerous and more localized (Baia Mare and Tăuții de Sus), indicating lower edaphic pressure compared to Pb.

***Heavy metal content in fruits.*** For Pb, the significant difference between the national threshold and the European/international threshold generates discrepancies in the

interpretation of compliance. Although the European threshold was exceeded in 2024, the values remained below the national limit, and a partial reduction was observed in 2025. For Cd, the uniform and more restrictive limit led to direct non-compliance in 2024 and 2025, highlighting a higher regulatory vulnerability compared to Pb.

***Transfer factor.*** Analysis of transfer using the AMTF indicator shows that, despite exceedances in soil and isolated non-compliances in fruit, the integrated transfer intensity remains predominantly in the lower classes for both elements. For Pb, isolated occurrences of the high transfer class at 30 cm indicate temporary episodes of mobilization, without reaching the higher classes. For Cd, AMTF values remain constant in the very low transfer class, suggesting that legislative exceedances are more a consequence of the restrictive regulatory threshold than of a structural amplification of mobility in the profile.

From a food safety perspective, the results indicate that the risk is not determined exclusively by the total concentration in the soil, but by the interaction between mobility, pedoclimatic conditions, and the severity of the legislative threshold. In areas with historical anthropogenic impact, even moderate variations in the mobile fraction can lead to exceedances of the permissible limits, especially for Cd.

Therefore, it is necessary to implement a periodic monitoring system that integrates the analysis of the mobile fraction and the assessment of transfer through synthetic indicators such as AMTF, to anticipate potential non-compliance and protect consumer health.

***Abstract***

*The rapid deployment of lithium-ion batteries in electric vehicles and stationary energy-storage systems is generating an increasing end-of-life waste stream with potential impacts on soil, water and air. This study combines an integrative literature review with mass-balance calculations based on a representative NMC811 battery composition. Electric-vehicle battery deployment reached approximately 1.2 TWh in 2025 and may approach 3 TWh by 2030, corresponding to estimated masses of 7.0 and 17.5 million tonnes, respectively. Global end-of-life battery waste is projected to increase from 0.9 million tonnes in 2025 to 20.5 million tonnes in 2040. Under the 2040 landfill/leaching stress scenario, potential releases were estimated at 7,754 t Li, 4,949 t Ni, 3,075 t Cu, 1,655 t Mn and 623 t Co. Relevant pollutants also include fluorides, electrolyte degradation products, fine cathode particles and persistent fluorinated compounds. High collection rates, chemistry-based sorting, fire-safe storage, controlled recycling and integrated soil and water monitoring are essential for reducing environmental risks and improving material circularity.*

***Key words****: battery recycling, end-of-life batteries, lithium-ion batteries, soil contamination, waste management.*

## INTRODUCTION

Lithium-ion batteries (LIBs) have become essential for electric mobility, portable electronics and stationary energy storage because of their high energy density, efficiency and long operating life. According to the latest international outlook, global electric-vehicle battery deployment reached approximately 1.2 TWh in 2025 and is expected to approach 3 TWh by 2030. This rapid increase in deployment is creating a delayed but substantial flow of batteries that will require collection, transport, reuse and recycling after reaching the end of their service life (Harper et al., 2019; International Energy Agency, 2026).

End-of-life lithium-ion batteries, hereafter referred to as EoL-LIBs, contain a complex mixture of potentially recoverable and hazardous materials. Depending on cathode chemistry, these materials may include Li, Ni, Co, Mn, Fe and P, together with Cu and Al current collectors, graphite, polymeric binders, separators, organic solvents and fluorinated lithium salts. NMC and NCA batteries contain economically valuable Ni and Co, whereas LFP batteries contain no Ni or Co in the active cathode material but retain Li, Cu, Al, graphite, phosphate compounds and fluorinated electrolyte components (Harper et al., 2019; Mrozik et al., 2021).

Environmental releases may occur through corrosion, mechanical damage, uncontrolled shredding, landfill disposal, battery fires and inadequately controlled recycling operations (Mosnegutu et al., 2025a). Soil may receive contaminants through direct leakage, contaminated dust, atmospheric deposition, leachate, firefighting water and the disposal of slags, sludge or other process residues. The subsequent mobility and persistence of these contaminants are influenced by pH, redox

conditions, soil texture, clay content, organic matter, rainfall and groundwater depth (Bolan et al., 2021; Mrozik et al., 2021).

The environmental assessment of EoL-LIBs must therefore consider more than lithium and the economically valuable cathode metals. Fluorides, electrolyte decomposition products, fine cathode and graphite particles, and emerging per- and polyfluoroalkyl substances may contribute to soil acidification, metal mobilisation, groundwater contamination and ecological toxicity (Guelfo et al., 2024; Rensmo et al., 2023; Mosnegutu et al., 2025b; Shojaei et al., 2025). Accordingly, the objectives of this study were to estimate the mass of batteries entering use and the projected EoL-LIB waste stream, quantify the potential release of selected contaminants under three management scenarios, examine a site-scale soil-contamination scenario involving an NMC811 battery pack, and compare the environmental release pathways associated with uncontrolled disposal, battery fires, mechanical pretreatment, pyrometallurgy, hydrometallurgy and direct recycling.

## MATERIALS AND METHODS

The study was conducted as an integrative review combined with mass-balance calculations, quantitative pollution-scenario modelling and a technology-specific environmental assessment. Scientific articles published mainly between 2015 and 2026 were identified through Scopus, Web of Science, ScienceDirect, SpringerLink, PubMed and Google Scholar, while older regulatory and foundational sources were retained where relevant. Institutional data were obtained from the International Energy Agency, the United Nations Development Programme, Argonne National Laboratory and the European Commission. The literature review focused on battery deployment, EoL-LIB waste generation, contaminant composition, environmental release pathways, soil impacts and recycling technologies.

Battery mass was estimated from energy deployment using a representative pack-level mass of 5.85 kg $kWh^{-1}$. This central value represents a simplified mixed NMC–LFP battery flow and falls within the range derived from BatPaC automotive pack simulations. In practical units, the calculation was:

Battery mass (Mt) = energy deployment (TWh) × 5.85 Mt $TWh^{-1}$.

Consequently, 1.2 TWh corresponds to approximately 7.02 Mt of batteries, while 3.0 TWh corresponds to approximately 17.55 Mt. These values represent batteries newly introduced into use and not waste generated during the same year (Ahmed et al., 2023; International Energy Agency, 2026).

Annual EoL-LIB quantities were obtained from the UNDP projection, which reports 0.90 Mt in 2025, 1.85 Mt in 2030, 7.85 Mt in 2035 and 20.50 Mt in 2040. The published values were used directly, without interpolation between the reported years (United Nations Development Programme, 2024).

An NMC811 battery pack was selected as a representative metal-containing chemistry for the pollution-screening model. The active cathode material, $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$, contains approximately 7.13% Li, 48.27% Ni, 5.65% Mn and 6.06% Co by mass. Assuming that active cathode material represents 25% of total pack mass, the corresponding pack-level fractions were estimated at 1.78% Li, 12.07% Ni, 1.41% Mn and 1.52% Co. Cu was assumed to represent 7.5% of pack mass. These fractions are modelling assumptions and do not describe every commercial battery pack (Ahmed et al., 2023; Rinne et al., 2024).

The potential annual release of contaminant *i* was calculated using the following mass-balance relationship:

Released mass = annual battery waste × mismanaged fraction × contaminant fraction × environmental release fraction.

Three quantitative screening scenarios were evaluated. Scenario A assumed that 1% of EoL-LIBs were mismanaged, with environmental release of 10% of Li and 1% of Ni, Co, Mn and Cu. Scenario B assumed 5% mismanagement, with release of 42.5% of Li, 11.45% of Mn and 4% of Ni, Co and Cu. Scenario C represented severe fragmentation, fire or uncontrolled disposal, assuming 15% mismanagement and release of 75% of Li, 20% of Mn and 10% of Ni, Co and Cu. Scenario B release factors reflect the order of magnitude reported in landfill-related leaching studies, whereas Scenarios A and C were used as lower and upper sensitivity

boundaries (Bolan et al., 2021; Mrozik et al., 2021). These scenarios represent comparative screening conditions rather than predictions of the actual proportion of battery waste that will be released into the environment.

In addition to the quantitative NMC811 release scenarios, a technology-specific assessment was performed for uncontrolled disposal, battery fires, mechanical pretreatment, pyrometallurgy, hydrometallurgy and direct recycling. Each management or treatment option was compared qualitatively according to its main potential releases, the principal affected environmental medium and the expected environmental implications. The assessment considered metal-bearing leachates and residues, fluorinated emissions, cathode and graphite particles, electrolyte vapours, acidic or saline wastewater, sludge and solid process residues. The comparison was based on evidence reported for EoL-LIB pollution and recycling systems (Harper et al., 2019; Mrozik et al., 2021; Rensmo et al., 2023; Claassen et al., 2024; Guelfo et al., 2024; International Energy Agency, 2024; Rinne et al., 2024; Aiello et al., 2025; Shojaei et al., 2025).

For example, Li release under Scenario B in 2040 was calculated as:

$20{,}500{,}000\ t \times 0.05 \times 0.0178 \times 0.425 = 7{,}754\ t\ Li\ yr^{-1}$.

The calculated values represent contaminant masses potentially released from the waste stream and not final concentrations in a particular soil or water body. Site-level concentrations require additional information on the affected area, mixing depth, hydrological conditions, soil properties, background concentrations and contaminant transport. Therefore, the results should be interpreted as comparative pollution-potential indicators rather than site-specific environmental predictions (Mrozik et al., 2021).

## RESULTS AND DISCUSSIONS

The conversion of energy deployment into mass indicates that approximately 7.0 Mt of batteries may have entered electric-vehicle applications in 2025. Deployment approaching 3 TWh in 2030 would correspond to approximately 17.5 Mt of batteries per year. The range could be wider because NMC packs generally have higher gravimetric energy density than LFP packs, while changes in cell-to-pack design or the introduction of solid-state and sodium-ion batteries may reduce or increase the future mass per unit of energy (Ahmed et al., 2023; International Energy Agency, 2026).

The annual quantity of EoL-LIBs is much lower than annual deployment because batteries normally remain in service for several years. However, the waste stream is projected to expand from 0.90 Mt in 2025 to 20.50 Mt in 2040, representing an increase of more than twenty times. Production scrap currently represents an important recycling feedstock, but approximately 94% of the projected 2040 flow is expected to originate from batteries removed from vehicles and other applications. The estimated mass of newly deployed batteries and the projected evolution of the EoL-LIB waste stream are summarised in Table 1.

Table 1. Estimated battery deployment and projected end-of-life waste

| Year | EV battery deployment | Estimated mass newly deployed | Projected EoL-LIB waste |
|---|---|---|---|
| 2025 | ≈1.2 TWh | ≈7.02 Mt | 0.90 Mt |
| 2030 | ≈3.0 TWh | ≈17.55 Mt | 1.85 Mt |
| 2035 | n.a. | n.a. | 7.85 Mt |
| 2040 | n.a. | n.a. | 20.50 Mt |

Source: Authors' calculations based on Ahmed et al. (2023), International Energy Agency (2026), and United Nations Development Programme (2024).

As shown in Table 1, the projected EoL-LIB waste stream increases rapidly after 2030 and gradually shifts from production scrap towards used batteries. This transition has practical consequences because production waste is generally homogeneous, documented and relatively uncontaminated, whereas used battery packs differ in chemistry, state of charge, degradation level, accident history and structural design. Recycling systems will therefore require improved identification, automated disassembly, chemistry-based sorting and safer transport as the proportion of used packs increases (Harper et al., 2019; International Energy Agency, 2024).

Li is potentially important because it is relatively mobile in many soils and may be weakly retained compared with transition metals. A landfill-related study synthesised by Mrozik et al. (2021) reported that approximately

42.5% of the Li inventory entered the leachate, compared with less than 4% for Ni, Co, Cu, Al and Fe. Mn release was approximately 11.45%. These values are not universal leaching factors, but they illustrate that contaminant mobility does not necessarily correspond to the total metal content of the battery (Bolan et al., 2021; Mrozik et al., 2021).

Ni, Co and Cu generally have stronger interactions with clay minerals, iron and manganese oxides and soil organic matter. Nevertheless, their mobility and bioavailability may increase when soil pH decreases. At elevated concentrations, Ni and Co can affect microbial enzymatic activity and plant growth, while Cu may impair microbial processes and modify the physical behaviour of clayey soils. Mn presents redox-dependent behaviour and may become more soluble under reducing or waterlogged conditions (Mrozik et al., 2021; Mishra et al., 2026).

Electrolyte degradation may amplify metal contamination. $LiPF_6$ is moisture-sensitive and may form HF and other fluorinated products. Local acidification can increase metal solubility, while organic carbonate solvents and their degradation products may affect soil microorganisms. Simulated landfill experiments have reported PFAS concentrations of up to approximately 100 mg $L^{-1}$ and inorganic fluoride concentrations of up to 1.4 g $L^{-1}$ for specific batteries and test conditions. These experimental maxima should not be treated as typical landfill concentrations but demonstrate the possibility of concentrated fluorochemical releases (Guelfo et al., 2024; Shojaei et al., 2025).

Battery fires create an acute pathway from the waste stream to air, soil and water. Experimental studies reported gaseous HF emission factors of approximately 10-81 mg $Wh^{-1}$, depending on chemistry and test conditions. Metal-containing particles and fluorinated combustion products may be deposited on soil or transported in firefighting water. Following the January 2025 Moss Landing battery-storage fire, increased Ni, Mn and Co concentrations were measured in nearby surface wetland soils, with a Ni ratio consistent with NMC532 cathode material. Enrichment was concentrated in the upper few millimetres and subsequently decreased after rainfall and tidal flushing, demonstrating both deposition and remobilisation (Claassen et al., 2024; Aiello et al., 2025).

The main EoL-LIB pollutants, their sources, dominant environmental pathways and potential effects are summarised in Table 2.

Table 2. Main EoL-LIB pollutants, pathways and environmental effects

| Pollutant or material | Main source | Dominant pathway | Potential environmental effect |
|---|---|---|---|
| Li | Cathode and electrolyte | Leachate and groundwater transport | Salinity and ionic imbalance; plant uptake |
| Ni and Co | NMC, NCA and LCO cathodes | Leachate, dust and fire deposition | Microbial toxicity, phytotoxicity and oxidative stress |
| Mn | NMC and LMO cathodes | Leachate under acidic or reducing conditions | Nutritional imbalance and toxicity at elevated concentration |
| Cu | Anode current collector | Dust, leachate and recycling residues | Microbial inhibition and alteration of clayey soil properties |
| HF and inorganic fluorides | $LiPF_6$ degradation and fires | Gas emissions, leachate and firefighting water | Acidification, metal mobilisation and acute toxicity |
| PFAS/bis-FASI | Some electrolytes and fluorinated materials | Manufacturing, recycling and landfill leachate | Persistent and mobile contamination |
| Cathode particles and graphite | Shredding and fires | Atmospheric dispersion and soil deposition | Particle toxicity and gradual metal dissolution |

Source: Authors' synthesis based on Mrozik et al. (2021), Rensmo et al. (2023), Claassen et al. (2024), Guelfo et al. (2024), Aiello et al. (2025), and Shojaei et al. (2025).

As shown in Table 2, EoL-LIB pollution involves both dissolved and particulate contaminants transported through leachate, atmospheric deposition, firefighting water and recycling residues. In addition to their chemical and biological effects, battery-derived contaminants may also influence the physical and geotechnical properties of soil. In controlled experiments using clayey soil contaminated with 3-9% Cu, Co or Ni powder, maximum permeability increases of 84%, 46% and 68%, respectively, were recorded, while shear strength decreased by 34%, 11% and 27%. These concentrations are much higher than typical diffuse contamination and should not be directly extrapolated to ordinary sites. Nevertheless, they demonstrate that severe battery-related contamination may influence soil plasticity, permeability, consolidation and geotechnical stability, in addition to chemical and biological functions (Mishra et al., 2026).

A representative 60 kWh NMC811 pack with an estimated mass of 312 kg contains approximately 5.6 kg Li, 37.7 kg Ni, 4.4 kg Mn, 4.7 kg Co and 23.4 kg Cu under the adopted composition assumptions. If 4% of the Ni inventory were released and mixed into 26 t of soil, corresponding to 100 m² to a depth of 0.20 m and an apparent density of 1.3 t $m^{-3}$, the Ni concentration would increase by approximately 58 mg $kg^{-1}$. When added to a background value of 20 mg $kg^{-1}$, the resulting concentration of approximately 78 mg $kg^{-1}$ would slightly exceed the Romanian alert threshold of 75 mg $kg^{-1}$ for sensitive land use (Ahmed et al., 2023; Ministry of Waters, Forests and Environmental Protection, 1997).

This calculation represents a conservative hotspot rather than an expected average concentration. It assumes that released material is retained within a small soil volume and does not account for runoff, wind dispersion, deep leaching or removal during emergency response. It nevertheless shows that even one damaged traction battery may generate locally relevant contamination when its contents are fragmented or deposited over a limited area (Mrozik et al., 2021).

Taken together, the experimental, field and modelling evidence indicates measurable forms of environmental degradation rather than only a theoretical possibility of contamination. Reported effects include HF emissions during battery fires, the deposition and remobilisation of cathode metals in surface soils, increased soil permeability, reduced shear strength and the potential exceedance of soil-quality thresholds (Claassen et al., 2024; Aiello et al., 2025; Mishra et al., 2026). Although these effects may be concentrated at individual accident, disposal or recycling sites, they demonstrate that EoL-LIB releases can affect air quality, soil chemistry, contaminant mobility, hydraulic behaviour and geotechnical stability.

At the global scale, the 2030 stress scenario produced potential releases of approximately 700 t Li, 447 t Ni, 278 t Cu, 149 t Mn and 56 t Co. These estimates were calculated by the authors using the waste projections reported by the United Nations Development Programme (2024) and the release assumptions derived from Mrozik et al. (2021). Although these values remain small compared with total battery waste, they represent significant dispersed contaminant loads, particularly when concentrated around informal processing sites, landfills or storage facilities.

By 2040, the strong increase in the EoL-LIB stream becomes the dominant driver of potential pollution. Scenario A, representing relatively effective control, produced releases ranging from approximately 29 t Mn to 365 t Li. Under Scenario B, the calculated quantities reached thousands of tonnes for Li, Ni and Cu. Scenario C generated substantially larger upper-bound values and illustrates the consequences of combining high waste quantities with fragmentation, fires or uncontrolled disposal. The increase in contaminant releases under Scenario B between 2030 and 2040 is illustrated in Figure 1, while the results obtained for all three scenarios in 2040 are presented in Table 3. As shown in Figure 1, lithium had the highest estimated release under the landfill/stress scenario, increasing from approximately 700 t $year^{-1}$ in 2030 to 7,754 t $year^{-1}$ in 2040. Nickel increased from 447 to 4,949 t $year^{-1}$, while the estimated Cu release rose from 278 to 3,075 t $year^{-1}$. Lower quantities were calculated for Mn and Co; however, their environmental relevance remains considerable because of their potential ecotoxicity and increased mobility under acidic or reducing soil conditions. The marked increase between 2030 and 2040 is mainly explained by

the expansion of the global EoL-LIB waste stream, since the assumed mismanagement and contaminant-release fractions remained unchanged.

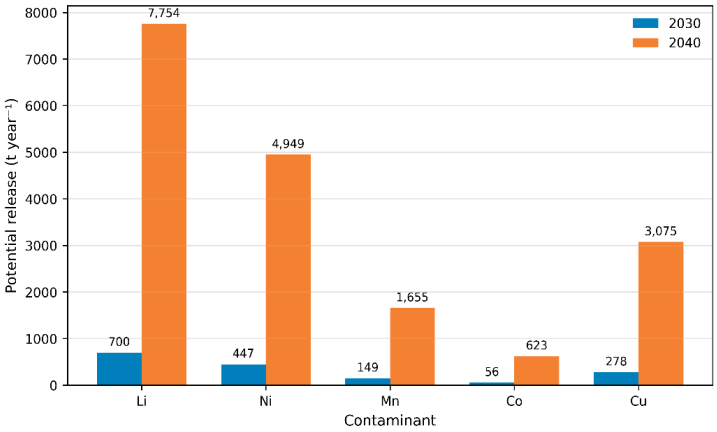

Figure 1. Estimated potential releases of lithium, nickel, manganese, cobalt and copper under the landfill/leaching stress scenario in 2030 and 2040 (Source: authors' calculations based on Mrozik et al., 2021, United Nations Development Programme, 2024, and the modelling assumptions described in Materials and Methods)

Table 3. Estimated potential contaminant releases from NMC811-type EoL-LIB waste in 2040

| Scenario | Li | Ni | Mn | Co | Cu |
|---|---|---|---|---|---|
| A | 365 | 247 | 29 | 31 | 154 |
| B | 7,754 | 4,949 | 1,655 | 623 | 3,075 |
| C | 41,051 | 37,115 | 8,672 | 4,674 | 23,062 |

Source: Authors' calculations based on Mrozik et al. (2021), United Nations Development Programme (2024), and the assumptions described in Materials and Methods.

Values are expressed in t $yr^{-1}$. A - controlled management; B - landfill/leaching stress; C - severe mismanagement.

The values presented in Table 3 are conservative screening estimates rather than forecasts. The future waste stream will include an increasing proportion of LFP batteries, which would reduce Ni and Co loads, while released contaminants may be distributed among soil, water, air, sludge and engineered residues. Consequently, the results are primarily useful for comparing management scenarios and demonstrating the importance of collection efficiency rather than predicting pollution at a specific location (Harper et al., 2019; International Energy Agency, 2024).

Mechanical pre-treatment generally involves discharge, dismantling, crushing, sieving and physical separation. It concentrates cathode and anode materials into black mass but may generate metal-bearing dust, volatile electrolyte compounds and fire risks. The quality and chemical homogeneity of black mass strongly affect the environmental and economic performance of subsequent recycling stages (Harper et al., 2019; Rinne et al., 2024).

Pyrometallurgical recycling can process mixed or contaminated feedstocks and efficiently transfer Ni, Co and Cu into an alloy. However, the process requires high temperatures, destroys graphite and organic components and may transfer Li, Al and Mn to slag. Fluorinated emissions require gas treatment, while the long-term leaching behaviour of slag and dust must be assessed before reuse or disposal. The low Ni and Co content of LFP batteries further reduces the economic attractiveness of conventional pyrometallurgy for this chemistry (Harper et al., 2019; Mrozik et al., 2021).

Hydrometallurgical recycling uses acid or alkaline leaching, precipitation, solvent extraction and crystallisation to recover Li and transition metals. It generally operates at lower temperatures and may achieve high recovery efficiencies, but the process consumes water, acids, bases and reducing agents and generates saline wastewater and sludge. A process-based life-cycle assessment found that reducing the initial acid concentration from approximately 2 M to below 0.5 M lowered several environ-

mental impacts by approximately 30-40%, illustrating the importance of reagent optimisation and internal recycling (Rinne et al., 2024).
Direct recycling seeks to preserve the functional structure of cathode materials through separation, purification, relithiation and thermal treatment. It may reduce energy and chemical requirements because the cathode is not completely decomposed into metals or salts. Its main limitations are the need for accurate chemistry identification, clean feedstocks and control of Cu, Al and electrolyte contamination. Direct recycling may be particularly important for LFP, where recovery based solely on the market value of individual metals is less favourable (Harper et al., 2019; International Energy Agency, 2024).
Recent hydrometallurgical work on waste LFP batteries reported Li leaching efficiencies of 54-97% using organic acids and reductants, with Li recovery of approximately 90% after precipitation. Such results indicate that LFP recycling can be technically feasible, although industrial environmental performance will also depend on reagent recovery, wastewater treatment, energy use and product quality (Avcı & Özdemir, 2026).
To assess the influence of management and treatment technologies on environmental pollution, the principal release pathways associated with uncontrolled disposal, battery fires, mechanical pretreatment, pyrometallurgy, hydrometallurgy and direct recycling are compared in Table 4.

Table 4. Technology-specific pollution pathways and environmental implications of EoL-LIB management and recycling

| Technology or scenario | Main potential releases | Main affected medium | Environmental implication |
|---|---|---|---|
| Uncontrolled disposal/landfill | Li, Ni, Co, Mn, Cu, fluorides, PFAS | Soil and groundwater | Chronic leaching and contaminant accumulation |
| Battery fire | HF, metal-rich particles, fluorinated compounds | Air, surface soil and water | Acute deposition and remobilisation |
| Mechanical pretreatment | Fine cathode dust, graphite, electrolyte vapours | Air and workplace surfaces | Particulate and VOC exposure |
| Pyrometallurgy | Combustion gases, slag containing Li, Al and Mn | Air and solid residues | High energy demand and residue-management risks |
| Hydrometallurgy | Acidic or saline wastewater and metal-bearing sludge | Surface water, groundwater and soil | High recovery but significant wastewater burden |
| Direct recycling | Dust, rejected mixed materials and damaged cathode fractions | Air and solid waste | Lower processing burden but requires clean feedstock |

Source: authors' synthesis based on Harper et al. (2019), Mrozik et al. (2021), Rensmo et al. (2023), Claassen et al. (2024), Guelfo et al. (2024), International Energy Agency (2024), Rinne et al. (2024), Aiello et al. (2025), and Shojaei et al. (2025).

As shown in Table 4, EoL-LIB management and recycling options generate different release profiles and may transfer environmental burdens between air, soil, water and solid residues. The dominant environmental compartment therefore changes according to the management route: uncontrolled disposal primarily threatens soil and groundwater, battery fires affect air and surface environments, pyrometallurgy concentrates burdens in gaseous emissions and solid residues, while hydrometallurgy transfers a substantial part of the burden to wastewater and sludge.
Recycling performance should therefore not be evaluated only through the total percentage of battery mass processed. A system may achieve a high mass-based efficiency by recovering steel, Cu and Al while losing Li, graphite, fluorinated compounds or fine active material. Environmental assessment should therefore combine overall recycling efficiency with element-specific recovery, energy and reagent consumption, wastewater quality and the leaching stability of final residues (Rensmo et al., 2023; Rinne et al., 2024).
European legislation requires a minimum recycling efficiency of 65% for lithium-based batteries by the end of 2025 and 70% by the end of 2030. Material recovery targets are 90% for Co, Cu, Ni and Pb and 50% for Li by the end of 2027, increasing to 95% and 80%, respectively, by the end of 2031. These targets create

incentives for improved Li recovery and more complete material balances, but effective environmental protection also depends on collection, traceability and control of fluorinated emissions and residues (European Commission, 2025; European Parliament and Council of the European Union, 2023).

The most favourable pollution-prevention scenario combines collection rates approaching 100%, digital battery identification, separation by chemistry, fire-resistant storage, rapid isolation of damaged batteries and recycling routes selected for the feedstock. Monitoring programmes around storage and recycling facilities should include Li, Ni, Co, Mn, Cu, total and soluble fluorides, pH, electrical conductivity and groundwater quality. PFAS screening should be considered where fluorinated electrolytes or polymers are produced or processed (Guelfo et al., 2024; Rensmo et al., 2023).

## CONCLUSIONS

Global electric-vehicle battery deployment reached approximately 1.2 TWh in 2025, corresponding to an estimated 7.0 Mt of batteries, and may approach 17.5 Mt annually by 2030.

The annual EoL-LIB waste stream is projected to increase from 0.90 Mt in 2025 to 20.50 Mt in 2040, requiring a rapid expansion of collection, storage and recycling infrastructure.

Environmental degradation may result from the combined action of Li, Ni, Co, Mn, Cu, fluorides, electrolyte degradation products, fine cathode particles and persistent organofluorinated compounds. Soil acidification may amplify pollution by increasing metal mobility and bioavailability.

The stress scenario for 2040 produced potential releases of approximately 7,754 t Li, 4,949 t Ni, 3,075 t Cu, 1,655 t Mn and 623 t Co. These values are sensitivity indicators rather than predictions, but they demonstrate that small percentages of mismanaged waste can generate substantial contaminant loads.

NMC and NCA waste presents a higher Ni and Co contamination potential, whereas LFP reduces these metal-related risks but maintains the need to recover Li, Cu, graphite, phosphate compounds and fluorinated electrolyte materials.

Pyrometallurgy is robust for mixed feedstocks but may transfer environmental pressure to energy use, emissions and slag. Hydrometallurgy provides broader metal recovery but requires strict control of reagents and wastewater. Direct recycling offers high circularity potential for clean, chemistry-specific streams.

Collection efficiency is the principal control variable. Chemistry-based sorting, traceability, fire-safe storage, capture of firefighting water and site-specific soil and groundwater monitoring are required to prevent the transfer of battery pollution between environmental compartments.

***Abstract***

*Electrochemical sensors are an efficient and versatile tools for monitoring environmental pollutants, providing information on target analytes in a rapid, sensitive and cost-effective manner and representing a good alternative to conventional methods such as spectrophotometry and chromatography in real time or on-site analysis. These sensors use electrochemical methods, including amperometry, voltammetry and potentiometry, to detect a wide range of environmental pollutants, including heavy metals, pesticides and other toxic chemicals, making them well-suited for environmental monitoring. Due to their simplicity, accuracy, low cost and their performance (stability, selectivity, LOD in the micro and nanomolar range) and because they can be modified with nanomaterials, enzymes and molecularly imprinted polymers, sensors and biosensors are increasingly used in environmental monitoring and pollution control. Therefore, this work proposes to present a review of the most recent developments in the detection of environmental pollutants using electrochemical sensors.*

***Key words:*** *electrochemical sensor, enzyme, nanomaterial, pollutant.*

## INTRODUCTION

Environmental health is important for maintaining life on Earth. Population growth and rapid industrialization have led to gradual environmental pollution, with harmful effects on ecosystems and human health. For this reason, pollution has become a public concern worldwide. Contamination and pollution occur when harmful compounds and pollutants are released into the air, soil, and water, either naturally (through fires or volcanic eruptions) or as a result of human activities. This pollution can have serious effects on human health, causing a range of diseases and conditions, including cancer, respiratory diseases, cardiovascular diseases, and other chronic illnesses. Chemical contaminants, released into the environment as a result of human activities, have become major pollutants that have led to increased toxicity in aquatic ecosystems, soil, and water. Pollution of natural ecosystems can also have consequences for the economy. High costs are incurred in cleaning up polluted areas or mitigating the adverse effects caused by prolonged exposure to a contaminant. High costs are generated by cleaning up polluted areas or mitigating the adverse effects produced by prolonged exposure to a contaminant (Awewomom et al., 2024; Rathod et al., 2024).

Currently, there are numerous methods for detecting and monitoring environmental contaminants. The most common techniques are: chromatographic techniques (liquid chromatography (LC) and gas chromatography (GC) coupled with various types of detection), spectroscopic techniques (atomic absorption spectroscopy (AAS) and ultraviolet-visible spectroscopy (UV-Vis)). Although these methods are effective in detecting compounds of interest, they also have a number of limitations - long sample preparation times, the need for qualified personnel to operate the equipment, the use of toxic solvents, high costs, and the complexity of the equipment. Therefore, it is necessary to use a new alternative that offers significant advantages in terms of cost, sensitivity, and selectivity, as well as in terms of processing time (Wang et al., 2021; Kassim et al., 2022; Dawra & Dabas, 2024; Gątarek et al.,

2025). Sensors and biosensors have become an effective tool for monitoring the environment, water quality, air pollution, soil analysis, and biodiversity conservation. These are widely used as cost-effective, portable, inexpensive, and sensitive analytical techniques that can be combined with other analytical methods to enhance their selectivity and sensitivity. These advantages have led to increased use of these methods in real-time monitoring of environmental pollutants, as a sustainable alternative to traditional methods that does not cause additional pollution (Tajik et al., 2021; Pal et al., 2025).

**Pollutants**

Substances that cause unwanted changes in the natural environment, with harmful effects on plants, animals and humans, are called pollutants. A compound becomes a pollutant when its concentration exceeds its natural abundance as a result of natural phenomena or caused by human activities (Khasanova et al., 2023).

**Classification of pollutants**

Pollutants can be classified according to several criteria:

- by nature (microbial or chemical);
- by origin: natural pollutants (which occur naturally but, over time, due to accumulation or a sudden increase in their concentration, exert toxic effects on the environment);
- artificial pollutants (introduced into the environment by humans and their activities);
- based on their elimination in nature in relation to ecosystems, they can be further classified as biodegradable and non-biodegradable pollutants (Khanmohammadi et al., 2020; Ajibade et al., 2021).

Worldwide, the most common pollutants are heavy metals, pesticides and pharmaceutical compounds. These compounds pose a high risk because they can accumulate in the tissues of living organisms, which can lead to the development of degenerative diseases, alter the chemical composition of soil and water (Kordbacheh & Heidari, 2023).

**Heavy metals**

Heavy metals are a natural component of the environment, but human activities (increased industrialization, exploitation of natural and mineral resources, and economic instability) have disrupted natural geochemical processes, turning this component into a threat to the environment. Their toxic nature, persistence, bioaccumulation, and stability in the environment have come to threaten both natural ecosystems and human health (Ali et al., 2021; Swain, 2024). Heavy metals directly influence the chemical and physical properties of soil, water, and sediment. They can affect the trophic balance in the environment, disrupting the food chain for an indefinite period of time. Sparingly soluble heavy metals can accumulate in excessive amounts and interfere with natural biological processes in living organisms (Ali et al., 2021). Heavy metals can enter water sources in two ways: naturally or artificially. Artificial contamination results from landslides, illegal dumping, and discharges into freshwater or marine habitats, while natural contamination is caused by forest fires, mineral erosion, and volcanic activity (Swain, 2024). Environmental monitoring is important because there is a close link between the pollution of natural ecosystems and human health and socioeconomic development (Huang et al., 2023). Exposure to environmental pollution remains a major risk to human health worldwide. Exposure levels are often uneven and can occur through various pathways (via air or water). The duration of exposure and the concentration of pollutants are increasing year by year. Exposure to multiple pollutants can have adverse effects not only on human health but also on the environment. Thus, environmental monitoring has become one of the most important tasks facing not only the EU but the entire planet (Bălă et al., 2021; Shetty et al., 2023).

**Pesticides**

Rapid population growth of the current century has led to the growth of the agricultural industry and, consequently, to the widespread use of pesticides. Their use has become widespread because they reduce losses, protect crops, and improve production yields on a global scale. Pesticides are classified according to several criteria: mode of action, chemical class, functional groups, and toxicity. The most important classification criterion is based on the different pest targets: herbicides, insecticides, fungicides, rodenticides, etc. (Tudi et al., 2021).The heavy use of pesticides, such as

chloridazon, methyl parathion and chlorpyrifos, has negative effects on the environment. A large proportion of this end up in the ecosystem, carried either by the wind or by water, with up to 95% of herbicides and over 98% of insecticides becoming pollutants. These pollutants eventually end up in surface and groundwater, lakes, and oceans, where, due to physical and chemical interactions, they can form highly toxic reaction byproducts (Abdollahdokht et al., 2021). Classic pesticides often have high concentrations of organic solvents with low dispersion that remain in soil and sediment for a long time and move in the environment, endangering biological systems (Rad et al., 2022).

**Pharmaceutical Products**

Of all the emerging pollutants of concern, pharmaceuticals (FP) attract the most attention globally because they cause a high level of environmental pollution (Argaluza et al., 2021). In recent decades, the production and consumption of pharmaceuticals (paracetamol, diclofenac, tetracyclines and azithromycin), have increased rapidly due to declining health, rising food consumption, and advances in medicine (Măghinici et al., 2025). Anti-inflammatory drugs, antibiotics, and analgesics are the most commonly used medications globally and are taken daily around the world. Consequently, water-soluble, pharmacologically active organic micropollutants have begun to enter the environment, causing various harmful effects (Ortúzar et al., 2022; Măghinici et al., 2026). This environmental pollution caused by pharmaceuticals occurs primarily through the discharge of effluents from wastewater treatment plants into surface waters. Urban wastewater contains high levels of compounds resulting from various activities, whether industrial- such as aquaculture and livestock farming - where the use of antibiotics and growth hormones has become common practice, or in human healthcare, where 30-90% of administered oral doses find their way into ecosystems (Zampelli & Verna, 2025). The increasing use of pharmaceuticals to treat, alleviate, or prevent health conditions, as well as their use in veterinary medicine, plays a major role in ecosystem degradation. These pharmaceuticals have toxic effects on ecosystem components, ranging from biota to water and soil quality. These compounds can disrupt the fragile balance of ecosystems, alter the pH of water and soil, and cause genetic changes and malformations in existing biota. In the case of fish, the active compounds in medications cause cellular damage and respiratory problems, with adverse effects on growth, development, and reproductive capacity (Mezzelani & Regoli, 2022; Ortúzar et al., 2022).

**Electrochemical methods for detecting environmental pollutants**

Contaminants of emerging concern (CECs) continue to threaten the health of natural ecosystems as well as human health, a situation largely attributable to human activities. It is particularly important to monitor ECs, as they tend to migrate from their source and affect various aspects of the environment (sediment, flora, or fauna). Thus, electrochemical (EC) methods are widely used in environmental monitoring, as they are versatile in detecting emerging contaminants (heavy metals, pharmaceuticals, pesticides) (Kumunda et al., 2021; Sivaranjanee et al., 2022). Electrochemical techniques such as voltammetry, amperometry, conductometry, and potentiometry are successfully used today in environmental monitoring for rapid, sensitive detection, as well as for their potential for miniaturization and field deployment (Sivaranjanee et al., 2022).

Sensors can also be classified based on the analysis method they use:

- amperometric sensors - measure current over time based on a constant potential applied to the electrode;
- conductometric sensors - measure a solution's ability to conduct electric current;
- impedance sensors - measure electrical impedance (capacitance and resistance) when a small alternating current is applied;
- potentiometric sensors - used to measure the difference in electric potential between the working electrode and the reference electrode under zero-current conditions;
- voltammetric sensors - measure current based on the variable potential applied to the electrode (Kiaune & Singhasemanon, 2011; Saputra, 2023).

Among voltammetric methods - cyclic voltammetry, square-wave voltammetry, and differential pulse voltammetry - these techniques offer significant advantages such as high precision, simplicity, speed, selectivity, sensitivity, cost-effectiveness, and repeatability (Sivaranjanee et al., 2022). Equally, recent technological advances in the field of nanotechnology (nanofabrication, printing, immobilization) have made it possible to adapt electrochemical sensors for the detection of a wide range of CECs (Hassan et al., 2022). Today, electrochemical sensors have revolutionized environmental monitoring, from water and soil to air quality. An electrochemical sensor is capable of responding continuously, selectively, and reversibly to the presence of a CEC, without disturbing the sample, and of providing accurate, timely information about the ecological status of a specific environment. Sensors consist of two components: a recognition element for the specific or selective binding of the analyte of interest, and a transducer element for transmitting the information. Carbon-based electrochemical sensors (CPE), glassy carbon electrodes (GCE), and screen-printed electrodes (SPE), examples from tables, have proven effective in determining and monitoring CECS in environmental samples. Their performance is determined by response time, signal-to-noise ratio (S/N), sensitivity, selectivity, linear range, and limits of detection (LOD) (Kanoun et al., 2021). Electrochemical sensors convert the chemical signal (the signal generated by the redox reaction occurring at the electrode surface) into a quantifiable electronic signal (Kiaune & Singhasemanon, 2011; Saputra, 2023). Electrochemical sensors can be modified with various materials to improve selectivity and sensitivity toward analytes of interest. Nanomaterials, metal nanoparticles, metal oxides, metal-organic frameworks, molecularly imprinted polymers, and biological elements (enzymes, antibodies, aptamers, DNA, RNA) are the main classes of materials with which electrochemical sensors can be modified to achieve analytical performance (Flores-Contreras et al., 2022; Rafaqat et al., 2022; González-González et al., 2023; Zheng et al., 2024).

## MATERIALS AND METHODS

To accomplish this work, articles from the specialized literature were studied and analyzed, from the Google Scholar database (Google Academic), selecting articles published in the last 5 years, between 2022 to the present, focusing on studies related to the configurations of electrochemical sensors used to detect different classes of environmental pollutants. Approximately 20 relevant articles were studied and presented in Tables 1, 2, and 3.

## RESULTS AND DISCUSSIONS

### Electrochemical sensors based on nanomaterials

Carbon-based nanomaterials (single-walled and multi-walled carbon nanotubes - SWCNT, MWCNT; carbon nanofibers - CNF; graphene quantum dots - GQDs), metallic nanoparticles (AuNPs, AgNPs, PtNPs), metal oxide nanoparticles (ZnO, NiO, $Fe_3O_4$), as well as polymeric nanomaterials (e.g., chitin nanocrystals - ChNCs) are frequently used as modifier materials for electrochemical sensors and biosensors because they exhibit superior mechanical strength, a high surface-to-volume ratio, enhanced electrocatalytic activity, properties that improve the selectivity and specificity of sensors, as well as response times (Alnahdi et al., 2022; Dinu et al., 2024; Masibi et al., 2025; Fakraoui et al., 2026; Wang et al., 2026).

### Electrochemical sensors based on metal-organic structures (MOF)

MOFs are structures formed by inorganic metal ions and organic ligands. MOFs are increasingly used in the modification of commercial electrochemical sensors due to their unique physicochemical properties such as large surface area, high porosity, tunable pore size and high catalytic activity. In recent years, MOFs that have metal ions such as copper, zinc, zirconium and nickel in their structure and carboxylic acid derivatives as organic ligands have been used in the electrochemical detection of environmental pollutants, including active pharmaceutical compounds, pesticides, metal ions, but also phenolic and nitroaromatic compounds (Tajik et al., 2021).

**Electrochemical sensors based on molecularly imprinted polymers (MIP)**

Molecularly imprinted polymers (MIPs) are polymers obtained by copolymerizing a functional monomer with a cross-linking agent that interacts with the target molecule (template) to form specific binding sites. After the template is removed, these specific binding sites are capable of recognizing and specifically binding the template (Udomsap et al., 2018). MIPs are the subject of intensive research due to their excellent properties, such as the ability to recognize the target analyte in a complex matrix, affordability, ease of synthesis, potential for miniaturization, durability, selectivity, and high physical and chemical stability - characteristics that make them suitable for electrochemical sensor applications in the detection of emerging pollutants, including pesticides and pharmaceuticals in environmental samples (Rao et al., 2018; Udomsap et al., 2018; Thimoonnee et al., 2022; Kamel et al., 2024; Poza-Nogueiras et al., 2026).

**Electrochemical sensors based on biological elements**

Electrochemical biosensors utilize a wide range of biorecognition elements (enzymes, antibodies, aptamers, DNA, RNA, whole cells) that provide high selectivity and sensitivity in the detection of target analytes. The performance of these electrochemical biosensors depends on the type of electrode, the type of transducer, the biological elements, and the techniques used to immobilize them (encapsulation, adsorption, covalent binding, cross-linking). The advantages of electrochemical biosensors include affordability, simplicity, fast response time, portability, high selectivity, and high sensitivity, making them useful for the detection and monitoring of CECs in environmental samples (Fdez-Sanromán et al., 2025; Hui et al., 2022).

Table 1. Electrochemical sensors for detecting heavy metals in environmental samples

| Sensor | Pollutants | Sample | Detection method | LOD | Linear range | Bibliographic reference |
|---|---|---|---|---|---|---|
| SPCE/$Fe_3O_4$-CNF | $Cd^{2+}$ | River water | SWASV | 0.0615 µM | 6-80 µM | (Dinu et al., 2024) |
| | $Pb^{2+}$ | | | 0.0154 µM | 14-80 µM | |
| | $Cu^{2+}$ | | | 0.0320 µM | 1-60 µM | |
| | $Hg^{2+}$ | | | 0.0148 µM | 6-80 µM | |
| SPCE/$Fe_3O_4$-MWCNT | $Cd^{2+}$ | | | 0.2719 µM | 6-70 µM | |
| | $Pb^{2+}$ | | | 0.3187 µM | 14-80 µM | |
| | $Cu^{2+}$ | | | 1.0436 µM | 1-60 µM | |
| | $Hg^{2+}$ | | | 0.9076 µM | 6-80 µM | |
| Bi-GC/RDE | $Cu^{2+}$ | River water | SWASV | 0.0105 µM | 0.04-0.35 µM | (Bounegru et al., 2025) |
| | $Pb^{2+}$ | | | 0.0207 µM | | |
| CNTs/UiO-66-$NH_2$@AuNPs/GCE | $Cd^{2+}$ | River water | DPSV | 0.021 µg/L | 0.06-400 µg/L | (Wang et al., 2026) |
| | $Pb^{2+}$ | | | 0.008 µg/L | 0.06-400 µg/L | |
| PTh/ChNCs/SA/SPCE | $Pb^{2+}$ | Wastewater | SWASV | 1.53 nM | 10-150 nM | (Fakraoui et al., 2026) |

*LOD = limit of detection; SWASV = square wave anodic stripping voltammetry; DPSV = differential pulse stripping voltammetry.

**Electrochemical sensors for the detection of heavy metals**

Dinu and his colleagues used various nanomaterials (iron oxide nanoparticles ($Fe_3O_4$ NPs), CNF, and MWCNT), in various combinations, to modify carbon-based electrochemical sensors for the detection of metal ions ($Cd^{2+}$, $Pb^{2+}$, $Cu^{2+}$, and $Hg^{2+}$) in river water samples. The analytical performance of the SPCE/$Fe_3O_4$-CNF and SPCE/$Fe_3O_4$-MWCNT sensors was evaluated using square-wave anodic stripping voltammetry (SWASV), yielding detection limits in the micromolar range. The SPCE/$Fe_3O_4$-CNF sensor exhibited superior analytical performance in terms of detecting the metal ions of interest, a performance that may be attributed to the CNF structure (thin and long structures) which allows for their homogeneous distribution among the $Fe_3O_4$ particles, as well as to the synergistic interaction between CNF and $Fe_3O_4$ (Dinu et al., 2024). In another study, a glassy carbon electrode with a rotating disk modified with a bismuth film (Bi-GC/RDE) was used for the simultaneous detection of $Pb^{2+}$ and $Cu^{2+}$ ions in river water samples, following prior

complexation with EDTA (ethylenediaminetetraacetic acid). The bismuth layer, deposited by electrochemical deposition, ensured the stability and reproducibility of the electrochemical signal in SWASV voltammetric measurements. Bi-GC/RDE exhibited competitive LODs of 0.0207 μM and 0.0105 μM for $Pb^{2+}$ and $Cu^{2+}$, respectively, detection limits that are significantly more sensitive compared to other RDE sensors reported in the literature for the detection of metal ions (Bounegru et al., 2025). The research conducted by Wang et al. demonstrates that a glassy carbon electrode (GCE) modified with a composite material consisting of modified Zr-MOF structures (UiO-66-$NH_2$), AuNPs, and CNTs can be successfully used for the simultaneous detection of two heavy metal ions (HMIs), exhibiting remarkable stability and sensitivity, with LODs of 0.021 μg/L for $Cd^{2+}$ and 0.008 μg/L for $Pb^{2+}$, obtained via DPSV (differential pulse stripping voltammetry) measurements. The sensor exhibited a large surface area and active sites due to the MOF structure, superior conductivity due to CNTs, and localized amplification of surface plasmon resonance due to AuNPs. Analysis of real samples (river water) demonstrated the practical applicability of the CNTs/UiO-66-$NH_2$@AuNPs/GCE sensor in the detection of environmental pollutants (Wang et al., 2026). As highlighted by Fakraoui and colleagues, the screen-printed carbon electrode (SPCE) modified with colloidally stabilized polythiophene (PTh) nanocomposites containing chitin nanocrystals (ChNCs), using sodium alginate (SA) as the matrix, exhibited excellent electroanalytical performance for the detection of $Hg^{2+}$ and $Pb^{2+}$ ions, with detection limits in the nanomolar range (3.26 nM and 1.53 nM). The novelty of the study lay in the use of a composite consisting of bio-natural polymers with conductive polymers, a composite that reduced the domain size, improved electron transfer kinetics, and prevented aggregation. The excellent results obtained with the PTh/ChNCs/SA/SPCE sensor on real wastewater samples were validated by atomic absorption spectrometry (AAS) (Fakraoui et al., 2026).

Table 2. Electrochemical sensors for detecting pesticides in environmental samples

| Sensor | Pollutants | Sample | Detection method | LOD | Linear range | Bibliographic reference |
|---|---|---|---|---|---|---|
| $Fe_3O_4$ /ITO | chloridazon | Surface water | SWV | 0.9 μmol/L | 1–22.5 μmol/L | (Alnahdi et al., 2022) |
| c-MWCNTs@$MoSe_2$-SPCE | methyl parathion | Tap and river water | DPV | 2.5 nM | 0.008–75 μM | (Beitollahi et al., 2025) |
| $La_2Sn_2O_7$@GO/GCE | paraoxon ethyl | Soil | DPV | 2.73 nM | 0.01-360 μM | (Akilarasan et al., 2024) |
| MSN-PtNPs@d-MIP/SPGE | paraquat | Reservoir and pond water | DPV | 3.1 nM | 0.025–500 μM | (Thimoonnee et al., 2022) |
| | glyphosate | Wastewater | | 4.0 nM | | |
| Cu/$Cu_2O$/CuO@C/GCE (Cu-BTB MOF) | diflubenzuron | Tap and river water Soil | DPV | 130 fM | $1.0 \times 10^{-4}$ M – $1.0 \times 10^{-12}$ M | (Ji et al., 2023) |
| AChE/Co-ExZrP/His-GQDs/SPSE | methyl parathion | Groundwater and drinking water | LSV | 0.01 μM | 0.2–50 μM | (Pengsook et al., 2026) |
| AChE/CS-GO/GO/CNFs/SPCE | chlorpyrifos | Drinking water | SWV | 2.2 nM | 2.5 nM–1 μM | (Thet Tun et al., 2023) |

*LOD = limit of detection; SWV = square wave voltammetry; DPV = differential pulse voltammetry; LSV = linear sweep voltammetry.

A study reported in the scientific literature demonstrated that the use of $Fe_3O_4$NPs significantly improves the performance of an indium tin oxide (ITO)-based sensor in detecting chloridazon, an organochlorine pesticide with harmful effects. Electrochemical detection was performed using square-wave voltammetry (SWV), yielding a LOD of 0.9 μmol/L. The $Fe_3O_4$/ITO sensor exhibited high sensitivity and selectivity, even in the presence of other interferents, when used for the detection of chloridazon in real surface water samples. The high specificity is due to $Fe_3O_4$ NPs, which can easily bind to the chlorine atoms in organochlorine pesticides (Alnahdi et al., 2023). Beitollahi and his colleagues developed a

screen-printed carbon sensor modified with core-shell nanostructures consisting of MWCNTs functionalized with carboxylic acid (-COOH) and molybdenum diselenide ($MoSe_2$) for the detection of methylparathion (MP) in tap water and river water samples. The DPV technique was used to evaluate the electrochemical response, with the c-MWCNTs@$MoSe_2$/SPCE sensor demonstrating superior analytical performance, characterized by a LOD of 2.5 nM and a wide linear range (0.008–75.0 μM). The performance of this sensor may be due to the synergistic effect between $MoSe_2$ nanostructures, which exhibit high catalytic activity, and MWCNTs, which feature large surface areas with active sites, hydrophilicity, and high electrical conductivity (Beitollahi et al., 2025). In a similar approach, pyrochlore-type lanthanum stannate ($La_2Sn_2O_7$) nanocomposites embedded in graphene oxide (GO) were synthesized and used as modifier materials for the glassy carbon electrode (GCE). Using the DPV technique, the $La_2Sn_2O_7$@GO/GCE sensor demonstrated the ability to detect ethyl paraoxon (POE) in soil samples with a detection limit in the nanomolar range (2.73 nM). The developed sensor showed remarkable results compared to other electrodes (unmodified or modified with other materials), indicating an increase in peak current and a reduction in potential (Akilarasan et al., 2024). A different strategy involves integrating nanomaterials (which provide sensitivity) into molecularly imprinted polymers (which provide selectivity) to detect pesticides in environmental samples. Such an approach was implemented by Thimoonnee and colleagues to detect paraquat (PQ) and glyphosate (GLY) in water samples from reservoirs and ponds, as well as in wastewater. The electrochemical sensor, consisting of a screen-printed graphite electrode (SPGE), modified with a dual-molecularly imprinted polymer (d-MIP), coated on a mesoporous silica-platinum core (MSN-PtNPs), demonstrated excellent detection limits in the nanomolar range (3.1 nM for PQ and 4.0 nM for GLY, respectively). Remarkable results, such as high specificity and selectivity for PQ and GLY, make the MSN-PtNPs@d-MIP/SPGE sensor suitable for on-site water quality monitoring (Thimoonnee et al., 2022). In parallel with approaches based on MIP polymers and nanomaterials, MOF structures were also investigated as modifier materials for the development of electrochemical sensors for pesticide detection. One such study focused on the detection of diflubenzuron, a non-electroactive insecticide from the benzoylurea class, using a Cu/$Cu_2O$/CuO@C/GCE electrochemical sensor. The electrochemical performance of the developed MOF-based sensor (Cu-BTB MOF) was evaluated using DPV, yielding a very good LOD (in the femtomolar range) and a wide linear range. These significantly improved values may be attributed to the large specific surface area of the octahedral MOF and the active sites of the composite, which enhance electron transfer. The sensor also proved effective on real samples, detecting diflubenzuron in tap water and river water, as well as in soil samples, with good recoveries (Ji et al., 2023). In addition to the materials listed above, researchers have also incorporated biological components - particularly enzymes - as immobilized elements on the surface of the electrodes, with the aim of improving the electrochemical detection of pollutants. A recent study showed that the use of the enzyme acetylcholinesterase (AChE) together with materials such as cobalt-modified exfoliated zirconium phosphate (Co-ExZrP), coated on histidine-functionalized graphene quantum dots (His-GQD) deposited on the surface of a silver screen-printed electrode (SPSE) can sensitively detect methyl parathion (LOD = 0.01 μM) in groundwater and drinking water samples (Pengsook et al., 2026). Another study utilized the immobilization of the AChE enzyme on an SPCE electrode modified with cellulose nanofibers, graphene oxide, and a composite of chitosan and graphene oxide (AChE/CS-GO/GO/CNF/SPCE) to detect chlorpyrifos, an organophosphorus pesticide. The electrochemical performance of the sensor, obtained through SWV measurements, indicated a LOD in the nanomolar range (2.2 nM) and is attributed to the inhibition of AChE's catalytic activity, as well as the use of nanomaterials that significantly improved conductivity (Thet Tun et al., 2023).

Table 3. Electrochemical sensors for detecting pharmaceuticals in environmental samples

| Sensor | Pollutants | Sample | Detection method | LOD | Linear range | Bibliographic reference |
|---|---|---|---|---|---|---|
| MIP-EDOT/SPCE | carbamazepine | Tap, river and sea water | DPV | 0.58 μM | 1-50 μM | (Poza-Nogueiras et al., 2026) |
| Zr-MOF/GCE | carbamazepine | Groundwater | DPASV | 0.0085 μmol·l$^{-1}$ | 0.010-0.25 μmol·l$^{-1}$ | (Lalawmpuia et al., 2025) |
| | ciprofloxacin | | | 0.0062 μmol·l$^{-1}$ | 0.01-0.25 μmol·l$^{-1}$ | |
| ZIF-8/PB/GCE | tetracycline | Lake water | SWV | 0.2 pM | 1-10$^6$ pM | (Chen et al., 2026) |
| TA-Au-Ag-ANpM/Fe-dop-PANI/NiO-NPs/GCE | azithromycin | River and lake water | SWV | 0.053 pM | 0.8 pM-250 μM | (Adane et al., 2025) |
| | enrofloxacin | | | 0.013 pM | 0.1 pM-550 μM | |
| NiTe-NPs/GCE | ronidazole | Tap and river water | DPV | 1.5 nM | 0.01-270 μM | (Barwa et al., 2025) |
| CNF@Pd-rGO/GCE | rifampicin | Industrial wastewater | DPV | 3.3 nM | 1-1062 nM | (Devi et al., 2026) |
| CNF-COOH/SPCE | paracetamol | River water | SWV | 0.002 mM | 0.0025-0.050 mM | (Fdez-Sanromán et al., 2025) |

*LOD = limit of detection; DPV = differential pulse voltammetry; DPASV = Differential Pulse Anodic Stripping Voltammetry; SWV = square wave voltammetry.

**Electrochemical sensors for the detection of pharmaceutical compounds**

Sensors modified with various nanomaterials have also been developed for the detection of pharmaceutical substances to improve sensitivity and detection times. In a recent study, the use of CNFs functionalized with carboxyl groups (-COOH) for SPCE improved the detection of paracetamol and 4-aminophenol in river water samples. The research highlighted that the carboxyl groups increased the density of active sites on the CNFs, leading to better adsorption of the analytes and improving electron transfer (Fdez-Sanromán et al., 2025). In a similar study, CNFs were used in combination with palladium nanoparticles (Pd NPs) and reduced graphene oxide (rGO) for a GCE to enable ultrasensitive detection of rifampicin, a drug used to treat tuberculosis. The nanomolar LOD, obtained via DPV measurements, indicates that CNF@Pd-rGO/GCE exhibits superior electrocatalytic activity, a performance that can be attributed to the synergistic effects of the nanoparticles used (Devi et al., 2026). Barwa and colleagues also used nanoparticles - this time nickel telluride nanoparticles (NiTe-NPs) - to detect ronidazole (RON), an antibacterial and antiprotozoal drug. Depositing NiTe-NPs onto the GCE surface improved electron transfer, facilitating the reduction of RON. The sensor exhibited a LOD of 1.5 nm, high sensitivity and selectivity even in the presence of other interferents, and was successfully applied for the detection of RON in tap water and river water (Barwa et al., 2025). In addition, two antibiotics, azithromycin (AZM) and enrofloxacin (ENF), were simultaneously detected in environmental samples (river and lake water samples) using a nanomaterial-based electrochemical sensor. The GCE was modified with thermally annealed gold-silver alloy nanocomposites (TA-Au-Ag -ANpM) that improved conductivity, active surface area, and catalytic activity; iron-doped polyaniline (Fe-dop-PANI) that enhanced selectivity by providing binding sites specific to the analytes of interest; and nickel oxide nanoparticles (NiO-NPs) that facilitated electron transfer kinetics. The sensor exhibited LOD in the picomolar range and demonstrated that it is an ideal device for the real-time detection of AZM and ENF in environmental samples (Adane et al., 2025). In parallel with the development of nanomaterial-based sensors for drug detection, researchers have also developed MIP- and MOF-based sensors to overcome the limitations of nanomaterials in terms of selectivity. For example, an SPCE sensor modified with an MIP-EDOT film (obtained by electropolymerization of the functional monomer 3,4-ethylenedioxythiophene in the presence of the target analyte as a template molecule) detected carbamazepine (CBZ) with very high accuracy in tap water, river, and

seawater samples, with recoveries ranging from 82 to 116%. The sensor exhibited superior sensitivity and selectivity for CBZ even in the presence of other interferents (diclofenac, diltiazem, CBZ 10,11-epoxide) (Poza-Nogueiras et al., 2026). Another recent study focused on the development of zirconium-based MOF (Zr-MOF) sensors for the detection of carbamazepine (an antiepileptic) and ciprofloxacin (an antibiotic) residues in groundwater samples. The sensor's improved electrochemical performance is due to the metal-organic framework, which has a large, highly porous surface, making the active surface area of the Zr-MOF/GCE twice as large as that of an unmodified GCE (Lalawmpuia et al., 2025). Another MOF sensor, but this time constructed from an imidazolate zeolite 8 (ZIF-8) structure composed of zinc ions and 2-methylimidazole ligands, onto which Prussian blue (PB) nanoparticles were deposited, successfully detected tetracycline (an antibiotic that can accumulate in aquatic ecosystems). With ZIF-8/PB/GCE, an ultra-low LOD (in the picomolar range), excellent selectivity, and stability were achieved - performance attributed to the synergistic effect between PB, which enhanced electrocatalytic activity, and ZIF-8, which exhibited a large surface area with adjustable porosity, as well as chemical and thermal stability (Chen et al., 2026).

## CONCLUSIONS

Environmental pollution is a major problem worldwide. In recent decades, natural ecosystems have been exposed to a range of pollutants that have disrupted their balance. Environmental degradation is largely caused by human activities, which is why constant monitoring of the effects that pollutants have on the environment is necessary. This review provides an overview of the concept of environmental pollution, emerging contaminants (heavy metals, pesticides, pharmaceutical compounds), the environmental components most affected by pollution, and modern methods for monitoring pollutants. Among current methods, electrochemical techniques coupled with new nanotechnologies have attracted global attention due to their promising characteristics. Recent research has shown that the integration of electrochemical sensors with various materials has improved response times, increased the efficiency of detecting analytes of interest in water samples, enhanced the surface-to-volume ratio, boosted electrocatalytic activity, enabled miniaturization, reduced costs, and improved physical and chemical stability, among other benefits.

***Abstract***

*This study investigated the structure and diversity of tree communities in relation to edge influence in a sector of the Hoia-Baciu peri-urban forest located near Cluj-Napoca, Romania. A total of 20 circular sampling plots (500 m²) were systematically distributed along transects covering varying distances from the forest edge. Within each plot, tree species and the number of individuals were recorded to characterize community composition and structural parameters. Species richness, tree density, and diversity indices (Shannon and Simpson) were calculated, and differences in community composition were explored using non-metric multidimensional scaling (NMDS). The results indicate a simplified tree community strongly dominated by C. betulus. Species richness ranged between one and four species per plot, while Shannon diversity values varied from 0 to 1.22, reflecting moderate spatial heterogeneity among sampling plots. The NMDS ordination revealed a central cluster of plots characterized by the dominance of C. betulus, with a few plots showing greater compositional divergence. These findings highlight the relatively simplified structure but noticeable small-scale variability of tree communities in this peri-urban forest ecosystem.*

***Key words****: edge influence; peri-urban forest; Romania; species diversity; tree community.*

## INTRODUCTION

Forests located in the immediate proximity of urban areas play an increasingly important role in maintaining ecological balance and supporting the quality of life of urban populations (Livesley et al., 2016; Sestras et al., 2018). In the context of continuous urban expansion and land-use transformation, peri-urban forests represent essential components of green infrastructure, providing multiple ecological, environmental, and social benefits (La Rosa et al., 2018). These ecosystems contribute to biodiversity conservation, climate regulation, carbon sequestration, and recreational opportunities, while also serving as transitional landscapes between urban environments and more natural forest ecosystems (Berglihn & Gómez-Baggethun, 2021; Mitchell et al., 2022).

The ecological importance of peri-urban forests has become particularly evident in recent decades, as cities have expanded into surrounding natural landscapes. Urban growth often leads to increased fragmentation of forest habitats, changes in environmental conditions at forest edges, and intensified anthropogenic pressure on vegetation communities (Harper et al., 2005; Seto et al., 2012; Dobbs et al., 2018). As a result, forest stands located near cities frequently exhibit structural and compositional characteristics that differ from those observed in more remote forest ecosystems. Understanding these differences is therefore essential for developing sustainable strategies for the management and conservation of urban and peri-urban green spaces (Zipperer & Guntenspergen, 2009; Salbitano et al., 2016).

One of the key aspects influencing vegetation structure in forest ecosystems situated near urban environments is the so-called edge effect. Forest edges represent zones where environmental conditions may differ from those found in the interior of forest stands (Hladnik et al., 2020). These gradients can influence species composition, vegetation structure, and

ecological processes within forest ecosystems (Murcia, 1995). Changes in light availability, temperature, wind exposure, and soil moisture may alter species composition and influence the regeneration dynamics of tree communities (Chen et al., 1995). In addition, edges located near urban infrastructure may be subject to direct human disturbances, including recreational activities, informal trails, or historical forest management practices (Hellenbrand et al., 2025).

Previous studies have shown that forest edges may exhibit both increased species diversity and simplified structural patterns depending on local environmental conditions and the intensity of human influence (Franklin et al., 2021). In some cases, edge environments may facilitate the establishment of opportunistic or light-demanding species, leading to higher local diversity. In other situations, repeated disturbances and anthropogenic pressure may favor the dominance of a limited number of species that are better adapted to altered environmental conditions. Consequently, the spatial distribution of tree species in peri-urban forests often reflects a complex interaction between ecological processes and human activities (Kodym et al., 2025).

In this context, analyzing tree community structure in relation to edge influence across forest stands can provide valuable insights into the functioning of peri-urban forest ecosystems (Hladnik et al., 2020; Baker et al., 2025). Such analyses enable the identification of patterns in species composition, diversity, and structural characteristics that may be associated with environmental gradients generated by forest edge effects (Murcia, 1995; Harper et al., 2005). Moreover, understanding these patterns is important for evaluating the ecological resilience of forest stands located near urban areas and for informing management practices aimed at maintaining biodiversity and ecosystem functions (Sousa-Silva et al., 2023).

Urban and peri-urban forests are frequently influenced by adjacent land-use systems that generate spatial gradients in environmental conditions and vegetation structure (Dobbs et al., 2018). The Hoia Hill area illustrates such a context, where two contrasting functional zones coexist along an east–west axis. Cultural, recreational, and agricultural activities dominate the upper part of the hill, while the lower sector has progressively developed industrial and economic functions (Boancă et al., 2023).

The Hoia-Baciu Forest, situated on the western outskirts of Cluj-Napoca in northwestern Romania, represents one of the most well-known forested areas within the peri-urban landscape (Deac et al., 2013). Due to its proximity to urban infrastructure and recreational areas, this forest sector is exposed to various forms of anthropogenic influence (Boancă et al., 2023). At the same time, it provides important ecological functions as part of the green landscape surrounding the rapidly expanding metropolitan area (Escobedo et al., 2011). Despite its ecological and social relevance, relatively limited information is available regarding the spatial variability of tree community structure within this peri-urban forest ecosystem.

Assessing tree species composition and diversity within such environments is important for understanding how vegetation communities respond to spatial gradients and environmental pressures associated with urban proximity (Alvey, 2006; McDonnell & Hahs, 2008). In particular, investigating variation in species distribution in relation to edge influence may reveal patterns related to forest structure, species dominance, and local heterogeneity in vegetation composition.

Therefore, the aim of the present study was to analyze tree community structure and diversity patterns in relation to edge influence in a sector of the Hoia-Baciu peri-urban forest. Using a systematic sampling design based on circular plots distributed along several transects covering varying distances from the forest edge, the study evaluates species composition, tree density, and diversity indices in order to identify spatial patterns within the forest stand. The results contribute to a better understanding of vegetation structure in forest ecosystems situated at the interface between natural landscapes and urban environments and provide useful information for the ecological assessment of peri-urban forests.

## MATERIALS AND METHODS

### Study area

The study was conducted in a sector of the Hoia-Baciu Forest located in the immediate vicinity of

the city of Cluj-Napoca, in northwestern Romania. This forest represents an important peri-urban green area situated at the interface between the urban environment and surrounding rural landscapes. Due to its proximity to the metropolitan area, the forest is frequently used for recreational activities and is influenced by nearby infrastructure and urban expansion.

The analyzed forest stand is characterized by mixed deciduous vegetation typical of temperate forest ecosystems. However, as in many peri-urban forests, the vegetation structure reflects the cumulative effects of past management practices and ongoing anthropogenic influences (Sousa-Silva et al., 2023). As a result, the tree community composition is relatively simplified and dominated by a limited number of species.

The study area forms part of the broader green landscape surrounding the city and plays an important role in maintaining ecological connectivity, biodiversity, and environmental quality in the peri-urban zone. The forest is dominated by hornbeam (*C. betulus*) stands typical for temperate deciduous forests of the Transylvanian region.

**Sampling design**

Field data were collected using a systematic sampling design based on circular plots arranged along transects across the forest, covering varying distances from the forest edge.

A total of 20 circular sampling plots were established in the analyzed sector of the Hoia-Baciu peri-urban forest. The distance between transects was approximately 70 m, while the distance between plots within each transect was about 40 m. This sampling design allowed the assessment of spatial variability in tree community structure along transects established across the forest. The spatial layout of the study area and the distribution of sampling plots are presented in Figure 1.

**Data collection**

Within each sampling plot, all tree individuals were recorded and identified at species level. For the purpose of the present study, the analysis focused on the species composition and abundance of trees within each plot.

The number of individuals belonging to each species was counted in order to determine the structure of the tree community. These data allowed the calculation of several basic structural and diversity parameters at the plot level, including: total number of trees; species richness; relative dominance of the main species.

Figure 1. Location of the study area and spatial distribution of sampling plots in the Hoia-Baciu peri-urban forest near Cluj-Napoca, Romania

**Data analysis**

The structure and diversity of the tree community were analyzed at the level of individual sampling plots. Several ecological indicators were calculated based on species abundance data using standard indices widely applied in community ecology (Shannon, 1948; Simpson, 1949; Pielou, 1966).

Species richness (S) representing the number of tree species recorded in each sampling plot.

Tree density expressed as the number of trees per hectare, calculated by extrapolating the number of individuals recorded within the 500 m² plots.

Shannon diversity index (H′) which reflects both species richness and the relative abundance of species within the community:

$$H' = -\sum(p_i \ln p_i)$$

where $p_i$ represents the proportion of individuals belonging to species $i$.

Simpson diversity index (1–D) which measures the probability that two randomly selected individuals belong to different species:

$$1 - D = 1 - \sum p_i^2$$

Pielou evenness index (J) which expresses the degree to which individuals are evenly distributed among species:

$$J = \frac{H'}{lnS}$$

In addition, the relative dominance of the main species within each plot was calculated as the

percentage of individuals belonging to the most abundant species. To explore potential spatial patterns associated with variation in edge influence across the study area, species richness values were analyzed accordingly across the sampling plots. All diversity indices were calculated based on the abundance data recorded in the sampling plots.

Differences among transects for tree density, species richness, Shannon diversity index, and the relative dominance of *C. betulus* were further evaluated using the Kruskal-Wallis non-parametric test, considering the small sample size and the likely non-normal distribution of the analyzed variables. Statistical significance was assessed at $p < 0.05$.

## RESULTS AND DISCUSSIONS

The tree community recorded within the sampling plots was relatively simplified and strongly dominated by *C. betulus*. This species occurred in the majority of plots and represented the highest proportion of individuals in most cases. Other species such as *Q. petraea*, *A. campestre*, *S. nigra* and *P. avium* were recorded locally and contributed to the variation in species composition among plots (Figure 2).

The relative dominance of *C. betulus* varied across the study area, exceeding 80% in several plots and reaching complete dominance in some cases. This pattern indicates a structurally simplified community typical of forest stands located in peri-urban environments. The spatial variation in the relative dominance of *C. betulus* among the sampling plots is illustrated in Figure 3.

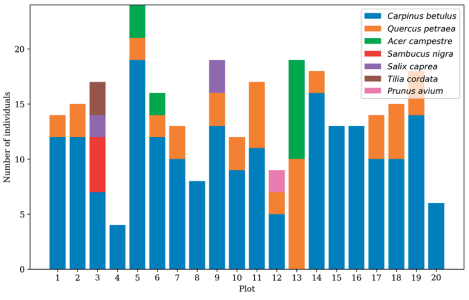

Figure 2. Tree species composition across sampling plots in the analyzed peri-urban forest stand. Bars represent the number of individuals belonging to each species in each sampling plot

### Structural characteristics of the sampling plots

The number of trees recorded within the sampling plots varied considerably across the study area. The lowest number of individuals was recorded in Plot 4 (three trees), while the highest values were observed in Plot 5 (21 trees) and Plot 19 (16 trees). When extrapolated to hectare level, tree density ranged between approximately 60 and 420 trees $ha^{-1}$.

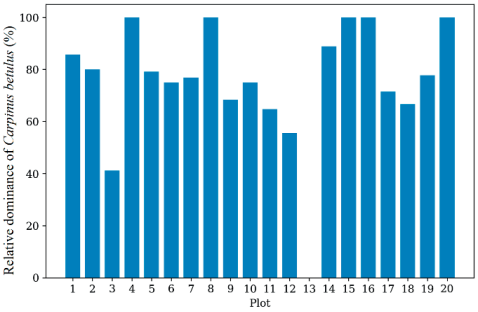

Figure 3. Relative dominance of *C. betulus* across the sampling plots in the analyzed peri-urban forest stand

Species richness showed relatively low values across the plots, ranging between one and four species per plot (Figure 4). Several plots, regardless of their position within the forest, contained only one species, indicating a high level of structural simplification. The structural characteristics of the sampling plots are summarized in Table 1.

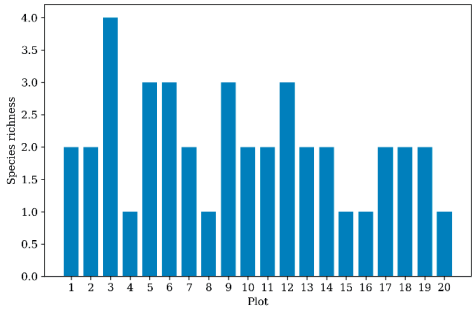

Figure 4. Species richness recorded in the sampling plots of the Hoia-Baciu peri-urban forest

Table 1. Structural characteristics of the sampling plots in the analyzed peri-urban forest stand

| Plot | Total trees | Tree density (trees ha$^{-1}$) | Species richness | Main species dominance (%) |
|---|---|---|---|---|
| 1 | 12 | 240 | 2 | 91.7 |
| 2 | 12 | 240 | 2 | 83.3 |
| 3 | 10 | 200 | 4 | 50.0 |
| 4 | 3 | 60 | 1 | 100.0 |
| 5 | 21 | 420 | 3 | 85.7 |
| 6 | 13 | 260 | 3 | 84.6 |
| 7 | 11 | 220 | 2 | 81.8 |
| 8 | 7 | 140 | 1 | 100.0 |

| 19 | 16 | 320 | 2 | 81.2 |
| 20 | 5 | 100 | 1 | 100.0 |

## Diversity patterns

Diversity indices calculated for each sampling plot indicate generally low to moderate levels of diversity across the analyzed forest sector. Shannon diversity index values ranged between 0 and 1.22 (Table 2). The highest diversity was observed in Plot 3, where four species were recorded and the distribution of individuals among species was relatively balanced.

Moderate diversity values were recorded in several plots, including Plot 9, Plot 11, Plot 12 and Plot 18. In contrast, plots dominated entirely by a single species showed Shannon index values equal to zero, reflecting the absence of species diversity. The spatial distribution of Shannon diversity values across the sampling plots is illustrated in Figure 5.

Table 2. Diversity indices calculated for the sampling plots

| Plot | Shannon index (H') | Simpson index (1–D) | Pielou evenness (J) |
|---|---|---|---|
| 1 | 0.29 | 0.15 | 0.41 |
| 2 | 0.45 | 0.28 | 0.65 |
| 3 | 1.22 | 0.66 | 0.88 |
| 4 | 0.00 | 0.00 | 0.00 |
| 5 | 0.50 | 0.25 | 0.46 |
| 6 | 0.54 | 0.27 | 0.49 |
| 7 | 0.47 | 0.30 | 0.68 |
| 8 | 0.00 | 0.00 | 0.00 |
| 9 | 0.74 | 0.41 | 0.67 |
| 10 | 0.50 | 0.32 | 0.72 |
| 11 | 0.64 | 0.44 | 0.92 |
| 12 | 0.87 | 0.50 | 0.79 |
| 13 | 0.69 | 0.50 | 1.00 |
| 14 | 0.69 | 0.50 | 1.00 |
| 15 | 0.00 | 0.00 | 0.00 |
| 16 | 0.00 | 0.00 | 0.00 |
| 17 | 0.56 | 0.38 | 0.81 |
| 18 | 0.62 | 0.43 | 0.89 |
| 19 | 0.48 | 0.30 | 0.70 |
| 20 | 0.00 | 0.00 | 0.00 |

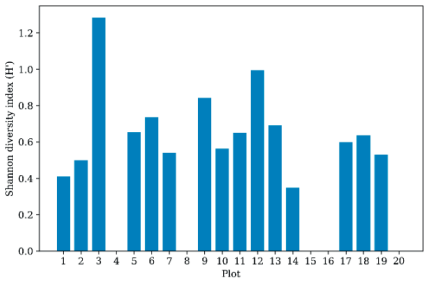

Figure 5. Shannon diversity index (H') calculated for the sampling plots

## Spatial variation in relation to edge influence

The analysis of species richness in relation to the distance from the forest edge revealed moderate spatial variability across the study area (Figure 6). Variation in species richness among plots suggests differences in exposure to forest edges across the study area.

To further explore differences in community composition among sampling plots, a non-metric multidimensional scaling (NMDS) ordination based on Bray-Curtis dissimilarity was performed (Figure 7).

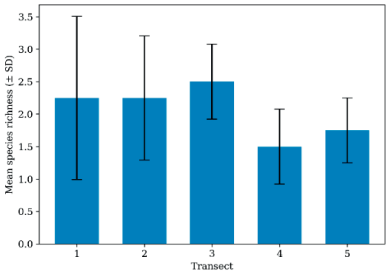

Figure 6. Mean species richness (± SD) across the five transects reflecting variation in edge influence in the Hoia-Baciu peri-urban forest

The NMDS ordination revealed a central cluster of plots dominated by *C. betulus*, while several plots showed greater compositional divergence, particularly Plot 13, which was characterized by the presence of *Q. petraea* and *A. campestre*.

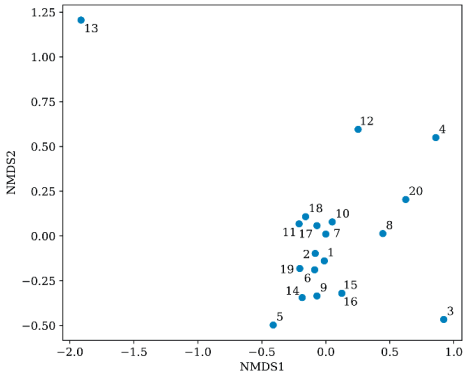

Figure 7. Non-metric multidimensional scaling (NMDS) ordination of tree community composition across sampling plots based on Bray-Curtis dissimilarity. Each point represents a sampling plot (1-20), and distances among points reflect differences in species composition

A summary of structural and diversity parameters at the transect level is presented in Table 3. Mean species richness ranged from 1.50 to 2.50 species per transect, while mean Shannon diversity values varied between 0.34 and 0.69. Mean tree density ranged from 185 to 260 trees ha$^{-1}$, and the relative dominance of *C. betulus* remained high across all transects, with values exceeding 70% in all cases.

Table 3. Summary of structural and diversity parameters across transects in relation to edge influence

| Transect | Mean tree density (trees ha$^{-1}$) | Mean species richness | Mean Shannon index |
|---|---|---|---|
| 1 | 185 | 2.25 | 0.49 |
| 2 | 260 | 2.25 | 0.38 |
| 3 | 235 | 2.50 | 0.69 |
| 4 | 210 | 1.50 | 0.34 |
| 5 | 230 | 1.75 | 0.42 |

These results indicate moderate variability among transects, without a consistent spatial pattern related to edge influence.

Differences among transects were further explored using the Kruskal-Wallis test (Table 4). No statistically significant differences were detected among transects for tree density, species richness, Shannon diversity index, or the relative dominance of *C. betulus* ($p > 0.05$ in all cases). Nevertheless, moderate variability was observed at the plot level, indicating small-scale heterogeneity within the peri-urban forest stand.

Table 4. Kruskal-Wallis test results for structural and diversity parameters across transects

| Variable | H statistic | p-value |
|---|---|---|
| Tree density | 1.484 | 0.829 $^{ns}$ |
| Species richness | 4.382 | 0.357 $^{ns}$ |
| Shannon diversity index | 3.969 | 0.410 $^{ns}$ |
| Relative dominance of *C. betulus* | 3.569 | 0.467 $^{ns}$ |

ns - not statistically significant differences among transects

**Simplified tree community structure in a peri-urban context**

From a landscape perspective, the Hoia-Baciu forest sector represents an important component of the peri-urban green infrastructure surrounding the city of Cluj-Napoca (Boancă et al., 2023). Such peri-urban forests may contribute to environmental buffering functions, including microclimatic regulation, dust and noise attenuation, and the mitigation of urban environmental pressures (Leca et al., 2023).

The results of this study indicate that the analyzed forest sector is characterized by a relatively simplified tree community structure, with a strong dominance of *C. betulus*. In most sampling plots, this species represented the majority of recorded individuals and in several cases it occurred as the only tree species present. Such patterns are commonly observed in forest stands that have been subjected to long-term anthropogenic influence or historical management interventions (Leca et al., 2023).

The occurrence of additional species such as *Q. petraea*, *A. campestre*, *P. avium*, and *S. nigra* was limited to a smaller number of plots and generally involved low numbers of individuals. As a consequence, species richness values remained relatively low across the study area, ranging from one to four species per sampling plot. Similar patterns of reduced tree species diversity have been reported in peri-urban forests where historical management practices and human pressure may influence stand composition and regeneration processes (Stamin & Cosmulescu, 2025).

**Spatial variability of diversity in relation to edge influence**

Although overall species richness was relatively low, the study revealed noticeable spatial variability in diversity among the sampling plots. Shannon diversity index values ranged from zero in monospecific plots to over 1.2 in the most heterogeneous plot. These differences indicate that local variations in stand structure and environmental conditions may influence the distribution of tree species within the forest.

Plots exhibiting higher diversity generally contained a more balanced distribution of individuals among species, whereas plots dominated by *C. betulus* showed considerably lower diversity values. Such patterns may reflect differences in microsite conditions, light availability, or past disturbance events that affected tree establishment and survival. The presence of localized areas with higher diversity suggests that even within relatively simplified forest stands, small-scale heterogeneity may contribute to maintaining a certain level of biodiversity (Harper et al., 2005).

**Influence of edge conditions and anthropogenic pressure**

The spatial arrangement of the sampling plots allowed the assessment of variation in community structure in relation to edge influence across the forest patch. Although the results did not reveal a strong linear relationship between distance from the forest edge and species richness, variability in community composition among plots suggests that edge-related processes operate in a spatially heterogeneous manner rather than along a single directional gradient (Murcia, 1995; Godefroid & Koedam, 2003; Harper et al., 2005).

Edge environments in peri-urban forests are often subject to multiple external influences, including changes in microclimatic conditions, increased light availability, and disturbances associated with nearby infrastructure or human activities (Franklin et al., 2021; Hellenbrand et al., 2025). These factors may create heterogeneous environmental conditions that facilitate the establishment of different species (Morgan et al., 2025). In contrast, plots less influenced by edge conditions tended to display more uniform species composition and stronger dominance of the main species (Hladnik et al., 2020).

Given the proximity of the studied forest sector to urban infrastructure and recreational areas, it is likely that anthropogenic factors have contributed to shaping the observed community structure (Hellenbrand et al., 2025). However, further studies integrating structural and microclimatic parameters would be required to better understand the mechanisms underlying these patterns (Morgan et al., 2025).

**Implications for peri-urban forest ecosystems**

Peri-urban forests represent important components of green infrastructure surrounding cities, providing ecological, environmental, and social benefits for urban populations (Mitchell et al., 2022; Kodym et al., 2025). The simplified tree community structure observed in the present study highlights the potential vulnerability of such ecosystems to disturbances and long-term anthropogenic pressure (Morgan et al., 2025).

Despite the relatively low species richness recorded in the analyzed plots, the presence of several accompanying species and the spatial heterogeneity observed across the study area suggest that these forest stands still retain ecological value. Maintaining and enhancing structural and compositional diversity in peri-urban forests may therefore represent an important objective for sustainable landscape management and biodiversity conservation in urbanized regions (Mitchell et al., 2022; Kodym et al., 2025; Morgan et al., 2025).

In the case of the Hoia-Baciu Forest located near Cluj-Napoca, the results underline the importance of monitoring vegetation structure and species composition in order to better understand how urban expansion and human activities influence forest ecosystems situated at the interface between natural and urban landscapes (Mitchell et al., 2022).

Although this study provides useful insights into tree community patterns along a peri-urban forest edge, a few methodological limitations should be acknowledged. The results may not be as applicable to other forest ecosystems because the study was carried out in a single peri-urban forest using a systematic sampling design. Furthermore, even though the study focused on tree community patterns and the forest edge, other environmental factors such as soil characteristics, light availability, and previous

management history, were not specifically evaluated and may also have influenced the observed patterns. Future research should include multiple peri-urban forests with contrasting edge characteristics, integrate additional environmental variables, and incorporate long-term monitoring to improve the understanding of edge effects on forest communities.

## CONCLUSIONS

The present study analyzed the structure and diversity of tree communities in a peri-urban sector of the Hoia-Baciu Forest located near Cluj-Napoca, Romania. The results indicate that the analyzed forest stand is characterized by a relatively simplified tree community structure, strongly dominated by *C. betulus*, while other species such as *Q. petraea*, *A. campestre*, *P. avium*, and *S. nigra* occur locally in lower proportions.

Species richness across the sampling plots was generally low, ranging between one and four species per plot, while diversity indices showed moderate spatial variability within the study area. The analysis of plots distributed across the forest revealed small-scale heterogeneity in community composition, although no strong linear trend in species richness with increasing distance from the forest edge was observed. The absence of statistically significant differences among transects suggests that, although moderate local variability exists, the edge influence does not generate a strong and consistent differentiation of the analyzed structural and diversity parameters at the spatial scale considered in this study.

These results suggest that local environmental conditions and anthropogenic influences may contribute to shaping the structure of tree communities in peri-urban forest ecosystems. Despite the relatively simplified species composition, the Hoia-Baciu Forest continues to represent an important component of the green landscape surrounding the city of Cluj-Napoca. Monitoring vegetation structure and diversity in such peri-urban forests is therefore essential for supporting sustainable landscape management and maintaining ecological functions in urbanizing regions.

***Abstract***

*The Prut River area represents an area of maximum importance, considering its international character and RAMSAR-type areas. In this study, we present the statistical analysis of the measurements carried out on the water quality parameters in the Prut River area, covering a period of 10 years. In this way, we were able to establish the trend of evolution of temperature, pH, turbidity, etc. and predictions can be made in this way. The methods used were ANOVA and especially multivariate analysis procedures. The conclusions that emerge are of great importance, especially for the evaluation of the protected area of Lake Beleu and the lower Prut floodplain area.*

***Key words:*** *ANOVA, multivariate methods, statistical methods, water quality parameters.*

## INTRODUCTION

In recent years, considering climate change, the monitoring and protection of water bodies have become extremely important topics (Banescu et al., 2020). In this context, the European Union has issued several important directives aimed at mitigating the threats and pressures exerted by anthropogenic activities on rivers and other categories of surface waters (Burada et al., 2016).
In this framework, the study of pollution factors in Eastern Europe represents a topic of major importance. The present study provides an investigation conducted over a 10-year period, between 2014 and 2023, based on measurements of monitored parameters in the Republic of Moldova, focusing on the water quality of the Prut River (Cordeli et al., 2023). The applied study methods are commonly used in the scientific literature, with emphasis on assessing the evolution trends of parameters considered essential for objectively describing the level of pollution (Resz et al., 2023).
The aim of this study is to investigate the evolution of water quality parameters in the Prut River, in the Cahul-Oancea sector, using a 10-year dataset covering the period 2014-2023.

## MATERIALS AND METHODS

The statistical analysis of the dataset was carried out following an algorithm frequently used in the literature: correlations between the sets of parameters were evaluated for each individual year, and then procedures based on Principal Component Analysis (PCA) were applied (Mocanu et al., 2021).
Principal Component Analysis (PCA) is a multivariate statistical method used to reduce data dimensionality and to identify patterns and correlations among variables.
In the final stage, the strongest correlations between the variables describing water quality - i.e., pH, alkalinity, and temperature, which shows a clear evolutionwere presented in the form of response surfaces (Popa et al., 2018).

The aim of this study is to highlight the evolution of water quality parameters in the Cahul area, Republic of Moldova. Correlations between the parameters were evaluated for each year of study. Table 1 presents the 12 physical parameters that were measured daily. Figure 1 shows the location of the monitoring point.

Figure 1. Map of Prut River

Table 1. Parameters monitored in the Cahul monitoring network

| Parameter | Measure unit | Evaluation |
|---|---|---|
| Temperature | [°C] | Daily averaged |
| Transparency | [cm] | Daily averaged |
| Colour | [degrees HU - Hazen Units] | Daily averaged |
| Turbidity | [mg/dm3] | Daily averaged |
| pH | pH unit | Daily averaged |
| Ammonium | [mg/dm3] | Daily averaged |
| Nitrites | [mg/dm3] | Daily averaged |
| Nitrates | [mg/dm3] | Daily averaged |
| Oxidability | [mg/dm3] | Daily averaged |
| Chlorides | [mg/dm3] | Daily averaged |
| Suspended matter | [mg/dm3] | Daily averaged |
| Alkalinity | [mg/dm3] | Daily averaged |

## RESULTS AND DISCUSSIONS

In this section, we present the results of the statistical analysis and, respectively, the results of the numerical simulations.

Obviously, the first step was to investigate the correlations between the measured physical parameters for the dataset corresponding to the years 2014–2023.

Subsequently, the PCA method was applied to each annual experimental dataset. Thus, for the year 2014, the obtained diagram is presented in Figure 2.

For the year 2014, the most significant correlations were identified between temperature and transparency (correlation= −0.8348, $p$=0.001), temperature and turbidity (correlation =0.7733, $p$=0.001), temperature and chlorides (correlation= −0.8607, $p$= 0.001), temperature and alkalinity (correlation = −0.7445, $p$=0.001), and temperature and nitrates (correlation=−0.7806, $p$= 0.001).

For the dataset corresponding to the year 2015, the most significant correlations were identified between temperature and chlorides (correlation =−0.9068, $p$=0.001), transparency and suspended matter (correlation= −0.7051, $p$=0.001), turbidity and suspended matter (correlation= 0.9998, $p$=0.001), as well as between temperature and chlorides (correlation= −0.9068, $p$=0.001) and temperature and alkalinity (correlation = −0.8840, $p$=0.001) and is a significant difference is noted between the considered data (Table 2).

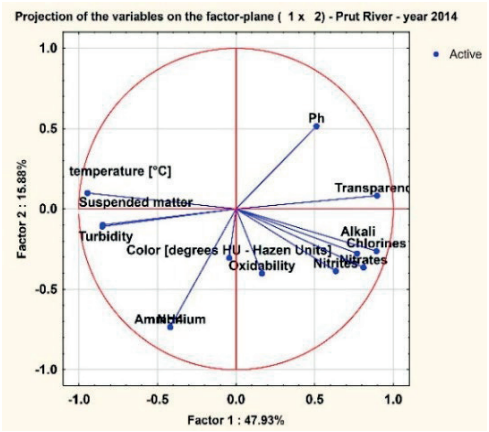

Figure 2. PCA diagram for 2014 database study case

Thus, in Figure 2 it can be observed that the first principal component, which explains the variance of the dataset, includes temperature, transparency, turbidity, pH, nitrites, nitrates, oxidability, chlorides, suspended matter, and alkalinity. In Figure 3, the PCA diagram for the dataset corresponding to the year 2015 is presented. The first principal component includes the following parameters: temperature [°C], colour [degrees HU – Hazen Units], pH, as well as nitrates, oxidability, chlorides, and alkalinity.

In Table 2 are presented the t-test results for average temperature. Many insignificant differences are observed.

Table 2. Results of t-test values for temperature

| Group 1 vs. Group 2 | Mean Group 1 | Mean Group 2 | t-value | *p* |
|---|---|---|---|---|
| t[°C] 2014 vs. t[°C] 2015 | 13.026 | 13.317 | -0.37 | 0.706 |
| t[°C] 2015 vs. t[°C] 2016 | 13.317 | 13.767 | -0.56 | 0.576 |
| t[°C] 2016 vs. t[°C] 2017 | 13.767 | 12.454 | 1.711 | 0.088 |
| t[°C] 2017 vs. t[°C] 2018 | 12.454 | 12.952 | -0.65 | 0.518 |
| t[°C] 2018 vs. t[°C] 2019 | 12.952 | 12.219 | 0.967 | 0.334 |
| t[°C] 2019 vs. t[°C] 2020 | **12.219** | **13.429** | **-2.01** | **0.045** |
| t[°C] 2020 vs. t[°C] 2021 | **13.429** | **12.227** | **2.231** | **0.026** |
| t[°C] 2021 vs. t[°C] 2022 | 12.227 | 13.086 | -1.32 | 0.1850 |
| t[°C] 2022 vs. t[°C] 2023 | 13.086 | 12.9128 | 0.237 | 0.813 |

In the same manner as Figure 2, were considered the PCA results for year 2015 (Figure 3), 2016 (Figure 4) and 2017 (Figure 5). Could be easily observed significand differences by comparing year 2105 (Figure 3), and year 2016 (Figure 4), especially for Factor 2. The PCA diagrams show the main groups operating during the studied period. Significant changes are observed from one year to another (Figure 5, Figure 6).

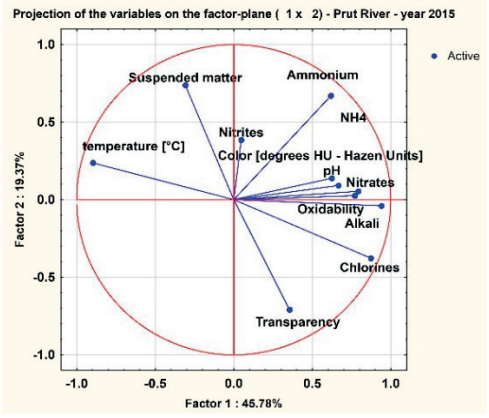

Figure 3. PCA diagram for 2015 database study case

For the dataset corresponding to the year 2018, the most significant correlations are those between pH and temperature (correlation = −0.7156, $p$ = 0.001), as well as between temperature and suspended matter (correlation = 0.76056, $p$ = 0.001) and temperature and alkalinity (correlation = −0.7856, $p$ = 0.001).

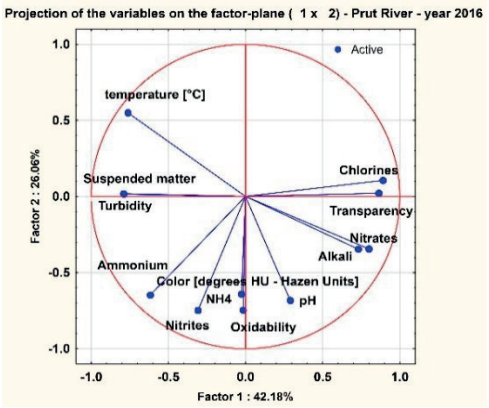

Figure 4. PCA diagram for 2016 database study case

Thus, PCA diagrams show the main group F1 operating during the studied period i.e. Suspended matter, Turbidity, Chorines, Nitrates (Figure 4). By comparing year 2016 and 2017, significant changes are observed from year to year (Figure 5, Figure 6). For example, Transparency became to F2 factor.

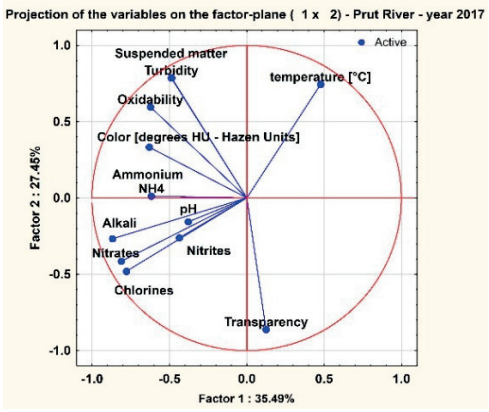

Figure 5. PCA diagram for 2017 database study case

For the dataset corresponding to the year 2018 (Figure 6) and 2019 (Figure 7), the following relationships can be identified: temperature and transparency (correlation = −0.7047, $p$ = 0.001), temperature and turbidity (correlation = 0.7599, $p$ = 0.001), temperature and chlorides (correlation = −0.7259, $p$ = 0.001), and respectively temperature and alkalinity (correlation = −0.7260, $p$ = 0.001). The same

relationships were also observed for the datasets corresponding to the years 2020–2023.

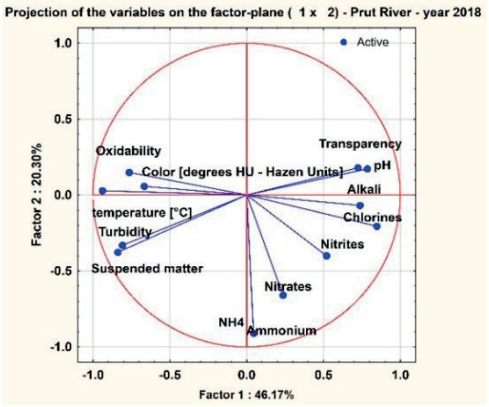

Figure 6. PCA diagram for 2018 database study case

In Table 3 are presented the t-test results for average pH values. Many significant differences are observed – the bold marked records.

Table 3. Results of t-test values for pH

| Group 1 vs. Group 2 | Mean Group 1 | Mean Group 2 | t-value | *p* |
|---|---|---|---|---|
| pH 2014 vs. pH 2015 | **8.064** | **8.189** | **-11.59** | **0.000** |
| pH 2015 vs. pH 2016 | **8.189** | **8.035** | **12.94** | **0.000** |
| pH 2016 vs. pH 2017 | **8.035** | **8.068** | **-2.89** | **0.004** |
| pH 2017 vs. pH 2018 | 8.068 | 8.046 | 1.70 | 0.094 |
| pH 2018 vs. pH 2019 | **8.046** | **8.382** | **-13.89** | **0.000** |
| pH 2019 vs. pH 2020 | **8.382** | **8.236** | **6.63** | **0.000** |
| pH 2020 vs. pH 2021 | **8.236** | **8.323** | **-6.93** | **0.000** |
| pH 2021 vs. pH 2022 | **8.323** | **8.608** | **-25.73** | **0.000** |
| pH 2022 vs. pH 2023 | **8.608** | **8.327** | **16.79** | **0.000** |

In Table 4 are presented the t-test results for average $NO_2$ values. Many insignificant differences are observed - the bold marked records.

For the dataset corresponding to the year 2020 (Figure 8) and 2021 (Figure 9), the following relationships can be identified: temperature and Ammonium (correlation = +0.787, $p$ = 0.001), temperature and Oxidability (correlation = 0.7699, $p$ = 0.001), temperature and chlorides (correlation = −0.079, $p$ = 0.001), and respectively temperature and alkalinity (correlation = −0.8260, $p$ = 0.001) - Figure 9.

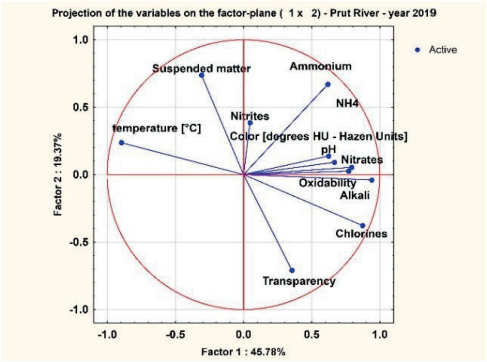

Figure 7. PCA diagram for 2019 database study case

Table 4. Results of t-test values for Nitrites

| Group 1 vs. Group 2 | Mean Group 1 | Mean Group 2 | t-value | *p* |
|---|---|---|---|---|
| $NO_2$ 2014 vs. $NO_2$ 2015 | **0.019** | **0.027** | **-3.30** | **0.019** |
| $NO_2$ 2015 vs. $NO_2$ 2016 | **0.027** | **0.033** | **-2.22** | **0.027** |
| $NO_2$ 2016 vs. $NO_2$ 2017 | **0.033** | **0.022** | **5.326** | **0.033** |
| $NO_2$ 2017 vs. $NO_2$ 2018 | **0.022** | **0.015** | **4.95** | **0.022** |
| $NO_2$ 2018 vs. $NO_2$ 2019 | **0.015** | **0.025** | **-10.43** | **0.015** |
| $NO_2$ 2019 vs. $NO_2$ 2020 | **0.025** | **0.018** | **17.04** | **0.025** |
| $NO_2$ 2020 vs. $NO_2$ 2021 | 0.012 | 0.031 | -7.68 | 0.0118 |
| $NO_2$ 2021 vs. $NO_2$ 2022 | 0.031 | 0.025 | 2.12 | 0.031 |
| $NO_2$ 2022 vs. $NO_2$ 2023 | 0.019 | 0.027 | -3.30 | 0.019 |

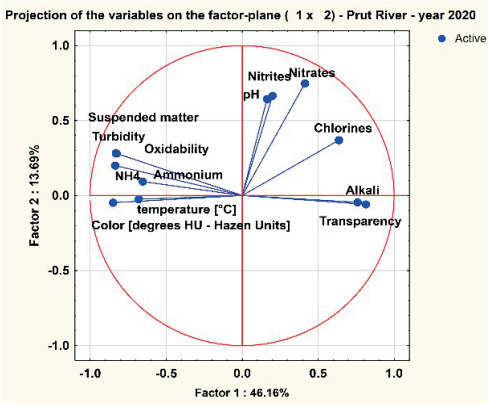

Figure 8. PCA diagram for 2020 database study case

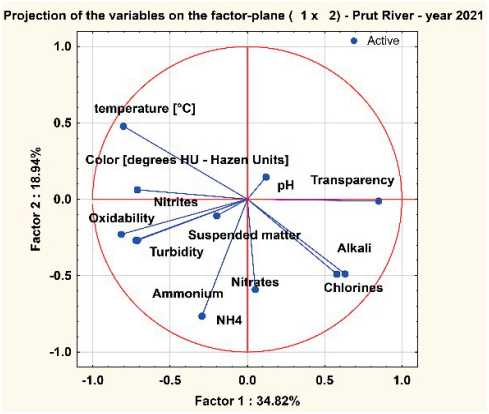

Figure 9. PCA diagram for 2021 database study case

In Table 5 are presented the t-test results for Nitrates average values. Many insignificant differences are observed – the bold marked records.

As is well known, in the case of nitrates, the concentration increases proportionally with agricultural and urban pollution; the concentration of chlorides increases proportionally with mineralization and agricultural contamination. On the other hand, oxidability measures the amount of oxidizable organic matter, while alkalinity is correlated with the salt content. In this sense, this first principal component has a general chemical character.

Table 5. Results of t-test values for Nitrates

| Group 1 vs. Group 2 | Mean Group 1 | Mean Group 2 | t-value | *p* |
|---|---|---|---|---|
| 2014 $NO_3$ vs. $NO_3$ 2015 | **7.279** | **5.233** | **9.578** | **0.000** |
| $NO_3$ 2015 vs. $NO_3$ 2016 | **5.233** | **4.504** | **3.430** | **0.001** |
| $NO_3$ 2016 vs. $NO_3$ 2017 | 4.504 | 4.614 | -0.594 | 0.553 |
| $NO_3$ 2017 vs. $NO_3$ 2018 | **4.802** | **5.080** | **-2.40** | **0.016** |
| $NO_3$ 2018 vs. $NO_3$ 2019 | **5.080** | **4.138** | **8.82** | **0.000** |
| $NO_3$ 2019 vs. $NO_3$ 2020 | **4.138** | **5.866** | **-16.0** | **0.000** |
| $NO_3$ 2020 vs. $NO_3$ 2021 | **5.866** | **5.096** | **5.897** | **0.000** |
| $NO_3$ 2021 vs. $NO_3$ 2022 | **5.096** | **4.267** | **7.363** | **0.000** |
| $NO_3$ 2022 vs. $NO_3$ 2023 | **7.279** | **5.233** | **9.578** | **0.000** |

The second principal component includes parameters such as $NH_4$, transparency, ammonium, and suspended matter. PC2 can be interpreted as the factor that evaluates the degree of organic pollution and the content of suspended particles.

Last but not least, significant differences are observed between the PCA diagrams corresponding to the years 2022 (Figure 10) and 2023 (Figure 11) respectively - for example: Nitrites are in Factor 1 in 2022 and then their contribution is added to Factor 2 in 2023.

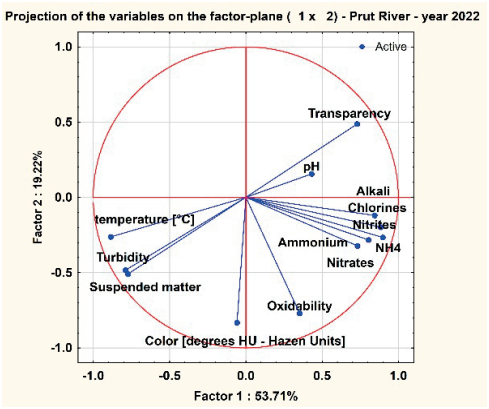

Figure 10. PCA diagram for 2022 database study case

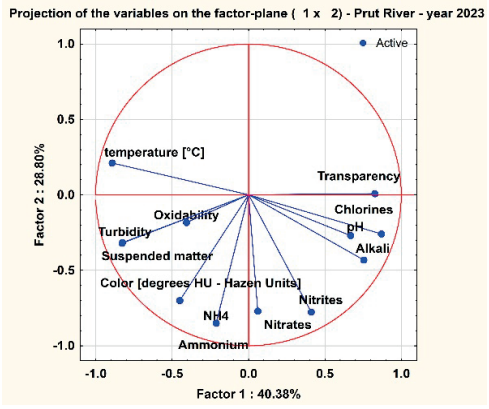

Figure 11. PCA diagram for 2023 database study case

In a short conclusion there are severe modification in these dynamics: in Figure 6, the two groups exhibit a switching, which means that the two processes associated with these groups have changed their relative importance in an inversely proportional manner.

Figure 12 presents the response surface for the dependence of pH on temperature and alkalinity for the dataset corresponding to the year 2014. The obtained surface shows a decreasing dependence of pH values on temperature (a fact also reported in the literature). What is interesting, considering that alkalinity determines how much pH can change when the equilibrium is altered, is that in this case the slope of the pH dependence on alkalinity is small (Figure 12).

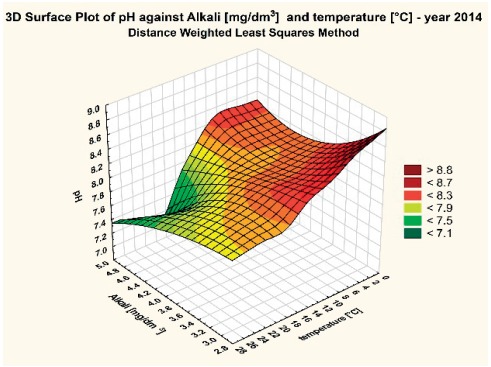

Figure 12. Surface plot pH against temperature and alkalinity for 2014 database study case

Figure 13 presents the response surface for the dependence of pH on temperature and alkalinity for the dataset corresponding to the year 2015. The obtained surface shows a completely different dependence of pH on temperature and alkalinity. However, it can be observed that in this case there is a stable dynamic equilibrium. Alkalinity determines a proportional increase in pH, which is contrary to the previous case.

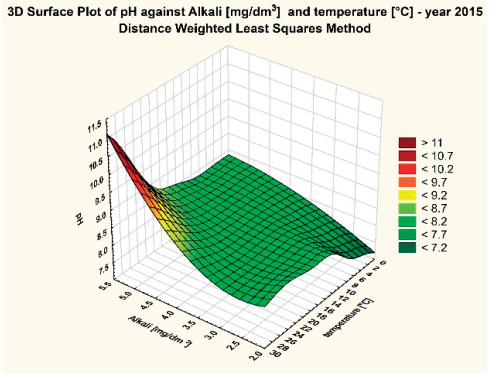

Figure 13. Surface plot pH against temperature and alkalinity for 2015 database study case

Figure 14 presents the response surface for the dependence of pH on temperature and alkalinity for the dataset corresponding to the year 2016. In this case, the surface is characteristic of an unstable dynamic equilibrium. Alkalinity determines a proportional decrease in pH, similar to the situation observed in 2014.

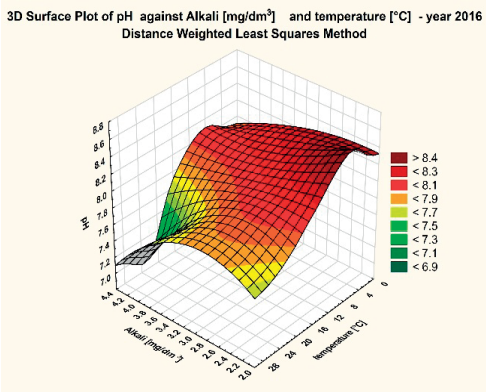

Figure 14. Surface plot pH against temperature and alkalinity for 2016 database study case

Figures 15 and 16 present the response surfaces for the dependence of pH on temperature and alkalinity for the datasets corresponding to the years 2017 and 2018.

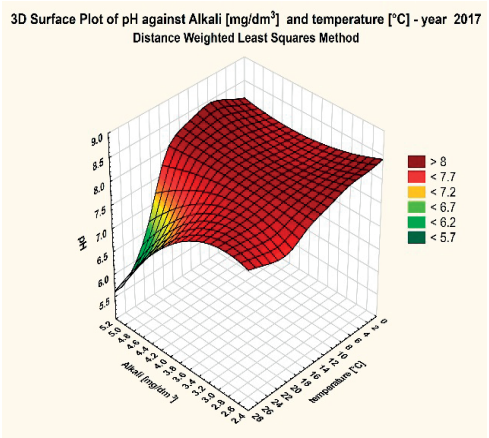

Figure 15. Surface plot pH against temperature and alkalinity for 2017 database study case

In these cases, as well, the surfaces are characteristic of an unstable dynamic equilibrium. Alkalinity determines a decrease in pH, similar to the situation observed in 2014.

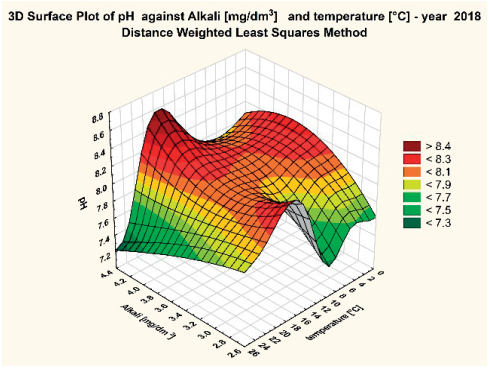

Figure 16. Surface plot pH against temperature and alkalinity for 2018 database study case

Figures 17 and 18 present the response surfaces for the dependence of pH on temperature and alkalinity for the datasets corresponding to the years 2019 (Figure 17) and 2020 (Figure 18).

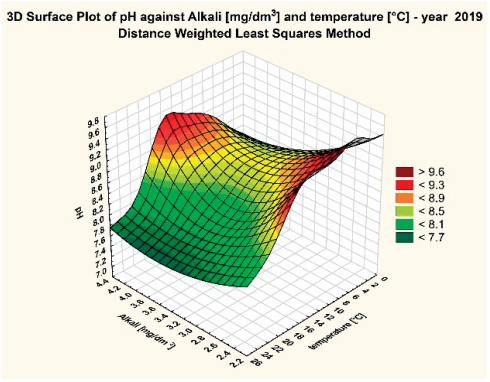

Figure 17. Surface plot pH against temperature and alkalinity for 2019 database study case

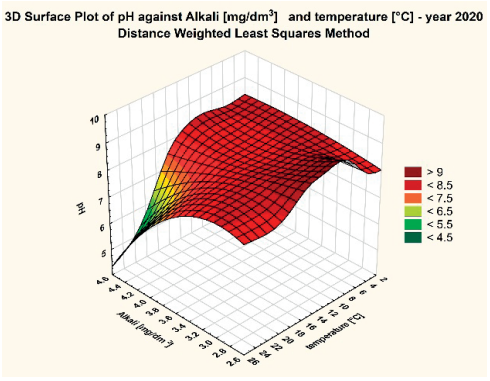

Figure 18. Surface plot pH against temperature and alkalinity for 2020 database study case

In the period 2021 - 2023, a dramatic change in the dependence of pH on the concentration of alkane as a function of temperature is observed (Figure 19, Figure 20 and Figure 21).

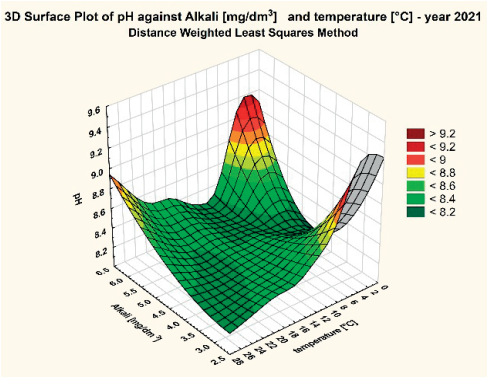

Figure 19. Surface plot pH against temperature and alkalinity for 2021 database study case

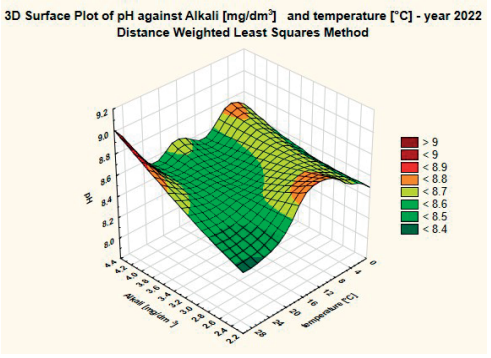

Figure 20. Surface plot pH against temperature and alkalinity for 2022 database study case

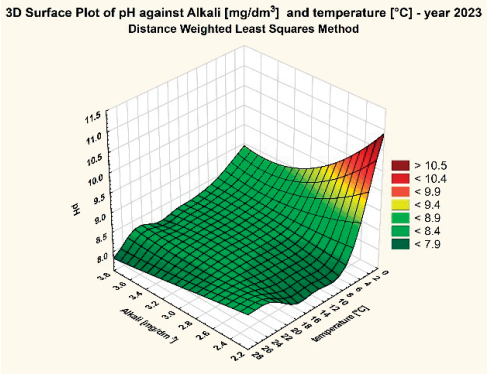

Figure 21. Surface plot pH against temperature and alkalinity for 2023 database study case

The present study aims to integrate a series of investigations conducted in the Prut River area (Dumitran, 2011). Many previous works have addressed heavy metal pollution (Matache et al., 2018) or the Water Quality Index (WQI) for this river (Duca et al., 2019). Furthermore, studies objectively describing the primary pollutants in the region where the river forms a natural border must also be considered (Teodosiu et al., 2009; Hrytsku & Hrytsku-Andriyesh, 2016). Naturally, research has also been conducted on the dynamics and interrelationships of key pollutants - such as NO3-N and NH4-N (Timofti et al., n.d.) - as well as on the environmental impacts of precipitation and temperature fluctuations (Corobov et al., 2021; Sava & Marusic, 2022).

In this context, we analyzed a 10-year period using a method capable of consistently addressing the entire dataset. The measured values correlate with those recorded for NO3-N, NO2-N, and NH4-N, generally aligning with observed trends regarding spatial variability and the gradient of this variability along the river's course (Neamtu et al., 2021). However, the present study clearly highlights significant differences between annual mean values, indicating that the processes specific to this natural aquatic system are undergoing changes. While previous studies focused on shorter timeframes - such as the five-year period from 2015 to 2019 (Neamtu et al., 2021; Duca et al., 2019) or even shorter intervals (Dumitran, 2011) - our study, utilizing a standardized dataset spanning a longer period, clearly revealed the existence of significant variations. It is also worth noting the strong correlation between N-NO2, N-NO3, and NH4, suggesting an underlying mechanism driving this relationship - a phenomenon previously observed using complementary methods (Timofti et al., n.d.). A particularly interesting finding emerges from the PCA analysis: the factors explaining the dataset's variability shift in relative importance over time. Specifically, during the 2014-2016 period, the primary factor (F1) encompasses turbidity, suspended matter, transparency, temperature, alkalinity, and chlorides; this represents a mixed physicochemical determinant - dominated by turbidity and suspended particles but also influenced by mineralization (alkalinity and chlorides) and temperature effects on these processes. Meanwhile, the secondary factor (F2) -comprising oxidability, nitrates, nitrites, ammonium, and pH - acts as a biochemical factor reflecting nitrogen transformations and organic matter degradation, essentially serving as a redox/organic and nitrogenous pollution factor. Starting in 2017, an interesting phenomenon was observed: the relative weights of the two previously identified factors shifted. This indicates that the biochemical factor - associated with nitrogen transformations and organic matter degradation - gained significance regarding data set variability, whereas the mixed physicochemical factor showed a stronger correlation along the Oy axis.

In the subsequent period (2018-2020), factors F1 and F2 reverted to their initial weightings; the mixed physicochemical factor became the dominant driver, contributing 45-46% to the overall variability, while factor F2 played a much smaller role, contributing 13-20%.

Finally, it is worth noting that between 2021 and 2023, the relative weights of the two main factors shifted once again. This periodic fluctuation reinforces a concept previously highlighted in the literature: the existence of two fundamental mechanisms explaining these correlations - pollution of industrial/anthropogenic origin and pollution resulting from natural and agricultural processes. Basing on the response surfaces shown in Figures 16, 18 and mainly on figures 19 and 20 - which represent stable equilibrium surfaces - we can conclude that the system is undergoing a "time-dependent oscillatory evolution," characterized by shifting contributions from organic and nitrogenous pollutants.

## CONCLUSIONS

The statistical analysis of the physicochemical parameters of the Prut River water in the Cahul sector for the period 2014-2023 highlights a pronounced thermal stability, concomitant with significant variations in nitrogen compounds and pH, indicating a high sensitivity of the aquatic system to anthropogenic pressures and regional biogeochemical dynamics. The average annual temperature did not show significant differences except in the period 2019-2021, which confirms that the thermal regime of the river is predominantly controlled by climatic factors and less by local influences.

In contrast, pH recorded statistically significant variations over almost the entire analysed period, with a single point exception (2017-2017), suggesting continuous changes in the processes of mineralization, photosynthesis and nutrient loading. The annual variability of nitrite concentrations (2014-2020) and the significant variations of nitrates in all analysed years indicate an unstable regime of nitrogen compounds, compatible with fluctuating nutrient inputs from agricultural activities, hydrological processes and microbial transformations.

Overall, the results show that, although the physical parameters of the water remain relatively constant, the chemical parameters relevant for the assessment of eutrophication show a pronounced dynamic, which reflects an ecosystem in a fragile balance, influenced by both natural conditions and anthropogenic pressures. These findings highlight the need for continuous monitoring and implementation of nutrient source management measures to maintain the ecological status of the lower Prut River. Dramatic changes are observed regarding the internal processes of the studied hydrological system.

## ACKNOWLEDGEMENTS

The work of Gabriel Murariu was supported by the internal research grant entitled “Internal research grant in the field of Environmental Engineering regarding the study of the distribution of polluting factors in the South-Eastern area of Europe”, financing contract no. 14886 / 11.05.2022, “Dunărea de Jos” University of Galaţi.

***Abstract***

*The present study aims to track the dynamics of airborne microorganisms in the territory of Sofia, Bulgaria in relation to the dynamics of fine particulate matter (FPM). Sampling points were 20, which cover territories with different dynamics - parks, intersections, central and peripheral parts, etc. Spin Air sampler was used. Sampling was carried out at a height of 1.5 m, for optimal consideration of the potential impact on human health. Specific microbiological characteristics were recorded - total microbial number in 1m$^3$ air, the main microbiological groups and their ratio and the percentage of pigment forms in relation to the change in the UV index. Specific environmental parameters related to airborne microorganisms were also recorded - amount of FPM, air temperature, humidity, atmospheric pressure, wind direction and speed, UV index. The data show a specific distribution of microbial groups, as well as a certain microbial load in points with intensive car traffic. There is a direct correlation between the amount of pigment forms and UV index ($r=0.92$; $p<0.05$). In the present pilot study, no direct correlation was found between the increase in fine particulate matter and microbial abundance (Pearson correlation matrix, significance thresholds 95%, $p<0.05$). However, there is a clear relationship between the reduced dust level and the higher percentage of woody vegetation.*

***Key words****: airborne microorganisms, air quality, fine particulate matter, pigment forms, UV index.*

## INTRODUCTION

Understanding the complex interaction between physical pollutants and biological components of air is crucial for modern urban ecology and public health. The air we breathe in urban areas is not just a mixture of gases, but a complex multiphase system containing solid particles and biological agents known as bioaerosols. Bioaerosols contain particles of biological origin, including all kinds of biological components and fragments, microorganisms, pollen, parts of plant fragments, etc. (Despres et al., 2012). For this reason, it is very important to distinguish between bioaerosols (which include any type of biological fragments) and airborne microorganisms (which include microorganisms from different groups such as bacteria, micromycetes, actinomycetes, etc.), as Kim et al. (2018), point out. In recent years, Sofia has been among the European capitals with the most serious challenges in terms of ambient air quality, mainly due to its geographical location in a valley and intense car traffic, which is why the study of ground-level air quality is of utmost importance. Modern research shows that airborne microorganisms are not just passive passengers. They use fine particulate matter (FPM) as a "vehicle" and substrate for growth and survival (Tignat-Perrier et al., 2020).

As Meola et al. (2015) and Haas et al. (2025) point out in their studies, fine particulate matter (FPM) act as transport nuclei for the transfer and spread of airborne microorganisms. It is important to note that airborne microorganisms are an important component of ambient air. Although they sometimes have a harmful effect on people and worsen the quality of the environment in urban areas, they are extremely important in the upper layers of the atmosphere, where they play the role of condensation nuclei, as a result of which it is believed that their increase as suspended units may have an impact on the ongoing climate changes (Zhai et al., 2018). It is precisely this complexity and intricacy that necessitates the in-depth study of airborne microorganisms.

Recent data suggest that the chemical composition of PM may selectively favor certain microbial taxa, making urban air a potential reservoir for pathogens or allergens (Cao et al., 2014; Wang et al., 2015). The link between fine

dust particles and the number of microorganisms in the air is undeniable. Last but not least, fine dust particles pose a risk to human health, as their increase not only leads to physical changes in air quality, but can also increase the risk of allergies and respiratory problems, given that large quantities of airborne microorganisms are adhered to PM (Arca-Lafuente et al., 2025). What is specific about fine dust particles is that, due to their size and extremely low relative weight, they can remain suspended in the air for a very long time, with their spread strongly depending on the speed and direction of the wind (He et al., 2021). The increase in PM concentration is not only due to natural sources such as volcanic eruptions, fires, earthquakes or landslides of large land masses (Zanoletti et al., 2024; Whitty et al., 2026), but also exclusively to human activity, such as construction, industrial combustion, car traffic, etc. (Edo et al., 2024; Morales et al., 2025). If wind is the main factor influencing the concentration and distribution of FPM, then changes in temperature, solar radiation index and humidity are of key importance for the vitality, quantity and distribution of airborne microorganisms (Tang, 2009).

The main goal of this study is to track the dynamics of airborne microorganisms in the territory of Sofia, Bulgaria in relation to the dynamics of fine particulate matter (FPM) and specific environmental conditions.

## MATERIALS AND METHODS

Airborne microorganisms are a major component of both atmospheric aerosols and the composition of air, which is highly dynamic. The quantitative and qualitative distribution of microbial groups is of great importance for both urban air quality and public health. However, airborne microorganisms remain poorly understood. In order to identify differences in environmental influences (type of urban environment, intensity of car traffic, vegetation cover) twenty samples were collected in three replicates from different locations with different levels of anthropogenic pressure in the capital of Bulgaria, Sofia, in the autumn of 2025. Points with increased anthropogenic pressure are marked as hot points (HP), and points with low anthropogenic pressure, located in park areas, as green zones (GZ), Figure 1:

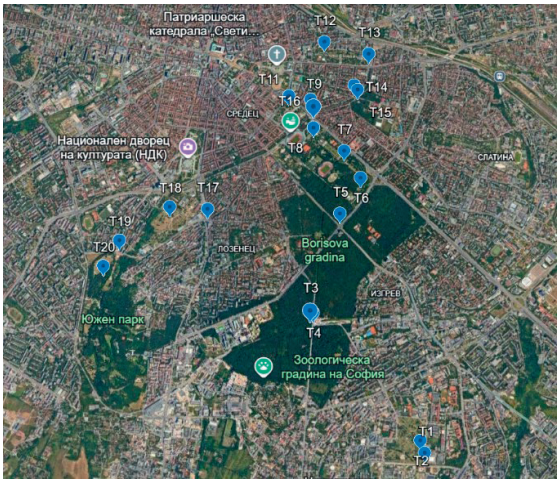

Figure 1. Location of selected sampling points (T1 Crossroad of Osmi Dekemvri Street and Rosario Street (HP); T2 Student Park (GZ); T3 Hunting Park (GZ); T4 Crossroad of Simeonovsko Shosse and Nikola Gabrovski Blvd. – "Loven Park Intersection" (HP); T5 Television Tower - Roundabout (HP); T6 Observatory, in Upper part of Borisova Gpadina Park (GZ); T7 Lily Pond - Middle part of Borisova Gradina Park (GZ); T8 Lower part of Borisova Gradina Park (GZ); T9 Orlov Bridge (HP); T10 V. Levski Blvd. intersection with Tsar Osvoboditel Blvd. (HP); T11 Prince's Garden (GZ); T12 Zaimov Park (GZ); T13 Madrid blvd. Crossroad (HP); T14 Crossroad Evlogii Geogriev Blvd And Shipka str. (HP); T15 Military Academy Park (GZ); T16 Iranian Embassy on Evlogii Georgiev Blvd (HP); T17 Hotel Hemus (HP); T18 Park behind the Museum of Land and People (GZ); T19 Crossroad Vitoshka str. и South Park (HP); T20 South Park (GZ))

For the purposes of the study, the following nutrient media were used: Mesopeptone agar for the cultivation of bacteria, Czapek-Dox agar for the cultivation of micromycetes, and Starch Ammonia Agar for the cultivation of actinomycetes. Air sampling was carried out using an IUL Spin Air impactor, which has high accuracy and resolution. The device works by means of a rotary mechanism, which allows for complete utilization of the nutrient medium layer in the Petri dish, thus ensuring an even distribution of the columns in the Petri dish, which facilitates reading. The measurement was carried out at a height of 1.5 m above the ground surface, corresponding to the human respiratory zone. The sampling parameters are as follows: 120 seconds for each studied group of microorganisms at a flow rate of 100 L/min. These parameters were selected after a series of preliminary test analyses to establish the optimal air flow rate. After sampling, the samples were transferred in specialized bags to the laboratory, where subsequent incubation was performed. Bacteria were cultured for 48 hours at 28°C, fungi - 7 days at 30°C, and actinomycetes - 10 days at 35°C. The counting of the developed colonies was performed using a digital colony counter, with the data converted into CFU*$10^2/m^3$.

Along with the taking of microbiological samples, the levels of fine particulate matter were measured, and meteorological parameters were also recorded. The concentration of PM was recorded using the Envea PM Cairsense device. The device simultaneously measures the PM10, PM2.5 and PM1 fractions, using laser diffraction. During sampling, meteorological data were also recorded: air temperature, humidity, UV index, wind speed and direction. The data for the microbiological analyses were statistically processed using the StatSoft Statistica 12 program, Pearson correlation matrix, at significance thresholds of 95%, $p<0.05$.

## RESULTS AND DISCUSSIONS

The results for the reported meteorological parameters are presented in Figure 2.
Meteorological data indicate slightly lower temperatures than usual for the season. Humidity is also low, ranging between 48% and 65% throughout the sampling period, with the lowest values shortly after noon. This is the period when the temperature and UV index increase. The wind speed of 6.7 m/s from the west-northwest is a constant factor for all measurements.

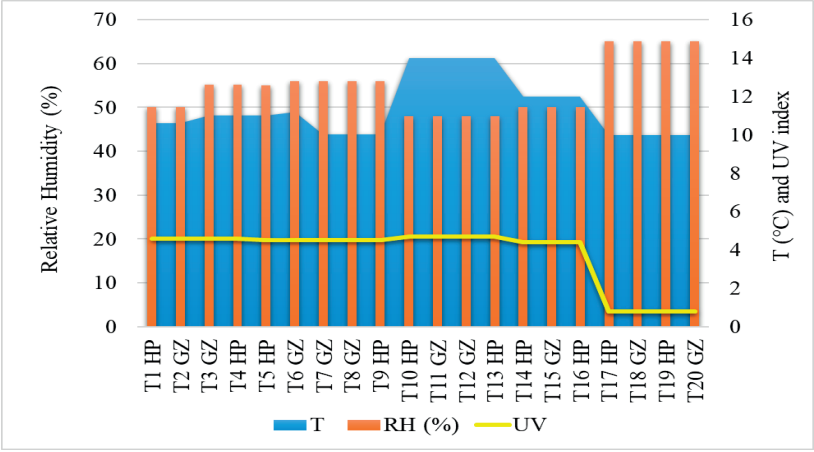

Figure 2. Recorded climatic characteristics during sampling

Such a speed is theoretically sufficient to facilitate the transport of fine dust, bioaerosols, and airborne microorganisms from the outskirts to the city center, suggesting a potential directional transport pathway that warrants further meteorological analysis, while also helping to disperse larger PM10 particles.

The temperature range of 10°C to 14°C is relatively favorable for many of the mesophilic microorganisms commonly found in the air environment (Haas et al., 2020).

The results for the reported amounts of fine particulate matter, by individual fractions, are presented in Table 1.

Table 1. Fine particulate matter (μg/m$^3$)

| | PM 10 | PM 2.5 | PM 1 |

| T20 GZ | 39.90 ± 5.35 | 28.50 ± 4.34 | 20.30 ± 3.49 |

The data from the measurements conducted in Sofia reveal clear spatial heterogeneity in the levels of particulate matter pollution of the fractions PM10, PM2.5 and PM1. These differences reflect the influence of local emission sources, such as road transport, and the protective role of urban vegetation.

The highest levels of PM10 were recorded at point T4 (Loven Park Intersection) - 67.25 μg/m$^3$, which exceeds the average values with 68% (average value = 40.01 μg/m$^{3)}$ for the inner parts of the parks. This fact illustrates the so-called "edge effect", in which areas in the immediate vicinity of busy transport arteries accumulate both primary emissions from fuel combustion and re-suspended dust from the road surface, which is rich in microorganisms, including those of soil origin, as has been found in other studies (Rathnayake et al., 2016). For comparison, point T14 (Military Academy Crossroad) shows the lowest PM10 values (23.4 μg/m$^3$), which is probably due to specific air circulation in the area of this crossroad, which is also confirmed by our other studies (Grigorova-Pesheva & Peshev, 2025).

Analysis of the ratio between the different fractions is essential for microbiology. Fine particles PM2.5 and PM1 have a larger relative surface area, making them more effective carriers of small bacterial cells and fragments of fungal mycelium, which increase the risk of allergies (Thangavel et al., 2022). The average PM2.5/PM10 ratio at the surveyed points varies, but in heavily congested areas such as Orlov Most (T9) and Blvd. V. Levski (T10), PM2.5 concentrations reach 38.00 μg/m$^3$ and 39.44 μg/m$^3$, respectively.

The results of the microbiological analyses performed are presented in Table 2.

Figure 3 presents a comparison of the reported biogenicity of the individual points, for which purpose the green areas are depicted in green and the hot points in red. The graph also shows the reported values of fine particulate matter in μm/m$^3$.

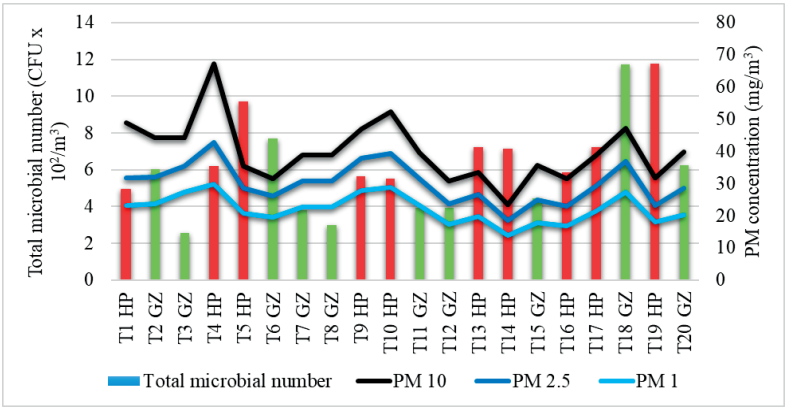

Figure 3. Total microbial number of the studied points and FPM load

Analysis of the results shows that green areas generally have a lower microbial load than hot points, although there are exceptions. Green areas with a low percentage of woody vegetation (T2 and T18) stand out with a higher microbial load, close to that of hot points. These are park areas dominated by grasslands and low shrub vegetation. Similar data have been found in our previous studies, as well as in the work of other colleagues (Mhuireach et al., 2016; Grigorova-Pesheva & Peshev, 2025). Specifically, green zone T2 once again shows high levels of microbial abundance. This is a park area that is built at a lower level than the street. During sampling, dust swirling and its transfer to the park area were observed. Similar to previous studies, higher levels of both fine dust particles and microorganisms were observed here again. Such results confirm the need to comply with the requirements and guidelines of environmental hygiene when carrying out urban planning. As indicated by (Revich, 2022), green areas

increase not only the physical, but also the mental health of the population, therefore their proper planning is key to building an environmentally friendly urban environment.

In the present study, no direct correlation was found between the increase in fine particulate matter and microbial abundance. (*Pearson correlation matrix, significance thresholds 95%, $p<0.05$*). However, there is a clear relationship between the reduced dust level and the higher percentage of woody vegetation. As Cohen et al. (2014), point out in their study, the presence of trees strongly reduces the amount of dust in green areas, which leads to an increase in air quality.

The specific dynamics of the results prove that when analyzing it is necessary to consider the data in pairs, green zone, hot spot, because depending on the specific conditions and dynamics of the characteristics of the environment, specific differences are observed both in the fine dust load and in the microbial abundance. However, the influence of the way the green zones are managed on the amount of PM reported and the total number of airborne microorganisms is undeniable. So again, at T3 (Hunting Park), where we have a green area imitating a natural dense forest, the levels of microorganisms are the lowest (2.55 CFU*$10^2$/$m^3$), including much lower levels of dust compared to the nearby heavily trafficked intersection (T4). Although the sample in the green zone was taken only 70 meters inland, in the park, a strong positive impact on air quality is observed. Similar results are also obtained for T7 (3.79 CFU*$10^2$/$m^3$) and T8 (3.00 CFU*$10^2$/$m^3$), which are located in Borisova Gradina - one of the largest green zones in Sofia, which has a large percentage occupied by woody vegetation - not accidentally called the "Tsar's Garden". Interesting data are for T11 (3.95 CFU*$10^2$/$m^3$), this is a green zone that has a smaller percentage of woody vegetation, but is closed on two sides with pedestrian zones, and in the center, there is a large water area. This again shows how specific urban planning can improve air quality, not only by increasing the percentage of woody vegetation, but also by reducing the intensity of car traffic.

The results for the percentage distribution of the individual microbiological groups are presented in Figure 4.

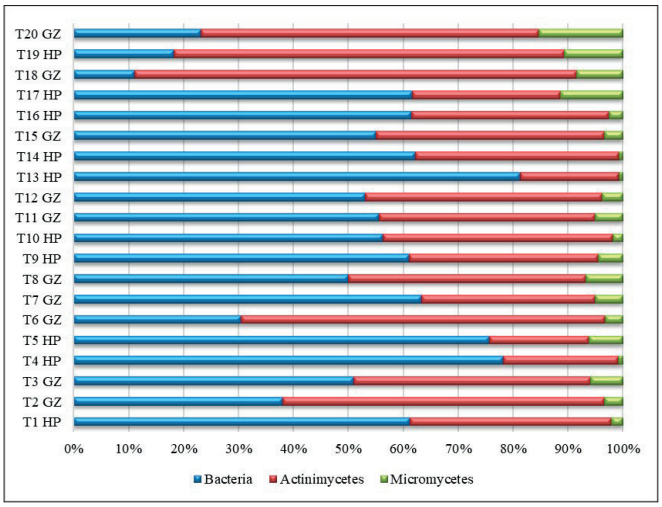

Figure 4. Percentage distribution of individual microbiological groups

The results show a very low percentage participation of the micromycetes group, which is probably due to the reduced humidity for the season.

One of the main microbiological parameters related to the vitality of microorganisms is the relative humidity (RH). Research shows that humidity levels in the range of 40-60% can be suppressive for many airborne microorganisms due to specific physicochemical processes in aerosol particles. However, most studies focus on indoor air quality, indicating that the optimal

humidity at which the possibility of transmitting pathogens and other microorganisms is seriously reduced is 40-60% (Skanata et al., 2022). There is insufficient data on the effect of humidity on airborne microorganisms in outdoor environments. Our data show that as the % humidity increases, the percentage of the micromycetes group (T17, T18, T19 and T20) increases. There are other studies available that prove that as humidity increases, the number of airborne fungi increases, explaining that high humidity levels facilitate the growth of this microbial group (Sajjad et al., 2023).

The results for the percentage of pigment forms, as well as the reported UV index levels, are presented in Figure 5.

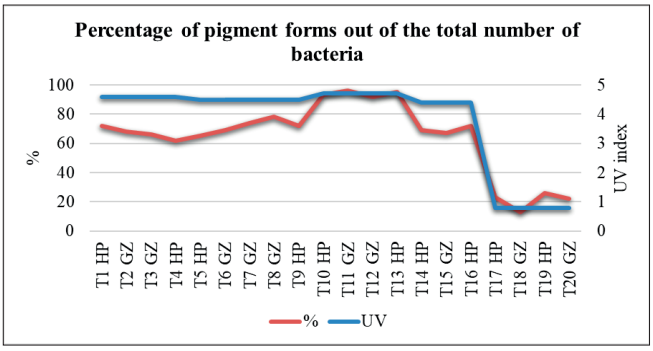

Figure 5. Percentage of pigment forms relative to the reported UV index

The results of the percentage participation show an increase in the number of pigment forms relative to the total number of bacterial colonies with increasing UV index. Similar results were also found by Tong & Lighthart, 1997. As the authors point out, pigmentation is a protective mechanism that ensures the survival of bacteria at high levels of UV radiation. At high UV index, non-pigmented bacteria, which are sensitive to light, die rapidly in the atmosphere. This leads to a relative increase in the proportion of surviving microorganisms that form pigment forms, which then form colonies on the nutrient medium in microbiological analysis (Figure 5). The increase in the percentage of pigmented colonies at higher UV index is a direct result of the defense mechanisms of microorganisms against intense solar radiation and the process of selective pressure in the atmosphere. Namely, such high results for the percentage of pigment forms indicate the strong adaptability of the air microflora (Park & Fowler, 2026).

It is important to note, however, that most studies indicate that the maximum proportion of pigment forms during peak hours of UV radiation is around 50-60% (Tong & Lighthart, 1997), while in the present study the results indicate higher values, which suggests that the air microflora probably responds not only to an increase in the UV index, but also to additional stress factors such as increased oxidative stress, increased concentration of pollutants in the air, etc.

## CONCLUSIONS

The main objective of this study was to analyze the dynamics of airborne microorganisms according to environmental conditions. A total of 20 sample points were studied - 10 green areas and 10 hot points. No direct correlation was established between the fine dust load, regardless of the fraction, and the microbial abundance. The results confirm the need to analyze the data in pairs - green area - hot spot. The results indicate that in green areas with a high percentage of woody vegetation, both the microbial load and the fine dust load are lower. The present study confirmed the importance of urban planning. Thus, for park areas located below the roadway level, increased levels of PM and microorganisms were found. The present study found that the microbial community is influenced by environmental factors – humidity and UV index. Thus, in samples with increased % humidity, the participation of the micromycetes group increases. It was also found that an increase in the UV index leads to an

increase in the percentage of pigment forms regardless of the study point. This pilot study can serve as the basis for an expanded study covering major cities in Bulgaria to account for the influence of regional climate on shaping the microbial air community.

## ACKNOWLEDGEMENTS

This research work was carried out with the support of Research Fund of Ministry of Education and Science in Bulgaria, project №: КП-06-Н74/5 „Relationships between the amount of fine particulate matter and airborne microorganisms in "hot spots", park areas, urban background areas and control forest areas''.

***Abstract***

*Euonymus fortunei* (Turcz.) Hand.-Mazz. *(Fortune's spindle) is an evergreen ornamental species widely used in landscape design due to its adaptability to urban stress conditions such as pollution, drought, high insolation, low temperatures, and degraded soils. This study aimed to improve in vitro establishment and shoot multiplication of the cultivars 'Emerald 'n' Gold' and 'Emerald Gaiety'. Nodal segments and shoot tips from mature plants were surface sterilized and established on Murashige and Skoog (MS) medium supplemented with 1 mg/L 6-benzylaminopurine (BAP), 0.5 mg/L indole-3-acetic acid (IAA), 0.5 mg/L gibberellic acid ($GA_3$), with or without 0.2% (v/v) Plant Preservative Mixture (PPM™). PPM increased contamination-free explants from 55.56% to 88.89% in 'Emerald 'n' Gold' and from 48.39% to 95.71% in 'Emerald Gaiety'. During multiplication, MS medium containing 2 mg/L meta-topolin (mT) and 1 mg/L IAA produced the highest shoot numbers, with an average of 4.71 and 4.40 shoots per explant, respectively, compared with 1.30 and 1.45 on medium with 2 mg/L BAP alone. Meta-Topolin media also reduced basal callus formation, whereas shoot tip necrosis and callus browning were more frequent of media with BAP. These findings identify mT, particularly combined with IAA, as a promising alternative to BAP for in vitro multiplication of these E. fortunei cultivars and provide a basis for further protocol optimization and large-scale propagation and results demonstrate that meta-topolin-based media provide an efficient system for rapid in vitro multiplication of E. fortunei cultivars for use in urban landscaping and ecological restoration of degraded environments.*

***Key words****: landscape, meta-topolin, micropropagation, plant growth regulators, shoot proliferation.*

## INTRODUCTION

The genus *Euonymus* L (commonly known as spindle or spindle tree) comprises ornamental shrub species with both deciduous and evergreen foliage (creeping, climbing or upright forms) belonging to the Celastraceae family. These plants are highly valued for their adaptability, attractive foliage (sometimes variegated), and their spectacular autumn coloration. The genus is widely distributed and includes around 200 species, native to temperate and subtropical regions of Asia, Europe (including the native flora of Romania and the Republic of Moldova) and North America (Savinov, 2022).

*Euonymus fortunei* (Turcz.) Hand.-Mazz (Fortune's spindle) is an evergreen ornamental species widely used in landscape design due to its adaptability to urban stress conditions such as pollution, drought, high insolation, low temperatures, and degraded soils (Percival & Sheriffs, 2002). Its use in urban greening and land rehabilitation makes it relevant for sustainable environmental engineering applications. However, due to its adaptability to various conditions, *Euonymus fortunei* can naturalize in seminatural and synanthropic habitats, outside the area of the original cultivation (Bauer & Reynolds, 2016; Savinov, 2022). Native to East and Southeast Asia, it was reported to be naturalized in the Caucasus region and fragmentary on the Black Sea coast and other places (Savinov, 2022). Occasionally, problems with pests and diseases such as euonymus scale (*Unaspis euonymi*) (Cockfield & Potter, 1986; Gutue et al., 2015) or anthracnose (*Colletotrichum gloeosporioides*)

(Ningen et al., 2005) may occur. However, anthracnose mostly occurs in nurseries, and the production of new plantlets can be significantly decreased due to this disease (Ningen et al., 2004; Boyer et al., 2007; Cole et al., 2009). Heavier infestations with *Unaspis euonymi* can lead to massive defoliation and eventual loss of plants (Jefferson & Schultz, 1995). Plant tissue culture and micropropagation provide effective techniques for the mass multiplication of genetically consistent, pathogen-free plant material, regardless of seasonal variations or environmental limitations. *In vitro* propagation has been done on several species of the genus, as *Euonymus alatus* (Smith & Jernstedt, 1989; Chen et al., 2006; Thammina et al., 2011; Woo et al., 2021), *Euonymus europaeus* (Biahoua & Bonneau, 1999), *Euonymus bungeanus* (Ning et al., 2021; Cui et al., 2025) *Euonymus verrucosus* (Kirillov et al., 2022), *Euonymus japonicus* (Shang et al., 2006) *Euonymus koopmannii* (Gubaidullin et al., 2024; Kali et al., 2024)**,** *Euonymus fortunei* (Wang et al., 2004; Shang et al., 2009) or cell cultures in *Euonymus maximowiczianus* for anthocyanin and VLCFA (very-long-chain fatty acids) accumulation (Nosov et al., 2024)**.**

Despite these advances, microbial contamination remains a major limitation in the micropropagation of woody plants. In particular, endophytic contamination can be difficult to control because microorganisms residing within plant tissues may not be eliminated by conventional surface sterilization procedures. To date, no standardized protocol specifically addressing endophytic contamination during the in vitro establishment of the *E. fortunei* cultivars 'Emerald 'n' Gold' and 'Emerald Gaiety' has been reported. Contamination by endophytic bacteria is a common problem in the micropropagation of woody species (Permadi et al., 2025). Endophytic microorganisms inhabit internal plant tissues without necessarily causing visible symptoms of disease or harm to their hosts. They may colonize intercellular spaces, cell walls, and xylem vessels. Endophytes have also been detected in reproductive and storage organs, including flowers, fruits, pollen grains, and seeds, demonstrating their widespread distribution within plants (Chebotar et al., 2016; Boiu-Sicuia & Cornea, 2019).

Surface sterilization of explants does not guarantee complete elimination of microorganisms because endophytic bacteria and fungi may reside within internal tissues and therefore remain protected from surface disinfectants (Marino et al., 1996; Quambusch & Winkelmann, 2018). Newly inoculated explants may initially appear free of contamination because some endophytic microorganisms can remain dormant. Changes in culture conditions may subsequently stimulate their growth, resulting in visible contamination at the explant base and in the culture medium (Leifert & Cassells, 2001; Izarra et al., 2020). Endophytic bacteria belonging to genera such as *Bacillus*, *Pseudomonas*, *Paenibacillus*, *Erwinia*, and *Burkholderia* have been reported in various woody plant tissues (Chebotar et al., 2016) The cultivars 'Emerald 'n' Gold' and 'Emerald Gaiety' were selected because they are widely recognized ornamental forms of *E. fortunei*, characterized by distinctive variegated foliage and desirable growth characteristics that contribute to their value in landscape applications. Their attractive foliage and ornamental performance make the development of reliable propagation protocols particularly relevant for the production of uniform planting material. However, the establishment of mature *E. fortunei* tissues *in vitro* may be constrained by microbial contamination, highlighting the need for improved disinfection strategies.

Therefore, this study aimed to develop an efficient *in vitro* propagation protocol for the cultivars 'Emerald 'n' Gold' and 'Emerald Gaiety', with particular emphasis on improving explant establishment and shoot multiplication to support the production of uniform planting material.

## MATERIALS AND METHODS

### Inoculation

For inoculation, nodal segments and shoot tips of two cultivars of *Euonymus fortunei* – 'Emerald 'n' Gold' and 'Emerald Gaiety' - were used. They were collected from green shoots that were harvested in August 2025 from mature plants grown in Chișinău, Republic of Moldova and brought to Bucharest, Romania (Figure 1). All experiments in this study were

carried out in the Plant Micropropagation Laboratory, part of the Research Center for Studies of Food Quality and Agricultural Products, of the University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania.

Figure 1. *Euonymus fortunei* 'Emerald 'n' Gold' (left) and 'Emerald Gaiety' (right) shoots

For culture initiation, two variants of MS (Murashige and Skoog, 1962) media supplemented with growth regulators were used (as detailed in Table 1).

Table 1. Composition of media variants used for *in vitro* inoculation of *Euonymus fortunei* cultivars

| No. | Media variant | Media composition |
|---|---|---|
| 1. | I1 | MS + 1 mg/L BAP + 0.5 mg/L IAA + 0.5 mg/L $GA_3$ |
| 2. | I2 | MS + 1 mg/L BAP + 0.5 mg/L IAA + 0.5 mg/L $GA_3$ + 0.2% (v/v) PPM |

The difference consisted in the addition of 0.2% (v/v) of commercial stock solution of Plant Preservative Mixture™ (PPM) in variant I2, corresponding to 2 mL PPM per litre of culture medium. Commonly used as an ingredient in culture media, especially for woody species, Plant Preservative Mixture™ (PPM) is a biocide with broad-spectrum that contains 0.1305% 5-Chloro-2-methyl-3(2H)-isothiazolone and 0.0459% 2-methyl-3(2H)-isothiazolone as active ingredients (Plant Cell Technologies, 2026). To minimize tissue browning, the culture media was enriched with 200 mg/L polyvinylpyrrolidone (PVP) and 1 g/L activated charcoal. To stimulate shoot regeneration, 1 mg/L 6-benzylaminopurine (BAP), 0.5 mg/L indole acetic acid (IAA) and 0.5 mg/L gibberellic acid ($GA_3$) were added to the media, prior to sterilization in the autoclave. Surface sterilization was performed sequentially using 1% citric acid, 0.5% sodium dichloroisocyanurate (NaDCC) for 5 min, 70% ethanol for 60 s, and 0.3% mercury(II) chloride ($HgCl_2$) for 5-7 min. Due to the high toxicity of mercury (II) chloride ($HgCl_2$), all handling was performed using appropriate laboratory safety precautions, and mercury-containing waste was collected separately and disposed of in accordance with institutional hazardous-waste procedures. After the explants were rinsed with sterile distilled water, they were inoculated on the two variants of media used for culture initiation: I1 and I2 (Table 1). In order to reduce phenolic oxidation, the explants were incubated for 10 days at 6°C, in complete darkness. Following this, they were transferred to the growing room, where they were grown at 22-25°C, under white, red and blue LED lights and a 16 hours photoperiod (Figure 2). All contaminated explants (including those contaminated with endophytic bacteria were removed from the experiment).

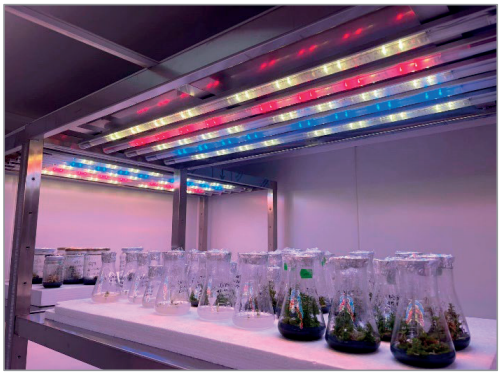

Figure 2. Culture conditions used for *in vitro* cultivation of *Euonymus fortunei* cultivars

**Multiplication on media with BAP or mT**

Following culture establishment and stabilization, explants were transferred to MS media containing either 6-benzylaminopurine (BAP) or meta-Topolin (mT) and indole acetic acid (IAA), as detailed in Table 2. For each medium variant, 10 explants were used per cultivar (n = 10 explants per treatment). The multiplication experiment was conducted following two subculture cycles. Data were recorded after a total culture period of 70 days. Media was prepared using stock solutions prepared individually for each element. Sucrose was supplemented in concentration of 30 g/L and the media was solidified with 7 g/L agar. To prevent oxidation, 100 mg/L

polyvinylpyrrolidone (PVP) and 1 g/L activated charcoal were added.
The pH value was adjusted at 5.70 and the media was sterilized in the autoclave for 20 minutes, at 121°C. All plant growth regulators (BAP, mT, and IAA) were filter sterilized with PES syringe filters (0.22 µm) and added after sterilization in the autoclave. Media was poured in sterile 250 ml Erlenmeyer flasks and covered with aluminum foil. Culture conditions were the same as before (Figure 1).

Table 2. Composition of media variants used for *in vitro* inoculation of *Euonymus fortunei* cultivars

| No. | Media variant | Media composition |
|---|---|---|
| 1. | M1 | MS + **2 mg/L BAP** + 0.2% Plant Preservative Mixture™ (PPM) + 1g/L activated charcoal |
| 2. | M2 | MS + **2 mg/L BAP** + **1 mg/L IAA** + 0.2% Plant Preservative Mixture™ (PPM) + 1g/L activated charcoal |
| 3. | M3 | MS + **2 mg/L mT** + 0.2% Plant Preservative Mixture™ (PPM) + 1g/L activated charcoal |
| 4. | M4 | MS + **2 mg/L mT** + **1 mg/L IAA** + 0.2% Plant Preservative Mixture™ (PPM) + 1g/L activated charcoal |

At the end of the 70-day multiplication period, biometric measurements were performed. The following parameters were evaluated: (i) mean number of shoots per explant, determined by counting the shoots regenerated from each explant; (ii) mean shoot length (mm), measured using a digital caliper; and (iii) mean fresh callus mass (g), determined by carefully excising the callus tissue from the explants and weighing it immediately using an analytical balance. The measurements were performed at the end of the multiplication experiment.

**Statistical analyses**
All statistical analyses were conducted using Microsoft Excel 2021 in combination with the Real Statistics Resource Pack (www.real-statistics.com). For each evaluated parameter, descriptive statistics were generated to summarize the data, with results expressed as the mean ± standard error (SE). The homogeneity of variances was assessed using Levene's test before selecting the appropriate statistical approach. Data satisfying the assumption of equal variances were analyzed by one-way analysis of variance (ANOVA). When significant treatment effects were identified, pairwise comparisons were carried out using Tukey's honestly significant difference (HSD). Statistical significance was established at a threshold of $p < 0.05$.

## RESULTS AND DISCUSSIONS

Use of Plant Preservative Mixture™ (PPM) was proven to be effective in reducing endophytic bacteria contamination. After 16 days, surface sterilization of explants resulted in 55.56% and 48.38% uncontaminated explants, whereas the addition of PPM increased the percentage to 88.89% and 95.71% in 'Emerald 'n' Gold' and 'Emerald Gaiety', respectively (Figure 3).

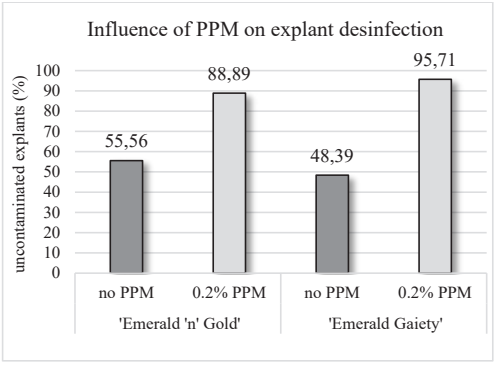

Figure 3. Influence of PPM on the percentage of explant disinfection

The beneficial effect of PPM observed in the present study is consistent with previous reports of its application in the establishment of woody plant material. Niedz and Bausher (2002) reported that PPM reduced contamination in greenhouse- and field-derived Citrus sinensis buds, although the effectiveness depended on the sterilization treatment used. PPM has also been successfully incorporated into culture systems for several woody species, including *Malus* spp. (Romadanova et al., 2022), *Corylus avellana* (Kushnarenko et al., 2025), *Rubus idaeus* (Trzewik et al., 2025), *Vitis vinifera* (Bettoni et al., 2019), and *Cryptocarya massoy* (Fajrisani et al., 2026).

Together with the present results, these studies support the usefulness of PPM as an additional measure for controlling persistent microbial contamination during the establishment of woody explants.

The effectiveness and phytotoxicity of surface disinfectants are also strongly dependent on their concentration and exposure time. In Euonymus koopmannii, for example, prolonged treatment with 5% sodium hypochlorite caused tissue injury and death of axillary buds (Kali et al., 2024). For field-derived nodal segments of Euonymus bungeanus, Cui et al. (2025) reported successful sterilization using 75% ethanol for 30 s followed by 0.1% $HgCl_2$ for 7 min. In the present study, NaDCC was incorporated into the sterilization procedure, followed by $HgCl_2$ treatment and the addition of PPM to the culture medium. The high proportion of uncontaminated explants obtained with PPM suggests that controlling microorganisms that persist after surface sterilization was particularly important for the establishment of the mature E. fortunei material used in this study.

The literature also indicates that no single disinfectant is universally optimal. NaDCC has been reported to provide effective surface sterilization with relatively limited tissue damage compared with some other disinfectants (Parkinson et al., 1996; Caton, 2008; Simran & Narasimhan, 2021). Reddy et al. (2025), for example, found 0.5% NaDCC to be more effective than 1% sodium hypochlorite or 1% calcium hypochlorite for sterilizing rhizome explants of Siphonochilus aethiopicus. Conversely, Mihaljević et al. (2013) reported that 1–2% NaDCC resulted in a higher contamination rate and lower survival of sour cherry axillary buds than some alternative disinfectants. These contrasting findings emphasize that sterilization efficiency depends on explant type, physiological condition, plant species, disinfectant concentration, and exposure duration. In the present study, the addition of PPM after surface sterilization provided an additional means of reducing contamination and consequently increased the proportion of explants suitable for culture establishment.

Information regarding the efficient sterilization of shoot tips and nodal segments of *Euonymus* remains relatively limited, as several previous studies on *in vitro* propagation or conservation have used seeds as starting material (Smith & Jernstedt, 1989; Biahoua & Bonneau, 1999; Chen et al., 2006; Shang et al., 2008; Thammina et al., 2011, 2012; Woo et al., 2021). For young shoot tips of *Euonymus verrucosus*, Kirillov et al. (2022) recommended 70% ethanol for 1 min followed by treatment with 0.025% thimerosal and a 7% aqueous sodium hypochlorite-based commercial bleach solution. The present results therefore provide additional information on the establishment of mature shoot-derived explants of *E. fortunei*, particularly regarding the potential contribution of PPM to contamination control.

**Multiplication**

***Average number of shoots obtained from each explant***

Both varieties, 'Emerald 'n' Gold' and 'Emerald Gaiety' reacted similarly when cultivated on the four media variants (Figure 4). Highest number of shoots was obtained on media variant M4 (2 mg/L mT and 1 mg/L IAA): 4.71 ± 2.05 shoots in 'Emerald 'n' Gold' and 4.4 ± 2.65 shoots on 'Emerald Gaiety'. Media variant M3 (2 mg/L mT) produced fewer shoots, however the recorded values were higher than the ones obtained on BAP-supplemented media: 3.3 ± 1.0 shoots ('Emerald 'n' Gold') and 2.6 ± 1.02 shoots ('Emerald Gaiety').

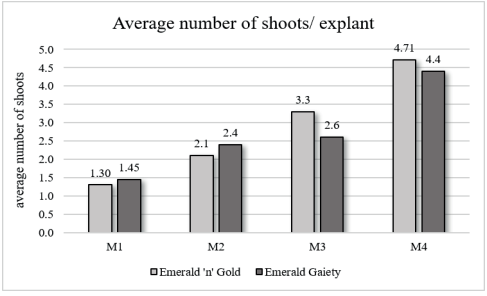

Figure 4. Average number of shoots obtained from each explant

The synergic interaction of meta-Topolin with auxins such as NAA, IBA and 2,4-D is well documented, by increasing the number of shoots, shoot length and stimulating organogenesis in species such as *Eucomis autumnalis* (Masondo et al., 2015), *Coleonema*

*album* (Fajinmi et al., 2014), *Manihot esculenta* (Chauhan & Taylor, 2018) *Hypericum frondosum* (Meyer et al., 2009) or *Huernia hystrix* (Amoo et al., 2009). mT-containing media also produced shoots without visible signs of oxidative damage (Figure 5). Previous studies have suggested that mT may reduce some of the undesirable effects associated with BAP, including oxidative stress and tissue damage, which can negatively affect plant growth and subsequent acclimatization (Keshari et al., 2020). The absence of visible oxidation in the mT treatments in the present study (Figure 5), together with their greater shoot proliferation, further supports the suitability of mT for multiplication of the investigated *E. fortunei* cultivars.

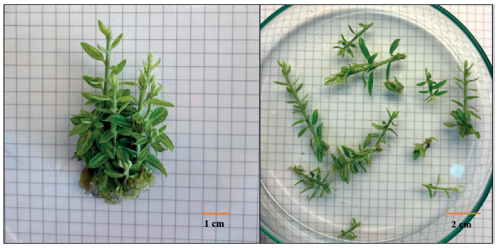

Figure 5. *E. fortunei* 'Emerald Gaiety' shoots obtained on media with 2 mg/L meta-Topolin and 1 mg/L indole acetic acid

The lowest shoot regeneration was observed on media M1 (2 mg/L BAP), with an average of 1.30 ± 0.46 ('Emerald 'n' Gold') and 1.45 ± 0.66 shoots ('Emerald Gaiety') and media M2 (2 mg/L BAP and 1 mg/L IAA), with an average of 2.1 ± 1.0 'Emerald 'n' Gold') and 2.4 ± 0.8 shoots ('Emerald Gaiety'). However, the difference between M1 and M2 was not statistically significant according to Tukey's HSD test ($p > 0.05$). Thus, although the numerical increase following IAA supplementation was apparent, it should not be interpreted as a statistically confirmed improvement. However, for shoot regeneration of *Euonymus* species, most studies focus on using BAP in combination with NAA (Shang et al., 2006). In *E. alatus*, adventitious shoot formation from hypocotyl segments can be achieved on media with 0.3 mg/L BAP and 0.1 mg/L NAA (Smith & Jernstedt, 1989). For direct shoot regeneration, Kali et al. (2024) recommend using media with BAP (1 mg/L), NAA (0.5 mg/L), and KIN (0.2 mg/L), both for nodal segments and internode explants, reaching a regeneration potential up to 90%. In *E. fortunei* var. *radicans,* Shang et al. (2009) obtained an average of 5.1 shoots from hypocotyl explants cultivated on media with 1.0 mg/L BAP and 0.01 mg/L NAA, with a regeneration frequency of 94%. For further proliferation of the regenerated shots, the concentration of NAA can be increased to 0.1 mg/L. *Euonymus bungeanus* plantlets can be successfully regenerated from leaf explants on induction media with 0.5 mg/L BAP and 0.5 mg/L NAA under red radiation and then transferred to media with 1 mg/L BAP and 0.5 mg/L NAA (Ning et al., 2021).

All multiplication media contained the same concentration of PPM (0.2%, v/v); therefore, PPM was not an experimental factor in the comparison among M1–M4. Consequently, differences in shoot proliferation observed among these treatments are interpreted primarily in relation to the cytokinin type and the presence or absence of IAA. Nevertheless, because PPM may have biological effects in addition to its antimicrobial activity, its potential contribution to plant growth cannot be completely excluded. The constant PPM concentration across all multiplication treatments, however, allows the relative effects of BAP and mT to be compared under the same PPM conditions.

***Average shoot length***

Shoot length also varied among the multiplication treatments (Figure 6). The highest numerical mean shoot length was 34.17 ± 4.94 mm on M2 (2 mg/L BAP and 1 mg/L IAA) for 'Emerald Gaiety' and 34.10 ± 9.99 mm on M3 (2 mg/L mT) for 'Emerald 'n' Gold', followed by 34.05 ± 9.64 mm on M4 (2 mg/L mT and 1 mg/L IAA) for 'Emerald Gaiety'. Lowest results were obtained on media M1 (2 mg/L BAP), 23.93 ± 5.76 mm for 'Emerald Gaiety' and 24.76 ± 5.11 mm (2 mg/L BAP and 1 mg/L IAA) for 'Emerald 'n' Gold'. Tukey's HSD test indicated that M2, M3, and M4 did not differ significantly from one another, whereas significant differences were detected between M1 and M2 ($p < 0.05$), M1 and M3 ($p < 0.05$), and M1 and M4 ($p < 0.05$). Thus, although the numerical ranking of M2, M3, and

M4 differed between cultivars, these differences should not be interpreted as statistically significant.

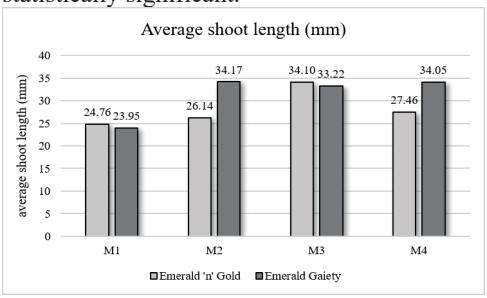

Figure 6. Average shoot length (mm)

Even though results regarding shoot length are similar between the media variants, shoots obtained on media with BAP (M1 and M2) exhibited shoot tip necrosis. Necrosis is a negative effect attributed to BAP during the multiplication phase, as excessive accumulation of cytokinin 9-glucosides has been associated with the occurrence of shoot tip necrosis in plants cultured *in vitro* (Bairu et al., 2011). In *Persea americana*, the use of mT has successfully alleviated dieback of the shoot apex, premature leaf abscission, and tissue necrosis (Hiti Bandaralage et al., 2015). Moreover, culture on media with BAP can also cause rooting inhibition and other abnormal growth patterns that have been attributed to the accumulation of biologically inactive storage forms, which are gradually released over time (Werbrouck et al., 1996). Such inactive reserves originate from the glucosylation of cytokinins such as BAP on the purine ring, either directly as glucosides or through the action of β-glucosidase enzymes (McGaw et al., 1985; Krishna Vrundha et al., 2021)

***Average basal callus mass***

Regarding the growth of basal callus, results show significant differences between the culture media variants ($p < 0.05$). In Figure 7 it can be observed that the highest mass (g) was obtained on the two media variants containing BAP: 1.90 ± 0.32 g for 'Emerald 'n' Gold' and 1.87 ± 0.32 g in 'Emerald Gaiety' on M2 and 1.81 ± 0.30 g in 'Emerald Gaiety' and 1.80 g in 'Emerald 'n' Gold' on M1; however, results from Tukey's HSD test revealed no significant differences between these two values. Lowest basal callus formation was observed on the explants cultivated on the two media variants containing mT instead of BAP: 0.77 ± 0.17 g in 'Emerald 'n' Gold' and 1.11 ± 0.47 g in 'Emerald Gaiety' on variant M3 and 1.54 ± 0.45 g in 'Emerald Gaiety' and 1.65 ± 0.44 g in 'Emerald 'n' Gold' on variant M4. Results from Tukey's HSD Test have shown that M3 and M4 to be statistically different ($p < 0.05$); however, no statistically significant differences were recorded between M4 and media variants M1 and M2 ($p > 0.05$ in both cases).

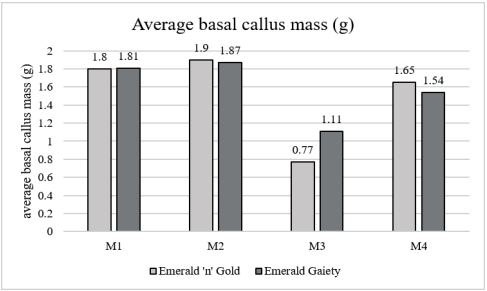

Figure 7. Average basal callus mass (g) per explant

Results obtained by Clapa et al. (2014) have also shown that media with mT reduces the formation of basal callus, compared to BAP during *in vitro* multiplication of *Paulownia* sp.. Moreover, besides a higher growth, the basal callus obtained on the media variants containing BAP progressively turned brown, accompanied by the tip necrosis of the shoots (Figure 8).

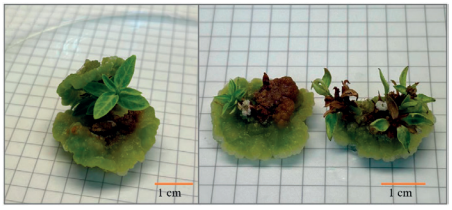

Figure 8. Effects of high concentrations of BAP – callus and shoot tip necrosis – on *E. fortunei* 'Emerald 'n' Gold' explants

Moyo et al. (2011) observed that explants cultivated on media with high concentrations of BAP resulted in the formation of non-organogenic basal callus, which was not able to differentiate into any organs. Moreover, the callus progressively turns brown during the

culture, which may be associated with the accumulation of biologically inactive cytokinin N7- and N9-glucoside conjugates, thereby reducing the availability of active cytokinins for further shoot proliferation, which may also explain the reduced number of shoots obtained from the explants cultivated on media supplemented with BAP (van Staden & Crouch, 1996; Auer, 1997; Moyo et al., 2011).

## CONCLUSIONS

This study presents an efficient *in vitro* establishment and shoot multiplication protocol for the ornamental cultivars *Euonymus fortunei* 'Emerald 'n' Gold' and 'Emerald Gaiety'. The addition of 0.2% (v/v) Plant Preservative Mixture™ (PPM) during culture establishment substantially reduced visible contamination, increasing the proportion of contamination-free explants from 55.56% to 88.89% in 'Emerald 'n' Gold' and from 48.39% to 95.71% in 'Emerald Gaiety'. During the multiplication phase, meta-topolin (mT) was more effective than 6-benzylaminopurine (BAP) under the conditions tested. The highest shoot numbers were obtained on medium containing 2 mg/L mT and 1 mg/L IAA (M4), with 4.71 shoots per explant for 'Emerald 'n' Gold' and 4.40 shoots per explant for 'Emerald Gaiety', compared with 1.30 and 1.45 shoots per explant, respectively, on the BAP-only medium (M1). In addition, mT-containing media were associated with lower basal callus formation, while shoot tip necrosis and progressive basal callus browning were predominantly observed in BAP-containing treatments. These findings indicate that mT, particularly in combination with IAA, represents a promising alternative to BAP for the multiplication of *E. fortunei* cultivars.

The present study contributes to the limited information available on *in vitr*o propagation of these *E. fortunei* cultivars, particularly by providing comparative evidence on the responses of two ornamental cultivars to mT- and BAP-based multiplication media. However, the study was limited to two cultivars and explants collected during a single sampling period, and PPM was evaluated at only one concentration. Furthermore, rooting, *ex vitro* acclimatization, genetic fidelity, and long-term field performance were not assessed. Therefore, the protocol should be considered a promising strategy for the establishment and multiplication phases rather than a complete production system. Further studies addressing rooting and acclimatization, as well as performance under environmental conditions relevant to urban and degraded sites, are required to validate its practical application. Nevertheless, the efficient production of healthy shoots may provide a useful basis for the subsequent development of planting material for sustainable urban greening, green infrastructure, and the rehabilitation of degraded urban sites where the use of these ornamental *E. fortunei* is considered environmentally appropriate.

## ACKNOWLEDGEMENTS

This work was conducted within the doctoral thesis “Biological Characteristics of Representatives of the Genus *Euonymus* L. in the Republic of Moldova” at the Doctoral School of Natural Sciences, Moldova State University, Chișinău, Republic of Moldova. The experimental studies on the *in vitro* propagation of *Euonymus fortunei* cultivars 'Emerald 'n' Gold’ and 'Emerald Gaiety' were carried out in the Plant Micropropagation Laboratory of the Research Center for Studies of Food Quality and Agricultural Products at University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania.

***Abstract***

*The transition toward sustainable and decentralized energy systems has accelerated the deployment of hybrid renewable energy supply systems (HRESS) in remote and off-grid areas worldwide. Hybrid systems that combine photovoltaic (PV) and wind energy technologies are particularly attractive because they exploit complementary renewable resources, reduce dependence on fossil fuels, and improve energy security for isolated users. Although the literature contains numerous technical studies on hybrid renewable energy systems, detailed analyses of annual storage requirements that explicitly account for seasonal variations in renewable generation remain limited. The main objective of this paper is to address this gap by proposing an analytical method for determining the annual energy storage capacity required to ensure a continuous power supply to an isolated consumer while accounting for seasonal variations in PV output. We illustrate the proposed method through a case study involving a 2–3 ha vineyard with a small guesthouse located in a mountainous region of Romania.*

***Key words:*** *Hybrid Renewable Energy System, seasonal photovoltaic (PV) energy storage, sizing method of storage.*

## INTRODUCTION

Hybrid Renewable Energy Systems (HRES), particularly those combining photovoltaic (PV) and wind energy generation, have been the subject of extensive research due to their potential to improve the reliability and sustainability of power supply in remote and off-grid locations. Several comprehensive reviews highlight that the integration of multiple renewable sources significantly enhances energy availability and reduces the dependency on conventional fuels, making hybrid configurations well-suited for isolated demand scenarios (Ahmad et al., 2024). Hybridization helps to mitigate the intermittency inherent in solar and wind resources by exploiting their complementary behaviour over daily and seasonal cycles, thus improving overall system performance and reliability (Hassan et al., 2023).

A critical aspect of HRES design is the sizing and optimization of both generation and storage components. Reviews on PV-wind-based hybrid systems report a wide range of deterministic and stochastic methods used to size system components, including energy production units and storage elements, based on historical climate data and user load profiles (Anoune et al., 2018). Many studies emphasize that appropriate sizing directly influences system reliability, cost-effectiveness, and the ability to meet energy demand throughout the year. However, they also point out that most sizing approaches tend to focus on capacity and reliability indices without deeply addressing the long-term or seasonal storage needs aligned with annual variability in renewable generation (Kafando et al., 2024).

Energy storage plays a central role in balancing supply and demand in hybrid systems. Storage systems such as batteries, hydrogen storage, or hybrid storage configurations are critical for accommodating fluctuations in renewable generation and sustaining continuous power availability during low resource periods. Systematic reviews in the field underscore that efficient energy storage integration and energy management strategies are essential to offset the intermittency of PV and wind resources and to improve system performance over extended temporal scales (Ma et al., 2015). Research also

highlights that hybrid storage solutions (e.g., battery-supercapacitor combinations) and advanced energy management systems can enhance storage utilization and extend equipment life while providing better operational flexibility (Kafando et al., 2024).
Despite the inclusion of storage sizing in many studies' optimization frameworks, a principled, analytical analysis of annual or seasonal storage requirements remains infrequent.
Most existing approaches focus on short-term sizing (daily or monthly) and rely on optimization tools such as HOMER or artificial intelligence-based techniques for short-term energy balance and reliability criteria (Ahmad et al., 2024). While these frameworks are useful for determining optimal component sizing under given climatic conditions, they often do not explicitly model annual storage autonomy that accounts for significant seasonal mismatches between renewable supply and demand.
Furthermore, research on the complementarity of solar and wind resources suggests that combining these sources can inherently reduce the magnitude of storage needed by smoothing variability. Studies employing metrics such as stability coefficients and capacity credits demonstrate that optimal PV–wind configurations provide more uniform generation profiles than single source systems, potentially lowering the storage burden required for year-round operation (Badea et al., 2019). Nevertheless, these studies generally focus on large-scale or grid-connected applications rather than isolated, remote systems with stringent autonomy requirements.
In summary, the recent literature (Hassan et al., 2023) underscores the advantages of hybrid PV–wind systems in enhancing renewable energy reliability, the necessity of integrating storage for autonomous operation (Dagdougui et al., 2012) and the variety of sizing and optimization methodologies available (Anoune et al., 2018).
Yet a gap remains in explicitly characterizing annual storage requirements that fully capture the seasonal dynamics of renewable resources.
This gap motivates the analytical method proposed in the present paper, which aims to quantify the storage capacity needed to ensure continuous energy supply for isolated users across an annual cycle, considering seasonal variation of the PV source.

## MATERIALS AND METHODS

### Conceptual physical model of a HRES

In this paper, a hybrid energy supply system will be an analysed, considering a conceptual physical model that contains the al00main components of the system: the photovoltaic electricity generator, end users of electricity, and the energy storage subsystem, as well as the connections necessary to ensure its functionality. The HYBRID system offers a partially or fully autonomous energy supply that relies solely on renewable energy sources, specifically the photovoltaic (PV) source in this case.
Figure 1 shows a diagram of such a hybrid autonomous electricity supply system.
As energy end users, there can be, for example, small tourist complexes or vineyards of 2-3 ha with a small guesthouse, located in isolated areas.

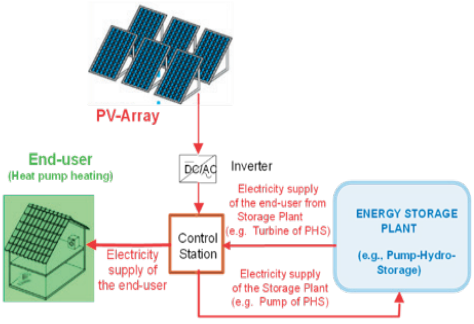

Figure 1. Conceptual physical model of a Hybrid Renewable Energy Systems (HRES) (Simão & Ramos, 2020)

The most important component of the system is the energy storage system (e.g. a Pump-hydro-storage) which ensures the seasonal energy balance between the required energy load of the end-user and the variable PV energy due to the solar radiation variability. Red lines with arrows show the flow of electrical energy between system components.

### Required energy supply for end-user

The type of user determines the required energy demand that the hybrid photovoltaic storage system must meet.
End users such as tourist establishments or households use energy for lighting and electrical appliances, space heating and hot water, space

cooling, cooking, and other end uses. In Figure 2 we can follow the average distribution of household energy in the EU (EUROSTAT, 2026).

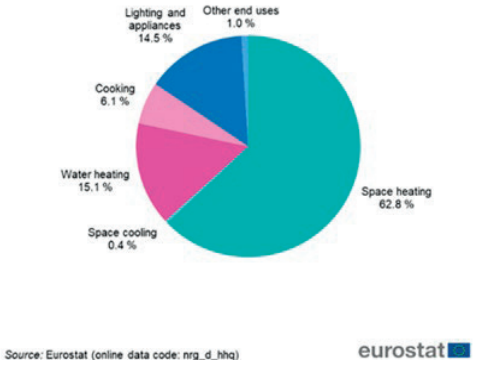

Figure 2. Averaged energy sharing in a household in EU (https://ec.europa.eu/eurostat/statistics-explained/index.php?title=Energy_consumption_in_households)

It can be seen in Figure 2 that, in a household, approximately 20% represents the direct consumption of electricity, and the remaining 80% is consumed mainly for heating and the preparation of domestic hot water.

From the European statistical data (EUROSTAT, 2026) follows that the specific total energy consumption in households per capita and year ($e_{ECH}$) is approximately:

$e_{ECH}$ =6800 kWh/cap/a in EU and $e_{ECH}$ =53200 kWh/cap/a in Romania. (Anoune et al., 2018)

Knowing the specific energy consumption, the total energy consumption for N people can be calculated:

$$E_{L/a} = N \cdot e_{ECH} \text{ in kWh/a} \quad (1)$$

For another type of end user, like guesthouse or vineyard of 2-3 ha with a small guesthouse, the required energy can be estimated using data from Malvoni & Cponcedo (2017), INSSE/Eurostat (2020-2025), OIV (2025) or REHVA. Such a user will be considered an example in the next paragraph - *The PV component*.

From the annual energy load $E_{l/a}$ (kWh/a) the annual average power demand can be determined $P_{l/a}$ (kW):

$$P_{l/a} = E_{l/a}/8760 \text{ in kW} \quad (2)$$

It is worth noting that energy consumption for heating, representing approximately 70-80% of a household's total energy consumption, can be substantially reduced (by approximately 50-75%) by using a heat pump, which operates on the electricity produced by PV. Thus, the entire energy consumption can be covered from the green electric current produced by PV

The analysis of heat pump efficiency based on the so-called Coefficient of Performance (COP) (i.e., the generated heating energy (kWh) divided the electricity consumed to generate heat (kWh) can be followed in detail in (WOLF, 2026).

**The PV component**

The PV-array component (Figure 1) is used to supply the consumer and, as appropriate, the storage system, respectively. Photovoltaic (PV) energy is a renewable energy source that does not produce emissions or pollutants while being a cost-effective energy source available everywhere (Quaschning, 2010; Badea et al., 2019).

The main disadvantage of a photovoltaic energy source (PV), in addition to its benefits, is the fluctuation in electricity output caused by the day and night cycle of solar radiation and seasonal variations, which result in higher output during the summer months and lower output in the winter months, as depicted in Figure 3.

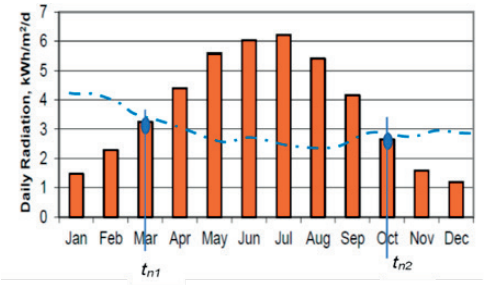

Figure 3. Example to schematic diagrams showing the annual distribution of monthly average solar radiation (https://www.researchgate.net/figure/Monthly-average-daily-solar-radiation_fig2_346271383)

For comparison, the required energy load (blue line) was also depicted. This juxtaposition is important for understanding the necessity of storing solar energy during times when solar radiation (i.e., PV-generated electricity) exceeds the required load ($t_{n1}<t_i<t_{n2}$) and for returning stored energy to meet demand during periods of

low solar radiation (e.g., the winter months: $t_i<t_{n1}$ and $t_i> t_{n2}$).

The annual output energy $E_{PV/a}$ generated by PV panel can be determined from the annual solar radiation ESR/a considering the *PR*-Performance Ratio (about 0,70-0,75) and the performance coefficient of PV panel $\eta \cong 0{,}18$-$0{,}25$ (Quaschning, 2010); https://www.solar.com/learn/solar-panel-efficiency/; https://strom-profis.net/produkt/ja-solar-jam72s20-455-mr-455-wp-solarmodul-bfr/).

An average value can be estimated as:

$$E_{PV/a}=\eta \cdot PR \cdot E_{SR/a}=\eta \cdot E_{PVP/a}\cong 0{,}145 E_{PVP/a} \quad (3)$$

For a given location, the solar radiation $E_{SR/a}$ is given in databases like NASA POWER and Global Solar Atlas.

For the design and analysis of the efficiency of a photovoltaic system (PV array), it is beneficial to develop a mathematical model that describes the influence of seasonal variations in solar radiation, a topic that has been less researched in the specialized literature.

In this context, it is noteworthy that the shape of the solar radiation distribution curve (Figure 3) is close to a sinusoidal one, which suggests the possibility using a mathematical representation based on trigonometric functions.

Based on these observations, the following trigonometric function is proposed to calculate the annual distribution of the average monthly power $P_{PV}(ti)$ (i.e. the monthly energy in kwh/month generated by the PV plant):

$$P_{PV}(t_i) = A\,(1-B\cos(\pi t_i)/6) \quad (4)$$

- A and B are specific parameters of the solar energy distribution diagram (e.g. Figure 3).
- In this context, ti represents the month number i of the year (for example, for January, $t_i=t_1=1$; for February, $t_i=t_2=2$; and for December, $t_i=t_{12}=T=12$).

To determine the parameter A, observe that by integrating equation (4) over a period of one year (Ta=12 month) the integral of the left-hand term represents the annual PV energy $E_{PV/a}$. On the other hand, $E_{PV/a}$ can be expressed using the annual average $P_{PV0}$ of the monthly average powers $P_{PV}$ (ti) as $E_{PV/a}=12\ P_{PV0}$.

Since the integral over the time interval Ta of the function *cos (πti)/6*) is zero, it follows that the integral of the right-hand side of equation (4) has the value 12A. Based on these results, the value of the parameter *A* is equal to $P_{PV0}$, meaning $A = P_{PV0}$.

To determine the parameter B, equation (4) will be applied for two characteristic points of the distribution diagram (Figure 3): the maximum monthly average power ($P_{PVmax}$) in the months June-July (i.e. $t_i=6$), respectively the minimum monthly average power ($P_{PVmin}$) in the months January and December (i.e., $t_i=0$ and $t_i=12$)

$$B = \frac{P_{PVmax}-P_{PVmin}}{P_{PVmax}+P_{PVmin}} \quad (5)$$

It is noted that the parameter B represents the maximum deviation of the maximum monthly mean power, $P_{PVmax}$. For this reason, B continues to be designated as σ.

Based on the above considerations and results, the mathematical model of the seasonal variation of the monthly average photovoltaic power (4) can be written in the form

$$P_{PV}(t_i) = P_{PV0}\left(1-\sigma_S \cos\frac{\pi t_i}{6}\right) \quad (6)$$

This proposed mathematical model will be further used (in paragraph entitled *Calculation method of the required energy storage to balance seasonal variation of PV*) to determine the PV energy storage required to balance seasonal variations of solar radiation.

**Calculation method of the required energy storage to balance seasonal variation of PV**

We can establish the characteristic operating intervals of the PV energy supply system using the representation from Figure 3, where the times marking $t_{n1}$ and $t_{n2}$ indicate the intersection points of both curves' load and photovoltaic (PV) energy production.

During the intervals $t < t_{n1}$ and $t > t_{n2}$ (i.e., the winter months) when the consumption requirement is higher than the PV-generated energy, the energy supply must be provided from the energy storage system (Figure 1) (i.e. turbine operation in the case of PHS). In the interval $[t_{n1} – t_{n2}]$ (i.e. during the months with higher solar radiation) the PV-generated energy is higher than the required energy by the consumer; the excess energy can be stored (i.e. pump operation in the case of PHS pump operation).

Denoting with $P_{L(t)}$ the power demand and with $P_{PV(t)}$ the photovoltaic power at the current

month t, the required *annual energy stored capacity* $E_{S/a}$ can be expressed as

$$E_{S/a} = \int_0^{t_{n1}} [P_L(\tau) - P_{PV}(\tau)]d\tau + \int_{t_{n2}}^{T} [P_L(\tau) - P_{PV}(\tau)]d\tau \quad (7)$$

Relation (7) can be rearranged using the proposed analytical model of the solar power (6) and a series of mathematical transformations, obtaining the following form:

$$E_{S/a} = 2\int_0^{t_{n1}} \left[P_L(\tau) - P_{PV0}\left(1 - \sigma_S cos\frac{\pi\tau}{6}\right)\right] d\tau \quad (8)$$

In the mathematical developments to obtain relation (8) the following simplifications were considered: the function *cos πτ/6 h*as approximately the same values in the time intervals [0, $t_{n1}$]and [$t_{n2}$, T] (Figure 3).
The photovoltaic energy ($E_{PVE/a}$), which exceeds the energy demand during the time interval $t_{n1}$-$t_{n2}$, can also be expressed in a similar integral form.

$$E_{PVE/a} = \int_{t_{n1}}^{t_{n2}} [P_{PV}(\tau) - P_L(\tau)]d\tau \quad (9)$$

respectively, using (6)

$$E_{PVE/a} = \int_{t_{n1}}^{t_{n2}} \left[P_{PV0}\left(1 - \sigma_S cos\frac{\pi\tau}{6}\right) - P_L(\tau)\right] d\tau \quad (10)$$

To analyse different HESS electricity supply options, a parameter can be introduced and defined as the ratio between the annual produced photovoltaic (PV) energy and the load that defines the degree of energy autonomy:

$$\lambda = \frac{E_{PV/a}}{E_{L/a}} = \frac{P_{PV0}}{P_{L0}} \quad (11)$$

For feasibility studies it is sufficient to consider a simplified case of a constant average power demand i.e.,

$$P_L(t) = P_{L0} = \frac{E_L/a}{12} \quad (12)$$

Using the parameter $\lambda$ and (12) the equation (8) of the required annual storage can be rearranged by obtaining the following form:

$$E_{S/a} = \frac{E_{L/a}}{6}\int_0^{t_{n1}} \left[1 - \lambda\left(1 - \sigma_S cos\frac{\pi\tau}{6}\right)\right] d\tau \quad (13)$$

Integration yields the following equation for required annual storage:

$$E_{S/a} = E_{L/a}\left[(1-\lambda)\frac{t_{n1}}{6} + \lambda\frac{\sigma_S}{\pi} sin\frac{\pi t_{n1}}{6}\right] \quad (14)$$

Similarly, (10) can be written in the following form:

$$E_{PVE/a} = \frac{E_{L/a}}{12}\int_{t_{n1}}^{t_{n2}} \left[\lambda\left(1 - \sigma_S cos\frac{\pi\tau}{6}\right) - 1\right] d\tau \quad (15)$$

Performing the integration, we obtain

$$E_{PVE/a} = E_{L/a}\left[(\lambda - 1)\frac{t_{n2} - t_{n1}}{12} - \lambda\frac{\sigma_S}{2\pi}(sin\frac{\pi t_{n2}}{6} - sin\frac{\pi t_{n1}}{6})\right] \quad (16)$$

The values of $t_{ni}$ (i=1,2) are the abscissas of the intersection points of the load curve $P_L$ with the seasonal $P_{PV}$ variation curve (Figure 3). Equations (13) and (6) yield:

$$t_{n1} = \frac{6}{\pi}\cos^{-1}(\frac{\lambda - 1}{\lambda\sigma_S}) \quad (17)$$

Equation (14) allows the calculation of the required annual storage $E_{S/a}$, given the annual consumption $E_{L/a}$ and the parameter λ, which defines the usage scenario for the photovoltaic (PV) energy supply in the planned HESS.
For an energy autonomous HESS, the annual photovoltaic energy production ($E_{PV/a}$) should be greater than or at least equal to the annual load ($E_{L/a}$), i.e. $\lambda \geq 1$. For the security of a standalone energy supply with a HESS, a λ value of 1.25 or even 1.5 is recommended (Quaschning, 2010).
For the simplified case when considering usual values for $t_{n1}$ and $t_{n2}$, namely $t_{n1}$ =3 and $t_{n2}$=9, the calculation equation (14) of the storage capacity per year ($E_{S/a}$) becomes the simplified form:

$$E_{S/a} = E_{L/a}\frac{\sigma_S}{\pi} \quad (18)$$

We remind you also that currently, the maximum deviation of the monthly solar radiation, has values between 0.5 and 0.6
The method and the calculation formulas presented above can be used to determine the required storage capacity of HESS, which ensures the annual energy balancing between the photovoltaic (PV) energy source and

consumption, considering the seasonal variation of photovoltaic (PV) energy.

**Storage systems, Pump-Hydro-Storage**

Luo et al. (2015) present a comprehensive overview and analysis of the current development of various types of technologies in electrical energy storage (EES).

Batteries and Pump-Hydro-Storage systems (PHS) are the most used storage systems (Kousksou et al., 2014).

Batteries are commonly employed as storage in stand-alone renewable energy systems have well known limitations (Hassan et al., 2023).

Regarding the economics of this technology, pumped hydro energy storage seems more economical than batteries as well for standalone applications (Ma et al., 2015) and has relatively low payback periods.

These aspects are the reason why we in our paper choose pumped hydro storage (PHS) as storage example. PHS is a storage system that uses excess PV electricity to pump water from a lower reservoir to an upper reservoir to store energy, and conversely, the water is released from the upper reservoir to the lower reservoir, assuring the energy supply of user at lower or missing solar radiation (Figure 4).

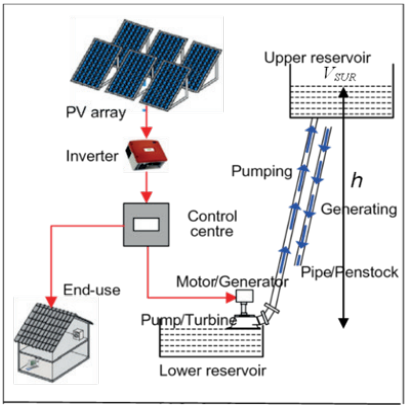

Figure 4. Scheme a PV electricity supply system with Pump-Hydro-Storage (Simão & Ramos, 2020)

If there are geographical conditions for PHS implementation, a hybrid system represented in Figure 4 can provide a reliable and cost-effective solution for providing electricity in remote areas. Additionally, such a hybrid energy supply system reduces substantially the environmental pollution (Rastler, 2010).

The two most significant parameter for the design of a PHS are the volume of the upper and lower reservoirs, which are the same value ($V_{UR/LR}$) and the turbine/pump head (h) (Figure 4) For a concrete study, the head of the turbine/pump (h) must be determined based on local topographic.

Therefore, for operating and sizing the PHS, only the volume of the upper reservoir ($V_{UR/LR}$) must be carried out.

The required input power for the pump $P_P(t)$ can be expressed as:

$$P_P(t) = \frac{1}{\eta_P} \rho g h \cdot q_P(t) \quad (19)$$

$\rho$ is the density of water (1000 kg/m3),
$g$ is the gravity acceleration and
$\eta_P$ is the overall pumping efficiency
$h$ is the pump head

The output power from the turbine $P_T(t)$ can be expressed as

$$P_T(t) = \eta_T \rho g h \cdot q_T(t) \quad (20)$$

$\eta_T$ is the overall efficiency of the turbine;
$q_{T(t)}$ is the flow rate of the turbine
$h$ is the turbine head

The other parameters have the same meaning as in the formula (19). In the case of standalone supply, the option of annual compensation is required for the security of a user's correct and safe energy supply in a remote area throughout the year.

The required annual energy storage $E_{S/a}$ can be determined using (14) or, in the simplified case, (18). Knowing $E_{S/a}$ we can calculate the volume of the upper/lower reservoir $V_{UR/LR}$. For this purpose, we note that, integrating the relationship (20) in relation to time (over one year), the left term is the energy stored $E_{S/a}$, and in the right member, the turbine flow $q_T$ integrated represents the volume to be calculated $V_{UR}$.

So, the required water volume in the upper reservoir for energy storage in case of annual energy balance of the PV-PHS energy supply system, i.e., the volume of the upper reservoir $V_{UR}$, can be expressed as

$$V_{UR} = \frac{E_{S/a}}{\eta_T \rho g h} \quad (21)$$

## RESULTS AND DISCUSSIONS

This section presents and illustrates the application of the calculation methods presented in the preceding sections for an end user in a remote area with an annual electricity consumption of $E_{L/a}$ 25,000 kWh. This consumption would correspond to an end user like a vineyard of 2-3 hectares with a small guesthouse of 4-5 rooms powered by photovoltaic panels and a heat pump (Malvoni & Cponcedo, 2017; INSSE/EUROSTAT, 2020-2025).

Here is the rationale for the considered electricity consumption of 25,000 kWh:

- Guesthouse (approx. 150-200 m²): a well-insulated building with 5 rooms consumes approximately 10,000-12,000 kWh/year for heating and hot water (using a modern air-to-water heat pump).
- Household consumption (lighting, kitchen, electronics): Approx. 4,000-5,000 kWh/year. These rationales are based on data from REHVA.
- Winery (Technology): for 2 hectares of vineyards (production of approximately 10,000–14,000 litters), the processes of must cooling, controlled fermentation, and stabilization require concentrated, but not enormous, energy consumption estimated at 8,000–10,000 kWh/year. This estimation is based on data from (OIV, 2025). Thus, the total estimated consumption is 22,000-27,000 kWh/year.

To ensure that this annual load is covered, a minimum annual photovoltaic energy production of $E_{PV/a}$ which is achieved using PV modules. In our example, a mountainous region of Romania, the annual solar irradiance can be estimated using the data in Figure 5 at a value of =1241 kWh/m$^2$. If we select JA Solar JAM72S20 455/MR 455 Wp PV modules with an efficiency of η = 20.05% and a module area Ap = 2.2 m² (https://www.enfsolar.com/pv/panel-datasheet/crystalline/46963) the PV potential of one solar module is:

$$E_{PV/p} = \eta \cdot A_P \, E_{PV/m^2} \cong 550 \, kWh/p \quad (22)$$

Thus, the required number of solar modules (NP) to be installed for a photovoltaic (PV) energy production of EPV/a (e.g. EPV/a =25,000) is:

$$N_P = \frac{E_{PV/a}}{E_{PV/p}} = \frac{25000}{550} \cong 45 \, modules \quad (23)$$

Furthermore, the next component of HESS will be analysed, namely the storage. As presented in the introduction and in paragraph - *Calculation method of the required energy storage to balance seasonal variation of PV*, the storage component of the HESS (Figure 3) is crucial to balancing the fluctuations of the renewable energy generation (PV) to ensure a secure and stable energy supply throughout the year. Knowing the annual load of $E_{L/a}$ =25,000 kWh/a, different scenarios for HESS can be analysed using the parameter λ defined as the ratio between the annual photovoltaic (PV) energy production ($E_{PV/a}$) and the annual load ($E_{L/a}$).

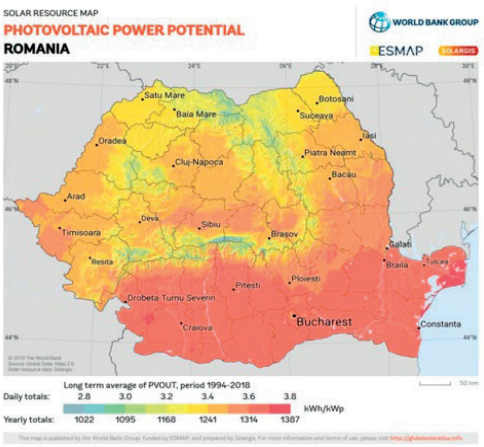

Figure 5. Solar energy resource map of Romania ((https://solargis.com/maps-and-gis-data/download/romania)

As reference case, we consider that discussed above in which the energy consumption $E_{L/a}$ corresponds to the generated photovoltaic energy $E_{PV/a}$ and thus from (11) λ=1. Any other value of λ corresponds to an energy supply scenario as follows:

- λ <1, when the annual photovoltaic energy production is less than energy consumption: $E_{PV/a}<E_{L/a}$
- λ>1, when the annual photovoltaic energy production exceeds the annual energy consumption: $E_{PV/a}>E_{L/a}$

The first case (λ<1) corresponds to partially energy autonomous scenarios of HESS i.e., when only a part of the energy supply ensured

from the PV source. To cover the difference between consumption $E_{L/a}$ and $E_{PV/a}$, it is necessary to use an additional energy source.
The second case ($\lambda>1$) corresponds to a scenario of energy autonomy for HESS, meaning that the entire energy supply is provided by photovoltaic systems integrated with appropriate storage solutions.
It should be noted that for the security of energy autonomy with a HESS, a $\lambda$ value of 1.25 or even 1.5 is recommended (Quersching, 2010).
Based on these considerations, it is relevant to discuss three further scenarios of HESS in addition to the reference case ($\lambda=1$). Two of these scenarios correspond to cases of secure energy supply with HESS, where $\lambda$ has values of 1.25 and 1.5, respectively.
One of scenarios corresponds to the case when only a part (e.g. about 75%) of the energy supply comes from PV source (i.e. $\lambda$ =0,75). For the remaining 25% other sources are needed, such as electricity from power grid.
Using the proposed method and calculation formulas presented in the paragraph -*Required energy supply for end-user,* Table 1 shows the results for the end user – a tourist facility that consists of a 2-hectare vineyard with a small guesthouse in a mountainous region of Romania – with an annual consumption of $E_{L/a}$ = 25,000 kWh/a. Four scenarios were considered: $\lambda$ = 0.75; $\lambda$ = 1.00; $\lambda$ = 1.25; $\lambda$ = 1.50.

Table 1. Required energy supply for tourist facility

| $\lambda$ | 0.75 | **1.00** | 1.25 | 1.50 |
|---|---|---|---|---|
| $E_{PV/a}$ [kWh/a] | 16,670 | **25,000** | 31,250 | 37,500 |
| NPV [-] | 30 | **45** | 57 | 68 |
| $t_{n1}$ [month] | 4.4 | **3** | 2.21 | 1.6 |
| $E_{S/a}$ [kWh/a] | - | **4,000** | 2,250 | 1,125 |
| $E_{PV/a}$-$E_{L/a}$ [kWh/a] | -8,330 | **0.00** | +6,250* | +12,500* |
| $V_{UR}$ [m$^3$] | - | **81,550** | 127,422* | 254,844* |

For each scenario, the following values are calculated:

- the annual energy production of the PV system ($E_{PV/a}$, equation (9))
- the number of PV modules ($N_P$)
- the required annual storage to compensate for seasonal fluctuations of PV production ($E_{S/a}$), equation (12))
- the energy difference between the annually produced photovoltaic (PV) energy ($E_{PV/a}$) and the annually required consumption ($E_{L/a}$)
- the required storage volume $V_{UR}$ of the upper/lower reservoir when using a pump hydro storage system (paragraph - *Storage systems, Pump-Hydro-Storage*, equation (21)).

The additional energy ($E_{PV/a}$ - $E_{L/a}$) generated in the scenarios with $\lambda$ =1.25 and $\lambda$ =1.5 (row 3 in the Table 1), which exceeds the effective annual energy consumption (25,000 kWh) marked with an asterisk (*) in Table 1, serves to ensure the consumer's security of supply. This generated photovoltaic (PV) energy is lost if it is not used by other consumers, fed into the grid (if available), or stored.
The last rows of Table 1 show the required storage volume for a pumped-storage hydroelectric plant.
It is evident that the additional water volume required to store the extra energy generated is very high: over 50% for variant $\lambda$ =1.25 and over 200% for variant $\lambda$ =1.5. Therefore, a techno-economic analysis is necessary to assess the viability of such storage.

## CONCLUSIONS

This paper presented a novel analytical approach to determining the annual energy storage requirements for Hybrid Renewable Energy Supply Systems (HRESS), specifically addressing the challenges posed by seasonal PV output variations. By employing a trigonometric mathematical model to describe the sinusoidal distribution of annual solar radiation, this study bridged a critical gap in existing literature, which often overlooks long-term seasonal dynamics in favour of short-term technical optimizations.
The application of the proposed method to a case study - a vineyard and guesthouse in mountainous Romania - provided several key insights:
Analytical Precision: The introduction of the energy autonomy parameter ($\lambda$) proved to be a robust metric for sizing HRESS. The mathematical derivation of the required annual

storage via the intersection points of load and generation curves allows for a precise quantification of storage needs without the necessity for computationally expensive hour-by-hour simulations.

Impact of Autarky Levels: The results demonstrate that while a reference case theoretically covers annual demand, it necessitates maximum storage capacity to bridge seasonal deficits. Increasing the PV capacity to security levels of or above significantly enhances energy security but results in substantial surplus energy. This highlights a critical design trade-off: over-dimensioning the PV array can reduce the relative storage burden but requires effective ategies for utilizing excess energy, such as grid-feeding or secondary thermal loads.

Storage Feasibility: The study quantified that for a typical 25,000 kWh/a consumer, the seasonal storage requirements are substantial. For isolated systems, the results suggest that Pumped Hydro Storage (PHS) or advanced long-term battery solutions are indispensable, as conventional short-term storage cannot compensate for the sinusoidal "winter gap" identified in the model.

In conclusion, the proposed analytical equations provide a valuable tool for engineers and policymakers in the early feasibility stages of decentralized energy projects. Future research should extend this trigonometric model to include stochastic weather fluctuations and the complementary integration of wind energy to further optimize the parameter λ and reduce the physical footprint of the required storage systems.

***Abstract***

*Efficient light management represents a key challenge in protected cultivation systems, particularly when cost constraints limit the use of advanced dimmable lighting technologies. This study presents a low-cost, open-source, sensor-based approach for practical light management in protected horticultural environments. A custom-built multi-stage lighting system was combined with a multispectral light sensor used as a control variable, while a reference PAR sensor was employed for calibration under real operating conditions. Light intensity was regulated through automated multi-stage switching with integrated energy monitoring, enabling feedback between illumination targets and electrical power consumption. The control logic was implemented using an open-source automation platform, allowing data acquisition, logging, and system adaptability. The experimental setup was evaluated under greenhouse conditions using Capsicum spp. as experimental plant support. Rather than replacing professional photometric instruments, the proposed approach demonstrates the functional integration of low-cost sensors and open-source tools for scalable and energy-efficient light management applications.*

***Key words:*** *artificial lighting; DLI control; Home Assistant; open-source automation; PPFD estimation.*

## INTRODUCTION

Protected cultivation systems are increasingly expected to deliver higher productivity, better resource use efficiency, and improved crop quality under variable environmental and economic constraints. In this context, light management has become one of the central technical challenges of greenhouse and other protected horticultural systems. Although natural solar radiation remains the dominant light source in most structures, its quantity and temporal distribution are often insufficient or highly variable, especially during winter, cloudy periods, or in densely developed canopies where self-shading limits light penetration to lower leaf layers. As a result, supplemental lighting is widely regarded as an effective tool for stabilizing photosynthesis, supporting plant development, and improving yield and product quality in protected crops (Moe et al., 2006; Hemming, 2011; Hao et al., 2018).

The physiological importance of light in horticultural systems is not limited to total irradiance. Crop responses depend on several interrelated parameters, including photosynthetic photon flux density (PPFD), daily light integral (DLI), photoperiod, spectral composition, and vertical light distribution within the canopy. For fruiting vegetables and other greenhouse crops, insufficient light reduces assimilate production, affects vegetative–generative balance, and may limit both yield and crop quality. In high-density canopies, most incident radiation is intercepted by the upper leaf layers, leaving the lower canopy under-illuminated. This uneven distribution reduces the contribution of lower leaves to whole-plant photosynthesis and has motivated the development of strategies such as interlighting and spectrum-tailored supplemental illumination (Jokinen et al., 2012; Guo et al., 2016; Hao et al., 2018).

During the last decade, light-emitting diode (LED) technology has become increasingly important in horticultural lighting because it offers several practical advantages over conventional discharge lamps. These include

high photon efficiency, low radiant heat output, long operational lifespan, compact size, and the possibility of spectral tailoring according to plant needs. In addition, LED systems can be integrated more easily into digital control architectures than older lighting technologies. This has enabled not only supplemental and interlighting strategies, but also increasingly precise forms of control based on crop demand and environmental variability (Morrow, 2008; Moe, 2012; Bergstrand et al., 2016; Palmitessa et al., 2021). From the perspective of plant lighting, efficiency should be considered primarily in terms of delivered photosynthetic photons rather than conventional human-centered luminous metrics, because plant responses are driven by photon flux in the photosynthetically active radiation (PAR) region (400-700 nm) (Nelson & Bugbee, 2014). At the same time, there is increasing evidence that lighting strategies should not be treated as simple on/off supplementation. Instead, effective greenhouse lighting must be understood as a dynamic management problem in which light intensity, light quality, timing, and canopy distribution are coordinated with crop requirements and available natural radiation. Reviews and experimental studies have shown that optimized supplemental lighting can improve productivity, accelerate development, and increase the efficiency of canopy light use in crops such as tomato and sweet pepper. This applies not only to northern regions with severe winter limitations, but also to Mediterranean or transitional climates where natural light is often variable rather than consistently limiting (Li et al., 2016; Paucek et al., 2020; Palmitessa et al., 2021). The relationship between PPFD delivery and crop nutrient demand also underlines the importance of precise light quantification in closed growing environments.

Despite these advances, practical implementation in small or medium-scale protected cultivation remains constrained by cost. Professional dimmable lighting systems, quantum sensors, and commercial greenhouse control platforms can be effective, but they are often too expensive for experimental, educational, or low-budget horticultural installations. This creates a technological gap: the biological need for intelligent light management is well established, but affordable systems capable of continuous sensing, automated control, and energy-aware operation are still limited. In practice, many growers and researchers require solutions that are not necessarily perfect substitutes for industrial systems, but are sufficiently robust, transparent, and adaptable for real use under greenhouse conditions.

One of the key barriers to low-cost light management is the measurement of PPFD itself. Professional quantum sensors provide direct and reliable PAR measurements, but their cost may restrict deployment density or routine use in custom automation systems. As a result, low-cost multispectral sensors have attracted increasing interest as potential alternatives for estimating PPFD and related light metrics. However, such sensors do not directly measure PPFD; instead, they provide channel-specific responses that depend on spectral composition, optical geometry, and environmental conditions. Therefore, their use in horticultural applications requires calibration against a reference PAR instrument under relevant operational conditions. The AS7341 is a ten-channel multispectral sensor covering the full PAR range (415-680 nm) plus broadband and NIR channels, at low component cost, making it particularly suitable for integration into custom greenhouse sensing systems. Recent work has demonstrated that compact multi-channel spectral sensors of this type can estimate PAR or PPFD with useful accuracy when appropriately calibrated (Bäumker et al., 2021). The combination of multiple spectral channels for sensor fusion has also been shown to substantially improve estimation accuracy compared to single-channel approaches (Li et al., 2018; Yang et al., 2020). Hyperspectral and multispectral approaches more generally have demonstrated the broader value of spectral sensing in crop monitoring and physiological estimation (Kawasaki et al., 2008; Thorp et al., 2017; Shafaei et al., 2018).

A second major barrier is control architecture. In recent years, smart greenhouse research has increasingly moved toward sensor networks, IoT-based monitoring, cloud-connected platforms, and data-driven automation. These systems can improve environmental control, reduce labor, and increase resource efficiency

by linking sensors, actuators, and supervisory logic in a single platform (Rath & Kawollek, 2009; Sagheer et al., 2021). However, many published systems remain relatively complex or infrastructure-heavy and are not always directly transferable to simple protected cultivation structures or researcher-built installations. Open-source platforms represent an attractive alternative because they allow custom hardware integration, real-time logging, flexible control logic, and direct transparency of algorithms and thresholds.

For lighting control specifically, the combination of instantaneous PPFD estimation with daily light integral (DLI) tracking is especially promising. PPFD enables rapid decisions in response to transient changes in natural radiation, while DLI provides an integrative measure of total daily photosynthetic light received by the crop. Together, these variables support a biologically meaningful control strategy: supplemental lighting can be activated when natural light is insufficient and limited when the daily light target has already been reached. Such an approach is well aligned with commercial greenhouse principles, yet it can also be implemented in simplified form using discrete lighting stages and open-source automation (Kim et al., 2006; Hao et al., 2018).

Therefore, the novelty of the present study does not lie in proposing a new photometric standard or replacing professional horticultural instrumentation. Instead, it lies in demonstrating that a practical light management system for protected cultivation can be built from low-cost components and open-source tools, provided that calibration, control logic, and energy monitoring are treated rigorously. The system presented here combines a custom-built multi-stage LED lighting fixture, a multispectral AS7341 sensor used as a control variable, a reference quantum sensor for calibration, and a Home Assistant-based automation framework for PPFD estimation, DLI integration, and stage-based lighting control under real greenhouse conditions.

The objective of this study was to develop and evaluate a low-cost, open-source, sensor-based lighting management approach suitable for protected horticultural environments. More specifically, the study aimed to: (i) calibrate a multispectral AS7341 sensor against a reference quantum sensor for estimating canopy-level PPFD under real greenhouse conditions; (ii) implement an adaptive, multi-stage supplemental lighting strategy based on estimated PPFD and DLI; and (iii) integrate lighting control with energy monitoring through an open-source automation platform in order to demonstrate a scalable and practically useful alternative for protected cultivation systems, using *Capsicum* spp. as experimental plant support.

## MATERIALS AND METHODS

### *AS7341 Sensor Calibration for PPFD Estimation*

In modern protected cultivation systems, accurate light management is essential for both optimizing photosynthesis and minimizing the energy costs associated with supplemental lighting. Professional quantum sensors, which directly measure photosynthetic photon flux density (PPFD, $\mu mol \cdot m^{-2} \cdot s^{-1}$), serve as reference instruments but are costly and impractical for multi-point deployment in experimental or commercial greenhouses (Hemming, 2011; Nelson and-Bugbee, 2014).

In this context, the AS7341 multispectral sensor represents an attractive low-cost alternative, providing separate measurements across ten spectral bands in the visible and NIR range (415-680 nm, Clear, NIR). However, the AS7341 does not measure PPFD directly; instead, it outputs raw digital counts that depend on the spectral composition of the light source, the angle of incidence, and local optical conditions. Consequently, the use of this sensor in horticultural applications requires rigorous calibration under conditions as close as possible to real-world operation (Bäumker et al., 2021).

The objective of this calibration step was to establish a mathematical relationship (regression model) between the raw channel outputs of the AS7341 and the actual PPFD values measured by a reference quantum sensor, enabling the AS7341 to subsequently estimate canopy-level PPFD, compute the Daily Light Integral (DLI), and support automated supplemental lighting control.

The AS7341 breakout board was soldered with a four-wire I²C cable (SDA, SCL, VCC, GND) and mounted inside a custom 3D-printed

enclosure designed specifically for this experiment (Figure 1). The enclosure provides mechanical protection and ensures a fixed, reproducible optical geometry for the sensor. An opal diffuser dome was positioned above the optical capsule of the sensor. The dome serves a dual purpose: (1) uniformizing the angle of incidence, thereby reducing sensitivity to the sun's position (sunrise vs. sunset), and (2) approximating the angular response of a cosine-corrected quantum sensor, which integrates photon flux across a full hemisphere. The enclosure was sealed and weatherproofed, enabling permanent installation in the greenhouse environment.

Figure 1. AS7341 sensor assembly components. Left: multispectral breakout board in the custom 3D-printed enclosure with I²C wiring. Centre: opal diffuser dome above the AS7341 optical capsule prior to assembly. Right: sensor mounted upward-facing on the greenhouse support post

A LightScout Quantum Light Meter (Spectrum Technologies, USA) was used as the reference instrument, capable of directly measuring PPFD in the 400-700 nm range, expressed in $\mu mol \cdot m^{-2} \cdot s^{-1}$. This sensor served as the calibration standard throughout the entire measurement campaign. It was positioned at canopy level, in a fixed upward-facing orientation, without adjusting the angle of incidence during measurements.

It is important to note that the sensor angle was not adjusted toward the sun to maximize PPFD readings, even under strong direct irradiance. Although orienting the sensor toward the sun could have produced values exceeding 1000 $\mu mol \cdot m^{-2} \cdot s^{-1}$, this approach would have introduced an additional source of geometric error and compromised the comparability of measurements across different times of day.

The AS7341 sensor was mounted in a fixed position on a dedicated steel support post inside the greenhouse, approximately 3 m from the reference quantum sensor. Although this separation introduces the possibility that one sensor may occasionally be partially shaded by the greenhouse structure or covering film, this was not systematic and was considered acceptable for calibration under real operating conditions.

Calibration was performed exclusively under natural light, with all supplemental LED lighting switched off, over multiple days (12-13 January 2025), across different times of day covering a broad range of PPFD values from approximately 1-10 $\mu mol \cdot m^{-2} \cdot s^{-1}$ up to approximately 700 $\mu mol \cdot m^{-2} \cdot s^{-1}$. This approach ensured that the calibration dataset included a wide variety of illumination conditions: overcast sky, diffuse light, direct sunlight at different solar angles, and spectral variations caused by solar position and greenhouse film transmittance.

For each calibration point, the following procedure was applied: (1) the PPFD value was read from the quantum sensor ($\mu mol \cdot m^{-2} \cdot s^{-1}$); (2) the exact time was recorded (hh:mm); (3) a screenshot of the raw channel counts of the AS7341, as displayed in the Home Assistant platform, was captured; and (4) values were subsequently entered manually into a centralized data table. Approximately 100 individual measurements were collected in total, distributed across the full PPFD range of interest (Figure 2).

Figure 2. Calibration data collection procedure

The LightScout quantum sensor (reading 148 $\mu mol \cdot m^{-2} \cdot s^{-1}$) is positioned at canopy level alongside *Capsicum* spp. experimental plants. The data recording sheet on the clipboard is visible in the foreground, illustrating the parallel manual logging of quantum sensor values and timestamps.

Raw unprocessed channel values were used for regression, without internal normalization, in order to preserve the direct relationship between the received optical signal and the electronic response of the sensor. The Clear and NIR channels were analyzed separately; however, the final model was built primarily on channels within the PAR range (415–680 nm), as these are directly relevant to photosynthesis (Kim et al., 2004; Nelson & Bugbee, 2014).

The relationship between PPFD and AS7341 signals is not perfectly linear across the full measurement range, particularly at very low light levels where the ratio of diffuse to direct light varies substantially and the contribution of non-PAR spectral components becomes relatively larger. For this reason, calibration was approached using multiple linear regression, followed by a critical analysis of its domain of validity. The resulting model expresses estimated PPFD as a weighted sum of the AS7341 spectral channels:

$$PPFDest = a_0 + a_1 \cdot Ch415 + a_2 \cdot Ch445 + \ldots + a_n \cdot Ch680$$

Coefficients were determined by the least-squares method using the complete collected dataset. Subsequently, the use of a piecewise model was found necessary, separating the low-light domain from the medium–high illuminance domain, in order to improve accuracy under reduced illumination conditions (Bäumker et al., 2021). The combination of multiple spectral channels substantially improves estimation accuracy compared to single-channel broadband approaches (Li et al., 2018; Yang et al., 2020).

The final calibration model allows: (1) PPFD estimation with satisfactory accuracy across the horticultural range of interest; (2) real-time integration into Home Assistant; and (3) use for DLI computation and supplemental lighting control. The objective of this calibration was not to replace a laboratory-grade quantum sensor, but to obtain a robust, reproducible, and sufficiently accurate instrument for practical greenhouse control applications (Figure 3).

The dashed line represents perfect agreement (1:1); the shaded band indicates ±RMSE. Right: MLR regression coefficients per spectral channel. Channels at 445 nm and 480 nm show the strongest positive contributions; the 590 nm channel shows the largest negative coefficient.

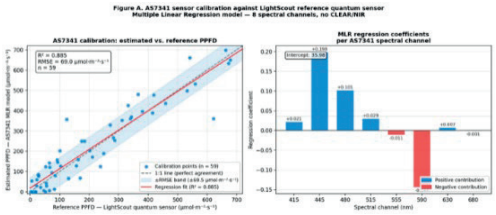

Figure 3. AS7341 calibration against the LightScout reference quantum sensor. Left: scatter plot of AS7341-estimated PPFD vs. reference PPFD (n = 59; $R^2 = 0.896$; RMSE = 69.5 µmol·m$^{-2}$·s$^{-1}$).

### *Lighting System Configuration*

The supplemental lighting fixture was custom-built from 20 full-spectrum LED bulbs (2.5 W real consumption each), mounted on a 3 m aluminium rail suspended horizontally above the crop canopy. The bulbs were arranged in three independently controlled circuits of 7, 7, and 6 lamps respectively, connected in parallel within each circuit (Figure 4 and Figure 5).

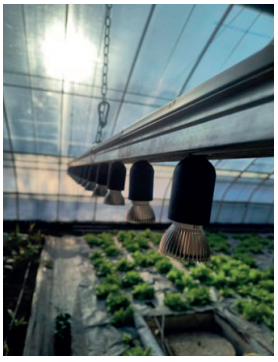

Figure 4. Custom-built supplemental lighting fixture consisting of 20 full-spectrum LED bulbs mounted on an aluminium rail, photographed under natural daylight conditions with lamps switched off. The three independently controlled circuits are arranged along the rail

The three circuits define three cumulative lighting stages, activated in succession:

- Stage 1 (circuit 1 only, 7 lamps): approximately 30 µmol·m$^{-2}$·s$^{-1}$
- Stage 2 (circuits 1+2, 14 lamps): approximately 70 µmol·m$^{-2}$·s$^{-1}$
- Stage 3 (circuits 1+2+3, all 20 lamps): approximately 150 µmol·m$^{-2}$·s$^{-1}$.

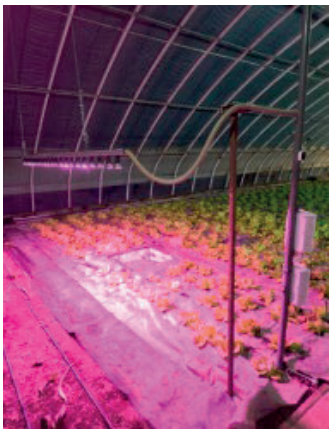

Figure 5. Supplemental lighting fixture operating at full output (Stage 3, all 20 lamps) during nighttime, illuminating the crop canopy with characteristic pink-magenta spectrum

The smart plug control box is visible on the support post (right). The AS7341 sensor post is positioned in the background.

PPFD values associated with each stage were determined experimentally at canopy level using the reference quantum sensor, under nighttime conditions with natural light fully excluded. Given the directional nature of the LED sources and the spatial variability inherent to a DIY fixture (particularly the disproportionate contribution of the six overhead lamps in stage 3, which illuminate the plant canopy perpendicularly), measured values ranged approximately 20-30% around the mean at each stage. The representative values of 30, 70, and 150 $\mu mol \cdot m^{-2} \cdot s^{-1}$ were adopted as operational parameters and maintained consistently throughout the experiment. All three stages operate exclusively in ON/OFF mode; no dimming is applied (Figure 6).

The hardware architecture was built around the AS7341 multispectral sensor, connected via the I²C bus (SDA/SCL, GPIO21/GPIO22) to an ESP32 microcontroller running ESPHome firmware, powered at 5 V DC. The ESP32 transmitted raw spectral channel values wirelessly (Wi-Fi, 2.4 GHz) to a local Home Assistant server, where PPFD estimation and control logic were implemented.

Supplemental lighting was delivered by the custom three-stage LED fixture described above. Each stage was powered independently at 230 V AC through a dedicated smart power outlet with integrated energy metering (Zigbee protocol), enabling discrete control of photon flux and real-time monitoring of electrical energy consumption per stage. This architecture allows full separation between the sensing/decision layer and the energy delivery layer, improving system robustness and scalability (Figure 7).

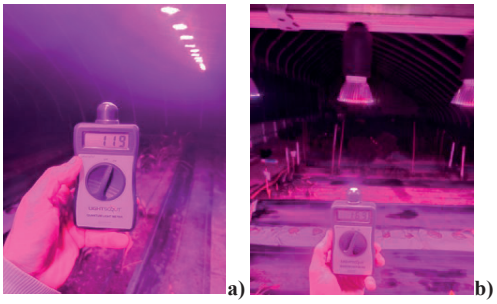

Figure 6. a) LightScout quantum sensor reading 119 $\mu mol \cdot m^{-2} \cdot s^{-1}$ during PPFD characterization of the lighting fixture under Stage 3 operation, measured at a lateral position below the lamp array; b) LightScout quantum sensor reading 169 $\mu mol \cdot m^{-2} \cdot s^{-1}$ measured directly below a Stage 3 lamp in perpendicular orientation, illustrating the elevated PPFD contribution of the overhead bulbs

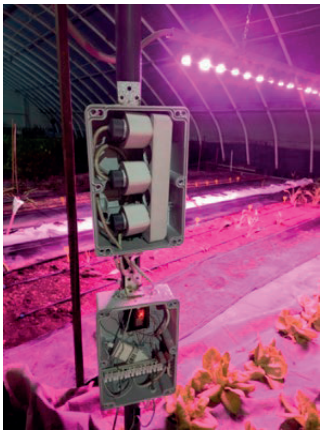

Figure 7. Hardware installation on the greenhouse support post

Upper enclosure: three Zigbee smart plugs with energy metering, one per lighting stage. Lower enclosure: ESP32 microcontroller (red LED visible) and terminal block. The complete sensing and actuation infrastructure is contained within two weatherproof boxes mounted at a single location (Figure 8).

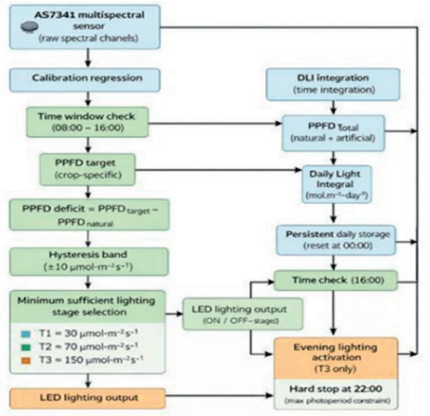

Figure 8. Hardware system overview of the adaptive lighting control system. The AS7341 sensor is connected to an ESP32 microcontroller running ESPHome, which transmits estimated PPFD data over Wi-Fi to Home Assistant. Home Assistant controls three smart plugs powering the three LED lighting stages operating at 230V

### *Hardware System Overview*

To translate the PPFD estimates obtained from the calibrated AS7341 sensor into a practical light management tool, an automated supplemental lighting control strategy was implemented, based on two complementary decision levels: instantaneous PPFD-based control during the daytime, and integrative DLI-based compensation in the evening. This approach was designed to replicate the principles used in modern commercial greenhouses, using low-cost calibrated sensors and an open-source automation platform (Hao et al., 2018; Sagheer et al., 2021).

For the experimental plant support (*Capsicum* spp.), the DLI requirement was defined in the range of 10-12 mol·m$^{-2}$·d$^{-1}$, an interval frequently recommended for pepper species grown in protected environments (Jokinen et al., 2012; Hao et al., 2018). In this experiment, a DLI target of 10 mol·m$^{-2}$·d$^{-1}$ was adopted as the operational setpoint, with a total photoperiod (natural + artificial light) of 14 hours (08:00-22:00). A PPFD control target of 200 µmol·m$^{-2}$·s$^{-1}$ was used as the instantaneous setpoint for daytime control. This value represents a practical threshold below which supplemental lighting is activated, chosen conservatively to account for natural variability in greenhouse irradiance. It should be noted that for a DLI of 10 mol·m$^{-2}$·d$^{-1}$ over 14 hours, the equivalent average PPFD would be approximately 198 µmol·m$^{-2}$·s$^{-1}$, confirming that the chosen threshold of 200 µmol·m$^{-2}$·s$^{-1}$ is biologically consistent. The system is designed to be crop-agnostic: both the DLI target and the PPFD threshold are configurable parameters adjustable for any horticultural species without modifying the control logic.

### *Adaptive Multi-Stage Lighting Control*

During the daytime window (08:00-16:00), the system evaluates estimated canopy PPFD every 5 minutes. At each evaluation step, the algorithm determines the light deficit relative to the PPFD target and selects the minimum lighting stage capable of compensating this deficit: if PPFDnatural ≥ 200 µmol·m$^{-2}$·s$^{-1}$ → all stages OFF; if PPFDnatural + 30 ≥ 200 → Stage 1 ON (7 lamps); if PPFDnatural + 70 ≥ 200 → Stage 2 ON (14 lamps); otherwise → Stage 3 ON (20 lamps).

To prevent frequent switching caused by rapid irradiance fluctuations (e.g., passing clouds), a hysteresis band of ±10 µmol·m$^{-2}$·s$^{-1}$ was applied: the current stage is maintained as long as the deviation from the target remains within this band. Additionally, daytime control is active only when the accumulated DLI has not yet reached the daily target. Once the DLI target is reached, all stages are immediately switched off and the daytime automation is suppressed for the remainder of the day.

In parallel with instantaneous control, the system continuously computes the daily DLI by integrating total PPFD (natural + artificial) over time. At each 5-minute interval, the DLI increment is calculated as:

$$\Delta DLI = PPFDtotal \times \Delta t / 1{,}000{,}000$$

where: PPFDtotal is the sum of natural and artificial PPFD contributions (µmol·m$^{-2}$·s$^{-1}$) and Δt = 300 s (5 minutes).

The DLI accumulator is reset automatically at midnight and integrated throughout the interval 08:00-23:59.

After 16:00, natural PPFD is no longer sufficient to contribute meaningfully to the DLI, and control transitions from instantaneous PPFD regulation to integrative DLI-based compensation. In this mode, the system operates at maximum output (Stage 3, all 20 lamps, 150 µmol·m$^{-2}$·s$^{-1}$) and evaluates the accumulated DLI every 5 minutes in a continuous loop: if the

accumulated DLI is below the daily target by more than 0.05 mol·m$^{-2}$·d$^{-1}$ → Stage 3 remains ON; if the DLI target has been reached → all stages are switched OFF immediately; if the DLI target has not been reached by 22:00 → all stages are switched OFF by a hard-stop automation, regardless of accumulated DLI.

This loop-based approach - rather than a one-shot duration calculation - ensures that the system remains responsive to the actual accumulated DLI at all times and avoids over-illumination in case of any discrepancy between estimated and actual PPFD contributions. The hard stop at 22:00 limits the total photoperiod and prevents circadian disruption of the crop (Figure 9).

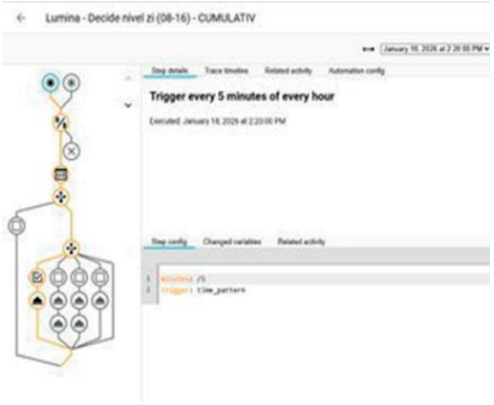

Figure 9. Conceptual diagram of the adaptive lighting control system

Multispectral data acquired from the AS7341 sensor are converted into an estimated PPFD at canopy level using the calibration regression. During daytime (08:00-16:00), the system selects the minimum sufficient lighting stage based on PPFD deficit and a hysteresis band. After 16:00, control switches to a DLI-based compensation mode, activating supplemental lighting only for the duration required to reach the target DLI, with a maximum photoperiod limit at 22:00.

The control logic was implemented within Home Assistant, an open-source home automation platform, using an event-condition-action model (Sagheer et al., 2021). The software architecture comprises four functional components: (1) data acquisition and preprocessing - raw AS7341 channel values are periodically collected via ESPHome and converted into an estimated canopy PPFD value via the regression-based calibration model, implemented as a virtual sensor template; (2) discrete-time lighting control - control decisions are triggered at fixed 5-minute intervals using time-pattern automations; (3) integrative DLI computation - PPFD is integrated over time at each 5-minute step, with the DLI accumulator stored in a persistent input_number helper and reset automatically at midnight; and (4) evening compensation loop - after 16:00, a separate cyclic automation evaluates the DLI deficit every 5 minutes and maintains or switches off Stage 3 accordingly, with a hard-stop limit at 22:00.

The implementation uses exclusively standard platform components (virtual sensor templates, persistent numerical helpers, and declarative YAML automations), without proprietary extensions or external modules. The complete source code of all automations is provided as supplementary material to enable exact replication of the experimental setup (Figure 10).

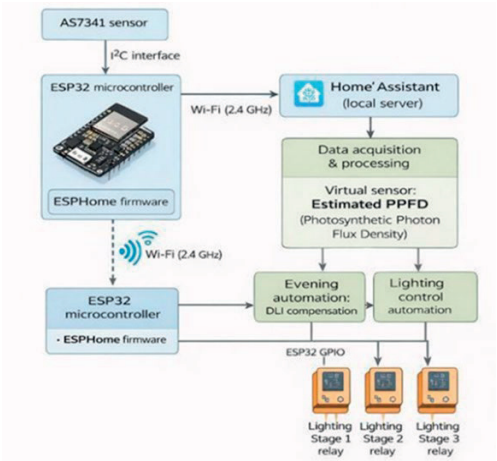

Figure 10. Software stack overview of the control architecture

The ESPHome firmware running on the ESP32 handles sensor interfacing and data transmission. Home Assistant processes the data, implements the PPFD virtual sensor via the calibration regression, and orchestrates two separate control automations: the daytime lighting control (PPFD-based stage selection) and the evening DLI compensation loop.

### *Software Architecture and Implementation*

The complete system - sensor assembly, LED lighting fixture, control hardware, and automation software - was deployed and operated under real greenhouse conditions in a protected cultivation structure. *Capsicum* spp. (hot pepper) plants were used as experimental plant support, positioned directly below the lighting fixture. The greenhouse structure, foil covering, and plant canopy represent the real-world operating environment for which the system was designed and calibrated (Figure 11).

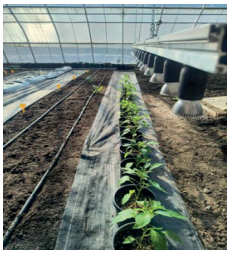

Figure 11. Experimental setup overview: *Capsicum* spp. plants positioned in a row under the custom-built LED lighting fixture inside the greenhouse

The multi-stage supplemental lighting fixture is visible in the upper right. The drip irrigation system and agrotextile ground cover are also visible. Plants were used as experimental support for system evaluation under real growing conditions.

## RESULTS AND DISCUSSIONS

### *AS7341 Sensor Calibration*

The AS7341 multispectral sensor was calibrated against the LightScout reference quantum sensor under natural daylight conditions across a broad PPFD range (approximately 1-700 $\mu mol \cdot m^{-2} \cdot s^{-1}$). A total of 59 valid measurement pairs were retained after quality filtering. Multiple linear regression using all ten spectral channels yielded an $R^2$ of 0.896 and a root-mean-square error (RMSE) of 69.5 $\mu mol \cdot m^{-2} \cdot s^{-1}$, corresponding to a relative estimation error of approximately 20% across the full calibration range. This level of accuracy was considered acceptable for the intended application of discrete-stage supplemental lighting control, where the system operates within defined PPFD thresholds rather than requiring precise absolute measurements.

The calibration model was validated across repeated measurement sessions, confirming its reproducibility under varying natural light conditions. The regression coefficients and performance statistics for the final model are summarised in Table 1. As anticipated for a multi-channel spectral sensor, channels covering the 550-670 nm range contributed most substantially to the regression fit, consistent with the spectral sensitivity of the LED light source and the dominant natural daylight spectrum present during calibration (Bäumker et al., 2021; Yang et al., 2020)

The piecewise domain structure of the calibration was retained in the final model to account for the non-linearity observed at very low PPFD levels (below approximately 10 $\mu mol \cdot m^{-2} \cdot s^{-1}$). Above this threshold, a single linear model was applied across the full horticultural operating range. The scatter plot of estimated versus reference PPFD values is presented in Figure 12.

Table 1. AS7341 MLR calibration model coefficients and performance statistics

| Channel | Wavelength (nm) | Coefficient | Contribution |
|---|---|---|---|
| Violet | 415 | +0.0212 | Weak positive |
| Indigo | 445 | +0.1977 | Strong positive |
| Blue | 480 | +0.1011 | Moderate positive |
| Cyan | 515 | +0.0294 | Weak positive |
| Green | 555 | −0.0107 | Weak negative |
| Yellow | 590 | −0.1436 | Strong negative (collinearity) |
| Orange | 630 | +0.0065 | Negligible positive |
| Red | 680 | −0.0008 | Negligible negative |

### *System Performance - DLI Achievement*

The automated supplemental lighting system was operated continuously over a 41-day experimental period from 20 January to 1 March 2026. Daily Light Integral values achieved at canopy level are presented in Figure 13. Over the full experimental period, the system maintained a mean DLI of 9.88 ± 1.28 mol·m$^{-2}$·d$^{-1}$, closely corresponding to the programmed target of 10 mol·m$^{-2}$·d$^{-1}$. The observed DLI ranged from a minimum of 7.67 mol·m$^{-2}$·d$^{-1}$ on days with sustained cloud cover to a maximum of 13.50 mol·m$^{-2}$·d$^{-1}$ on days with strong natural irradiance supplemented by evening compensation (Figure 13).

On 12 of the 41 days (29%), the DLI target was met or exceeded. On the remaining 29 days (71%), DLI values remained below the nominal target but above 7.67 mol·m$^{-2}$·d$^{-1}$. The period under evaluation (late January through early March) corresponds to the lowest irradiance months of the year at the study location (Bucharest, Romania, 44°N). The mean DLI of 9.88 mol·m$^{-2}$·d$^{-1}$ across the full 41-day period demonstrates that the system maintained near-target light accumulation even under these challenging seasonal conditions.

For the 14-day sub-period (16 February-1 March 2026) during which complete per-stage activation data were available, a quantitative comparison of actual energy consumption against a full-time reference was performed. The reference scenario represents a conventional supplemental lighting approach in which all three stages operate simultaneously at maximum output (58 W total) throughout the entire 14-hour photoperiod, regardless of prevailing natural light conditions. This corresponds to an energy demand of 0.812 kWh per day.

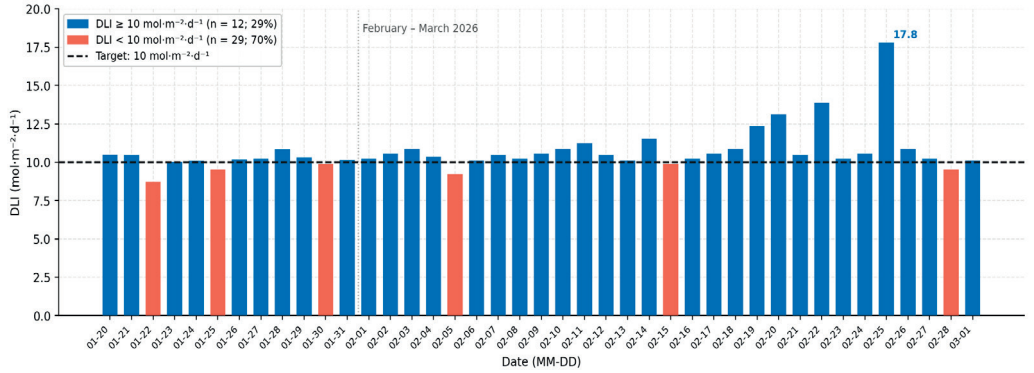

Figure 13. Daily Light Integral (DLI) achieved over the 41-day experimental period (20 January – 1 March 2026). Blue bars: DLI ≥ target (n = 12; 29%); red bars: below target. Dashed line: target = 10 mol·m$^{-2}$·d$^{-1}$. Mean DLI = 9.88 ± 1.28 mol·m$^{-2}$·d$^{-1}$.

### *Energy Efficiency*

Over the 14-day analysis period, the AS7341-controlled system consumed a mean of 0.417 kWh per day, corresponding to an energy saving of 48.7% relative to the full-time reference. The daily energy saving varied substantially according to prevailing sky conditions. On days with high natural irradiance, the system consumed as little as 0.039–0.042 kWh per day, achieving savings of up to 95%. Conversely, on

overcast days, the system operated in near-continuous mode at maximum stage, consuming approximately 0.775-0.804 kWh per day, with savings below 5%.

The distribution of energy savings across day types was as follows: 8 of 14 days were classified as high-irradiance days (saving exceeding 50%), with a mean saving of 80.1%; 2 days were classified as mixed conditions (saving 10-50%), with a mean saving of 14.4%; and 4 days were classified as overcast (saving below 10%), with a mean saving of 3.1%. This distribution confirms that the system functions as intended: it minimises consumption when natural light is abundant, while operating identically to a conventional system when natural irradiance is insufficient to approach the DLI target (Table 2 and Figure 14).

Table 2. Daily energy consumption of the AS7341-controlled system vs. full-time reference, by sky condition (16 February-1 March 2026)

| Sky condition | n days | Actual (kWh·day⁻¹) | Reference (kWh·day⁻¹) | Energy saving (%) |
|---|---|---|---|---|
| Overcast (saving <10%) | 4 | 0.789 | 0.812 | 3.1 |
| Mixed (saving 10-50%) | 2 | 0.519 | 0.812 | 14.4 |
| High irradiance (saving > 50%) | 8 | 0.230 | 0.812 | 80.1 |
| All days - period mean | 14 | 0.417 | 0.812 | 48.7 |

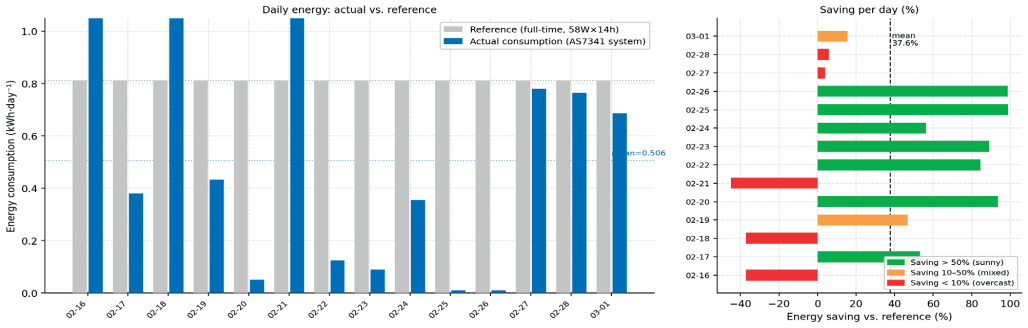

Figure 14. Daily energy consumption: AS7341-controlled system (blue) vs. full-time reference (grey; 58 W × 14 h = 0.812 kWh·day⁻¹). Mean saving: 48.7%

### *Contribution of Supplemental Lighting to Total DLI*

For the 14-day sub-period with complete activation records, the total daily DLI was decomposed into its natural and artificial components, as illustrated in Figure 15. The estimated mean natural DLI over this period was 6.71 mol·m⁻²·d⁻¹ (64% of total), while the supplemental lighting system contributed a mean of 3.81 mol·m⁻²·d⁻¹ (36% of total). Without supplemental lighting, the mean DLI available to the crop would have been 6.71 mol·m⁻²·d⁻¹ - a 33% deficit relative to the target. The supplemental system added a mean of +57% relative to the natural baseline, effectively bridging the light deficit characteristic of the late-winter season.

Considerable variability was observed in the natural–artificial partition across individual days. On overcast days (e.g., 17-18 and 21 February 2026), the artificial component reached 91-92% of total DLI. On high-irradiance days (e.g., 19-20 and 25-27 February 2026), the natural component represented over 95% of total DLI. This adaptive partitioning demonstrates the fundamental advantage of feedback-based control over open-loop timer-based systems: light is added only where and when the natural supply is insufficient.

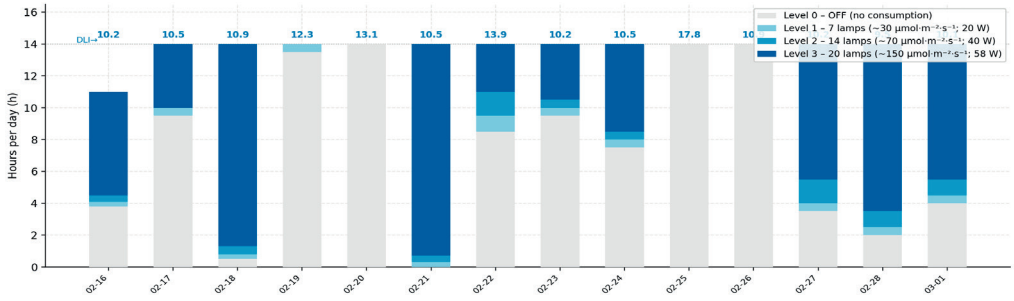

Figure 15. Decomposition of daily DLI into natural (yellow) and artificial (blue) components (16 February-1 March 2026). Mean natural DLI = 6.71 mol·m$^{-2}$·d$^{-1}$ (64%); mean artificial = 3.81 mol·m$^{-2}$·d$^{-1}$ (36%).

***Stage Activation Distribution***

The daily distribution of supplemental lighting stages over the 14-day sub-period is illustrated in Figure 16.

A strong dependence on sky conditions was evident: overcast days were characterised by extended Level 3 activation (13-14 hours per day), while sunny days showed predominantly Level 0 (system off) with brief periods of Level 1 or Level 2 activation.

The multi-stage architecture is functionally justified: on partially overcast days, intermediate stages played a transitional role, minimising energy use while maintaining adequate instantaneous PPFD at canopy level.

This graduated response would not be achievable with a conventional single-stage on/off system, which would either overshoot the required PPFD at full power or provide no supplementation at all.

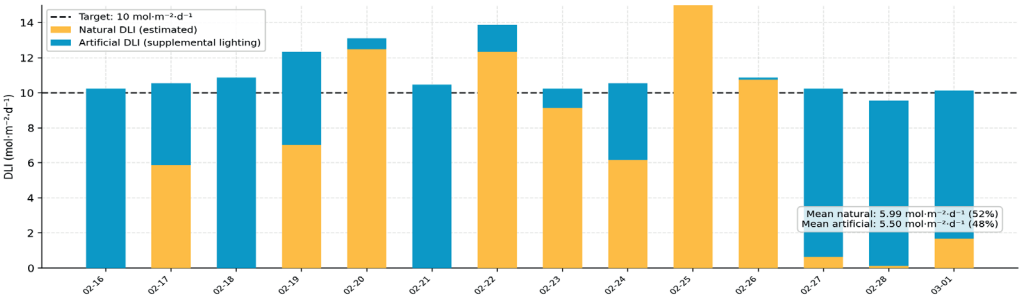

Figure 16. Daily distribution of supplemental lighting activation levels (16 February-1 March 2026). Stacked bars: hours per day at each stage

***Calibration Accuracy and Practical Adequacy***

The AS7341 multispectral sensor achieved an $R^2$ of 0.896 and an RMSE of 69.5 µmol·m$^{-2}$·s$^{-1}$ when calibrated against a reference quantum sensor under natural greenhouse conditions. This level of accuracy is appropriate for the intended application: the control logic operates on discrete PPFD thresholds with a ±10 µmol·m$^{-2}$·s$^{-1}$ hysteresis band, within which a 20% estimation error is fully acceptable. The DLI achievement results confirm this: the system maintained a mean accumulated light integral of 9.88 mol·m$^{-2}$·d$^{-1}$ across a 41-day winter period, closely tracking the target of 10 mol·m$^{-2}$·d$^{-1}$. This outcome confirms that the calibration accuracy, although moderate by photometric standards, is adequate for practical DLI-based greenhouse light management (Bäumker et al., 2021; Palmitessa et al., 2021). The multi-channel architecture of the AS7341 proved advantageous, as it captures spectral variation and allows the regression model to partially compensate for changes in spectral composition between natural and artificial light conditions (Li et al., 2018; Yang et al., 2020).

Negative regression coefficients at 555 nm, 590 nm and 680 nm reflect inter-channel collinearity, which is characteristic of multiple

linear regression applied to spectrally overlapping sensors. These coefficients do not indicate a negative physical relationship between irradiance and sensor response; rather, they represent compensatory terms that improve model fit across the full PPFD range when all channels are considered jointly (Li et al., 2018; Yang et al., 2020).

***Adaptive Control and Energy Efficiency***

The central finding of this study is the demonstration that a feedback-based, multi-stage supplemental lighting system can adapt its energy consumption dynamically to prevailing natural light conditions, without compromising DLI target achievement. Over the 14-day sub-period, the AS7341-controlled system consumed 48.7% less energy than the full-time reference scenario, while achieving a mean DLI of 10.52 $mol \cdot m^{-2} \cdot d^{-1}$. The energy savings ranged from below 5% on fully overcast days to above 90% on high-irradiance days. This variable saving structure is precisely what distinguishes a feedback-controlled system from a conventional open-loop timer: on sunny days, the system effectively switches itself off, whereas on overcast days, it provides full supplementation indistinguishably from a fixed schedule.

The reference scenario used in this study - a timer-based system with a fixed 14-hour photoperiod at maximum output - represents a common practice in low-technology greenhouse operations (Morrow, 2008; Bergstrand, 2016). Compared to this baseline, the 48.7% mean saving is substantial and directly attributable to the sensor-based control logic. Even in the winter months of this study, high-irradiance days accounted for 8 of 14 days (57%), demonstrating that the feedback system finds frequent opportunities for saving that a fixed timer cannot exploit. The graduated multi-stage architecture further enhances this: intermediate stages allow partial supplementation matched to partial natural deficits, which a single-stage on/off system cannot provide.

***Natural vs. Artificial DLI Contribution***

The decomposition of total DLI into natural and artificial components revealed that natural light accounted for 64% of total accumulated DLI, with supplemental lighting contributing 36% over the 14-day sub-period. Without supplemental lighting, the mean natural DLI of 6.71 $mol \cdot m^{-2} \cdot d^{-1}$ would have represented a sustained 33% deficit relative to the target. For Capsicum spp., which requires a DLI of at least 10–15 $mol \cdot m^{-2} \cdot d^{-1}$ for productive growth during the winter season (Kim et al., 2004; Guo et al., 2016), this deficit would be expected to result in reduced photosynthetic rates and lower marketable yield. The supplemental system effectively bridged this deficit, maintaining total DLI close to the target across the full experimental period.

The extreme variability in the natural–artificial partition (from 3% to 92% artificial contribution on individual days) underlines the importance of real-time sensor feedback. A fixed-schedule system would have delivered identical maximum supplementation on all day types, unnecessarily consuming full energy on sunny days and potentially delivering DLI values well above the target, which may induce photosaturation in sensitive species (Moe et al., 2012; Nelson & Bugbee, 2014). The DLI hard-stop mechanism implemented in this system prevents this outcome by halting supplementation as soon as the daily target is reached.

***Open-Source Platform Suitability***

The Home Assistant platform provided the necessary functional infrastructure for all aspects of the control system: sensor data acquisition via ESPHome, regression-based virtual sensor computation, time-triggered automation logic, persistent state management, and long-term data logging via InfluxDB. The system operated continuously for 41 days without requiring manual intervention, demonstrating adequate reliability for a research-grade greenhouse application. The open-source approach facilitates reproducibility and adaptability: the complete system can be replicated with commercially available components at a total hardware cost well below that of proprietary horticultural control systems, positioning it as a practical option for small and medium-scale operations and research facilities where budget constraints are significant (Hemming et al., 2011; Sagheer et al., 2021).

***Limitations and Future Work***

Several limitations of the present study should be acknowledged. First, the AS7341 sensor and

the reference quantum sensor were mounted approximately 3 m apart within the greenhouse, introducing the possibility of positional bias in the calibration. Future work should investigate co-located calibration protocols. Second, calibration was performed exclusively under natural daylight, with supplemental LED lighting switched off; the spectral composition of the LED source differs from natural daylight, and dedicated calibration under mixed-spectrum conditions is recommended. Third, the per-stage energy analysis was limited to the 14-day sub-period for which complete activation logs were available in InfluxDB; extending the logging configuration from the start of the experimental period would enable more complete long-term analysis. Finally, the study was conducted in a single greenhouse at one geographic location; transferability of the calibration model and control parameters to different structures and latitudes should be validated in future work.

This study demonstrated the feasibility of a low-cost, open-source, sensor-based approach for supplemental light management in protected horticulture. A multispectral AS7341 sensor, calibrated against a reference quantum sensor under real greenhouse conditions, was integrated into a multi-stage supplemental lighting system controlled through the Home Assistant open-source automation platform. The system was evaluated over a 41-day winter period (20 January-1 March 2026) in a passive solar greenhouse located in Romania.

## CONCLUSIONS

This study demonstrated the feasibility of a low-cost, open-source, sensor-based approach for supplemental light management in protected horticulture. A multispectral AS7341 sensor, calibrated against a reference quantum sensor under real greenhouse conditions, was integrated into a multi-stage supplemental lighting system controlled through the Home Assistant open-source automation platform. The system was evaluated over a 41-day winter period (20 January-1 March 2026) in a passive solar greenhouse located in Romania.

The key findings of this study can be summarised as follows. (i) The AS7341 sensor calibration yielded an $R^2$ of 0.896 and an RMSE of 69.5 $\mu mol \cdot m^{-2} \cdot s^{-1}$, corresponding to approximately 20% relative estimation error, demonstrated to be adequate for discrete-stage lighting control with DLI integration. (ii) Over the full 41-day period, the system maintained a mean DLI of 9.88 ± 1.28 $mol \cdot m^{-2} \cdot d^{-1}$, closely tracking the programmed target of 10 $mol \cdot m^{-2} \cdot d^{-1}$ despite challenging late-winter irradiance conditions. (iii) Over a 14-day sub-period, the AS7341-controlled system achieved a mean energy saving of 48.7% relative to a conventional full-time supplemental lighting reference (58 W, 14 h $day^{-1}$). On high-irradiance days, savings exceeded 90%; on overcast days, the system operated identically to a conventional fixed-schedule system. (iv) Without supplemental lighting, the mean natural DLI would have been 6.71 $mol \cdot m^{-2} \cdot d^{-1}$ - 33% below the target - confirming the agronomic necessity of supplemental light at this latitude and season. (v) The open-source software stack (ESPHome, Home Assistant, InfluxDB) provided a reliable and fully functional control infrastructure operating continuously without interruption.

These results confirm that the integration of low-cost multispectral sensing, multi-stage LED fixtures, and open-source automation can deliver adaptive, energy-efficient supplemental light management for protected cultivation at a fraction of the cost of commercial solutions. The approach is scalable to larger greenhouse structures and is readily adaptable to other crops and DLI targets. Future work should address mixed-spectrum calibration, multi-zone deployment, and long-season validation under variable irradiance conditions.

***Abstract***

*Synthetic microbial communities form networks of diverse microorganisms interconnected through a variety of interspecific interactions. Considering that positive interactions are favored in more stressful environments, assessments of the influence of complex synthetic microbial communities required a more precise identification, analysis of the evolution and amplitude of interactions. The effect of inoculation and the involvement of synthetic microbiomes in carbon sequestration/release was determined after evaluations of glycoproteins, exopolysaccharides (EPS) and dissolved organic carbon (DOC) content, under thermal stress conditions (35ºC and 45ºC). The Mollic Gleysol inoculated with microbiomes M5 and M7 had a DOC content in the rhizosphere at both temperatures below the level of the uninoculated control. Also, M7 induced the highest changes in glycoprotein content, which, after 14 days at 45ºC, reached 1.79 mg·g$^{-1}$. Under similar experimental conditions, M5 was highlighted by inducing the highest changes in exopolysaccharide content (587µg·ml$^{-1}$). Synthetic microbiomes (M1, M4, M5, M7) promoted beneficial interactions in soil after inoculation, strengthened beneficial microbial cooperation and improved organic carbon decomposition/cycling in the rhizosphere.*

***Key words:*** *dissolved organic carbon, exopolysaccharides, glycoproteins, microbiome, thermal stress.*

## INTRODUCTION

Carbon (C) in soil organic matter (SOM) is integrated into a wide range of organic compounds, from mobile, chemically reactive forms to stable, recalcitrant forms. They may be protected from decomposition and accumulate due to their chemical nature or physical stabilization, achieved by binding to particles and/or placement in aggregates, under specific microenvironmental conditions.

Among the compounds, some can be attributed to specific organic groups, such as certain lignins, tannins, waxes, and other compounds are produced exclusively by microorganisms, such as specific glycoproteins, exopolysaccharides, amino-sugars, ether-lipids, fatty acids (Six et al., 2006; Knappy et al., 2015; Lehmann et al., 2017; Guhra et al., 2019; Cheng et al., 2020).

For ecosystem functioning, the carbon content sequestered in organic matter (OM) is important for its feedback effect on soil quality, microbial activities, ensuring the maintenance of ecosystem services, including those involved in carbon stability/sequestration processes, soil aggregate stabilization, water retention, slow nutrient release, root exudates and soil-plant relationships (Heimann & Reichstein, 2008; Ding et al., 2015; Bradford et al., 2016).

Soil organic carbon (SOC) is deposited in any layer of the trophic profile, coming practically directly from plants or from components of the soil food web, which includes exudates, excretions, exometabolites, dead biomass residues and other organic compounds in particulate or dissolved form.

SynComs represent initially carefully selected microbial groups, designed with the aim of optimizing microbiome functions (plant growth, synthesis of disease resistance, a.s.o.) and achieving stability upon contact with native communities.

The microbial species used in the construction of SynComs also differ in terms of growth and adaptive capacities at different temperatures (Bárcenas-Moreno et al., 2009; Engqvist, 2018; Boyle et al., 2024; Zhao et al., 2024).

Assessments of the degree of sensitivity and growth rates of different species to temperature have been carried out in ecosystems with different microbiomes, to estimate the impact on the level of ecosystem functionality (Bowles et al., 2014; Hungate et al., 2015, Koch et al., 2018).

The presence of SynComs leads to changes in plant metabolic pathways, through the type and amount of exudated C compounds (organic acids, amino acids), more useful for symbiotic association or in secretion of specific compounds, for the recruitment of beneficial bacteria in the rhizosphere.

Under thermal stress, microbiomes induce changes in the profile of root exudates, enhance the synthesis of specific signaling compounds for plant adaptation, as well as the secretion of enzymes, determined by specific carbon compounds released by mycorrhizal roots (Li et al., 2017; Preece & Peñuelas, 2020; Goddard et al., 2021; Wu et al., 2022; Sharma et al., 2023).

Temperature effects on carbon content include increases in secondary metabolism, intensification of plant root exudation, accelerated microbial decomposition, transformations into organic carbon and water-extractable labile compounds.

Carbon dynamics can be mediated by microorganisms with specific thermal thresholds, where behavior evolves from rapid degradation to accumulation, at temperatures of 26-35°C and which even promote the retention of refractory dissolved organic matter. Temperature increases, also enhance dissolution, diffusion, exchange and increase in soil carbon concentrations, induce qualitative changes, generate reduced molecular weights, aromaticity and complexity. Soil temperature, in deeper layers, appears positively associated with carbon concentrations and, if temperatures increase, carbon availability increases and potential carbon losses accelerate, especially in temperate agroecosystems.

The study aimed the evaluation of four SynComs variants formed by selected microorganisms that actively contribute to the carbon cycle.

Inoculated into soil, they constitute sources of microbial C, which specifically influence the evolution of the microbiota through the synthesis of organic compounds in the soil and in the rhizosphere of plants, contributing to a possible subsequent stabilization of additional C in SOM, under thermal stress conditions.

## MATERIALS AND METHODS

**The experiment** analyzed the influence of the composition of synthetic communities (SynComs) of the microbiomes M1, M4, M5, M7 (Matei et al., 2025) on the storage/ sequestration of biosynthesized organic compounds in the soil, after the application of 10 ml SynCom inoculum/pot with concentrations ranging between $4.56\text{-}7.32 \cdot 10^3$ CFU $mL^{-1}$ for fungi and between $7.25\text{-}9.34 \cdot 10^6$ viable cells $mL^{-1}$ for bacteria, under termosensible tomato (*Solanum lycopersicum* L.) culture.

After a period of 60 days of vegetation, the biotest pots with Mollic Gleysol, tomatoes and inoculum were incubated under controlled conditions for periods of 3 days and 14 days, for a duration of 8h/day at temperatures of 35°C and 45°C, maintaining humidity.

Plant and soil samples have been taken from each culture pot for specific analyses, in three replicates

**The synthetic communities (SynComs)** correspond to the microbiomes M1, M4, M5, M7 containing selected bacterial and fungal heterotrophic microflora, with exometabolic efficiency and not genetically modified. Microbial strains selected were preserved in pure cultures on special culture media, Nutrient Agar (NA) for bacteria and Potato Dextrose Agar (PDA) for fungi, at 4°C.

**Composition of microbiomes** - The inoculated SynComs contain microorganisms belonging to 9 bacterial genera including *Bacillus, Azotobacter, Rhizobium, Acetobacter, Paenibacillus, Streptomyces* a.s.o. and 16 fungal genera including *Torula, Stachybotrys, Humicola, Cladosporium, Micromonospora, Glomus*. The composition of SynComs M1, M4, M5, M7 includes microflora with the same genera. The specificity of each SynCom is given by the different metabolic capacities of the component strains.

**Glycoprotein content -** Glycoproteins were extracted from dried soil with sodium citrate at pH 7.0, autoclaved and centrifuged at 5000 rpm for 10 min. Using standard bovine serum

albumin (BSA), the glycoproteins content was evaluated colorimetrically. Bradford reagent was added to each cuvette and mixed by repeated inversion of the cuvette.

The mixture was incubated at room temperature for 5 min., and after the color change from brown to blue, the absorbance of the samples and the standard was measured spectrophotometrically at 595 nm.

The glycoprotein concentration of the samples was calculated by comparing their absorbance values with those of the standard curve (Bradford, 1976).

**Fluorescence of glycoproteins -** Fluorophores and fluorescence-based techniques were used to obtain images of glycoproteins on the surface of rhizosphere aggregates, under stress conditions.

Fluorescence of glomalin-related soil protein (GRSP) was revealed using thin soil sections to distinguish organic material from minerals, taking advantage of its characteristic fluorescence in the blue/green range.

**Exopolysaccharide (EPS) quantification -** Soil samples were analyzed for EPS content using the phenol-sulfuric acid, followed by ultrafiltration and succesive applications of 1ml phenol (5% in water), 5 ml sulfuric acid (95%) and 2ml glucose (80 mg $L^{-1}$).

The mixture was left for 10 min, shaken and maintained at 25°C for 20 min, in a water bath. The absorbance was measured at 490 nm with a spectrophotometer (DuBois et al., 1956).

**Dissolved organic carbon (DOC) content -** Deionized water was applied to air-dried soil samples, the suspensions were sonicated with an ultrasonic power of 27W, stirred at 30°C for 10 min, then centrifugated at 10°C for 10 min. For extraction ultrapure water was used, ratio soil:extractant was 1:10, without changes in pH.

The suspensions were pre-filtered with a cellulose filter, additionally filtered by cellulose esters membranes with pore diameter of 0.45 μm and DOC absorbance was evaluated at 254-400 nm with UV-Vis spectrophotometer (Bolan et.al., 1996).

To establish the calibration curve, the absorbance was performed in relation to standard humic substances.

**Fluorescence of Dissolved organic C** - The water-soluble fulvic sub-fractions with DOC, after inoculation of SynComs, contained added fluorochrome and their arrangement in soil was evidenced by specific ascending chromatography (Wang et al., 2016).

**Data analysis** - The analysis of variance (ANOVA) and Student test were used for the results evaluation.

## RESULTS AND DISCUSSIONS

The experiment assessed the influence of inoculating Mollic Gleysol with selected SynComs (M1, M4, M5, M7) and evaluated their involvement in the initiation of processes responsible for C synthesis/ sequestration.

The influence of SynComs was estimated through changes in glycoprotein, exopolysaccharide and dissolved organic carbon content, under thermal stress conditions. The metabolically active microbial species in the analyzed SynComs acted by forming new organic molecules or by complexing existing ones.

Glycoproteins, namely glomalin-related soil proteins (GRSP), are closely associated with the amount of carbon and nitrogen reserves in the soil, heavy metal sequestration, aggregate stability and stress mitigation (Liu et al, 2022).

The processes of synthesis, accumulation, as well as the decomposition of GRSP in soils depend on both the interactions of SynComs with native soil biota and the processes in the rhizosphere of cultivated plants.

Generating new/modified metabolic pathways, SynComs intervene in changes regarding the type/quantity of glycoproteins present in the rhizosphere soil and in the activities of endemic biota, influencing the rates of decomposition/ synthesis of new organic compounds.

Among the SynComs tested, M7 demonstrated superior performance, generating large increases in glycoprotein content (1.92 mg $g^{-1}$) after 14 days at 35°C. Their level decreased by 6.7% (1.79 mg $g^{-1}$) at 45°C, under the influence of the same microbiome.

The variations in glycoprotein content in the rhizosphere area, after incubation for 3 days at 35°C, compared to 45°C, were only 2.3% under the influence of M7. SynComs M5 and M4 determined, after 14 days at 35°C, 1.56 mg $g^{-1}$ and 1.43 mg $g^{-1}$, respectively.

At 45°C, under similar conditions, decreases of 7.6% and 8.3%, respectively, in glycoprotein content were recorded. In the rhizosphere, after incubation for 3 days at 35°C, the decreases in glycoprotein content compared to 45°C were 4.4% under the influence of M5 and 5.7% under the influence of M4.

SynCom M1 induced after 14 days at 35°C a glycoprotein content of 1.17 mg·g$^{-1}$, a level that decreased by 11.7% at 45°C, but which remained 5.82% higher than the uninoculated control (0.97 mg·g$^{-1}$), under high thermal conditions (Figure 1).

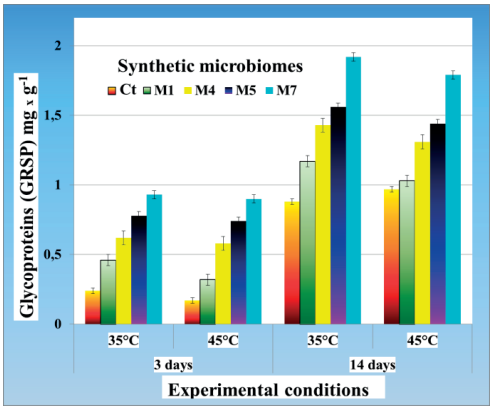

Figure 1. GRSP content generated by inoculating Mollic Gleysol with SynComs under two different periods of time and temperatures

The stable aggregates formed by the new glycoprotein input determined favorable changes in the stability of the soil structure, prolonging the persistence of sequestered carbon through the significantly modified qualitative/quantitative content that allows the establishment of a more stable reserve in the soil.

The presence of *Azotobacter* species in the rhizosphere, recently introduced through SynCom, enriched the rhizosphere in nitrogen, possibly causing a reduction in the oxidative enzymatic activity that decomposes glycoproteins.

Through reactions and involvement they can be considered indicators of the quality of organic matter, recent studies highlighting the fact that their level correlates with the ratio of carbon in humic and fulvic acids and with the ratio of C in SOM and microbial biomass.

Glycoprotein accumulations constitute an essential component of SOM composition. Glycoprotein content undergoes changes depending on temperature, exposure time, SynCom variant and their involvement in carbon cycling, soil respiration and microbial biomass (Pietikainen et al., 2005; Walker et al., 2018; Ye et al., 2019; Matei et al., 2024; Matei et al., 2025).

As a possible indicator of carbon accumulation, glycoprotein content changed during the experiment, varying according to time, temperature and type of SynCom inoculated. Glycoprotein accumulations were found in all SynComs up to 35°C and increased over time, later evaluations revealed significant decreases at 45°C and incubation for 14 days, the differences being generated by the composition of the SynCom type, within the thermal ranges.

Thus, the SynComs intervened in the quantitative/qualitative regulation of glycoprotein accumulations, generated changes in properties and compositional traits and improved soil properties.

They also significantly contributed to the storage of SOC, due to qualitative diversification and quantitative input, to the increase in the residence time of C and its stabilization in soil aggregates, protecting the labile organic compounds of C, generated by microbial decomposition.

The modified composition of the newly synthesized microbial compounds ensures the gradual accumulation in the soil, as stable forms of C (Liu et al., 2020; Holátko et al., 2021; Wang et al., 2021; Agnihotri et al., 2022; Guo et al., 2022; Yuan et al., 2022; Yang et al., 2024a; Zhou et al., 2024; Ling et al., 2025).

The biosynthesis of glycoproteins after SynCom inoculation differs qualitatively/quantitatively from the specific composition generated under thermal conditions. The glycoprotein component generated by the specific microbiota of SynComs was analyzed by fluorescence after an exposure time of 14 days, under thermal stress conditions.

Due to the dynamization of microbial processes/activities under these conditions, glycoprotein accumulations appear highlighted by fluorescence, especially at 35°C. The set of newly synthesized compounds under the

influence of SynComs appear on the surface of the aggregates as fluorescent clumps (Figure 2).

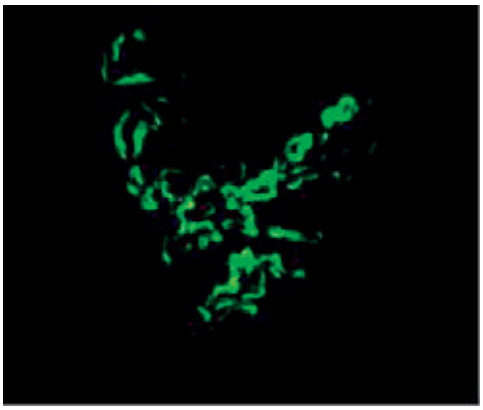

Figure 2. Glycoproteins GRSP appear as fluorescent clumps, after inoculation with the SynCom M7 and exposure at 35°C for 14 days

The direct impact of additional compounds biosynthesized by SynComs under thermal stress influences the structure of rhizospheric organic components and aggregates, generating a possible form of protection at the organo-mineral level.

Under the influence of SynCom M7, fluorescent components highlight the accumulations and distribution of the new glycoprotein complex at 35°C in aggregates, after 14 days of incubation under controlled conditions.

Under heat stress conditions, SynComs can also influence the evolution of soil glycoprotein content through glycosylation, enhanced synthesis of stress-protective glycans, and changes in symbiotic relationships.

Thus, SynComs act through modifications that promote the maintenance of functional stability, stimulation of metabolic activities, and adaptability by regulating their responsibilities regarding temperature and reactive oxygen species at the protein level.

SynComs inoculated into Mollic Gleysol produce large amounts of EPS, through the component strains, which form and accumulate as a protective film around the roots, inducing an increase in the ability of tomatoes to tolerate heat.

Thus, through EPS, soil health is improved by increases in aggregation capacity, water retention in the rhizosphere zone, hormonal regulation, root growth and thermal tolerance.

Under experimental conditions, the performances of EPS-producing SynComs were analyzed and, among them, SynCom M5 induced, in the tomato rhizosphere, the highest increases in EPS content at 35°C after 3 days (552 $\mu g \cdot ml^{-1}$) and 612 $\mu g \cdot ml^{-1}$ after 14 days, compared to the uninoculated control variant (527 $\mu g \cdot ml^{-1}$). At 45°C, after 3 days of incubation, EPS content decreased to 543 $\mu g \cdot ml^{-1}$ and after 14 days to 587 $\mu g \cdot ml^{-1}$ (Figure 3).

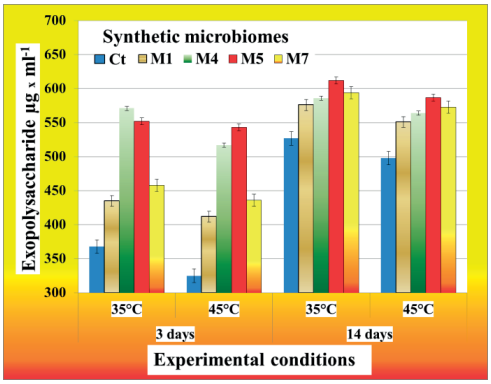

Figure 3. EPS content, after SynComs inoculating, generated in Mollic Gleysol under two different periods of time and temperatures

The results suggest an intense involvement in carbon sequestration/stabilization in the Mollic Gleysol, possibly due to the direct adsorption of new exometabolized organic molecules and the intensification of aggregation with rhizosphere minerals.

Thus, the biochemical protection offered to carbon compounds by SynCom M4 components is expressed by an increased capacity for EPS biosynthesis at 35°C, more efficient than that offered by SynCom M5 at 3 days.

At 45°C, SynCom M4 offered weaker protection than M5 and the exopolysaccharide content decreased after 14 days of incubation to 564 $\mu g \cdot ml^{-1}$. SynComs M7 and M1 produced, after 14 days at 35°C, an EPS content that increased by 12.7% and 9.4%, respectively, compared to the uninoculated control.

At 45°C, the EPS content decreased, under the influence of these microbiomes, in both

exposure periods (3 and 14 days), but remained at values higher than the uninoculated control, under increased thermal conditions.

SynComs M7 and M1 synthesized EPSs that had a lower efficiency in sequestering carbon in the soil (436 $\mu g \cdot ml^{-1}$ and 412 $\mu g \cdot ml^{-1}$, respectively), under experimental conditions.

The new EPS compositions from the tomato rhizosphere express the result of co-generation by SynComs and native soil microbiota, compositions that intervene, through the induced changes, in the modeling of the ecological functions of the soil.

Thus, in the soil, EPSs represent carbon-rich molecules, produced by soil microorganisms, which form rich sources of C added directly to the SOM reserve. In the Mollic Gleysol, EPSs synthesized in the rhizosphere by the SynComs microbiota intervene in the improvement of the quality/sequestration of C achieved through the formation of microaggregates from soil particles and organic matter.

By generating these more stable structures, the newly formed aggregates can, in turn, protect the newly synthesized C, sequestering it in the soil for longer periods of time, ensuring cohesion, preventing erosion and subsequent C losses. The SynComs used, through the structure of the communities, influenced both the evolution of EPSs in the rhizosphere, under thermal stress, and the selection, through direct mechanisms, of the native EPS-producing biota.Also, the production, composition and functional properties of EPSs in inoculated soil can be significantly influenced by temperature, which can constitute a stress factor involved in triggering the increase in EPS synthesis and ensuring microbial survival (Sandhya & Ali, 2015; Nouha et al., 2018, Cania et al., 2019; Silambarasan et al., 2019; Asgher et al., 2020; Yang et al., 2022; Yang et al., 2024b).

For the composition of native and synthetic soil microbiota, temperature is one of the critical environmental signals that influences the production of EPSs with a protective, survival and modeling role of soil properties (More et al., 2014; Op De Beeck et al., 2021).

The soil structure can undergo changes induced by EPSs produced under thermal stress through actions similar to soil particle binding agents, which lead to increases in stability, water retention and nutrient availability. Also, the qualitative/quantitative evolutions of EPSs, under thermal stress, intervene in the stimulation of microbial activities, with microbial processes showing a remarkable variation in terms of temperature sensitivity, as well as in the clearer expression of their membership in a community.

The evolution of dissolved organic carbon (DOC) content under the influence of SynComs inoculation was analyzed in order to evaluate the stability/sequestration of C in the Molic Gleysol, taking into account its complex role in soil C dynamics.

Inoculation of SynComs M5 and M7, at 35°C and 3 days of incubation, determined in the rhizosphere of tomatoes a low DOC content of 2.82 $mg \cdot L^{-1}$ and 3.43 $mg \cdot L^{-1}$, respectively, both below the DOC level determined in the uninoculated control variant of 5.64 $mg \cdot L^{-1}$. DOC assessments at 45°C, in the rhizosphere, after inoculation with SynComs M5 and M7 were 3.17 $mg \cdot L^{-1}$ and 3.92 $mg \cdot L^{-1}$, respectively, compared to the uninoculated control (6.87 $mg \cdot L^{-1}$).

In the case of SynComs M4 and M1, incubated for 3 days, the DOC content at 35°C was 3.62 $mg \cdot L^{-1}$ and 3.48 $mg \cdot L^{-1}$, respectively, and at 45°C DOC increased by up to 18.76% and 20.26%, respectively, for SynComs M4 and M1, compared to their level reached at 35°C.

The Mollic Gleysol inoculated with SynCom M5 at 35°C and 14 days of incubation had a DOC content of 14.22 $mg \cdot L^{-1}$ and when inoculated with SynCom M7, under the same experimental conditions, the DOC determined was 15.29 $mg \cdot L^{-1}$, both quantitative values being below the DOC level analyzed in the uninoculated control.

DOC evaluated at 45°C, in the rhizosphere, after inoculation with SynComs M5 and M7 was 16.24 $mg \cdot L^{-1}$ and 17.66 $mg \cdot L^{-1}$, respectively, compared to the uninoculated control (22.28 $mg \cdot L^{-1}$).

In the case of inoculation with the M4 and M1 synthetic microbiomes, the DOC content in the soil at 35°C decreased by 12.32% and 21.27%, respectively, compared to the uninoculated control (17.84 $mg \cdot L^{-1}$) and at 45°C the DOC in the soil increased by up to 28.65%, under the influence of SynCom M1 (21.70 $mg \cdot L^{-1}$), compared to the DOC content at 35°C (Figure 4).

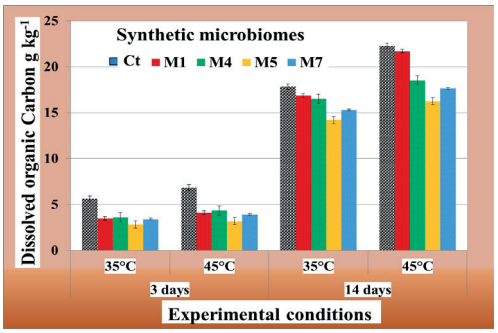

Figure 4. DOC content in Mollic Gleysol generated by inoculation with SynComs under two different periods of time and temperatures

Incubation of vegetation pots at temperatures considered as heat stress influenced the intensity of microbial activities in the soil, so that SynComs intervened in accelerating processes in the rhizosphere, making C use more efficient by enhancing sequestration and reducing free DOC.

The new communities of microorganisms in the rhizosphere act preferentially on more easily degradable compounds, either generating more DOC or participating in the construction of more stable aggregates, thus quantitatively reducing their presence.

The applied thermal stress had an effect on the DOC content in the inoculated rhizosphere also through the induced changes in the composition of root exudates, representing sugars, organic acids, metabolites, a.s.o., which constitute the main sources of DOC.

Thus, when temperatures increase, both the production of DOC by photosynthesis and the decomposition of organic matter undergo accelerations, causing their concentration in the soil to increase.

Possibly, thermal stress causes a photosynthetic stimulation, with tomatoes producing more organic compounds than they can process, generating their release in the form of DOC. Also, the high temperatures applied determined the growth and development of microorganisms in the rhizosphere, promoting an increase in the rate of decomposition of OM and the release of a greater amount of DOC into the environment (Campbell et al., 2022).

When the applied incubation temperature was 45°C, the photosynthetic capacity of tomatoes may have been oriented towards a hypersynthesis of organic compounds, far beyond their utilization capacities, causing their release in the form of DOC. Inoculation with SynComs enriched the rhizosphere with metabolites related to plant growth, stress inhibition and the structure of the overall DOC composition.

The inoculated SynComs promoted beneficial interactions, developed beneficial microbial cooperation and improved the dynamics of organic C in the rhizosphere.

Various studies have analyzed the impact of temperatures on DOC characteristics, investigated the ways in which high temperatures accelerate the decomposition processes of organic C for an increase in DOC production (Kalbitz et al., 2000; Smreczak & Ukalska-Jaruga, 2021).

Thus, the influence of temperature variations on the level of degradation, mineralization and DOC characteristics, interactions between microbial communities and DOC was evaluated (Liu et al., 2019; Garcia et al., 2022; Wang et al., 2022).

Soils contain natural organic matter (NOM) with a role considered essential in shaping their composition and microbiology and, through the amount and compositional specificity of NOM, influencing the types and concentrations of other compounds. In addition, temperature has been identified as a significant factor influencing DOC (Zhao et al., 2023; Huang et al., 2024; Ren & Cai, 2025).

To adapt to high temperatures, the lipid composition of the microbiota changes to express heat shock proteins and stabilize cell membranes. Warming intervenes in increasing the potential level of respiration of the heterotrophic saprophytic soil microbiota, enhancing $CO_2$ emissions, reducing SOM deposits necessary to maintain soil structure and water retention capacity (Karhu et al., 2014; Bond-Lamberty et al., 2018; Cavicchioli et al., 2019; Jansson & Hofmockel, 2019).

Under elevated temperatures, the application of SynComs inoculation resulted in an intensification of DOC production, through increases in metabolic activities, accelerated SOM decomposition, etc., which generated temperature-dependent dynamics.

Other effects of temperature on DOC include accelerated decomposition and microbial

transformation into particulate organic carbon (POC), water-extractable labile compounds, a microbiota with specific thermal thresholds and behavior that evolves from rapid degradation to accumulation at high temperatures (26-35°C), promoting the retention of refractory DOC.

Soil carbon fractions also suffer significant decreases in labile C, recalcitrant C, as elevated temperatures enhance the conversion of old, protected organic matter (SOM) into labile, soluble forms (DOC), accelerating the overall rate of C renewal in the soil.

Using UV illumination, images revealed differences between the uninoculated control and the inoculated variants, at different time (3 and 14 days) and temperature (35°C and 45°C) intervals (Figure 5).

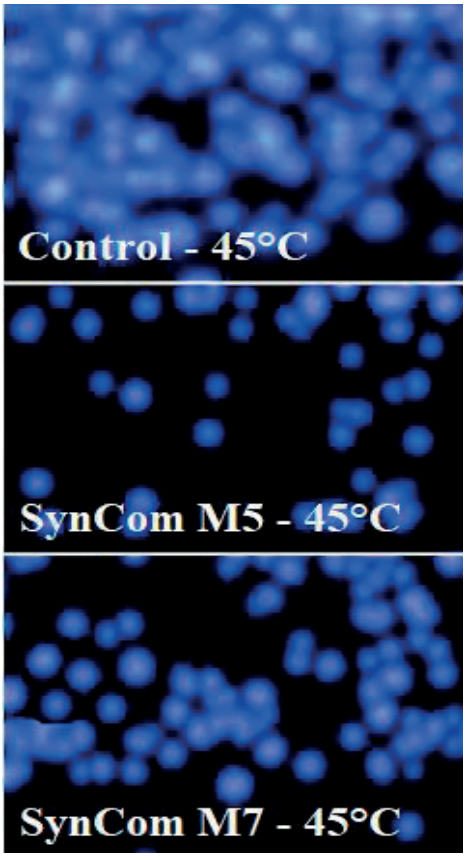

Figure 5. DOC from soil inoculated with SynComs M5 and M7, at 45°C after 14 days

The qualitative differences were generated by the specific composition of SynComs and were reflected, function by their affinity, in the aspects related to the level of accumulations of newly synthesized organic compounds.

The distribution of extracted organic carbon compounds DOC was highlighted based on fluorescence affinity. DOC showed different densities of organic compounds in the soil, after 14 days of incubation at 45°C, in the case of inoculated SynComs.Of these, SynCom M5 induced the lowest DOC content, at 45°C, after 14 days of incubation and the organic carbon structures appear well highlighted through less dense areas, with a lower molecular weight, compared to the DOC structures that appear under the influence of SynCom M7.

After 14 days of incubation at 35°C, the density differences are less evident and, in the case of SynComs M4 and M1, including the control, the differences are imperceptible.

After inoculation with SynComs M5 and M7, the stability of organic carbon compounds in DOC at temperature increased in the carbon subfractions, the biochemical protection offered by the composition of the newly secreted exometabolites was more intense and diverse, compared to the other inoculated SynComs. The images reveal the changes in the distribution and organization of newly biosynthesized DOC under the influence of SynCom M5, under thermal stress, compared to the uninoculated control.

It can be deduced that the stability of organic carbon in the soil inoculated with SynComs M5 and M7 also increased, compared to that provided by SynComs M1 and M4.

But, even under conditions of reduced protection of C compounds, SynComs M1 and M4 ensured better stability of organic C. compared to the uninoculated control.

The trend demonstrated by DOC under the influence of SynComs M5 and M7, after the 14 days of intermittent exposure at 45°C, is more pronounced than at 35°C, under the influence of the same synthetic microbiomes, which perhaps reflects a reaction model to the interactions between soil properties and the biochemical characteristics specific to SynComs.

The amount of C stored in the soil appears dependent on the metabolism of SynComs, the physico-chemical structure, interactions and chemical absorption of carbon molecules in

relation to the mineral component and their specific influence modifies the accessibility/stability of C.

Thus, microbial C biosynthesized by SynComs enriches DOC in the inoculated soil, can stabilize on mineral surfaces or in the soil solution, where it can compete for sorption sites.

Under controlled conditions of thermal stress, under the influence of the analyzed SynComs, labile substances were produced by both the inoculated synthetic communities and the native ones in the soil, to which substances from the organo-mineral reserve were added. The analyzed parameters, such as the content of glycoproteins, EPS and DOC, can be used as indicators for estimating the efficiency of carbon use under the conditions of increasing the supply of extracellular compounds on the long-term carbon storage and the dynamics of carbon capture/emission processes in the soil.

## CONCLUSIONS

SynComs selected for their exometabolic capacities intervened in the organic C dynamics, favoring the stabilization and sequestration of carbon in the soil, under thermal stress conditions.

In the soil, inoculated SynComs and native microbial communities, stimulated by their presence, enhanced the synthesis of GRSP and EPS, as a strategy of adaptation to stress conditions.

Inoculated SynComs and native communities influenced by their presence reduced the synthesis of DOC, as a strategy of resistance to thermal stress.

The content, quality and influence of additionally biosynthesized/ accumulated GRSP, EPS and DOC in the soil varied significantly depending on the type of SynCom.

Under heat stress conditions, the content of GRSP, EPS and DOC biogenerated after SynComs inoculation varied significantly between the two temperature ranges

Depending on the composition and characteristics of SynCom, the results obtained under heat stress conditions highlighted that soil microbial carbon pumps acted/functioned differently in the rhizosphere to compensate/stimulate the synthesis of GRSP, EPS and DOC.

Comparative evaluation of SynComs regarding influence on carbon stability and sequestration under heat stress conditions were observed at M5 and M7 in terms of the effect on functional efficiency of the new soil microbiota.

***Abstract***

*The Danube Delta is listed on UNESCO's World Heritage List for its exceptional value, attributed to the numerous natural ecosystems with remarkable characteristics and high biodiversity that have been preserved in an almost original state. Despite the significant environmental initiatives implemented in recent years, this place remains at risk from both natural and human-made stresses that could alter its ecosystems. This study focuses on determining the contamination degree with emerging and persistent pollutants in the deltaic and pre-deltaic Danube zone. In the present investigation, the pharmaceutical compounds in water samples and pesticides in sediment samples were assessed by considering the physicochemical properties of the targeted contaminants and their interactions with ecosystem matrices. Among the analysed water samples, the compound caffeine recorded the highest concentration (17.33 ng/L), while the compound carbamazepine registered the lowest value, 0.31 ng/L. The sediment samples were freeze-dried and analysed in terms of organochlorine and organophosphorus pesticides. The highest pesticide concentrations were identified in the terminal sampling point, including 3.45 ng/g of dichlorodiphenyltrichloroethane (DDT). The presence of both persistent and emerging pollutants in the Danube Delta imposes permanent monitoring to maintain biodiversity and the best possible environmental conditions.*

***Key words****: Danube Delta, pesticides, pharmaceuticals, sediments, water.*

## INTRODUCTION

The Danube Delta is a biodiversity sanctuary, providing habitat to numerous unique, exotic, and important species with considerable conservation and commercial importance (Bănăduc et al., 2016). It is one of the most important wetland ecosystems for animals on the continent, as it is the second biggest river delta in Europe and the largest natural wetland still in existence (ICPDR, n.d.). Over 300 bird species and 45 freshwater fish species may be found in the Danube Delta's various lakes and marshes (UNESCO World Heritage, n.d.). This area of rich biodiversity is greatly impacted by upstream pollution and discharge modification (ICPDR, n.d.). Water quality has undergone significant changes in the second half of the 20th century as a result of increased pressure from industrial and hydrotechnical activities, urban development, and agriculture. These changes have affected the Danube's physical conditions (suspended sediment, bedload transport, temperature), chemical (emerging pollutants, nitrite, nitrate, phosphorous, and ammonium), and biological (faecals, species loss, and biological community alterations caused by invasive organisms) (Mănoiu & Crăciun, 2021). Additionally, monitoring the quality of water by assessing the concentration of pollutants in surface and ground water has an immediate connection to human health (Iticescu et al., 2014). Surface river systems are contaminated by industrial sites and agricultural operations that are situated close to bodies of water, endangering aquatic life (Zlati et al., 2023). Pesticides, pharmaceuticals, microbiological contaminants, endocrine disruptors, heavy metals, polycyclic aromatic hydrocarbons, and polychlorinated biphenyls have all been identified by many monitoring studies (Chiţescu et al., 2021). The Danube is particularly susceptible to agricultural chemical contamination, which has an impact on regional

biodiversity as well as the quality of drinking water. Because of their environmental persistence, accumulation in biological organisms, and concerns about ecosystems and human health, a considerable number of pesticides are identified as persistent organic pollutants (Matei et al., 2025). Persistent organic pollutants are nonpolar organic chemicals that are potentially hazardous at threshold levels and have strong bioaccumulation and stability characteristics (Chiţescu et al., 2021). Because of their strong hydrophobicity, they tend to absorb into solid particles (Katsoyiannis & Samara, 2005). Numerous types of human and veterinary antibiotics, as well as human prescription and over-the-counter medications, such as antiepileptics, NSAIDs, blood lipid regulators, antidepressants, β-blockers, and analgesics, are among the pharmaceutical chemicals most frequently found in aquatic systems (Chitescu et al., 2015). The Danube Delta is a topical hotspot for assessing the combined presence of contaminants since it is the last accumulation area of the Danube River basin and is constantly impacted by incoming agricultural, local, and industrial discharges. In the context of the Water Framework Directive (WFD) which emphasizes maintaining both qualitative and quantitative status of water bodies, it is now essential to evaluate the ecological status in terms of chemical pollution. This study aims to perform an evaluation of both pesticides and pharmaceuticals in the Danube Delta area. The monitoring of these emerging and persistent organic pollutants is essential for many reasons: a) the protection and preservation of a unique ecosystem, b) the possibility of entering the food chain through drinking water and biota, c) the impact on organisms' health, and d) the need to establish concentration limits. Moreover, this paper fills a scientific gap in understanding the combined impact of contaminants on the aquatic ecosystem, with particular focus on a highly vulnerable and understudied area.

## MATERIALS AND METHODS

In order to characterize the pesticides from the sediment and pharmaceuticals from the water, the samples were collected according to the specificity of each class of compound to ensure their representativeness. A total of 6 water samples and 6 sediment samples were taken from the Sulina branch in May 2026, and these were chronologically coded according to the distance to the spillway (1 meaning the farthest to the spillway and 6 meaning the closest point to the spillway: Partizani, Maliuc, Gorgova, Crișan, Sulina Intermediar, and Sulina). Water samples were collected from a depth of 20 cm in prewashed containers and sediment samples were collected using a dredge and transferred to different specific containers for each target analysis. In Table 1, the coordinates of the samples are presented.

Table 1. Geographical coordinates of the samples

| Sample codes | Sampling stations | Geographical coordinates |
|---|---|---|
| 1 | Partizani | 45.19330, 28.95869 |
| 2 | Maliuc | 45.17459, 29.11427 |
| 3 | Gorgova | 45.18153, 29.17888 |
| 4 | Crișan | 45.17358, 29.42541 |
| 5 | Intermediate Sulina | 45.18125, 29.51804 |
| 6 | Sulina | 45.16208, 29.68527 |

Water samples for pharmaceutical analysis were filtered, and then the collected samples were carefully stored and preserved until further analysis. For the pesticide analysis, the sediment was freeze-dried to ensure the compounds' stability with the Table Top Freeze Dryer BioBase BK-FD10PT (BioBase, Shandong, China) equipment

### *Analytical standards*

- Organochlorine pesticide mix containing α-BHC; β-BHC; δ-BHC; γ-BHC (Lindane); α-Chlordane; γ-Chlordane; p,p′-DDD; p,p′-DDE; p,p′-DDT; Aldrin; Dieldrin; Endosulfan I; Endosulfan II; Endosulfan sulfate; Endrin aldehyde; Endrin; Endrin ketone; Heptachlor epoxide (Isomer B); Heptachlor; Methoxychlor.
- Organophosphorus pesticides mix containing Disulfoton, Dimethoate, Parathion-methyl, Famphur, Triethyl thiophosphate, Parathion, Sulfotep, Phorate, Thionazin.

- ***Internal standards***

4,4` - DDT-D8, 4,4` - DDD-D8, 4,4` - DDE-D8, γ-BHC-D6, PCB-143.

- Pharmaceutical residues in the examined water samples were identified and quantified using analytical standards for the following compounds: Caffeine, Carbamazepine, Ketoprofen, Metformin, Diclofenac, Clindamycin, Trimethoprim, Sulfamethoxazole, and Clarithromycin.

***QuEChERS extraction of pesticides***

The pesticides belonging to the organochlorine and organophosphorus classes were extracted from freeze-dried sediments using an optimized QuEChERS protocol. The sample was weighed and well hydrated with ultrapure water to better simulate the matrix composition. First, the internal standard was added, and the samples were allowed to rest for 30 minutes. The extraction procedure started with the addition of acetonitrile as solvent extraction, and after 15 minutes of sonication at 150 W, using an Elmasonic S60 H 100 2238 (Elma Schmidbauer GmbH, Singen, Germany) and homogenization, the extraction salts (6 grams of magnesium sulfate with 1.5 grams of sodium acetate) were added to the sample. The samples were vortexed for 5 minutes each and centrifuged at 4500 rpm for 10 minutes (OHAUS FC5916R Centrifuge) for 10 minutes in order to collect the resulting supernatant. A known aliquot of the sample was then mixed with the clean-up (150 mg magnesium sulfate, 25 mg C18, and 25 mg Primary-Secondary Amine), and the liquid was again centrifuged. The resulting supernatant was carefully evaporated under nitrogen stirring (Reacti-Therm™ Heating and Stirring Module - TS-18823 from Thermo Fisher Scientific, Waltham, MA, USA), redissolved in toluene, and filtered to be prepared for chromatographic analysis.

***Automatic SPE extraction of pharmaceuticals from liquid samples***

Sample preparation for the analysis of pharmaceutical compounds in water samples involved the use of an automated solid-phase extraction with a dedicated instrument Dionex AutoTrace 280 (Thermo Fisher Scientific, Waltham, MA, USA). The extraction was made using C18 cartridges, methanol, and water, and methanol as the elution solvent. An evaporator that allowed the concentration of analytes in a nitrogen atmosphere was also used to evaporate the samples, and 10% methanol for re-dissolution.

***The analysis of pesticides from sediment by GC-MS/MS***

The toluene extracts of sediment samples were analyzed using a TSQ 9000 Triple quadrupole GC-MS/MS instrument, a Thermo Scientific™ TRACE™ 1310 GC, and a Thermo Scientific™ TriPlus™ RSH autosampler (Waltham, Massachusetts, USA), 2 µL of extract was injected into a Thermo Scientific™ TraceGOLD TG-PAH 30 m × 0.25 mm I.D. × 0.10 µm film capillary column, which was used for the chromatographic separation. The ramped temperature within the GC oven was set up as follows: initial temperature 60°C - 2 min hold time, from 60°C to 120°C at a rate of 30°C/min, from 120°C to 320°C at a rate of 10°C/min, and the final step, 320°C with a hold time of 16 min. The total program run is 40 minutes.

Each targeted compound was identified and quantified using three SRM transitions, and the final results were processed using Chromeleon 7.3. The pesticides were quantified using an internal-standard calibration curve constructed from six concentration levels, with a concentration range between 2 and 80 ng/g.

***The analysis of pharmaceuticals from water by UHPLC-HRMS***

Qualitative and quantitative analysis of the identified pharmaceutical compounds was performed using liquid chromatography with high-resolution mass spectrometry, Vanquish Flex UHPLC - Orbitrap Exploris 120, and a mass spectrometer from Thermo Fisher Scientific (Waltham, Massachusetts, USA). The analysis method involved the use of two mobile phases represented by ultrapure water with 0.1% formic acid and methanol with 0.1% formic acid in a gradient with a flow rate of 0.4 mL/min. The separation of the compounds was done using an Accucore C18 column (100 x 2.1 mm, 2.6 µm) at a temperature of 40 °C. The analysis time was 20 minutes and the sample injection volume was 10 µL. The calibration

curve was performed in 6 points over the range 0.1 ng/L - 25 ng/L. Quantification of the compounds was performed based on the following internal standards: dihydrocarbamazepine for carbamazepine; phenacetin for metformin, caffeine and diclofenac and enrofloxacin for sulfamethoxazole.
The results obtained for both pesticides and pharmaceuticals were validated using the spiking method on 3 different levels.

## RESULTS AND DISCUSSIONS

Due to extensive development, inadequate pollution control, and inflows from severely polluted tributaries, the Middle and Lower Danube River's water quality quickly declined after the 1970s (Gati et al., 2019). The quality of the Danube Delta waters as well as the Black Sea's coastline region is impacted by the Danube River, which serves as the primary collector and emissary of all urban and industrial effluent from the whole river basin (Ene et al., 2025).
The sediment samples were analyzed in terms of pesticide content, and the results showed the presence of DDTs in all target points (Figure 1).
Generally, the organochlorine and organophosphorus pesticides were not detected in the samples, except for DDT and its metabolites. DDT levels in our samples varied between 0.90 and 3.45 ng/g DW with the highest concentration in the terminal sampling point. As expected, the highest abundance and concentration of DDTs were recorded in the closest point to the mouth of the Sulina branch (Figure 1 and Figure 2). The presence of the metabolite 4,4`-DDE could only be quantified in the final point of sampling, and for 4,4`-DDD in two of the collected points (Figure 1). The presence of both metabolites was confirmed in all points, but the concentrations were below the limit of quantification. The highest content within the DDTs metabolites was recorded also in the last point, 1.09 ng DDD/g DW. Sediment samples were also scanned for the presence/absence of organophosphorus pesticides, and no compounds from this category were identified. The absence of these compounds could be a reason for their rapid biodegradability, compared to organochlorines (Saad et al., 2025). It is clear that from the OCP category only DDTs have been identified. First of all, these compounds are indicators of historical pollution, being particularly persistent compounds with a high potential for bioaccumulation. The fact that other compounds from the pesticide category have not been identified does not necessarily indicate their absence, but the possibility of their degradation over time. Also, another argument could be given by the volatility of the substances. While DDTs are strongly persistent and hydrophobic, therefore almost immobile in solid matrices, pesticides such as lindane are more volatile and slightly more soluble.
In agreement with previous reports, the predominance of DDTs in environmental samples from the Danube Delta was observed by Covaci et al. (2006), who found concentrations of DDTs in Danube Delta sediments varying between 0.7 and 33 ng/g.
Belháčová-Minaříkova et al. (2020) reported DDT and its breakdown products in high amounts in the lower Danube, with the river delta containing the highest levels.
Sediments act as storage spaces for non-polar contaminants and sources for living organisms from the aquatic ecosystem. For example, Stancheva et al., 2013, reported in freshwater fish from the Danube river concentrations of DDTs from 19.2 to 30.3 ng/g WW. Despite the global initiative to minimize the use of pesticides, the risk of pesticide pollution is still present due to their high degree of bioaccumulation (Sharma et al., 2019). ICPDR (2005) reported that 71% of the samples from the Danube and 54% from the tributaries exceeded 0.01 µg/L 4,4`-DDT. DDT was banned in Europe in the 1970s due to its toxicity and environmental persistence and is now listed as a priority substance under European Directive 2013/39/EU and as a persistent organic pollutant under the Stockholm Convention (2001) (van den Berg et al., 2025). Since its use is prohibited, current contamination most likely reflects historical inputs and long-term environmental persistence. DDT is nevertheless utilized in many underdeveloped nations. This chemical is widely distributed throughout the environment

because of its persistence and long-distance atmospheric transport, causing high bioaccumulation and biomagnification potential (Tasselli et al., 2023).

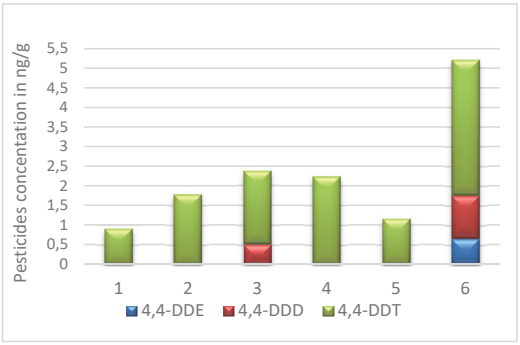

Figure 1. The concentrations of pesticides in sediments from the Danube Delta

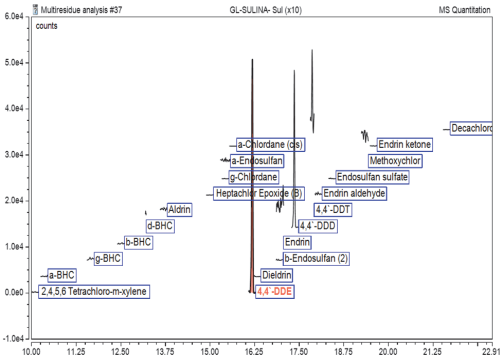

Figure 2. Chromatogram example (sample 6) of pesticide in a sediment sample analyzed from Danube Sulina branch

Following the investigation into the presence of pharmaceutical residues in water samples taken from the Danube Sulina branch, five compounds were detected at trace levels (Table 2; Figure 3): metformin, caffeine, sulfamethoxazole, carbamazepine, and diclofenac. In Figure 4, an example of chromatogram highlighting the presence of pharmaceuticals in water can be observed.

In Table 2, the concentrations of the identified pharmaceuticals are presented. One of the compounds identified in all 6 sampling stations is metformin, for which minimal variations in concentrations were obtained from one station to another, ranging between 1.7 ng/L (sample 1) and 1.93 ng/L (sample 6). Carbamazepine is another compound frequently identified in surface water; low values within the range 0.31 to 0.49 ng/L were measured on the Danube Sulina branch.

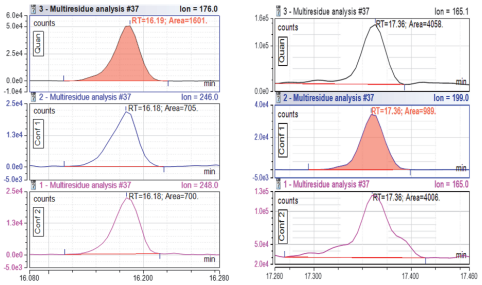

Figure 3. MS Components for 4,4`-DDE and 4,4`-DDD

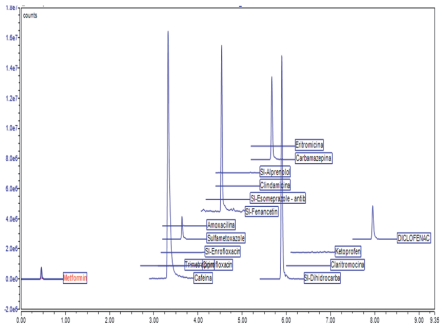

Figure 4. Chromatogram example of compounds in a water sample analyzed from Danube Sulina branch

Table 2. Concentration of pharmaceutical compounds identified in water samples taken from the Danube Sulina branch

| Pharmaceuticals concentration (ng/L) | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| Metformin | 1.7 | 1.77 | 1.9 | 1.86 | 1.86 | 1.93 |
| Caffeine | 14.06 | 13.31 | 17.33 | 8.92 | 8.79 | 9.56 |
| Sulfamethoxazole | 1.02 | 1.07 | 1.08 | 0.96 | 0.95 | 0.98 |
| Carbamazepine | 0.38 | 0.47 | 0.49 | 0.35 | 0.31 | 0.33 |
| Diclofenac | 4.42 | 2.37 | 3.3 | 3.34 | 2.23 | 3.97 |

The antibiotic sulfamethoxazole was also quantified in the analyzed samples, the highest value was 1.08 ng/L and the lowest measured 0.95 ng/L. The highest concentrations were obtained for the psychoactive substance caffeine, with values ranging from 8.79 ng/L to 17.33 ng/L. For the nonsteroidal anti-inflammatory drug diclofenac, concentration variations were recorded from 2.23 ng/L to 4.42 ng/L. Other studies have also reported that sulfamethoxazole, carbamazepine, and diclofenac were detected in the Sulina branch (Ene et al., 2025). Loos et al. (2017) reported

that on the Danube River, diclofenac values were recorded from upstream to the mouth in the range of 20 ng/L - 2 ng/L. Significant concentrations of metformin were also recorded in the Prut, a main tributary of the Danube, with values ranging from 100 ng/L to 240 ng/L (Moldovan et al., 2018). In a study conducted by Chitescu et al. (2015), values of carbamazepine identified in water samples taken from the Danube River basin in Romania territory were reported to be in the range of 4 ng/L - 40 ng/L. In other studies conducted on the Danube River, sulfamethoxazole values ranging from 3.7 ng/L to 141 ng/L were also reported (Loos et al., 2017).

All analytical results were validated using a spiking approach at three concentration levels. For pesticide analysis, limits of detection (LOD) and quantification (LOQ) ranged from 0.12 to 0.19 ng/g and from 0.26 to 0.57 ng/g, respectively. Recovery rates for DDT and its metabolites ranged between 96.62% and 115.07%. For pharmaceuticals, LOD and LOQ values ranged from 0.17 to 0.69 ng/L and from 0.30 to 0.98 ng/L, respectively, while recovery rates varied between 90.11% and 98.80%. Linearity was assessed based on calibration curves, with correlation coefficients ($R^2$) higher than 0.99 for all target pesticides and pharmaceuticals.

***Correlation analysis between pesticides from sediments and pharmaceuticals from water***

The pesticides were analysed from sediments and the pharmaceuticals from water according to the compound's chemical affinity from the matrices. Generally, the pesticides are hydrophobic while pharmaceuticals are more hydrophilic substances.

In Figure 5, the correlation between both classes is represented. First, the presence of DDE and DDD correlates strongly with the presence of DDT because they are metabolic breakdown products of the dichlorodiphenyltrichloroethane. This confirms again the persistence and also the historical pollution with DDT.

An interesting observation is that metformin tends to correlate with DDTs, especially DDT. This could suggest almost a possible common source of pollution or some specific conditions that facilitates the existence of both classes.

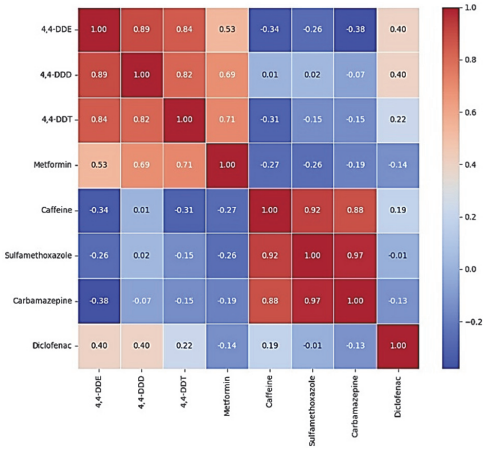

Figure 5. Correlation analysis between pesticides from sediments and pharmaceuticals from water

On the other hand, a negative correlation may be observed between pesticides and carbamazepine, sulfamethoxazole or caffeine, which may highlight different source of pollution (agriculture vs urban waste).

## CONCLUSIONS

This research provides an evaluation of emerging and persistent pollutants in water and sediment samples from a valuable, unique ecosystem in Europe. The present study detected DDTs, caffeine, metformin, sulfamethoxazole, diclofenac, and carbamazepine in the Danube Delta samples. While the pesticides analysis revealed only the presence of a restricted profile of OCPs suggesting both historical pollution and a dominated persistent pollutants profile, the pharmaceutical profile highlighted an actual anthropogenic pollution and a continuous pressure to the Danube ecosystem. However, some limitations regarding the present study should be considered.

Although the present study is relevant from the perspective of the presence of two categories of persistent and emerging pollutants, future studies could be expanded with additional surveys campaigns and a larger number of collected samples. Beyond this, the level of pollution could be underestimate because only two classes of pollutants were analysed. Future studies may include more sample, more sampling campaigns, and a wider spectrum of

compounds to analyze. The presence of these compounds in the aquatic environment of the Danube Delta, which is part of an UNESCO World Heritage Site, underscores the importance of continuous environmental monitoring. Over and above that, there is a need to implement measures to prevent, ensure, and support the well-being of the aquatic ecosystem aligned with the Water Framework Directive. Ecosystems are seriously threatened by pollution from a variety of sources, including industrialization, agriculture, urbanization, and untreated sewage. Over time, these pollutants may have detrimental effects on the environment and human health. Moreover, this research reflects the importance of future studies regarding the concentration levels of pollutants, also in biota. Monitoring priority substances, reducing pollutants discharge and strengthening the control measures would support and improve the quality of aquatic environment.

***Abstract***

*Cold atmospheric pressure plasma (CAPP) is a residue-free alternative for decontaminating surfaces and reusable equipment when chemical disinfectants are inconvenient, such as during field work in environmental engineering and land reclamation. Here, we tested an argon CAPP plume (atmospheric pressure, low-current DC discharge) against Staphylococcus aureus, Escherichia coli, and Pseudomonas aeruginosa after 5–120 s exposures. Antimicrobial activity increased with treatment time: inhibition-zone areas grew from 2.83 $cm^2$ (5 s) to 31.40 $cm^2$ (120 s). P. aeruginosa was the most sensitive (31.40 $cm^2$ at 120 s), whereas S. aureus and E. coli reached 11.30 $cm^2$. Viable counts for E. coli and P. aeruginosa dropped from >$10^6$ to $10^3$ CFU $mL^{-1}$ after 120 s, while S. aureus showed no significant reduction at 120 s; for P. aeruginosa, counts decreased from >$10^6$ to $10^5$ CFU $mL^{-1}$ after 15 s. Overall, these findings support CAPP as a practical, non-chemical option for rapid decontamination of hard surfaces (e.g., tools and sampling devices) in remediation and environmental monitoring workflows.*

***Key words:*** *bacteria, cold atmospheric pressure plasma, susceptibility, surface sterilization.*

## INTRODUCTION

Cold atmospheric pressure plasma (CAPP) is now widely studied as a tool for surface sterilization and disinfection, with reported uses in microbial decontamination and biomedicine (Joshi et al., 2011; Fricke et al., 2012; Mitra et al., 2014; Asenjo et al., 2015; Mai-Prochnow et al., 2016; Bourke et al., 2018; Hertwig et al., 2018; Corradini, 2020; Domonkos et al., 2021; Barjasteh et. al., 2024; Kazemi et al., 2024). Compared with chemical disinfectants-which can leave residues and raise material, environmental, and occupational issues (Whittaker et al., 2004; Singh et al., 2010) - CAPP typically requires only electrical power and a carrier gas and does not produce persistent chemical waste. Because the gas remains near room temperature, CAPP can be used on heat-sensitive materials and, in some cases, on living tissues (Fridman et al., 2008; Heinlin et al., 2010). It has also been explored for decontaminating sensitive electronics and hazardous agents (Singh et al., 2010). Many plasma sources and power-supply designs are available (Ehlbeck et al., 2011), but the dominant mechanisms of microbial inactivation are still being clarified. When the plasma interacts with air and water vapor, it generates reactive oxygen species (ROS) such as $O_2^-$•, $H_2O_2$, •OH, $O_3$, $^1O_2$, and atomic oxygen; together with charged particles, UV radiation, mild heating, and electric fields, these factors contribute to bacterial inactivation (Alkawareek et al., 2014).

How well CAPP works depends on practical details-such as the source design and geometry, as well as the carrier-gas composition, flow rate, and physicochemical properties (Mai-Prochnow et al., 2016; Baldanov et al., 2019). Since Laroussi first showed that CAPP can rapidly inactivate bacteria (Laroussi, 1996), subsequent studies have linked this effect mainly to reactive species and to damage of the membrane and cell wall, often accompanied by leakage of intracellular components. Differences in susceptibility between Gram-positive and Gram-negative bacteria have also been reported (Laroussi & Leipold, 2004; Deng et al., 2006;

Tipa et al., 2011; Flynn et al., 2015; Mai-Prochnow et al., 2016; Olatunde et al., 2019).
CAPP is also relevant for environmental engineering and land-reclamation work. In the field, teams often need to clean and decontaminate tools and reusable sampling or monitoring devices between locations to prevent cross-contamination (Jiang et al., 2014; Scholtz et al., 2015).
In this work, we tested a simple atmospheric-pressure CAPP source (argon carrier gas; low-current DC discharge) and measured its effects on two Gram-negative strains (*Escherichia coli* ATCC 25922 and *Pseudomonas aeruginosa* $IBB_{Po16}$ KT315654) and one Gram-positive strain (*Staphylococcus aureus* ATCC 25923).

## MATERIALS AND METHODS

### Experimental setup for cold argon plasma generation

Mechanical layout of the plasma source is shown in Figure 1, being similar to that described in (Stoican, 2011), except for a few minor changes. A sharp brass rod (1), 3 mm in diameter, is placed along the axis of a cavity (2), having axial symmetry, formed by two cylindrical segments, made in an aluminum block (3). One of the ends of the cavity is closed by the front disk (4), made by aluminum, having an output hole 2 mm in diameter. The plasma plume (5) is ejected through that hole, its external length being about 6-8 mm, depending on the experimental conditions. The other end of the outer cylinder is closed by a PTFE (polytetrafluoroethylene, Teflon) disk (6), which assures the mechanical support of the brass rod (1) and electrical insulation between the brass rod (1) and the aluminum block (3). An inlet (7) directed normal to the cavity axis, serves to deliver the carrier gas. The electrical discharge occurs between the brass rod (1), acting as cathode and the aluminum block (3) connected to ground, which serves as anode.
In Figure 2 the block diagram of the whole experimental setup is shown, including both the system to generate the CAPP and the biological sample holder. The electrical supply circuit for the plasma source operates according to the principle described in (Stoican, 2019). As a typical feature, the electrical discharge is initiated by a train of high voltage pulses and sustained by a common DC voltage source. A ballast resistor embedded into the DC voltage source circuit was used to keep the discharge stable and limit the discharge current, so as to obtain a CAPP with negligible thermal effect.

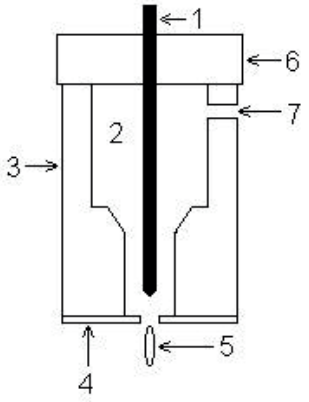

Figure 1. Plasma source mechanical layout representing a slightly modified version of that described in (Stoican, 2011) (not to scale) 1-brass rod (cathode); 2-cavity; 3-aluminum block (anode); 4-front disk with plasma plume output hole 5-plasma plume; 6-PTFE disk; 7-carrier gas input

For a short period of time, both voltages mentioned above are applied simultaneously to the discharge electrodes by means of a summing circuit. The high voltage pulses train is interrupted after the plasma plume occurs and becomes stable. Therefore, plasma is practically due to a low current, pure DC electrical discharge. According to the classification made in (Tendero et al., 2006) it operates as a current-carrying arc plasma torch.
The experimental setup is controlled by means of an electronic interface board that communicates with a personal computer through its RS-232 serial port. The electronic interface board comprises digital outputs necessary to switch on/off DC voltage and carrier gas electric valve, a digital output which provides the excitation signal for the high voltage pulses generator, and analog inputs necessary to measure voltages across terminals of a current sensor resistor Rs.
A software application allows maintaining the plasma plume for the requested period of time, monitoring voltage and current discharge during plasma plume existence, switching on/off the high voltage pulses generator, DC voltage, and carrier gas flow.

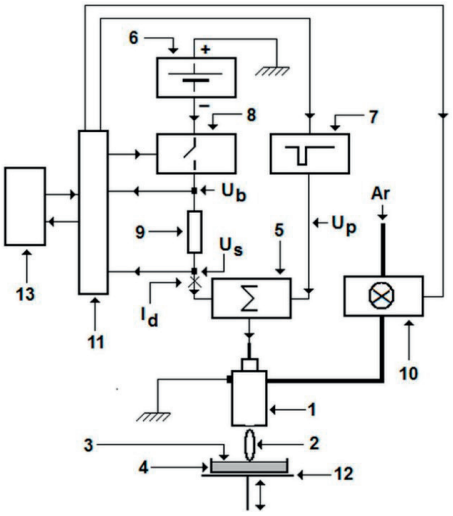

Figure 2. Experimental setup-block diagram
1-plasma source; 2-plasma plume; 3-biological sample;4-Petri plate; 5- summing circuit; 6-DC voltage source; 7-high voltage pulses generator; 8-DC high voltage switch; 9-current sensor Rs; 10-carrier gas electric valve; 11-electronic interface board; 12-metallic plate; 13-personal computer which communicates with the electronic interface board through a RS-232 serial port

The plasma plume is initiated by switching on simultaneously a high voltage pulse generator, DC voltage, and carrier gas flow. A high voltage pulses train is applied until the discharge current becomes greater than a threshold value. After the requested plasma exposure time (PET) has elapsed, the plasma plume is stopped by switching off the DC voltage and carrier gas flow. The PET is considered the time interval from the turn off of high voltage pulses train to the turn off the DC voltage. All necessary commands to perform the above operations are automatically sent by the software application to the electronic interface board.

**Evaluation of antimicrobial effects of argon cold plasma on Gram-negative and Gram-positive bacteria**

Three bacterial strains were used in this study: *Escherichia coli* ATCC 25922 (Minogue et al., 2014), *Staphylococcus aureus* ATCC 25923 (Treangen et al., 2014), and *Pseudomonas aeruginosa* $IBB_{Po16}$ (KT315654, Stancu, 2018). The strains were inoculated into Luria-Bertani (LB) medium and incubated overnight at 30°C with agitation at 150 rpm.

Reagents used in this study were purchased from Merck and Sigma.

**Bacterial growth inhibition assay**. The bacterial cultures were adjusted to an optical density of 0.1 at 660 nm ($OD_{660}$), and 500 µL of each suspension was spread onto LB agar plates using the lawn culture method. After air-drying for 15 min under a laminar flow hood, the inoculated plates were exposed to the plasma plume for different time intervals (5, 7, 10, 15, 30, 60, 90, and 120 s). The distance between the agar surface and the outlet of the plasma-generating device was approximately 2 mm. Following plasma exposure, the plates were incubated overnight at 30°C, and the area of the inhibition zone (defined as the clear region on the LB agar where no bacterial growth was observed) was measured.

**Quantification of bacterial survival**. Bacterial strains were inoculated into LB medium and incubated overnight at 30°C with agitation at 150 rpm. Subsequently, 10 µl of bacterial suspensions adjusted to an optical density of 0.1 $OD_{660}$ were pipetted onto the center of sterile, empty Petri plates, allowed to air-dry, and exposed to the plasma plume for varying time intervals (5, 7, 10, 15, 30, 60, 90, and 120 s). Control samples were prepared under identical conditions but were not subjected to plasma treatment. Following exposure, bacterial recovery and enumeration were performed using the Most Probable Number (MPN) method. Briefly, the bacterial cells were scrubbed from the surface of each Petri plate using sterile 0.9% saline solution. Serial dilutions were prepared, and 20 µl of aliquots of each dilution were inoculated into wells of a 96-well microplate containing 180 µl of LB medium. The microplates were incubated overnight at 30°C. Bacterial growth was assessed by adding 0.3% triphenyl tetrazolium chloride (TTC), as previously described (Stancu, 2019). The appearance of a red coloration in the wells, resulting from TTC reduction, was interpreted as a positive indication of bacterial growth.

To evaluate changes in cell membrane permeability following plasma exposure, a permeability assay (Ardelean et al., 2009) was performed. SYBR Green I and propidium homodimer served as selective fluorescent markers. The assay was conducted on chemically fixed cells (2% buffered formalin) at

5 h post-plasma exposure. SYBR Green I penetrates the membranes of all cells, while propidium homodimer, due to its larger molecule size and negative charges, penetrates only cells with severely compromised membrane integrity, which are considered non-viable (Noble & Fuhrman, 1998).

## RESULTS AND DISCUSSIONS

The effects of CAPP exposure on the inactivation of three bacterial species were investigated in this study. The selected strains belong to the two principal bacterial groups: Gram-positive, represented by *S. aureus*, and Gram-negative, represented by *E. coli* and *P. aeruginosa* IBBPo16.

Details on the plasma source, its electrical supply circuit, and biological sample arrangement are presented in Figures 1 and 2. The high voltage pulses had a peak value of $U_p$ ≈-3.9kV/60Hz (negative polarity with respect to ground), being applied for about 1-2 s in order to initiate the plasma plume. The average DC voltage $U_b$ (having negative polarity with respect to ground) was about 0.68kV. The DC discharge current has been calculated as $I_d$=$|U_b - U_s|/R_s$≈13-20mA. Argon (Ar) was used as a carrier gas. The biological sample was deposited in a Petri plate placed on a metallic support below the output hole of the plasma source.

Owing to structural differences between Gram-positive and Gram-negative bacteria, distinct responses to plasma exposure are anticipated among strains belonging to these groups. In view of the potential applications of CAPP in surface sterilization, argon was selected as the carrier gas, and three bacterial strains were chosen based on their opportunistic and pathogenic characteristics, which represent a potential risk to human health. Previous studies (Tipa et al., 2011; Baldanov et al., 2019) have demonstrated that argon exhibits higher bacterial inactivation efficiency compared with other carrier gases (e.g., helium), thereby justifying its use in the present study.

Several long-living ROS, such as $O_2^{-}$•, $H_2O_2$, and •OH, are capable of diffusing beyond the plasma plume, thereby affecting an area larger than the plasma jet diameter. The distance between the jet nozzle and the treated sample is a crucial parameter, as increasing this distance may lead to attenuation of photons and reactive species, resulting in reduced fluxes reaching the surface and consequently diminishing the antimicrobial efficacy. This aspect is particularly relevant because bacterial inactivation is predominantly mediated by ROS. Additionally, the intensity of UV radiation decreases proportionally to the square of the distance from the source (Lackmann & Badow, 2014).

To address this limitation, all treatments were performed at an approximate distance of 2 mm, corresponding to the condition in which the plasma plume directly contacts the surface and spreads across it, thereby facilitating the transport of reactive species to adjacent regions.

The inhibition zone area as a function of treatment time for each bacterial strain is presented in Figure 3a. According to our results (Figure 4), increasing the PET led to a progressive enlargement of the inhibition zone for all three tested strains, ranging from a minimum of 2.83 $cm^2$ (after 5 s) to a maximum of 31.40 $cm^2$ (after 120 s). The response of *S. aureus* followed a similar trend to that of *E. coli*, with no major differences observed between the two strains; both reached a maximum inhibition zone of 11.30 $cm^2$ after 120 s of exposure. In contrast, *P. aeruginosa* $IBB_{Po16}$ exhibited higher sensitivity to plasma treatment, showing a maximum inhibition zone of 31.40 $cm^2$ after 120s.

Tetrazolium salts are widely used to assess the viability of bacterial cultures. As reported (Moussa et al., 2013), the TTC-reducing activity of a culture is directly proportional to the number of metabolically active cells within the bacterial population. Figure 3b and Figure 5 present the relationship between PET and the number of colony-forming units per milliliter (CFU $mL^{-1}$).

*S. aureus* exhibited the highest resilience to plasma treatment, with no significant differences observed between the control sample and those exposed to 120 s of cold plasma. In contrast, *E. coli* and *P. aeruginosa* $IBB_{Po16}$ exhibited slightly higher sensitivity, showing a reduction in viable counts from $>10^6$ to $10^3$ CFU $mL^{-1}$ after 120 s of exposure. Compared with *S. aureus* and *E. coli*, plasma treatment exerted a more pronounced effect on *P. aeruginosa* $IBB_{Po16}$. Within 15 s of plasma

exposure, a CFU reduction from $>10^6$ to $10^5$ CFU $mL^{-1}$ was achieved. Overall, the results indicate that increasing PET leads to a progressive reduction in the cell viability in both Gram-positive and Gram-negative bacteria.

The permeability assay revealed a decrease in the number of viable bacterial cells (Figure 3c, green fluorescence) and a corresponding increase in the proportion of non-viable cells (Figure 3c, orange fluorescence) after 60 s of cold plasma exposure compared with the untreated control. Before plasma exposure, the proportion of non-viable bacterial cells was low relative to the total cell population. Following 60 s of treatment, a marked increase in non-viable cells was detected, with the majority of cells exhibiting membrane permeabilization and positive homodimer staining.

Figure 5. Gram-positive and Gram-negative bacterial cell viability after plasma exposure (5-120 s)

It should be noted that membrane permeabilization detected by fluorescence staining does not necessarily correspond to an immediate loss of reproductive capacity. While CFU enumeration reflects the ability of bacterial cells to recover and proliferate under nutrient-rich conditions, fluorescence-based assays evaluate membrane integrity at a specific time point. Therefore, the apparent differences between the permeability assay and the viability data (Figure 3b) may indicate the presence of sublethally injured cells within the treated population. Such cells may exhibit increased membrane permeability without complete loss of culturability. Further time-resolved investigations would be required to determine whether plasma-induced membrane alterations are fully irreversible or represent transient physiological responses.

Fluorescent staining methods capable of discriminating between cells with intact membranes (classified as viable) and those with severely compromised membranes (classified as non-viable) have previously been employed to evaluate bacterial responses following CAPP treatment (Deng et al., 2006; Waskow et al., 2018; Lee et al., 2019; Olatunde et al., 2019). These studies reported findings consistent with the results of the present investigation.

All tested strains exhibited a linear increase in inhibition zone area with no evidence of saturation even after 120 s of plasma exposure. Among the strains investigated, *S. aureus* presented the highest resistance to plasma treatment, followed by *E. coli* and *P. aeruginosa* $IBB_{Po16}$. These results are consistent with the known structural difference between Gram-positive and Gram-negative bacteria, particularly regarding cell wall architecture. Of the three strains, *S. aureus* showed significantly higher resistance after 120 s of plasma treatment, suggesting that the increased thickness and structural complexity of the Gram-positive cell wall contribute substantially to plasma-mediated resistance.

Cold plasma has been hypothesized to target multiple cellular components, including the cell membrane, cell wall, DNA, and intracellular proteins. The ROS are capable of breaking structurally critical bonds within peptidoglycan (e.g., C–O, C–N linkages), potentially leading to cell wall damage in Gram-positive bacteria (Misra et al., 2016). In Gram-negative bacteria, ROS primarily induce lipid peroxidation of the outer membrane (Joshi et al., 2011), compromising membrane integrity. This cascade of oxidative events promotes the leakage of intracellular constituents, such as nucleic acids and proteins, ultimately resulting in cell death. The increased susceptibility of Gram-negative bacteria compared to Gram-positive bacteria may also be attributed to the higher porosity of the outer membrane, which facilitates ROS penetration and enhances oxidative damage (Mai-Prochnow et al., 2016). These findings are consistent with our results, as *P. aeruginosa* $IBB_{Po16}$ and *E. coli* proved greater sensitivity to plasma exposure than *S. aureus*.

## CONCLUSIONS

The antimicrobial effect of CAPP using argon as the carrier gas was evaluated against *S. aureus*, *E. coli*, and *P. aeruginosa* $IBB_{Po16}$. *S. aureus* exhibited the highest resistance, while the Gram-negative strains showed greater susceptibility. Bacterial response was strain-

dependent and probably influenced by differences in cell wall architecture. Although plasma exposure reduced viable cell counts, complete inactivation was not achieved even after 120 s, indicating that longer exposure times are required for effective surface sterilization.

These findings demonstrate that CAPP represents a promising approach for surface sterilization and decontamination. Under extended exposure conditions, CAPP may support applications in environmental decontamination and surface treatment technologies.

## ACKNOWLEDGEMENTS

This work was funded by project LAPLAS VII, contract 30N/12.01.2023, supported by the Ministry of Research, Innovation and Digitalization, and by project no. RO1567-IBB05/2023 from the Institute of Biology Bucharest of Romanian Academy.

The authors dedicate this work to the memory of †Professor Dr. Ioan I. ARDELEAN, whose contributions were essential in the early stages of this research, but who sadly passed away before the completion of this manuscript. Thanks are due to Dr. C. Porosnicu (INFLPR) for institutional support, and Mrs. Cirnu Marinela (Institute of Biology Bucharest) for technical support.

***Abstract***

*Ozone ($O_3$) pollution is a serious global environmental threat, with tropospheric ozone levels frequently classified as some of the most toxic air pollutants. Elevated tropospheric ozone levels affect vital processes in plants, encompassing respiration, photosynthesis, and nutrient uptake, thereby causing a decline in plant growth and development. Plants display a complex set of defense strategies against $O_3$ stress, including stomatal regulation of $O_3$ influx into leaves, photosynthetic adjustments, modulation of antioxidant defense against $O_3$-induced reactive oxygen species (ROS), and secondary metabolism. Stomatal closure is the first response to $O_3$ stress in most plants, providing protection from high $O_3$ influx to the leaves. One negative outcome of this is the decreased influx of $CO_2$ into the leaves, resulting in a decline in the photosynthetic rate. In response to $O_3$ stress, plants strive to adjust their photosynthesis by regulating the photosynthetic electron transport chain through photorespiration, cyclic electron flow, or the alternative oxidase pathway, while also enhancing anthocyanin production to protect their photosynthetic systems. Plants are also equipped with a substantial antioxidant defense system that consists of both enzymatic and non-enzymatic antioxidants, which work together to neutralize the excess $O_3$-induced ROS. This review summarizes recent advances in understanding the strategies that plants use to protect their structural and functional integrity in response to $O_3$ pollution.*

***Key words:*** *air pollution, antioxidant defenses, photosynthetic adjustments, stomatal regulation.*

## INTRODUCTION

In the last several decades, global patterns of industrialization and rapid urbanization have led to an increase in the production of air pollutants, adversely affecting living organisms (Antenozio et al., 2024). Air pollutants refer to all substances in the air, whether inorganic or organic, that compromise air quality, generating adverse impacts on the environment (Stoykova et al., 2025). They can be classified into two categories: primary and secondary, depending on their source (Manisalidis et al., 2020). Primary pollutants, including carbon oxides, sulfur oxides, nitrogen oxides, particulate matter, and volatile organic compounds, are released directly from identifiable sources, whereas secondary pollutants are not released directly; instead, they are generated in the atmosphere through chemical reactions that involve primary pollutants and other air components such as water vapor or oxygen. A notable example is tropospheric ozone (Bălă et al., 2021; Cadar et al., 2023). Ozone ($O_3$) is an allotrope of oxygen, consisting of three oxygen atoms. The atmosphere contains two areas where $O_3$ exists: the stratosphere and the troposphere, both of which share the same chemical composition (Alvim-Ferraz et al., 2024). Most of the $O_3$, approximately 90%, is formed naturally in the stratosphere as a result of ultraviolet radiation interacting with $O_2$. Specifically, the interaction of ultraviolet rays with $O_2$ in the stratosphere leads to the splitting of the $O_2$ into two single oxygen atoms. A released oxygen atom then binds with $O_2$ to create an $O_3$ molecule (Bernhard et al., 2023).

Stratospheric $O_3$ is extremely important for life on Earth, as it prevents a large part of harmful ultraviolet radiation from reaching the Earth's surface. Regrettably, over the past few decades, human activities have notably led to the destabilization of the stratospheric ozone layer. The consequences of stratospheric $O_3$ depletion are manifested through the appearance of ozone holes, which are considered to be, among other things, a result of the adverse effects of various human-made chemicals such as chlorofluorocarbons, methyl bromide, carbon tetrachloride, and methyl chloroform (Chipperfield & Bekki, 2024).

$O_3$ in the lower atmosphere (tropospheric ozone), is created through intricate chemical reactions involving nitrogen oxide gases and volatile organic compounds under sunlight. In this context, it is necessary to note that the production of tropospheric $O_3$ is positively associated with sunshine hours and negatively associated with both relative humidity and wind speed. As a result, the concentration of $O_3$ varies throughout the season and even within the day, exhibiting higher levels during the daytime and in dry months, particularly in areas close to industrial facilities (Nowroz et al., 2024).

Tropospheric $O_3$ is extremely harmful to both humans and animals. Its inhalation, even at relatively low levels, can result in respiratory tract inflammation, migraines, burning eyes, irritation of mucous membranes, chest pain, and asthma attacks (Kim et al., 2020). $O_3$ is also highly toxic to plants. The effect of $O_3$ on plants is reliant on its concentration as well as the duration of exposure. Long-term exposure to low levels of $O_3$ impairs stomatal function, disrupts nutrient uptake and respiration, and decreases the photosynthetic rate, often without any evident destruction to the plant tissues. Conversely, short-term exposure to high levels of $O_3$ results in the initiation of visible lesion formation in leaves (Wang et al., 2024). These disturbances negatively influence plant development and reproductive success, ultimately resulting in lower crop yields and compromised quality. Over the past century, tropospheric $O_3$ levels have risen by 2 to 3 times, which implies that more severe and widespread challenges due to $O_3$ are likely to increase in the future (Donzelli & Suarez-Varela, 2024).

Several studies have demonstrated that plants adapt to $O_3$ pollution by undergoing changes in their molecular, biochemical, and physiological responses, involving large-scale changes in enzyme activities and gene expression (Günthardt-Goerg et al., 2023; Rao et al., 2025). It is also well documented that reactive oxygen species (ROS) generated from the breakdown of $O_3$ in the extracellular space (apoplast) activate multiple signaling pathways that are seamlessly integrated within the cell into a delicately balanced ROS signaling network, which is crucial for the plant's response to $O_3$ stress (Vainonen & Kangasjärvi, 2015). Despite the extensive research in this area, many of these signaling pathways against $O_3$ stress are still not well comprehended. Addressing these knowledge gaps is important for a deeper understanding of how plants react to $O_3$ stress and for creating strategies to reduce and control $O_3$ pollution, particularly in urban areas. This review summarizes recent advances in understanding the strategies that plants use to protect their structural and functional integrity in response to $O_3$ pollution.

## OZONE STRESS SIGNAL PERCEPTION AND TRANSDUCTION IN PLANTS

Several investigations into plant responses to $O_3$ pollution have confirmed that $O_3$, once it enters leaves through stomata, stimulates the excessive production of ROS in the apoplast, including superoxide anion radicals ($O_2^-$), singlet oxygen ($^1O_2$), and hydrogen peroxide ($H_2O_2$) (Podgórska et al., 2017; Montes et al., 2022; Yu & Blande, 2022; Simin et al., 2026). Furthermore, it is thoroughly documented that $O_3$ triggers plasma membrane-bound NADPH-dependent oxidases to create ROS (Sachdev et al., 2021). It is also noted that $O_3$ and $H_2O_2$ can diffuse directly into the cytosol through aquaporins, resulting in the generation of further ROS (Aranda-Rivera et al., 2022).

The overproduction of $O_3$-induced ROS may initiate a wide array of cellular changes, including depolarization of the plasma membrane, alterations in cell wall compounds, ozonolysis of double bonds present in the unsaturated fatty acids in cell membranes, and the activation of signal transduction proteins within the plasma membrane. Thus, the way in which plant cells perceive $O_3$ might be related to the to the modifications in cell walls and plasma membranes resulting from $O_3$-induced ROS (Rebouças et al., 2017). In this context, Kangasjärvi et al. (2005) indicated that three distinct mechanisms may play a role in $O_3$/ROS sensing. These include the generation of lipid-based signaling molecules that result from the oxidation of plasma membrane lipids, alterations in the cellular redox balance caused by the interaction of $O_3$/ROS with redox-active compounds, and the activation of apoplastic receptor proteins that are directly altered by

ROS. Once the sensing process is complete, the signals generated at the membrane-bound receptors or sensors are transformed into cellular responses through a series of signal transduction pathways, including $Ca^{2+}$ signaling pathways and mitogen-activated protein kinase (MAPK) cascades, in addition to numerous plant hormone-dependent pathways (Hasan et al., 2021).

It is also well documented that the signal from apoplastic ROS can be transmitted to the chloroplast via membrane-associated heterotrimeric G proteins, resulting in the subsequent production of chloroplastic ROS. The generation of ROS in chloroplasts also leads to the activation of multiple downstream signaling pathways that may work in parallel, in series, or through a combination of both (Shapiguzov et al., 2012).

Baier et al. (2005) reported that the ozone stress signal transduction in plant cells consist of a two-step process: (1) rapid signaling events that involve $Ca^{2+}$ influx and protein phosphorylation reaction from upstream receptor to downstream target, and (2) the activation of plant hormone-dependent pathways that serve to stabilize and enhance the plant's defense response to $O_3$ stress.

The influx of $Ca^{2+}$ ions from the apoplast into the cytosol through plasma membrane represents the initial step in ozone stress signal transduction in plant cells, occurring in only a few minutes. This event results in an increase in cytosolic-free $Ca^{2+}$ concentration, which then induces rapid changes in the protein phosphorylation pattern (Lee et al., 2021). Phosphorylation reactions are fundamentally significant in signal transduction pathways, facilitating signal transduction and integrating various signaling routes. Protein phosphorylation by specific mitogen-activated protein kinase (MAPK) cascades acts as a crucial pathway that functions downstream of sensors and receptors, translating extracellular signals into intracellular reactions in plant cells when exposed to $O_3$. Each MAPK cascade consists of three kinase modules: MAPK kinase kinases (MAPKKKs), MAPK kinases (MAPKKs), and MAPKs, which are interconnected in different manners to upstream receptors and downstream targets (Majeed et al., 2023). A pathway by which $Ca^{2+}$ influx leads to the activation of the MAPK pathway is well documented. In short, increases in cytosolic free $Ca^{2+}$ levels trigger MAPKKKs, which subsequently phosphorylate MAPKKs. The activated MAPKKs further phosphorylate MAPKs, which, in turn, can activate a diverse range of transcription factors (Lin et al., 2021).

Significant progress in associating MAPKs with $O_3$ stress signaling have emerged from the examination of the model plant *Arabidopsis thaliana* (L.) Heynh. Jagodzik et al. (2018) reported that the *A. thaliana* genome encodes 20 MAPKs, 10 MAPKKs, and 80 MAPKKKs genes. The high number of distinct kinases within the plant genome points to a likely complexity and interaction among MAPK cascades (Sun & Zhang, 2022). In the *A. thaliana* MAPK signaling pathways, two well-known MAPKs, MAPK3 and MAPK6, serve as crucial regulators that are activated in reaction to $O_3$ stress (Jiang et al., 2025). Their activation occurs within a period of 10 to 30 minutes after $O_3$ exposure, highlighting it as one of the earliest events in intracellular signaling. Once activated, MAPK3/6 translocate into the nucleus, where they regulate the expression of specific genes responsible for the synthesis of various stress-related proteins (Yadav & Mina, 2022). Several studies have shown that a considerable similarity exists in the gene expression patterns observed in plants exposed to $O_3$ and those showing responses to pathogen attack, suggesting that $O_3$-induced ROS may initiate programmed cell death (PCD) similar to a hypersensitive response in plant pathogenesis (Leppälä et al., 2022). PCD refers to an active and genetically regulated process through which plants eliminate unwanted and potentially harmful cells. It is also a common feature in plant development: it can be observed during floral organ abortion, senescence, tracheary element formation, and the formation of aerenchyma. The prevailing assumption is that $O_3$-initiated PCD acts as an initiator for lesion formation in leaves, which in turn limits the spread of oxidative bursts triggered by $O_3$ degradation in the apoplast (Bartoli et al., 2013). $O_3$-induced PCD is a highly organized process that is regulated by a complex network of signaling pathways, including those activated by plant hormones. Multiple research studies have demonstrated

that the accumulation of salicylic acid (SA) in $O_3$-exposed plants is correlated with the formation of leaf lesions, suggesting that SA plays an important role in $O_3$-induced PCD (Tamaoki, 2008; Poór, 2020; Modesti et al., 2023). Faoro and Iriti (2009) noted that SA can suppress $H_2O_2$-scavenging enzymes, thus promoting the adverse effects of ROS on plant cells, leading to PCD. Plant exposure to $O_3$ also activates signaling pathways that result in an increased accumulation of ethylene (ET) in plant cells (Guo et al., 2018). MAPK3/6 play a significant role in regulating ET production, as they are involved in the phosphorylation of aminocyclopropane-1-carboxylic acid synthase (ACCS), which is crucial for ET synthesis (Liu & Zhang, 2004). This leads to increased cellular ACCS activity and, as a result, enhanced ET production. It is generally accepted that ET has a role similar to that of SA in $O_3$-induced PCD; however, there are doubts about whether it carries out this function in conjunction with SA or independently (Vahala et al., 2003). The hypothesis that both SA and ET together modulate cell death in $O_3$-sensitive plant genotypes, and that $O_3$-induced ET synthesis is a result of increased cell death caused by SA, is widely accepted among scientists (Grantz & Vu, 2012; Xu et al., 2015). The heightened synthesis of jasmonic acid (JA) and its methyl ester, methyl jasmonate (MeJA), is another outcome of exposing the plant to $O_3$ stress (Rehman et al., 2023). Li et al. (2022) noted that JA derivatives are involved in limiting lesion spreading by antagonizing the cell death-promoting functions of SA and ET. This aligns with the conclusions presented in two previous studies (Rao et al., 2000; Zhou et al., 2020). Numerous studies have also confirmed that foliar abscisic acid (ABA) levels also escalate rapidly once plants are exposed to $O_3$ (McAdam et al., 2017; Guo et al., 2020; Xu et al., 2026). It is assumed that ABA plays a role in the response to $O_3$ stress by stimulating guard cells to close stomata, thereby reducing the likelihood of $O_3$ entry and lesion initiation (Kashtoh & Baek, 2021). However, recent studies have shown a decrease in stomatal sensitivity to ABA depending on ET, highlighting the antagonistic roles of ABA and ET in regulating stomatal movement when plants are faced with $O_3$ stress (Wilkinson & Davies, 2010; Müller, 2021). As an illustration, in various plant species, ET is noted to promote stomatal opening, consequently hindering ABA-induced stomatal closure (Song et al., 2023; An et al., 2025; Huang et al. 2025). Figure 1 displays a simplified schematic diagram that depicts the key signaling pathways related to plant responses under $O_3$ stress.

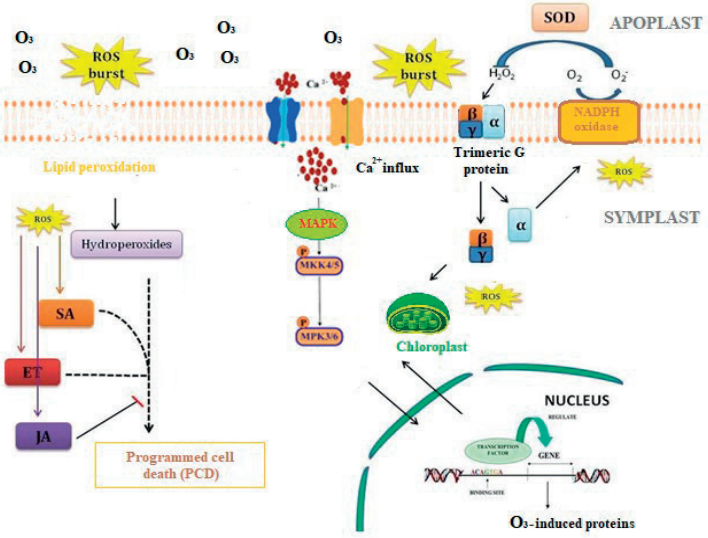

Figure 1. A schematic diagram of the key signaling pathways involved in the plant's response to $O_3$ stress

## PLANT DEFENSE MECHANISMS AGAINST OZONE STRESS

Plants display a complex set of defense strategies against $O_3$ stress, including stomatal regulation of $O_3$ influx into leaves, photosynthetic adjustments, modulation of antioxidant defense against $O_3$-induced reactive oxygen species (ROS), and secondary metabolism.

### Stomatal regulation

Stomatal closure is the first response to $O_3$ stress in most plants, which occurs within a few minutes of being exposed to $O_3$, thereby restricting the uptake of $O_3$ through the stomata. The anion channels in guard cells are crucial in controlling the size of stomatal pores (Chen et al., 2022). There are two categories of anion channels found in the plasma membrane of guard cells: R (rapid)-type and S (slow)-type, both activated in guard cells by the stress hormone ABA. Specifically, upon exposure to $O_3$ stress, guard cells show a substantial rise in ABA and ROS levels, which initiates a cascade of signaling events that activate anion channels. The outcome of this activation is the efflux of ions ($K^+$, $Cl^-$ and malate) from the guard cell, which ultimately decreases turgor pressure, thereby resulting in the closure of the stomata (Saito & Uozumi, 2019).

The S-type slow anion channel 1 (SLAC1) is recognized as one of the significant and extensively studied anion channels (Deng et al., 2021). The plant hormone ABA initiates the activation of SLAC1 via a signaling pathway that includes ABA receptors and protein phosphatase 2C (PP2C). These components are involved in the activity of $Ca^{2+}$-independent kinase Open Stomata 1 (OST1) along with various $Ca^{2+}$-dependent protein kinases that phosphorylate SLAC1 (Bharath et al., 2021). SLAC1 phosphorylation may also take place via an ABA-independent signaling pathway, which is triggered by $O_3$-induced ROS and facilitated by $Ca^{2+}$-dependent protein kinases (CDPKs) (Munemasa et al., 2015).

Despite the fact that stomatal closure under $O_3$ stress conditions is very beneficial for the plant's survival by minimizing $O_3$ uptake and its damaging oxidative effects, it should not be ignored that this closure has a detrimental effect on photosynthesis as a result of reduced $CO_2$ intake (Lee et al., 2021). Additionally, $O_3$-induced ROS can cause harm to the chloroplast ultrastructure and interfere with the photosynthetic electron transport chain, thereby further hindering the photosynthetic rate. As a consequence, plant growth and development are adversely impacted (Ramya et al., 2021).

### Photosynthetic adjustments

$O_3$-tolerant plants possess inherent defense mechanisms that enable them to adjust photosynthesis to $O_3$ stress, thus reducing the damage that arises from $O_3$. The main mechanisms encompass the regulation of the photosynthetic electron transport chain, the increase in anthocyanin production to protect the photosynthetic apparatus, and the regulation of photosynthetic protein transcription (Upadhyay et al., 2025).

The regulation of the photosynthetic electron transport chain under $O_3$ stress conditions can be achieved through photorespiration, cyclic electron flow, and the alternative oxidase pathway. These mechanisms work in unison to protect the plants from photoinhibition and maintain cellular redox homeostasis within the cell.

Photorespiration starts with the oxygenation of ribulose-1,5-bisphosphate (RuBP) resulting in the formation of 3-phosphoglycerate (3-PGA) and 2-phosphoglycolate (2-PG), which is partially recycled into the $C_3$ cycle through the photorespiration pathway. This process is commonly seen as a wasteful process because it generates 2PG, a compound that is harmful to numerous enzymes involved in photosynthetic metabolism, and it oxidizes organic carbon without apparently producing ATP (Shi & Bloom, 2021). However, under stressful conditions, photorespiration is of exceptional importance for plant functionality for several reasons. First, photorespiration acts as a protective mechanism to dissipate excess light energy, safeguarding the photosynthetic machinery from photoinhibition (Smith et al., 2024). Second, the oxygenation of RuBP requires large quantities of ATP and NADPH, resulting in the regeneration of ADP and $NADP^+$, which are crucial for the light-dependent reactions of photosynthesis (Nazari et al., 2024). Third, glycine, generated as the

ultimate product of photorespiration, is required for the synthesis of glutathione, a crucial part of antioxidant defense systems in plants (Voss et al., 2013).

Cyclic electron flow (CEF) serves as another protective mechanism for photosynthetic apparatus under $O_3$ stress. During CEF, electrons are recycled through photosystem I, leading to the production of ATP without concomitant production of NADPH, thus raising the ATP/NADPH ratio essential for the Calvin cycle (Wang et al., 2023a). Additionally, CEF helps to prevent the excessive reduction of the acceptor side of photosystem I (PSI), consequently reducing the generation of superoxide anion radicals and protecting PSI from photoinhibition (Cun et al., 2022).

Maintaining a fine balance between energy production and utilization is fundamentally significant for plants' survival in adverse conditions, including those caused by $O_3$ exposure. Several studies have shown that under abiotic stress, plant cells activate the alternative oxidase (AOX) pathway in their mitochondria, apart from the cytochrome (Cyt) pathway, which is the main mitochondrial electron transport chain (Vanlerberghe et al., 2013; Dinakar et al., 20160). This alternative AOX pathway features a cyanide-resistant ubiquinol oxidase located in the inner mitochondrial membrane, which facilitates the direct transfer of electrons from the ubiquinone pool to oxygen, circumventing the proton-pumping complexes III and IV. By circumventing Complex III and IV, AOX significantly diminishes ATP production, leading to the energy being transformed into heat (Li et al., 2024). Most importantly, AOX aids in preventing the overreduction of upstream electron-transport components, thereby decreasing ROS formation. Under stress conditions, this is of significant importance for the plant as it reduces further potential damage to cellular components, including the photosynthetic machinery (Manbir et al., 2022).

Anthocyanins, water-soluble pigments in plant cells, play a crucial role in alleviating photoinhibition due to their ability to absorb harmful UV radiation (280-315 nm), thus protecting intracellular components, including chloroplasts, from potential damage (Agati et al., 2021). They also possess strong antioxidant activities, preventing or reducing the damage caused by ROS. Anthocyanins exhibit their antioxidant effects mainly through hydrogen atom transfer (HAT) and single-electron transfer (SET) mechanisms. In the HAT mechanism, anthocyanin interacts with ROS by transferring one of its hydrogen atoms to the ROS through the homolytic cleavage of an -OH bond. In contrast, the SET mechanism involves the transfer of a single electron from the anthocyanin to the ROS, resulting in the ionization of both substances in the process (Sadowska-Bartosz & Bartosz, 2024).

Unlike anthocyanidins, the levels of chlorophyll and photosynthetic proteins significantly decrease under $O_3$ stress conditions, which in turn reduces photosynthetic capacity and efficiency, particularly in older leaves. This implies that the transcript levels of genes encoding proteins involved in the light-dependent reactions, the Calvin cycle, and pigment synthesis are significantly reduced under $O_3$ stress conditions (Han et al., 2023). Their reduction does not, however, necessarily translate to weakening the plant. Moreover, many scientists view a decline in the photosynthesis rate under stress conditions as a hidden cost of defense, as the plant reallocates its resources from growth to defense in order to overcome stressful conditions as quickly as possible (Huot et al., 2014; Serrano-Mislata et al., 2025; Zrimec et al., 2025). If this occurs, the plant increases the rate of photosynthesis to provide the resources necessary for its further growth and development.

Conversely, the genes involved in the signaling network and defense mechanisms against $O_3$ stress have different transcriptomic responses; their expression increases under $O_3$ stress (Ludwikow & Sadowski, 2008).

**Modulation of antioxidant defense system**

Plenty of studies have shown that $O_3$, after entering leaves, induces the accumulation of ROS in the apoplast through its conversion into superoxide anion radicals ($O_2^-$), hydrogen peroxide ($H_2O_2$), or singlet oxygen ($^1O_2$) upon interaction with water (Keutgen & Pawelzik, 2008; Vahisalu et al., 2010; Vaultier & Jolivet,

2015). ROS are well-known for their dual role in plants, functioning as both damaging and advantageous species (Panda et al., 2024). On the one hand, they are crucial in integrating external and intracellular signals, while also acting as critical regulators of plant growth and development. On the other hand, their overproduction at levels that go beyond the antioxidant scavenging capacity results in oxidative stress, recognized as a damaging process involved in the destruction of cell structures (Alam et al., 2025).

Antioxidant compounds in the apoplast serve as the initial defense against ROS, with ascorbate and glutathione being the main non-enzymatic ROS scavengers (Cannea & Padiglia, 2025). Piechowiak et al. (2026) reported that exposure of radish sprouts to $O_3$ stress resulted in a significant increase in ascorbate content by 14% and glutathione by 25% compared to the control. The observed increases in ascorbate and glutathione levels were associated with a heightened expression of proteins that play a role in the biosynthesis of these metabolites.

The ability of plants to neutralize $O_3$-induced ROS is not limited to only these two metabolites. The detoxification of ROS involves a sophisticated network that also includes various non-enzymatic antioxidants, such as tocopherols and flavonoids, along with enzymatic antioxidants (Hasanuzzaman et al., 2020). In this context, several studies have shown that under $O_3$ stress, plants are capable of enhancing their antioxidative systems by stimulating the gene expression and post-translational modifications of antioxidant enzymes such as superoxide dismutase (SOD), ascorbate peroxidase (APX), and catalase (CAT) (Mishra et al., 2023; Wang et al., 2023b; Jin et al., 2025). SOD catalyzes the dismutation of two molecules of $O_2^-$ to less hazardous molecules: $H_2O_2$ and molecular oxygen (Rajput et al., 2021). $H_2O_2$ is extremely dangerous when present in high concentrations, as it converts into hydroxyl radicals, the most reactive and destructive ROS, which can cause irreversible damage to cellular structures. However, plant cells possess a strong antioxidant defense mechanism to counteract $H_2O_2$, with CAT and APX serving as the main enzymes for neutralizing $H_2O_2$ (Černý et al., 2018). CAT protects the cell against $H_2O_2$ by facilitating its breakdown into $O_2$ and $H_2O$, while APX decomposes $H_2O_2$ using ascorbate as an electron donor (Gomes et al., 2022). In general, the plant under $O_3$ exposure initiates numerous signaling pathways, all aimed at enhancing antioxidant capacity, either by producing enzymatic or non-enzymatic antioxidants or by generating metabolites that contribute to repairing damage caused by oxidative stress.

**Secondary metabolism**

In response to $O_3$ stress, the plant enhances the production of secondary metabolites, which are organic compounds that serve as a defense against both biotic and abiotic stresses. Guo et al. (2024) reported that $O_3$ exposure greatly increased the rate of carbon flux into secondary metabolic pathways, causing a change in resource allocation that affected the synthesis of secondary metabolites. All plants are able to produce secondary metabolites (SMs), especially under $O_3$ stress conditions, but this process exhibits remarkable genotypic variation and high phenotypic plasticity (Gu et al., 2025). SMs consist of a broad spectrum of compounds, featuring more than 12,000 alkaloids, 40,000 isoprenoids, and 8,000 phenylpropanoids, all of which are uniquely produced by plants (Elshafie et al., 2023). It is estimated that the total number of SMs surpasses 200,000; nonetheless, the actual figure is likely much greater (Nomura et al., 2018).

On the basis of their chemical structures, SMs can be broadly divided into three categories: terpenoids, phenolic compounds, and nitrogen-containing compounds. Among terpenoids, the most common compounds include sterols, carotenoids, saponins, and glycosides. In the category of phenolic compounds, flavonoids, phenolic acids, lignin, and tannins are prominent, while among nitrogen-containing compounds, alkaloids are the most represented (Jan et al., 2021).

Depending on their volatility, SMs in plants can be classified as either non-volatile or volatile. Volatile SMs are often characterized by a complex mixture of low-molecular-weight lipophilic compounds that mainly arise from terpenoid biosynthetic pathways, seemingly produced as a defense mechanism to prevent $O_3$

uptake. Volatile SMs also affect the interactions between plants and their habitats, playing a crucial role in coordinating plant-environment relationships (Abbas & Wang, 2025).

The phenylpropanoid, terpenoid, and alkaloid pathways represent the major metabolic pathways through which plant SMs are synthesized. Among these, the phenylpropanoid metabolic pathway is recognized as the most important secondary metabolic pathway associated with defense against abiotic stress, as it contributes directly or indirectly to the antioxidant defense systems in plants (Jangpangi et al., 2025). Some of the more significant end products of the phenylpropanoid pathway are flavonoids, hydroxycinnamic acid esters, and the precursors of lignin and tannins, all of which belong to phenolic compounds (Ninkuu et al., 2025). The importance of phenolic compounds lies not only in their ability to enhance the antioxidant capacity of the plant but also in their contribution to aesthetic quality parameters like color and taste, indicating their significant role in the adaptation of plants to the specific conditions of their native habitats (Kisiriko et al., 2021).

Alkaloids are another important class of plant SMs that play an important role in the plant's response to challenging living conditions, such as $O_3$ stress. $O_3$-induced alkaloid accumulation in plants has been documented in various studies, indicating that plants initiate alkaloid biosynthesis as a compensatory defense mechanism (Ansari et al., 2021; Pant et al., 2021; Ansari et al., 2023). Overall, alkaloids act as strong chemical deterrents, enhancing the plant's defense systems against environmental challenges. It is also important to note that certain SMs, including plant hormones JA, SA, and ET, serve as signaling molecules that help plants initiate signaling pathways aimed at producing substances that support their adaptation to unfavorable living conditions, particularly pronounced under $O_3$ stress.

## CONCLUSIONS

$O_3$ pollution represents a significant global environmental issue, as its levels consistently rank among the most highly toxic air pollutants. Plants have evolved a complex set of defense mechanisms against $O_3$ stress, including $O_3$-induced stomatal regulation, photosynthetic adjustments, modulation of the antioxidant defense system, and secondary metabolism. In most plants, the first response to $O_3$ stress is stomatal closure, which takes place within a few minutes of $O_3$ exposure, consequently restricting $O_3$ uptake through the stomata. One negative outcome of this is the decreased influx of $CO_2$ into the leaves, resulting in a decline in photosynthetic rate. Additionally, $O_3$-induced ROS interfere with the photosynthetic electron transport chain, thereby further hindering the photosynthetic rate. However, plants possess inherent defense mechanisms that enable them to adjust photosynthesis to $O_3$ stress, including the regulation of the photosynthetic electron transport chain and an increase in anthocyanin production to protect the photosynthetic apparatus. Plants also possess various non-enzymatic and enzymatic antioxidants that assist in neutralizing the excessive production of ROS under $O_3$ stress conditions. A significant role in enhancing the plant's defense capacities against $O_3$ stress is played by numerous secondary metabolites that the plant intensively produces under such conditions. The value of these metabolites is twofold: they enhance the antioxidant capacity of the plant and serve as signaling molecules that facilitate the initiation of signaling pathways in plants aimed at producing substances that support the plant's adaptation to unfavorable living conditions.

***Abstract***

*Biosurfactants produced by microorganisms from saline environments have attracted increasing interest due to their potential to remain functional under conditions that limit the efficiency of chemical surfactants. The aim of the present study was to evaluate the physicochemical stability and emulsifying activity of a crude biosurfactant produced by a bacterial isolate from the Techirghiol saline lake. The experimental design included testing the biosurfactant at different pH values, NaCl concentrations, and temperatures, by determining the emulsification index at 24 h. Emulsifying performance was further evaluated in a simplified diesel-contaminated saline-water microcosm at different salinities. This study examines how the biosurfactant performs under high-salinity conditions and indicates potential value for hydrocarbon dispersion and microbial activity in saline environments.*

***Key words:*** *bacteria, biosurfactants, diesel, physicochemical stability, saline environments.*

## INTRODUCTION

Saline and hypersaline environments, from coastal salterns and salt lakes to industrial brines, are increasingly exposed to hydrocarbon contamination associated with oil extraction, transportation, and refining activities. In such ecosystems, high ionic strength and reduced water activity may limit the effectiveness of conventional chemical surfactants and hinder the natural attenuation of petroleum hydrocarbons. Therefore, halophilic and halotolerant microorganisms represent promising sources of surface-active compounds capable of retaining functionality under high salinity, as well as under pH and temperature conditions that inhibit many traditional surfactant-producing organisms (Edbeib et al., 2016).

Microbial biosurfactants decrease surface and interfacial tension and facilitate the emulsification of hydrophobic compounds, including petroleum hydrocarbons. This process enhances dispersion in aqueous environments and can increase substrate bioavailability for microbial degradation. Biosurfactants comprise a structurally diverse group of molecules, predominantly glycolipids, lipopeptides, and phospholipids, whereas high molecular weight bioemulsifiers primarily contribute to emulsion stabilization rather than lowering surface tension (Silva et al., 2022).

Many biosurfactants are biodegradable and exhibit relatively low toxicity. Moreover, they can remain active under environmental conditions in which certain synthetic surfactants show reduced performance. These features support their potential application in bioremediation, enhanced oil recovery, and the treatment of petroleum hydrocarbon-contaminated water (Sun et al., 2018; Ali et al., 2021; Lima et al., 2024).

Biosurfactants produced by isolates obtained from petroleum-impacted environments (e.g., soils and related sites) have been described to retain surface activity and emulsification capacity under high-salinity conditions (Sun et al., 2018; Ali et al., 2021; Silva et al., 2022). Similarly, investigations of biosurfactants derived from halophilic microorganisms indicate that these compounds can remain functional in saline conditions, although performance may vary depending on the producing strain and the biosurfactant class (Gomes et al., 2018; Barakat et al., 2017; Waghmode et al., 2019; Wu et al., 2022). Recent studies on diesel-contaminated saline soils further demonstrate that the addition of

biosurfactants can improve hydrocarbon removal under salinity stress (Barzegar et al., 2025). Together with similar reports, these findings highlight the biotechnological potential of halophilic or halotolerant microorganisms from saline environments, which are comparatively less explored than marine ecosystems.

Despite progress in this field, stability is not always evaluated using approaches that reliably predict performance under application-relevant conditions. In several studies, surface tension reduction is considered the primary indicator of stability, whereas assays involving petroleum-derived substrates are performed separately or with limited methodological integration. Consequently, establishing a direct link between reported physicochemical stability and actual functional performance in saline systems remains challenging.

In this context, the present study investigates a selected halotolerant isolate and its crude biosurfactant. The specific objectives were: (i) to evaluate the stability of the crude biosurfactant under different pH values, temperatures, and NaCl concentrations using the emulsification index, and (ii) to assess its diesel emulsification performance in simplified saline-water microcosm systems.

## MATERIALS AND METHODS

### Sampling and bacterial isolation

Water and mud samples used in this study were collected in summer 2024 from Lake Techirghiol (Latitude: 44.05318° N, Longitude: 28.60330° E), located in Constanța County, Romania. Surface water was sampled in sterile containers, and bottom mud was collected from a depth of 10 cm using a sterile spatula. Samples were kept in an icebox during transport and transferred directly to the laboratory for further analysis.

The isolation medium used for the bacteria included in this study was prepared according to Ventosa et al. (1982), with minor modifications, and had the following composition (g/L): $MgSO_4$ 1.0, $CaCl_2 \cdot 2H_2O$ 0.36, KCl 2.0, $NaHCO_3$ 0.06, NaCl 100, peptone 5.0, glucose 1.0, yeast extract 10.0, and agar 20.0.

Serial decimal dilutions ($10^{-1}$-$10^{-3}$) of the water and mud samples were prepared in sterile saline solution (5% NaCl, w/v) and inoculated onto the same agar medium (10% NaCl) by the pour plate method (Sanders, 2012). Briefly, 1.0 mL of each dilution was transferred to sterile Petri dishes and mixed with molten agar medium. The plates were incubated aerobically at 30°C for 5-7 days. The number of viable microorganisms was expressed as CFU/mL for water and CFU/g for the mud sample. Representative colonies were purified by repeated streaking on solid isolation agar until morphologically uniform growth was obtained. Isolates with distinct colony morphologies were routinely cultivated on Luria-Bertani (LB) (Sezonov et al., 2007) medium supplemented with 5% (w/v) NaCl. Stocks were prepared in glycerol and stored at −80°C.

Chloride concentration was determined by argentometric titration using the Mohr method (Hauser, 2002).

### Biosurfactant screening and assays

Isolates were cultivated in LB broth supplemented with 5% (w/v) NaCl at 30°C under agitation (150 rpm) for 72 h. Following incubation, cultures were centrifuged (7500 rpm for 10 min), and the resulting cell-free supernatant (CFS) was collected for subsequent analyses as crude biosurfactant extract. Emulsifying capacity was evaluated by determining the 24 h emulsification index ($E_{24}$), in accordance with the protocol described by Stancu (2024). CFS was mixed with diesel fuel, vortexed (3 min), and left to stand at room temperature for 24 h. Positive and negative controls were included. Biosurfactant production was also analyzed using the CTAB (cetyltrimethylammonium bromide) agar plate method as described by Neagu & Stancu (2025). Cultures were spot-inoculated (20 µL) onto the CTAB agar, air-dried, and incubated at 30°C for 3-5 days. A dark blue halo around the colony was considered a positive reaction.

### Characterization of halotolerant bacteria

#### Phenotyping features and rep-PCR fingerprinting

The selected isolates were preliminarily characterized based on colony morphology on saline agar (cell shape, pigmentation, colony margin), Gram reaction, motility, growth temperature, growth on LB agar supplemented

with 0-20% (w/v) NaCl, as well as the basic biochemical traits, including catalase and oxidase activities. Growth on eosin methylene blue (EMB) agar was recorded as part of differential phenotypic profiling.

Diesel tolerance was evaluated using the hydrocarbon overlay agar method (Stancu, 2025). Cultures were spot-inoculated (20 µL) onto LB and minimal salt (MSM) agar (Stancu, 2023), air-dried, and overlaid with diesel for 2 h. After removal of the diesel, plates were incubated at 30°C for 1-5 days. Tolerance was assessed by comparing colony growth with the control (plates not exposed to diesel).

Genomic DNA was extracted from bacterial isolates using the PureLink Genomic DNA Kit (Invitrogen, Carlsbad, CA, USA). Repetitive extragenic palindromic polymerase chain reaction (REP-PCR) was performed using genomic DNA, the $(GTG)_5$ primer, and GoTaq G2 Flexi DNA polymerase (Promega, Madison, WI, USA) according to the method previously described (Stancu, 2015). PCR was performed in a Mastercycler pro S (Eppendorf, Germany) with initial denaturation at 94°C for 10 min, 35 cycles (94°C for 1 min, 52°C for 1 min, 65°C for 8 min), and a final extension at 65°C for 16 min. PCR products were separated by electrophoresis on 2.0% (w/v) agarose gels stained with SYBR Safe DNA Gel Stain (Invitrogen).

**Salt tolerance and physicochemical stability of the biosurfactant produced by T3 isolate**

For the salt tolerance assay, a fresh overnight culture was grown in LB broth with or without 1% (v/v) diesel, and HM broth (Ventosa et al., 1982) with 1% (v/v) diesel. Then, cultures were spot-inoculated (20 µL) onto the LB agar with 0, 5, 10, 15, and 20% NaCl (w/v) and incubated at 30°C for 72 h.

The physicochemical stability of the crude biosurfactant produced by isolate T3, was evaluated by measuring the $E_{24}$ after exposure to different temperature, pH, and salinity conditions. Thermal stability was assessed by incubating CFS aliquots at 20-100°C for 60 min, followed by cooling to room temperature. pH stability was tested over a range of pH 4-9, adjusted using 0.1 N HCl or 0.1 N NaOH. Salinity stability was examined by adjusting NaCl to final concentrations of 0-20% (w/v). After each treatment, emulsification activity ($E_{24}$) was determined. A negative control was prepared under identical conditions without CFS.

**Diesel emulsification in simplified saline-water microcosms**

Diesel emulsification was evaluated in simplified saline-water microcosms at different salinity levels. Microcosms were prepared by mixing CFS, sterile saline solution (0, 5, 10, 15, or 20% NaCl, w/v), and diesel fuel at a 2:2:1 (v/v/v) ratio. Samples were vortexed for 3 min and left for 24 h at room temperature, after which $E_{24}$ was recorded. A negative control was prepared under identical conditions without CFS.

## RESULTS AND DISCUSSIONS

Lake Techirghiol is located in Constanța County, southeastern Romania, in the coastal zone of the Black Sea. It is described as a unique Romanian ecosystem due to its hypersaline character and the high productivity associated with the formation of therapeutic sapropelic mud. Long-term records indicate pronounced variations in water level and salinity, while the lake remains highly mineralized overall (Barbulescu & Barbes, 2013).

The physicochemical data obtained indicate that Lake Techirghiol is a salt-rich environment with high ionic strength, providing favourable conditions for the growth of halophilic and halotolerant microorganisms. The pH of the water was 8.35, consistent with the alkaline profile reported for this lake (Maftei et al., 2020). The chloride ion concentration in the water and mud samples was 60 g/L and 25 g/L, respectively. Bacterial abundance in the water sample was $9.3 \times 10^3$ CFU/mL, in line with previous reports for Techirghiol surface water (Aonofriesei, 2007). The higher viable count in the mud sample ($1.1 \times 10^5$ CFU/g) suggests that sediment provides a more favorable environment for bacterial growth, likely due to its greater organic matter content and protective conditions against environmental stress.

**Biosurfactant screening** was first performed on thirty-six isolates obtained from water and mud samples using the diesel emulsification assay. The results showed that six (T1-T6) isolates

produced extracellular compounds with high emulsification capacity, as indicated by $E_{24}$ values ranging from 90% to 100% (Table 1, Figure 1a). The $E_{24}$ index reflects the stability of the hydrocarbon-water emulsion after 24 h; high values therefore indicate strong biosurfactant-producing ability. While other halophilic and halotolerant bacteria have been reported to produce emulsifying compounds, their $E_{24}$ values are generally lower and depend on the strain, hydrocarbon type, and assay conditions. For example, haloalkaliphilic *Bacillus* strains showed $E_{24}$ values of approximately 56-57% (Barakat et al., 2017), while similar values (~56%) were reported for halophilic isolates from saltern environments (Berberov et al., 2026). The high $E_{24}$ values obtained in the present study suggest that the halotolerant isolates produce extracellular surface-active compounds capable of stabilizing the water-diesel interface. In saline environments, the secretion of extracellular products can contribute to stress adaptation (e.g., biofilm formation, exopolysaccharide matrix development), while also facilitating interaction with hydrophobic compounds (Bhat & Roach, 2025; Berberov et al., 2026). In contrast, none of the isolates produced a detectable halo on CTAB agar, consistent with the absence of detectable rhamnolipid production.

**Characterization of halotolerant bacteria**
**Phenotyping features**

Six representative halotolerant isolates (T1-T6) were selected from Lake Techirghiol water and mud samples and subjected to preliminary phenotypic characterization, including some biochemical assays. The results are summarized in Table 1.

Table 1. Characterization of halotolerant bacterial isolates

| Characteristics | Isolate | | | | | |

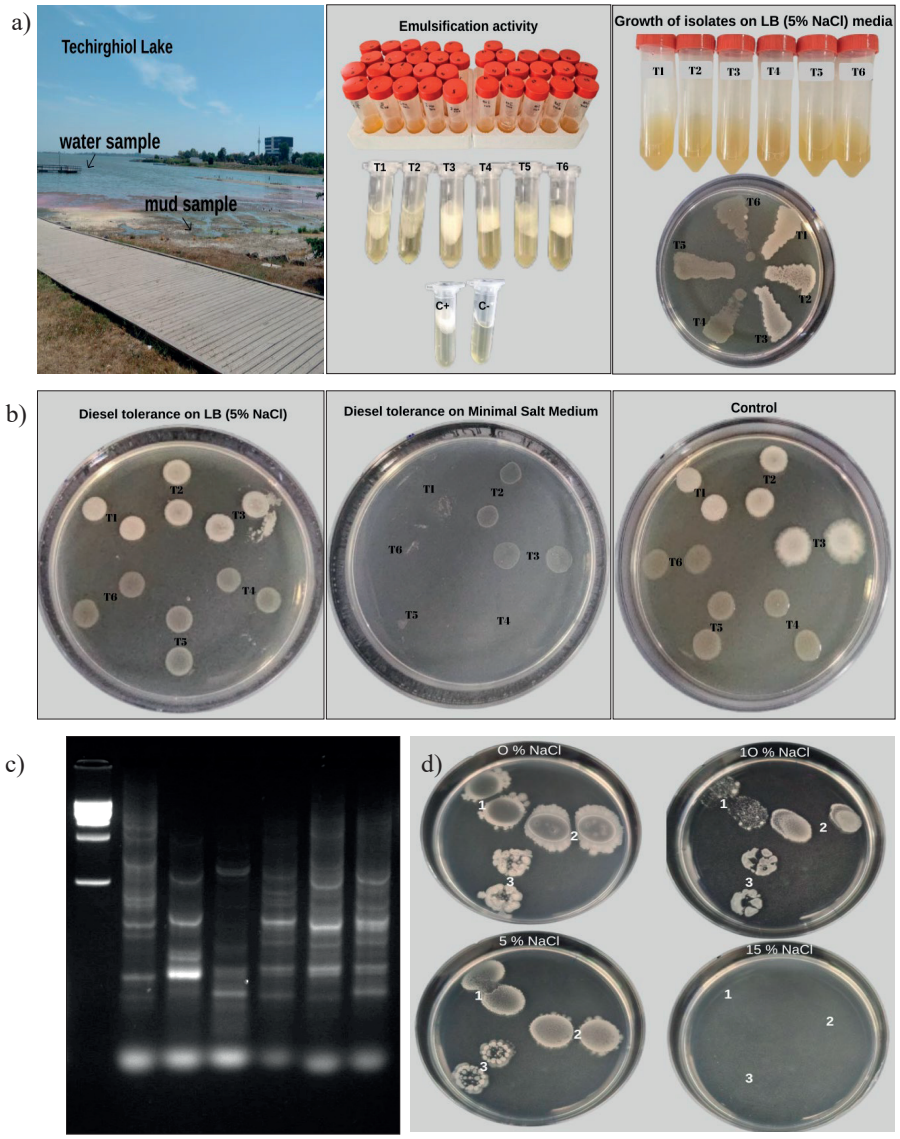

Figure 1. Isolation, screening and characterization of halotolerant bacteria
a) water and mud samples from Lake Techirghiol; emulsification activity of the CFS; isolates growth on LB-NaCl 5%; b) diesel tolerance of T1–T6 isolates on LB and MSM agars, as compared with control (LB agar); c) $(GTG)_5$ rep-PCR fingerprinting of T1–T6 isolates; 1 kb DNA ladder (M). d) Salt tolerance of T3 grown in LB broth (1), LB-diesel 1% (2), HM-diesel 1% (3)

T3 was isolated from Techirghiol mud, whereas T1, T2, T4, T5, and T6 were obtained from surface water. Gram staining revealed a differentiated profile among the isolates: T2, T3, T4, T5, and T6 were Gram-positive, whereas T1 was Gram-negative. Based on visual inspection, colony pigmentation was grouped into two categories: cream (T1-T3) and beige (T4-T6). Colony margins were predominantly regular, except for T3, which showed irregular margins. This isolate consisted of rod-shaped, motile cells. Salinity tolerance on LB agar was evaluated at 0%, 5%, 10%, 15%, and 20% (w/v) NaCl. Growth was robust up to 10% NaCl, whereas no colonies were observed at 15% or 20% NaCl, consistent with a halotolerant profile. All isolates grew at 30°C. On EMB agar, T2, T3 and T4 isolates showed no lactose-fermentation phenotype, indicating a lactose-negative reaction. In contrast, T1, T5, and T6 did not form colonies on this medium.

Diesel tolerance was observed for all six isolates on LB agar, as indicated by growth comparable to the control. In contrast, on MSM in the presence of diesel, only isolates T2 and T3 exhibited reduced growth, whereas T1 and T4-T6 showed no growth (Table 1, Figure 1b). Notably, isolates T1, T4, T5, and T6 failed to grow following hydrocarbon overlay, indicating strain-dependent differences under nutrient-limited conditions.

$(GTG)_5$ REP-PCR fingerprinting revealed distinct profiles for all selected isolates (Table 1, Figure 1c). The water-derived isolates (T1, T2, T4, T5, and T6) exhibited banding patterns ranging from approximately 200 to 3500 bp, whereas T3 displayed a narrower size range (approximately 200-1700 bp) and a clearly distinct fingerprinting. This distinct pattern indicates genetic variability among the isolates and highlights the divergent genomic profile of T3.

Overall, these findings suggest that biosurfactants produced by these halotolerant isolates exhibit properties that could be exploited for hydrocarbon bioremediation and the restoration of saline or contaminated soils, although further studies are needed to confirm their efficacy *in situ*.

**Salt tolerance and physicochemical stability of the biosurfactant produced by T3 isolate**

Based on its maximal $E_{24}$ and overall screening performance, T3 was selected for subsequent assays. Before evaluating the physicochemical stability of its biosurfactant, the salinity tolerance of T3 was assessed by spot growth on LB agar containing 0-20% (w/v) NaCl. The bacterium exhibited robust growth at 0-10% NaCl, whereas no growth was observed at 15% or 20% NaCl (Figure 1d). Colony morphology varied with the pre-culture medium, consistent with phenotypic adaptation (e.g., changes in cell-surface traits and extracellular polymers) rather than alteration in halotolerance.

The stability of the cell-free culture supernatant from T3 was subsequently evaluated under different temperature, pH, and salinity conditions after 60 minutes of exposure, using $E_{24}$ to quantify emulsification activity (Figure 2).

Thermal stability was tested between 20 and 100°C. Emulsification remained high at moderate temperatures, with $E_{24}$ values of 90-100% at 20-30°C and 80% at 40°C. Activity was still substantial at 50°C and 60°C (~73%), indicating notable heat tolerance. A sharp decline occurred at 80°C (~23%), and no emulsification was detected after exposure to 100°C, suggesting that prolonged heating severely impairs the biosurfactant's activity.

pH stability was evaluated from 4 to 9. The emulsification index remained high under acidic conditions, with $E_{24}$ values of ~93% at pH 4 to 5 and ~83.3% at pH 6. Activity decreased markedly at pH 7 (~27%) and remained low at pH 8 to 9 (~10%), indicating strong sensitivity around neutral to slightly alkaline pH values.

Salinity stability was tested by adjusting NaCl to final concentrations of 0-20% (w/v). $E_{24}$ values were maximal at 0-5% NaCl (100%) and decreased at 10% NaCl (80%), with complete loss of emulsification at 15-20% NaCl. These data suggest that the CFS from T3 is highly effective under moderate salinity, whereas higher salt concentrations significantly compromise its emulsifying performance.

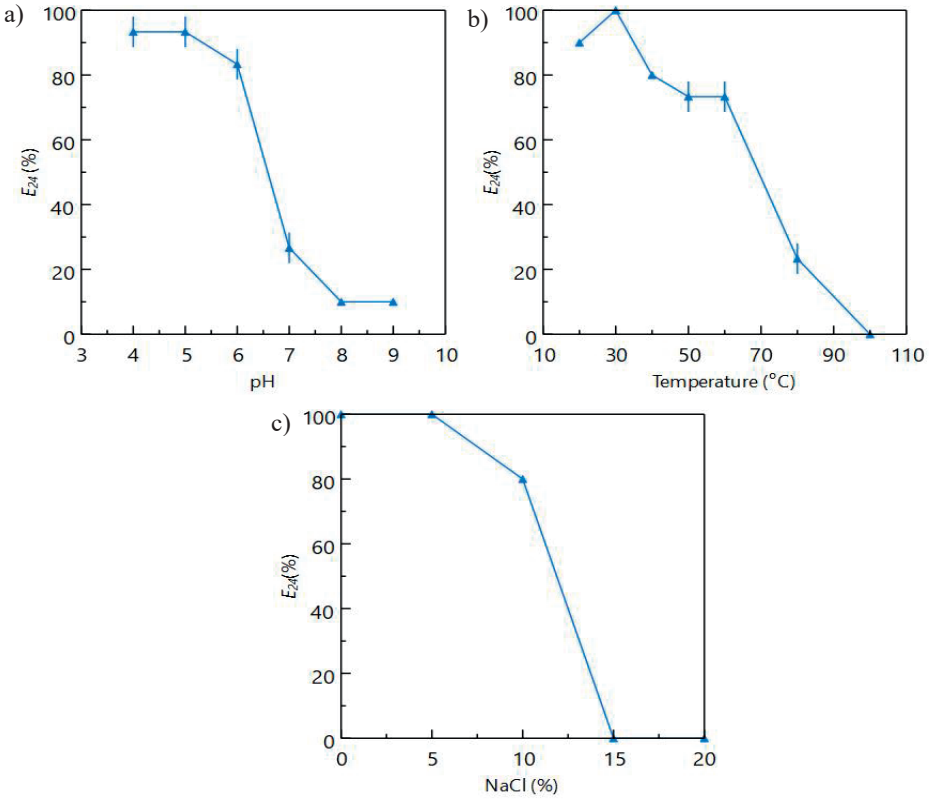

Figure 2. Physicochemical stability of the biosurfactant produced by T3 isolate
Biosurfactant stability under different (a) pH values (4-9); (b) temperatures (20-100°C); and (c) NaCl (5-20%) concentrations; error bars represent the standard deviation of n = 3 biological replicates

Our results further indicate that $E_{24}$ values obtained from crude CFS are strongly influenced by the producing strain and assay-specific parameters. Consequently, the apparent stability of CFS may vary substantially between studies, reflecting the influence of assay-specific parameters such as the nature of the hydrophobic phase, phase ratio, and exposure time (Qi et al., 2025).

**Diesel emulsification in simplified saline-water microcosms**

The $E_{24}$ stability assay showed how pH, temperature, and salinity affected the crude biosurfactant. To link these physicochemical stability results with functional behavior in saline systems, we further tested diesel emulsification in simplified saline-water microcosms at increasing NaCl concentrations (5-20%, w/v). The results showed that diesel emulsification by T3 CFS was strongly dependent on salinity. At 5% and 10% NaCl, emulsification was maximal ($E_{24}$ = 100%) (Figure 3).

In contrast, at 15% and 20% NaCl, no stable emulsion was detected ($E_{24}$ = 0%). Although the mechanism was not investigated, we did not observe visible precipitation in the 15% and 20% NaCl treatments, suggesting that the loss of emulsification was not associated with macroscopic precipitation of the active fraction. The obtained results are broadly consistent with the halotolerant growth profile of isolate T3, which showed robust growth up to 10% NaCl but not at 15-20% NaCl.

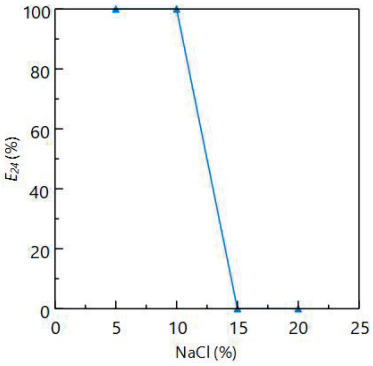

Figure 3. Diesel emulsification in simplified saline-water microcosms
Microcosm assay using diesel emulsification by T3 CFS at different NaCl concentrations (0-20%); data are presented as mean standard deviation of n = 3 biological replicates

Although biosurfactant production and emulsifying performance are not identical traits, the similar limits suggest adaptation to moderate salt levels. Thus, the crude biosurfactant is likely more suitable for low to moderately saline systems.

## CONCLUSIONS

The present work indicates that saline environments such as Lake Techirghiol host halotolerant bacteria capable of producing biosurfactants with strong diesel emulsification capacity. From the screened isolates, the cell-free supernatant of T3 showed an emulsifying activity profile that varied with pH and temperature, with high activity at moderate temperatures and acidic pH, but reduced activity at neutral to alkaline pH and after high-temperature exposure. Salinity-limited emulsification: activity remained maximal at 0-5% NaCl, decreased at 10% NaCl, and was lost at ≥15% NaCl. Importantly, the microcosm model showed the same overall trend, with stable diesel emulsification at 5-10% NaCl and no stable emulsion at 15-20% NaCl after 24 h.
In conclusion, these preliminary results suggest that the biosurfactant produced by the halotolerant isolate T3 may be useful for hydrocarbon dispersion in low to moderately saline waters or soils, as it may enhance diesel phase dispersion and potentially support the bioavailability of diesel-range hydrocarbons.

## ACKNOWLEDGEMENTS

The study was funded by project no. RO1567-IBB05/2026 from the Institute of Biology Bucharest of Romanian Academy.

***Abstract***

*Plants are essential for ecosystem stability, providing oxygen, food, and valuable bioactive compounds. However, urbanization, industrial expansion, habitat loss, and climate change are accelerating biodiversity decline. Plant tissue culture and micropropagation offer efficient methods for large-scale production of uniform, disease-free planting material independent of seasonal and environmental constraints. Aronia melanocarpa is a valuable berry shrub with high nutraceutical potential. This study aimed to develop an effcient micropropagation protocol by evaluating the effect of different cytokinins on in vitro shoot development. Explants were cultured on MS medium supplemented with meta-topolin, zeatin, kinetin, 2iP, or TDZ, combined with $GA_3$ and IAA. Meta-topolin resulted in the highest shoot proliferation, while kinetin and 2iP enhanced shoot elongation and rooting. TDZ induced hyperhydric and compact tissue formation. Rooting was successfully achieved on half-strength MS medium supplemented with activated charcoal and auxins, leading to effective plant acclimatization. The results demonstrate that meta-topolin is the most efficient cytokinin for rapid micropropagation of A. melanocarpa, providing a reliable system for large-scale propagation and conservation of valuable plant material.*

***Key words****: 2iP, kinetin, meta-topolin, thidiazuron, zeatin.*

## INTRODUCTION

*Aronia melanocarpa*, commonly known as black chokeberry, is a valuable shrub species recognized for its fruits that have a high content of bioactive compounds and growing potential in horticulture and nutraceutical production. Native to North America, this species has attracted significant attention in recent decades for its nutritional and medicinal potential, leading to its widespread use in the food, cosmetic, and pharmaceutical industries (Piras et al., 2024). Berries are rich in phenolic compounds, as flavonoids: anthocyanins, proanthocyanidins, flavanols, flavonols; phenolic acids (chlorogenic, neochlorogenic, caffeic), tannins (Sidor & Gramza-Michałowska, 2019; Lee et al., 2021; Petre et al., 2021; Dufour et al., 2022; Popa et al., 2023). They also contain carbohydrates (sorbitol, fructose, glucose, and sucrose), organic acids (quinic, malic, citric, shikimic, oxalic and succinic acids), amino acids, proteins and minerals (K, Ca, P, Mg, Na, Fe, Se, and Zn), vitamins (ascorbic acid, vitamins C, E, B, and K), aromatic compounds, fibers, fatty acids, and essential oils (Catană et al., 2017; Lazăr et al., 2020; Wójtowicz et al., 2023; Piras et al., 2024; Pop et al., 2025). Due to their pronounced astringent flavor and distinctive bitter-almond scent, the fruits are primarily utilized in processed products and are less frequently eaten fresh. The fruits can be processed into a diverse array of products, including syrups, juices, jams, and jellies due to their high pectin content, as well as beverages such as wines, schnapps, and fruit infusions (Scott & Skirvin, 2007; Kulling & Rawel, 2008; Catană et al., 2021; Toma et al., 2022). They are also used in baked goods, desserts, and powdered dietary supplements (Catană et al., 2018; Sidor & Gramza-Michałowska, 2019). *Aronia melanocarpa* is

highly adaptable to a diverse range of soil types and pH levels (Brand, 2010; Dragomir et al., 2022), but it is sensitive in high salinity conditions (Nas et al., 2023). It also exhibits resistance to pests and fungal diseases (Scott & Skirvin, 2007; Palancean et al., 2015; Golache et al., 2024). Since 2020, *Aronia melanocarpa* micropropagation has advanced to support disease-free, genetically uniform plantlet production for cultivars like 'Nero' (Borsai et al., 2021; Rusea et al., 2022; Bayhan & Yücesan, 2024; Kaya & Özatay, 2024; Ekinci et al., 2024), 'Viking' (Nas et al., 2023; Yaman et al., 2025) and on other cultivars, such as 'Melrom' and 'Galicjanka' (Jakab et al., 2022; Isac & Plopa, 2022) and 'Eastland' (Celebi-Toprak & Alan, 2020). Effective micropropagation protocols employing shoot tips and nodal explants cultured on MS medium supplemented with BAP and IBA have resulted in high rates of shoot multiplication and root formation (Rusea et al., 2018; 2022). Common physiological problems, such as hyperhydricity, can be reduced through adjustments of agar and sucrose concentrations, as well as improved ventilation inside the growing vessels (Bayhan & Yücesan, 2024). Studies have also advanced techniques for callus formation (Calalb et al., 2014; Szopa et al., 2018), adventitious shoot regeneration (Rusea et al., 2018), and the establishment of cell cultures for the production of secondary metabolites (Shishkova et al., 2026). These advances contribute to the development of reliable propagation protocols, preservation of elite germplasm, and scalable production valuable *Aronia melanocarpa* cultivars.

*In vitro* tissue culture techniques play and important role in the propagation this woody species, as they enable the production of disease-free and genetically uniform planting material. Woody species are generally recalcitrant to *in vitro* propagation (Grzelak et al., 2024), and we face problems such as: polyphenols oxidation, endophytic bacterial contamination (Quambusch & Winkelmann, 2018; Permadi et al., 2025), hyperhydricity of tissues, formation of basal callus, somaclonal variation, unsuccessful rooting, dormancy during acclimatization (Jain & Häggman, 2007; Nowakowska et al., 2023).

Phytohormones (plant hormones) are naturally occurring organic molecules found within plant tissues that function as signaling agents, regulating a wide range of physiological activities (Davies, 1995). Although present in very small amounts - typically below 1 nM to 1 μM - they exert significant effects on plant growth and development. These compounds are frequently synthesized in particular plant organs and then transported to other regions, where they trigger physiological, biochemical, and structural responses (Salisbury & Ross, 1992). Cytokinins, a group of phytohormones, play a fundamental role in plant biology, regulating numerous developmental and physiological processes. They are key contributors to cell division and differentiation, stimulate the formation and expansion of vegetative tissues, promote chloroplast development, and influence overall plant growth and metabolism. Through these functions, cytokinins help coordinate plant development and maintain proper physiological activity (Krikorian et al., 1987). In plant tissue culture, BAP is the most commonly used cytokinin, but it can lead to hyperhydricity, shoot tip necrosis, inhibit rooting during the acclimatization and cause early senescence (Werbrouck, 2021). Nevertheless, while higher concentrations of BAP can enhance the rate of shoot regeneration, they may also increase the likelihood of vitrification. During the acclimatization phase, plants affected by vitrification showed impaired development, characterized by reduced shoot elongation, smaller and narrower leaves, fewer and shorter roots, and lower survival percentages. These adverse effects were especially pronounced when plants were exposed to environments with lower humidity levels (Bayhan & Yücesan, 2024). Meta-Topolin (mT, 6-(3-hydroxybenzylamino) purine) is an exceptionally potent natural aromatic cytokinin that was first extracted by Strnad (1997) from the mature foliage of *Populus* x *canadensis* and has since been recognized for its biological activity. Can be used as an alternative to BAP, as it promotes rapid, high multiplication rates, improve rooting and *ex vitro* adaptation, while reducing structural abnormalities and somaclonal variations (Amoo et al., 2011; Cardoso, 2021; Zaytseva et al., 2021). Moreover, it can lead to improve both rooting success and acclimatization in plants (Nowakowska & Pacholczak, 2020). The

present study aims to evaluate the *in vitro* response of 'Alexandrina', a Moldavian cultivar, to 5 different types of cytokinins, others than BAP: 6-(γ, γ-dimethylallylamino) purine (2iP), kinetin, meta-Topolin, thidiazuron and zeatin.

## MATERIALS AND METHODS

'Alexandrina' is a Moldavian cultivar bred by the researchers at the National Botanical Garden (Institut) 'Alexandru Ciubotaru' of the State University of Moldova (Palancean et al., 2015). The initial plant material - *in vitro* cultures (Figure 1) was obtained from the National Botanical Garden 'Alexandru Ciubotaru' of Chișinău. It was subsequently multiplied *in vitro* at the University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania, as part of the BioMedPlant project (*Valorization of medicinal spontaneous and cultivated plants through the use of advanced micropropagation techniques as sources of bioactive compounds*).

Figure 1. Initial *in vitro* cultures obtained from the National Botanical Garden 'Alexandru Ciubotaru' of the State University of Moldova

### I. Multiplication phase

*In vitro* multiplication of *Aronia melanocarpa* 'Alexandrina' was performed out on Murashige and Skoog (MS) medium, supplemented with five different cytokinins, each at a concentration of 1 mg/L: meta-topolin (mT), zeatin (Z), kinetin (kin), 6-(γ, γ-Dimethylallylamino) purine (2iP) and thidiazuron (TDZ). To ensure proper multiplication, all media were supplemented with 0.5 mg/L IAA and 0.2 mg/L $GA_3$, as shown in Table 1.

Other media components included sucrose (3%), Kobe I agar (0.7%) and to reduce tissue oxidation, PVP (polyvinylpyrrolidone) was added in concentration of 100 mg/L. The pH was modified at 5.75 and the media was sterilized in the autoclave at 121°C for 20 minutes. indole-3-acetic acid (IAA) and gibberellic acid ($GA_3$) were co-autoclaved with the rest of the media components. All cytokinins were filter-sterilized after the media was autoclaved, using sterile polyethersulfone (PES) syringe filters (0.22 µm pore size).

Table 1. Types and concentrations of plant growth regulators (PGRs) supplemented to the multiplication media

| Medium variant | Plant growth regulators | | |
|---|---|---|---|
| | Cytokinins | Auxins | Gibberellins |
| V1 | 1 mg/L mT | 0.5 mg/L IAA | 0.2 mg/L $GA_3$ |
| V2 | 1 mg/L Z | 0.5 mg/L IAA | 0.2 mg/L $GA_3$ |
| V3 | 1 mg/L KIN | 0.5 mg/L IAA | 0.2 mg/L $GA_3$ |
| V4 | 1 mg/L 2iP | 0.5 mg/L IAA | 0.2 mg/L $GA_3$ |
| V5 | 1 mg/L TDZ | 0.5 mg/L IAA | 0.2 mg/L $GA_3$ |

### II. Rooting phase

Shoots regenerated on media containing meta-topolin were subsequently cultured on half-strength MS medium supplemented with 1 g/L activated charcoal and different concentrations of either indole-3-butyric acid (IBA) or indole-3-acetic acid (IAA), as detailed in Table 2.

Table 2. Concentration of auxins (IBA and IAA) supplemented to the rooting media

| Medium variant | Auxins | |
|---|---|---|
| | IAA (mg/L) | IBA (mg/L) |
| R1 | 0.5 | - |
| R2 | 1 | - |
| R3 | - | 0.5 |
| R4 | - | 1 |

Sucrose, agar and PVP were added to the media in the same concentrations as in the multiplication media. Both auxins were sterilized with the rest of the media components, by autoclavation at 121°C for 20 minutes.

The concentration of $CuSO_4 \cdot 5H_2O$ was increased tenfold, to 0.125 mg/L, compared to the concentration present in the conventional half-strength MS formulation. This adjustment was made to stimulate root development and improve plantlet vigor, given the importance of copper in carbon dioxide fixation and ATP production (Marques et al., 2018).

The medium was dispensed into 720 mL glass jars at approximately 83 mL per vessel to ensure adequate air volume for shoot development.

The jars were fitted with lids containing air-permeable filters to facilitate gas exchange, thereby reducing ethylene accumulation and improving leaf adaptation to *ex vitro* conditions. Tamimi & Othman (2020) observed an increase in multiplication parameters (including number and length of shoots) and chlorophyll content on media with increased copper sulphate concentration on *Musa acuminata* shoots cultivated *in vitro*. Similarity, *Capsicum annum* cotyledons showed improved bud differentiation and elongation on media supplemented with higher concentrations of $CuSO_4$ x $5H_2O$ (Joshi & Kothari, 2007).

Total dry matter was determined by weighing 250 mg of finely cut and homogenized plant material (from 5 shoots/media variant), in crucibles, in 3 repetitions/variant, followed by drying for 14 hours at 105°C using a UN110 Memmert drying oven. This can be a good indicator of how the leaves will perform during the acclimatization phase.

**III. Acclimatization phase**

*In vitro* rooted shoots of 'Alexandrina' were placed in sowing trays with peat (sterilized in the autoclave at 121°C for 20 minutes) then covered with plastic lids to keep a high level of humidity (Figure 2). Prior to planting, the roots were washed of all agar traces and they were shortened at approximately 5 cm.

Figure 2. *In vitro* rooted shoots of *A. melanocarpa* 'Alexandrina' used for the acclimatization phase

The trays were kept in laboratory conditions at 20-25°C room temperature and illuminated using LED lamps composed of white, red and blue lights (Figure 3). The acclimatization of the shoots was carried out by periodically removing the lid and gradually exposing the shoots to the new humidity conditions, until the leaves were able to maintain their turgidity at normal laboratory humidity (approximately 40-50%).

Figure 3. Acclimatization of *Aronia melanocarpa* 'Alexandrina' shoots in laboratory conditions

The trays were kept in laboratory conditions at 20-25°C room temperature and illuminated using LED lamps composed of white, red and blue lights (Figure 3). The acclimatization of the shoots was carried out by periodically removing the lid and gradually exposing the shoots to the new humidity conditions, until the leaves were able to maintain their turgidity at normal laboratory humidity (approximately 40-50%).

Acclimatization of *Aronia melanocarpa* can also be done in a growing chamber with high humidity (Figure 4). Both methods work as long as proper humidity, temperature and light can be ensured.

Figure 4. Acclimatization of *in vitro* obtained shoots in a Memmert growing chamber with high humidity

**Statistical analysis**

Statistical analyses were performed using Microsoft Excel 2021 with the Real Statistics Resource Pack (www.real-statistics.com). Descriptive statistics, including the mean and standard error, were calculated for all measured variables. Prior to inferential analysis, the assumption of homogeneity of variances was evaluated using Levene's test. Depending on whether this assumption was met, differences among treatments were analyzed using either one-way analysis of variance (ANOVA) or the non-parametric Kruskal-Wallis test. When statistically significant differences were detected ($p < 0.05$), multiple comparisons were performed using Tukey's honestly significant

difference (HSD) test following ANOVA or Dunn's post hoc test following the Kruskal–Wallis test. Results were considered statistically significant at $p < 0.05$.

## RESULTS AND DISCUSSIONS

### I. Multiplication phase

#### *Average number of shoots obtained from each explant*

Meta-Topolin medium enhanced the multiplication rate (Figure 5), by generating highest number of shoots/ explant (20.7 ± 4.59) (Figure 6), followed by variant V2 with zeatin, with an average of 4.7 ± 1.36 shoots/ explant. Lowest results were obtained on V3 with kinetin (1 shoot/explant) and variant V4 with 2iP (with 1.16 shoots/explant), with no statistically significant differences between them, as confirmed by Dunn's test.

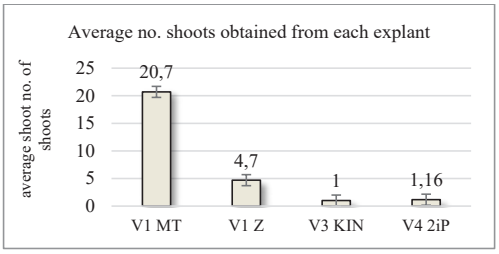

Figure 5. Average number of shoots obtained from each explant

Meta-Topolin has increased *in vitro* multiplication in several woody species, such as *Actinidia arguta* (Shakshi et al., 2026), *Daphne mezereum* (Nowakowska et al., 2023), *Salix tetrasperma* (Reshi et al., 2025), *Feronia limonia* (Anis et al., 2023) *Rubia cordifolia* (Kunal et al., 2025). Use of meta-Topolin was also shown to stimulate the development of the photosynthetic apparatus in *Musa* spp., which is a crucial aspect in the rooting and acclimatization phases, as it increases the survival rates of the plantlets (Aremu et al., 2012). Similarly, in *Momordica balsamina*, leaves that were obtained from shoots cultivated on media with meta-Topolin showed veins and trichomes that were more developed and an increase in the density of stomata and stomatal index, compared to the leaves obtained on shoots cultivated in the presence of BAP (Chouhan et al., 2025). In addition, in *Oxystelma esculentum*, the use of media with mT was shown to also enhance cutin deposition and the development of vascular and ground tissue systems (Jayaprakash et al., 2021).

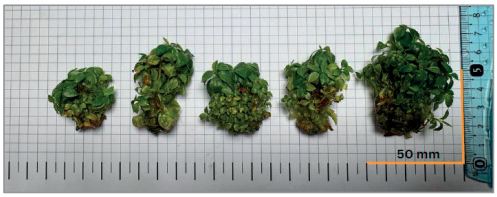

Figure 6. High shoot proliferation of explants cultivated on media with meta-Topolin

Rusea et al. (2018) obtained an average of 6.08-10.2 shoots per explant on media with 0.5-2.0 mg/L BAP combined with 0.1-1.0 mg/L IBA. By comparison in our previous study, we obtained averages between 8.3 and 13.3 shoots/explant in 'Alexandrina' and 5.21-8.37 shoots/explant in 'Nero' on media with 0.3-0.5 mg/L BAP and 0.2 mg/L $GA_3$ (Nicolae et al., 2025). Litwińczuk (2013) recommends the use of BAP (1 mg/L) and IBA (0.05 mg/L) supplemented to media with a 150% increase in magnesium and calcium salts to enhance axillary shoot proliferation.

#### *Average shoot length*

Regarding shoot growth, explants grown on medium with KIN (Figure 7), even although showing limited proliferation, exhibited the greatest shoot elongation (44.94 ± 9.52 mm), followed by variants V4 (39.29 ± 9.24 mm) and V2 (33.09 ± 8.45 mm). The explants cultivated on the mT-supplemented medium produced shortest shoots (21.53 ± 5.17 mm).

Rusea et al. (2018), observed that 'Nero' explants cultivated on media with BAP and IBA can reach lights of 1.45-2.24 mm, however, this is highly dependent on the cultivar, as our past studies have also shown that 'Nero' grows smaller in comparison with 'Alexandrina' (Nicolae et al., 2025).

Additionally, in this experiment, *A. melanocarpa* 'Alexandrina' shoots that were obtained on KIN medium showed shoots with more lignified tissue and higher leaf surface area (data not shown). In micropropagation of *Quercus robur*, KIN promotes the formation of a more developed secondary xylem and

enhances cell wall lignification. Furthermore, the shoots cultured in the presence of KIN exhibit anatomical characteristics associated with increased cellular differentiation rather than vigorous proliferative growth (Martins et al., 2022). Moreover, the low shoot induction efficiency of cytokinins such as KIN or 2iP may be linked to fast cytokinin catabolism by cytokinin oxidase/dehydrogenase enzymes (Schmülling et al., 2003; Khablak et al., 2024).

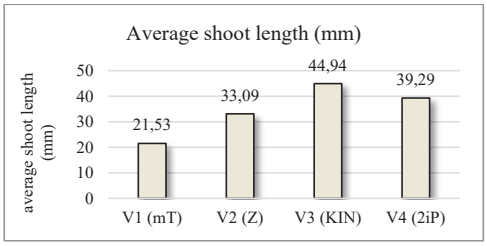

Figure 7. Average shoot length (mm) of explants cultivated on the multiplication media

***Average biomass*** (g)

Highest biomass was accumulated on explants cultivated on V5 – TDZ (2.33 ± 1.07 g/explant) and V1 – mT (1.95 ± 0.72 g/explant), with no statistically significant differences between them, as it was pointed out by Dunn's test (Figure 8).

Even though variant V5 – TDZ generated the highest biomass/explant, the inclusion of TDZ resulted in the formation of compact, globular masses of shoots that were small, highly friable, and hyperhydrated rendering them unsuitable for further multiplication (Figure 9).

Thidiazuron (TDZ) is a is a non-purine phenylurea and possesses cytokinin-like properties; however, unlike adenine-based cytokinins such as BAP, KIN and Z, it lacks a purine ring in its molecular structure (Dewir et al., 2018; Nautiyal et al., 2022).

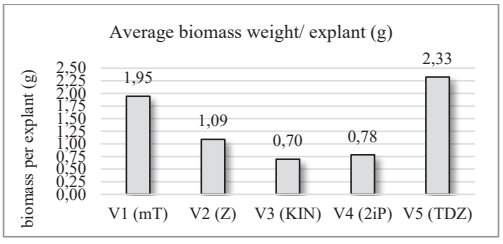

Figure 8. Average biomass (g) produced from explants cultivated on multiplication media variants

TDZ is extremely potent and effective in stimulating cell division and organogenesis (Manokari et al., 2026), which could be associated with its resistance to cytokinin/dehydrogenase-mediated breakdown and increased internal cytokinin concentrations (Brunoni et al., 2021). However, it is known to cause several anomalies in plant tissue culture (Dewir et al., 2018). Most common effects include fasciated and compact shoots, hyperhydricity, and reduced rooting capacity (Huetteman & Preece, 1993; Lu, 1993).

Figure 9. Explants obtained on multiplication media with TDZ

***Average basal callus mass*** (mg)

Regarding the production of basal callus, figure 10 shows that variant V2 with Z produced the highest basal callus mass (327.42 ± 42.75 mg/explant), followed by V1 (mT) with 219.90 ± 70.67 mg/explant; however, Dunn's test indicated that the difference between these two variants was not statistically significant. Callus on V4 (2iP), which generated an average of only 1.16 shoots/ explant. By comparison, callus tissue obtained on V1 (mT) had strong organogenic potential, as the explants obtained generated a high number of shoots (20.7 ± 4.59 shoots/ explant), while the average on V2 (Z) was very low (4.7 ± 1.36 shoots/ explant). Variants V3 (KIN) and V4 (2iP) produced the lowest amounts of basal callus; nevertheless, the callus formed on V3 (KIN) showed no shoot regeneration capacity, as explants cultured on this medium developed solely via the apical

meristem, yielding only one shoot per explant. Similar observations can be made about the callus on V4 (2iP), which generated an average of only 1.16 shoots/ explant.

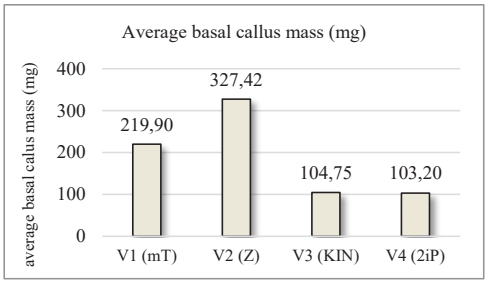

Figure 10. Average basal callus mass (mg) per explant

***Average number of leaves/explant***

Highest values regarding the number of leaves were observed on variant V3 (KIN) (Figure 11), with an average of 25.80 ± 8.05 leaves/explant, followed by V4 (2iP), with an average of 17.67 ± 4.26 leaves/explant, but with no statistically significant differences.

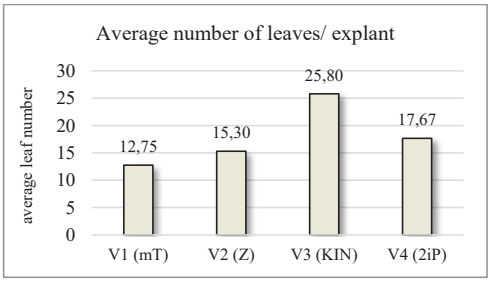

Figure 11. Average number of leaves/explant on the multiplication media variants

The lowest values were recorded for V1 (mT), with 12.75 ± 2.41 leaves per explant, and for V2 (Z), with 15.30 ± 3.24 leaves per explant; these variants also exhibited the lowest shoot heights. This parameter is an important indicator, as it is directly correlated with the number of axillary buds and, consequently, with the potential multiplication rate. In relation to shoot height, it can also provide information on internodal length and the spatial distribution of axillary buds.

*Rhizogenesis during multiplication phase:*

Rhizogenesis only occurred on variants V3 (KIN) and V4 (2iP), and, in a very low percentage, on V2 (Z) - only 10% (Figure 12). Variants V3 (KIN) and V4 (2iP) produced an average of 3.3 ± 2.21 roots/ explant and 3.1 ± 1.60 roots/ explant, respectively. Analysis of variance (Kruskal-Wallis Test) pointed out no significant differences between these values. Highest root length was obtained on V2 (Z): 92.67 ± 12.02 mm, followed by V3 (KIN): 79.47 ± 13.23 mm (Figure 13).

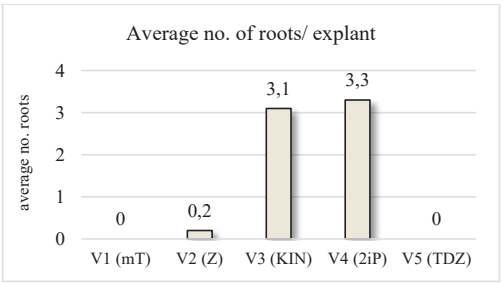

Figure 12. Average roots number of explants cultivated on multiplication medium variants

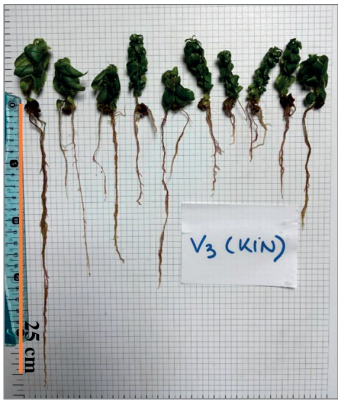

Figure 13. Rhizogenesis on explants cultivated on multiplication media with kinetin

The lowest values were observed on variant V4 (2iP) with 49.48 ± 9.21 mm; however, no statistically significant differences were identified regarding root length.

**II. Rooting phase**

***Average number of roots and root length***

Rooting was successfully achieved in 100% across all media variants. Differences between the growing parameters, such as shoot height, number of leaves were relatively minor, and statistically unconfirmed (using ANOVA in all cases), except for the average shoot height - R4 and R1 recorded significant differences.

IBA is the most commonly used auxin in the rooting phase of *Aronia melanocarpa*, supplemented to a media recipe with a lower concentration of minerals (Almokar & Pırlak, 2018; Celebi-Toprak & Alan, 2020; Ekinci et al., 2024; Abduganiyeva et al., 2025). For varieties such as 'Melrom' and 'Nero', Isac & Plopa (2022) recommend the use of IBA in concentration of 0.7 mg/L. Other medias, such as half-strength Shrub Plant Medium (SPM) in combination with NAA and IBA, can also be used to obtain high rooting percentages in cultivars such as 'Viking' (Yaman et al., 2025). Concentrations over 3 mg/L IBA cand lead to an increase in callus formation and size (Abduganiyeva et al., 2025), which can be an undesirable aspect during the rooting stage. Jakab et al. (2022), recommend using IBA concentrations, as low as 0.5 mg/L. Litwińczuk (2013) recommends using IBA in concentrations as low as 0.05 mg/L.

Highest number of roots was obtained on the variant with 1 mg/L IBA (R4), 7.4 ± 1.74 roots/ shoot and on variant with 1 mg/L IAA (R2), 7 ± 2.41 roots/ shoot (Figure 14).

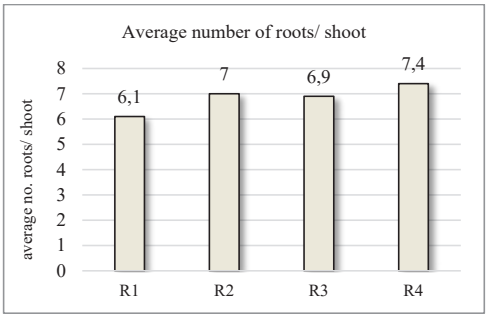

Figure 14. Average root number of explants cultivated on the rooting media variants

Both variants with lower concentrations of auxins generated a lesser number of roots: 6.9 ± 2.02 roots/ shoot on media with 0.5 mg/L IAA (R3) and 6.1 ± 3.14 roots/ shoot on media with 0.5 mg/L IBA (R1).

***Average shoot height*** (mm)

Regarding the growth of these shoots, highest values were observed on variant with 1 mg/L IAA (R2) (Figure 15), with an average of 33.64 ± 5.12 mm and on the variant with 0.5 mg/L IBA (R3), with an average of 33.07 ± 3.30 mm. The Tukey HSD test indicated significantly lower shoot heights in R1 (0.5 mg/L IAA): 21.80 ± 2.48 mm and R4 (1 mg/L IBA): 26.34 ± 3.76 mm (Figure 16).

Figure 15. *In vitro* rooted shoots obtained on media with 1 mg/L IAA

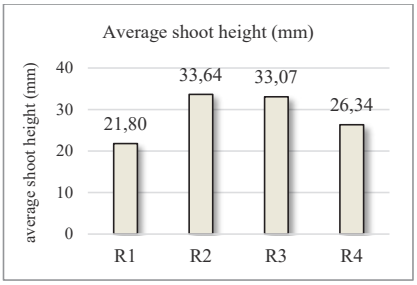

Figure 16. Average shoot height (mm) of explants

***Average number of leaves***

Proper growth and development of leaves is an important factor in the next phase, when the plantlets are acclimatized to *ex vitro* conditions. The subsequent growth of plantlets under *ex vitro* conditions depends both on the formation of new leaves and on the adaptation of existing leaves that were regenerated *in vitro*.

In regards with this aspect, variant with 1 mg/L IBA (R4) recorded the highest average number of leaves (8.5 ± 1.12 leaves/ explant). Middle values of 7.9 ± 1.81 leaves were obtained on variant with 0.5 mg/L IAA (R1) and 7.8 ± 0.60 on variant with 0.5 mg/L IBA (R3). Lowest values were recorded on media with 1 mg/L IAA (R2), only 7.4 ± 0.92 leaves/ explant (Figure 17). However, analysis of variance (ANOVA) recorded no statistically significant differences between the four variants of rooting media.

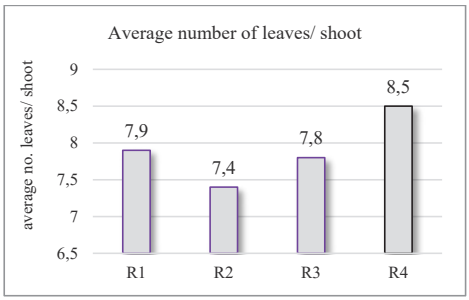

Figure 17. Average number of leaves/shoot of the explants cultivated on the rooting media variants

***Dry matter of in vitro obtained leaves***

Leaves that were regenerated from the shoots cultivated on media supplemented with IBA (0.5 and 1 mg/L) had an overall higher dry matter content, compared to the ones cultivated on media with IAA (Figure 18). Higher dry matter content (%) was obtained from the leaves from variant R4 (1 mg/L IBA): 34.16 ± 2.63% and R3 (0.5 mg/L IBA): 29.57 ± 1.81%.

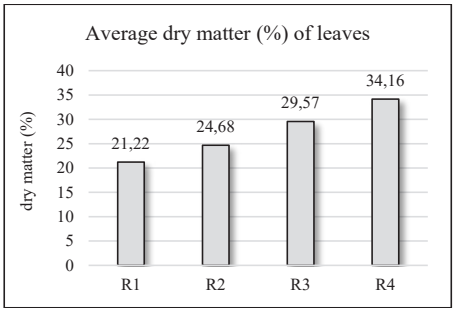

Figure 18. Average dry matter (%) of leaves obtained from shoots cultivated on rooting media variants

Leaves regenerated from the explants cultivated recorded lower values, of 24.68 ± 0.52% on R2 (1 mg/L IAA) and 21.22 ± 3.35% on R1 (0.5 mg/L IAA). For comparison, the average dry matter content was 15.11 ± 0.94% during the multiplication phase (on meta topolin medium) and 35.51 ± 0.92% in young greenhouse-grown plants of *Aronia melanocarpa* 'Alexandrina'

The dry matter can be a good indicator of how the leaves will perform during the acclimatization phase because it reflects how well the leaves are developed. Due to the culture environment of explants (high humidity, lower light intensity, controlled temperature, and heterotrophic or mixotrophic nutrition), leaves formed *in vitro* often have low dry matter due to high water content, thin cell walls, poor cuticle development, and limited lignification. Such leaves are fragile and poorly adapted to *ex vitro* conditions, making them highly susceptible to desiccation and transplant shock when humidity drops. Moreover, the stems of plantlets developed *in vitro* are often hypo lignified, their cell walls are thin, and the intercellular spaces are large, with limited development of vascular tissue (Ziv, 1995; Nowakowska et al., 2023).

For woody species, the rooting phase is not only important to generate a well-developed rooting system, but also to stimulate the proper development of leaves and stems (through using well-ventilated culture vessels, adapting culture media nutrients and growth regulators, use of plant elicitors) in order to ensure high survival rates during the acclimatization phase.

**III. Acclimatization phase**

All rooted shoots were successfully acclimatized. After 3 weeks of culture in laboratory conditions, they were planted individually in small pots and transferred to greenhouse conditions where they developed into healthy, uniform plants (Figure 19).

Figure 19. *In vitro* obtained plants of *Aronia melanocarpa* 'Alexandrina' grown in the greenhouse at USAMV Bucharest

Generally, if the rooting phase is carried on properly, acclimatization of *Aronia melanocarpa* can be achieved successfully. Several authors report good results (Celebi-Toprak & Alan, 2020; Borsai et al., 2021; Isac & Plopa, 2022; Rusea et al., 2022; Coşkun et al.,

2026), as long as the tissues are not vitrified, which can delay shoot and leaf growth, reduce the development of the rooting system and increase the risk of plant loss due to the dehydration of the tissues (Bayhan & Yücesan, 2024).

## CONCLUSIONS

Meta-topolin (mT) is the most effective cytokinin for *in vitro* multiplication of *A. melanocarpa* 'Alexandrina', yielding the highest shoot proliferation (20.7 shoots/explant) and good biomass, without hyperhydricity. TDZ induced high biomass but led to compact, hyperhydric, non-viable shoot clusters — unsuitable for further multiplication. KIN and 2iP promoted shoot elongation and leaf formation but showed low multiplication rates and limited organogenic potential. IBA (especially 1 mg/L) is recommended for rooting to improve leaf dry matter content and acclimatization success. Leaf dry matter content is a reliable indicator of plantlet physiological quality prior to *ex vitro* transfer. Optimizing ventilation, light, and nutrient balance during rooting is critical for high survival rates during acclimatization.

The results demonstrate that meta-topolin is the most efficient cytokinin for rapid micropropagation of *A. melanocarpa* 'Alexandrina', providing a reliable system for large-scale propagation and conservation of valuable plant material.

## ACKNOWLEDGEMENTS

This work was supported by a grant of the Ministry of Research, Innovation and Digitization, CNCS - UEFISCDI, project number PN-IV-P8-8.3-ROMD-2023 0307, within PNCDI IV. Project title: Valorization of medicinal spontaneous and cultivated plants through the use of advanced micropropagation techniques as sources of bioactive compounds (BioMedPlant).

***Abstract***

*Situated in south-west Romania (Mehedinți County), with a temperate-continental with sub-Mediterranean influences climate, the protected area Dealurile Strehaia-Bâtlanele (Natura 2000 code ROSCI0405 and ROSAC0405) is a small area (803,9 ha) designated on the basis of the presence of Hermann`s tortoise (Testudo hermanni) and two forest habitats (91M0 Pannonian-Balkanic turkey oak –sessile oak forests and 91Y0 Dacian oak & hornbeam forests). There is very little information about this site (standard forms and national & international websites). Following field trips (summers 2018-2019), our assessment of plant, herpetofauna and invertebrate species and habitats highlighted the existence of species listed in the Habitats Directive, some of them having here a new distribution locality in Romania. The human impact (trash, habitat fragmentation, agricultural field development, forest clearcutting, distribution of invasive species, etc.) is increasing in recent years, and thus this protected area is threatened as a whole. This study highlights the high biological value of the site. The increasing intensity of human pressures poses a major threat to ecosystem integrity, emphasising the need for appropriate conservation and management measures.*

***Key words****: Natura 2000 site, community interest species and habitats, high biological value.*

## INTRODUCTION

The Natura 2000 network represents the cornerstone of the European Union's biodiversity conservation policy, established under the Habitats Directive 92/43/EEC and the Birds Directive 2009/147/EC (Evans, 2012). This European network of protected areas aimed at conserving habitats and species of high ecological value (EEA, 2025). Its main objective is to ensure the long-term survival of Europe's most valuable and threatened species (Trochet & Schmeller, 2013) and habitats by designating protected areas such as Sites of Community Interest (SCI) and Special Protection Areas (SPA) (Mücher et al., 2009; Popescu et al., 2014).

In Romania, sites coded ROSCI and ROSAC are part of Natura 2000, the European ecological network created to conserve biodiversity across the European Union. This network operates under the Habitats Directive 92/43/EEC and the Birds Directive 2009/147/EC (H.D., 1992; B.D., 2009).

Within the Romanian classification system, ROSCI (Romanian Sites of Community Importance) designate areas proposed and approved at the European level as Sites of Community Importance because they host habitat types and species listed in the annexes of the Habitats Directive. After the establishment of conservation measures and management plans, many of these sites are formally designated as ROSAC (Romanian Special Areas of Conservation), representing the final conservation status under the directive (EEA, 2020; ANANP, 2022; M.O., 2023a).

The transition from ROSCI to ROSAC reflects the implementation stage of conservation policy, indicating that concrete management measures are in place to maintain or restore the favourable conservation status of protected habitats and species. Together, these sites represent an essential component of Romania's protected area system and contribute to biodiversity conservation and ecological

connectivity within the Natura 2000 network (M.O., 2023b).

Standard forms (Standard Data Forms - SDFs), are official documents used to describe and report key information about each Natura 2000 site. They include data on site location, area, habitat types, species presence, conservation status, and threats (H.D., 1992). Specifically, SDFs cover habitat classifications following the EU Habitats Directive, population estimates of protected species, and human pressures affecting the site. The role of these forms is threefold: firstly, they provide a consistent framework for reporting across EU member states; secondly, they support the monitoring and assessment of site conservation status; and thirdly, they serve as a legal and management tool for planning conservation measures (EEA, 2020; Spiliopoulou et al., 2023). By standardising data collection, SDFs facilitate decision-making, help identify priority conservation actions, and ensure compliance with EU environmental legislation. Thus, Natura 2000 standard forms are essential for effective biodiversity management and long-term ecological sustainability.

In Romania, the implementation of Natura 2000 network has played a crucial role in the conservation of biodiversity, particularly in regions characterised by high ecological diversity and unique habitat types (Gafta & Mountford, 2008; Stancioiu et al., 2010; Manolache et al., 2017).

The SDF (2020) states that the protected area ROSCI0405 Dealurile Strehaia-Bâtlanele is a Site of Community Interest located in Mehedinți County, in southwestern Romania, within the Continental biogeographical region. The site covers approximately 803.90 hectares and occupies parts of the administrative territories of the town of Strehaia and the commune of Greci, representing approximately 5.1% and 6.3% of their respective areas. Although relatively small in size, the site plays an important role in maintaining regional biodiversity (M.P., 2019; M.O., 2023a; 2023b).

From a biogeographical perspective, the area is characterised by a temperate-continental climate with sub-Mediterranean influences, which creates favourable conditions for the development of thermophilous habitats and species that reach their northern or eastern distribution limits in this region. The ecological value of the site is primarily associated with two forest habitat types of community interest: **Habitat 91M0 - Pannonian-Balkanic turkey oak-sessile oak forests**, dominated by species such as *Quercus cerris* and *Quercus frainetto*, covering approximately 385 hectares, and **Habitat 91Y0 - Dacian oak-hornbeam forests**, characterised by *Carpinus betulus* and *Quercus robur*, which occupy around 325 hectares. The site was designated primarily for the conservation of the Hermann's tortoise, *Testudo hermanni boettgeri*, a species listed in Annex II of the Habitats Directive and considered one of the flagship species of this protected area (SDF, 2020).

The site is legally protected through national regulations (M.O., 2023b), its management is currently coordinated by the National Agency for Natural Protected Areas (ANANP), which implements conservation measures through officially approved management plans. These measures aim to maintain favourable conservation conditions for protected species and habitats, including the preservation of open clearings required for tortoise thermoregulation and the control of invasive species.

Biodiversity inventories and long-term ecological monitoring are essential components of effective management within protected areas. As a member state of the European Union, Romania has the obligation to maintain or restore the favourable conservation status of habitats and species of community interest. Reliable data on species distribution, population dynamics, and ecological pressures are therefore necessary to define appropriate management objectives and evaluate the effectiveness of conservation actions. Previous information regarding the biodiversity of the ROSCI0405 site was relatively limited and often derived from general surveys or standard reporting forms, which frequently focused on mountainous regions while overlooking hilly landscapes such as those found in the Strehaia area. In the Management Plan of the protected area (M.P., 2019), within the section 'Species of conservation interest for which the protected natural area was designated', the subsections regarding lower and higher plants, invertebrates, ichthyofauna, and other flora and fauna species

relevant to the protected area are empty (not filled).

In this context, the present study aimed to conduct an updated inventory of flora and fauna within the ROSCI0405 Dealurile Strehaia-Bâtlanele site, to identify species of community interest and other important species that had not been previously recorded in the area, and to perform a quantitative assessment of habitat conservation status and of the population status of the flagship species *Testudo hermanni*. By integrating field observations with multivariate statistical analyses, this research seeks to provide a robust scientific basis for improving conservation strategies and supporting the implementation of the recently approved management plan for the protected area.

## MATERIALS AND METHODS

The ROSCI0405 Dealurile Strehaia-Bâtlanele site is situated in south-western Romania, forming part of the South-West Oltenia Development Region. The site lies entirely in the Continental biogeographical region and encompasses the Strehaia Hills, a subunit of the Getic Plateau, located in the north-western section of the Wallachian Platform (Figure 1).

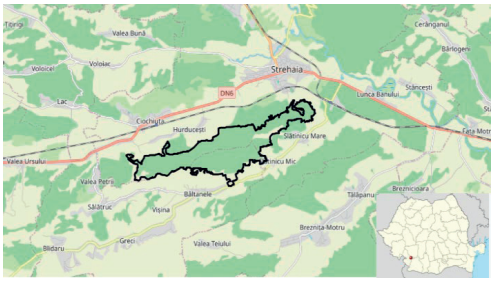

Figure 1. Location of the studied area in Romania and its position in the region (After EEA, 2024)

The topography is dominated by hills with elevations ranging between 200 and 310 metres, with slopes of 5 to 20 degrees and varying orientations. The abiotic environment is characterised by mean annual temperatures of approximately 6.43-11.52°C and mean annual precipitation between 48.33 and 74.83 mm. The forest administration is handled by the Strehaia Forest District (M.O., 2023b).

Biodiversity data were collected during two vegetation seasons (2018-2019), for developing the management plan.

Vegetation assessment was carried out using two complementary methods: transect itineraries and phytosociological relevés. Relevés were performed in plots distributed to cover the homogeneity and diversity of the forest habitats (91M0 and 91Y0) (Figure 2).

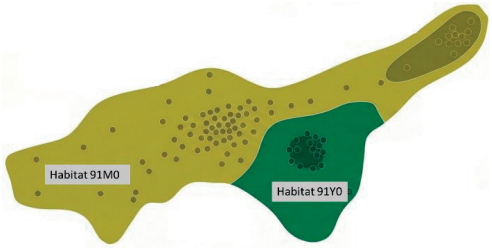

Figure 2. The map of the habitats and inventorying plots' distribution in ROSCI0405 Dealurile Strehaia-Bâtlanele

Plant species abundance-dominance was recorded using the Braun-Blanquet scale (5 = 75-100%; 4 = 50-75%; 3 = 25-50%; 2 = 10-25%; 1 = 1-10%; + = 0.1-1%). Identification of plants and habitats followed standard Romanian floras and manuals (Doniță et al., 2005; Gafta and Mountford, 2008; Ciocârlan, 2009; Sârbu et al., 2013). The characteristics of the plant species follow Oltean et al. (1994), Ciocârlan (2009), Sârbu et al. (2013), IAS (2025). The community interest species *Ruscus aculeatus* distribution and density were recorded in 5 x 5 m plots established along areas where relevés were performed.

Using software package PAST (Hammer et al., 2001), we grouped sites based on plant species abundance (Bray-Curtis Similarity Index), analysed groupings based on plant species presence-absence (Jaccard Similarity Index) and identified associations between specific plant species and sampling locations (Principal Component Analysis - PCA).

Surveys for herpetofauna targeted 10 designated open areas preferred by reptiles for thermoregulation and foraging. The studies were conducted between July and October 2019 to coincide with peak activity and avoid hibernation periods. For each observation, GPS coordinates, species, number of individuals, sex, and reproductive state were recorded.

Observations for community interest invertebrates were conducted concurrently with habitat assessments in the forest sectors.

## RESULTS AND DISCUSSIONS

The study confirmed the two main forest habitats within the ROSCI0405 Dealurile Strehaia-Bâtlanele site, which play a key role in regional biodiversity conservation, particularly for the Hermann's tortoise (*Testudo hermanni*), as it is specified in SDF (2020) and M.O. (2023a; 2023b).

**Habitat 91M0 (Pannonian-Balkanic turkey oak-sessile oak forests)** is the dominant habitat, covering about 369.92 ha. It occurs at altitudes of 200-300 m on sunny, moderately dry slopes (5-20°). The tree layer (50-80% cover) is formed mainly by *Quercus petraea*, *Quercus cerris*, *Quercus frainetto*, and *Tilia tomentosa*. The shrub layer includes species such as *Crataegus monogyna* and *Cornus mas*, while the herb layer (10-60% cover) is dominated by species like *Helleborus odorus* and *Melica uniflora*.

**Habitat 91Y0 (Dacian oak-hornbeam forests)** covers 162.31 ha, occurring at 200-310 m on mainly west-facing slopes (5-15°). The canopy includes *Quercus robur*, *Fraxinus angustifolia* ssp. *oxycarpa*, and *Carpinus betulus*, with a diverse herb layer dominated by *Ornithogalum pyrenaicum* and *Scutellaria altissima*.

Both habitats are in generally favourable conservation condition, although affected locally by invasive species such as *Ambrosia artemisiifolia* and the spread of *Robinia pseudoacacia* from nearby plantations.

Our records on seedlings/saplings of trees from the area showed that natural regeneration is generally very good, reaching in some areas a coverage of 50%. Some species are typical for one habitat type but there are many species common to both of them. From about 130 herbaceous plant species registered in the studied protected area, we present only the species with higher abundance in the two Natura 2000 habitats (Table 1).

The list of recorded species comprises *Ruscus aculeatus* (Figure 3)*, Ruscus hypoglossum, Asparagus verticillatus, Epipactis helleborine, Galium kitaibelianum, Neottia nidus-avis, Platanthera bifolia,* rare taxa with reduced world populations, not threatened yet but at risk (as a result of their reduced distribution area) (Oltean et al., 1994).

Table 1. The characteristics of the plant species

| Species' name | Trees | Seeedling /sapling | Common | Typical for 91M0 | Typical for 91Y0 | I&P |
|---|---|---|---|---|---|---|
| *Acer campestre* | + | + | + | | | |
| *Acer platanoides* | + | + | + | | | |
| *Acer tataricum* | + | | | + | | |

| *Pteridium aquilinum* | | | | | | + |
| *Setaria viridis* | | | | | | + |
| *Tanacetum corymbosum* | | | | + | | |

In Table 1, invasive and pest species (I & P) refer the presence of non-native flora within the

protected area. *Ambrosia artemisiifolia* and *Robinia pseudoacacia* are not currently included in the Union List of Invasive Alien Species of Union Concern (IAS, 2014; 2025), but they represent a significant ecological threat at the national level. *Ambrosia artemisiifolia* poses a major risk to public health due to its highly allergenic pollen, while *Robinia pseudoacacia* acts as an ecosystem transformer, displacing native vegetation and altering soil nitrogen levels. Furthermore, species such as *Gleditsia triacanthos* and *Erigeron annuus* show aggressive expansion in ruderal and riparian habitats, potentially compromising the structural integrity of local plant communities.

Other two species recorded in the site: *Pteridium aquilinum* (native species which, in this context, acts as a dominant taxon) indicate the degradation of local pastures, rather than being an exotic threat; *Setaria viridis* (common weed) has limited impact on the primary conservation objectives of the area. Only *Asclepias syriaca* recorded at the edge of the protected area is a IAS species under European cocern.

*R. aculeatus* is presented in Annex V of Habitat Directive (animal and plant species of community interest whose taking in the wild and exploitation may be subject to management measures) (H.D., 1992).

Figure 3. *Ruscus aculeatus*: individual with fruit (a) and local density in Str.8 (b)

In Natura 2000 Strehaia-Bâtlanele, this European interest species was found in 11 of the 31 recorded plots and distributed sometimes as rare, but having high abundance in other plots and significant cover at certain stations (Str.5 and Str.8) (Figure 4). It occurs in both main protected forest habitats: 91M0 and 91Y0. In habitat 91M0, *R. aculeatus* is a constant component of the herbaceous layer, typically developing on rocky substrates in sunny, mesoxerophilous conditions.

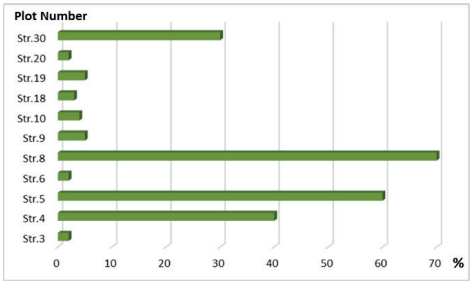

Figure 4. The distribution and density of *Ruscus aculeatus*

In habitat 91Y0, *R. aculeatus* is part of the stratified forest structure, and in some vegetation stands, *R. aculeatus* reaches remarkable ground cover values of up to 50%.

Although the species shows good local abundance, some populations may be affected by anthropogenic pressures, particularly the development of forest access roads that intersect its distribution areas.

The recorded presence of *Ruscus aculeatus* in the site represents a new distribution locality for the species in Romania.

The ordination analysis using Principal Component Analysis revealed a moderate differentiation of sampling sites based on species composition. The first axis explained 12.0% of the total variance, while the second axis accounted for 9.2% (Figure 5).

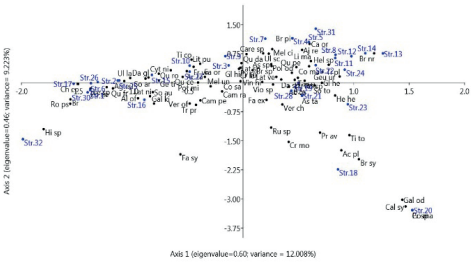

Figure 5. The ordination analysis using Principal Component Analysis of the recorded species

Sampling sites were distributed along the first axis, forming two partially separated groups. Sites located on the left side of the ordination diagram (e.g., Str.17, Str.26, Str.30) showed a particular species composition, while those positioned on the right side (e.g., Str.13, Str.14, Str.24) were associated with a different set of species.

Several species were positioned close to specific sampling sites, suggesting a stronger association with those locations. In contrast, some species occurred near the centre of the diagram, indicating a broader ecological distribution.

Two sampling sites (Str.20 and Str.32) were clearly separated from the main cluster of sites, suggesting distinct species assemblages compared with the rest of the study area.

Cluster analysis based on the Bray-Curtis similarity index and Jaccard similarity index revealed patterns of similarity among the sampling sites according to species composition (Figure 6a and 6b).

In the dendrogram based on the Bray-Curtis index (Figure 6a), the sampling sites were grouped into several clusters reflecting similarities in species abundance. A major cluster included sites such as Str.6, Str.17, Str.1, Str.2, and Str.15, which showed relatively high similarity values. Another group consisted of sites Str.11-Str.14 and Str.21-Str.23, indicating comparable species composition among these locations. Some sampling sites, such as Str.3 and Str.20, were separated from the main clusters, indicating lower similarity with other sites.

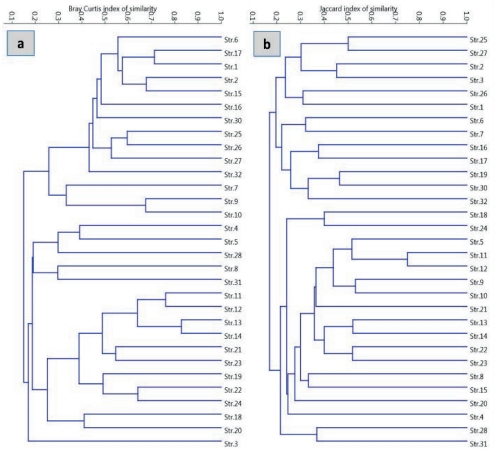

Figure 6. Cluster analysis based on the Bray-Curtis similarity index (a) and Jaccard similarity index (b)

The dendrogram based on the Jaccard index (Figure 6b), which considers species presence-absence, showed a similar overall grouping pattern, although with slight differences in cluster structure. Several sampling sites, including Str.25, Str.27, Str.2, and Str.3, formed a cluster with relatively high similarity. Other groups included sites such as Str.11-Str.12 and Str.9-Str.10, suggesting shared species composition among these locations.

Overall, both similarity indices indicated the presence of multiple clusters of sampling sites with comparable species composition, while a few sites appeared more distinct from the main groups.

Field research regarding herpetofauna revealed that the distribution of main target species, Hermann's tortoise (*Testudo hermanni*) (Figure 7), is highly localised to open glades.

Figure 7. *Testudo hermanni*
(the pattern of the shell design)

The total population of tortoises within the site is estimated at 179-182 individuals, with an average density of 2.88-2.93 individuals per hectare, significantly lower than densities recorded in more favourable habitats. Only adult individuals were observed, with no juveniles recorded during the hatching period. However, the conservation status of the Hermann's Tortoise (*T. hermanni*) is highly concerning. The "Unfavourable-Bad" assessment is driven by low population density and a lack of recruitment (juveniles). The high proportion of forest cover (over 80%) in the site limits the available habitat for tortoises, which require open meadows for foraging and nesting. Current management focuses on non-intervention in forest sectors, but for tortoises, this policy may lead to the "closing" of glades as the canopy density increases, further reducing habitat availability.

Several additional amphibian and reptile species that were newly recorded during this study had previously been absent from the official site documentation. Among amphibians, the *Pelophylax kl. esculentus* (edible frog) (Figure 8) was observed in ruderalised meadows with active springs and small water bodies, which provide suitable feeding and breeding conditions.

Figure 8. *Pelophylax kl. esculentus* recorded in a pond

Four new reptile species were also recorded (Figure 9). The most common was *Lacerta viridis* (European green lizard), a thermophilous species frequently observed in open habitats and on sunny slopes, with at least seven individuals recorded during surveys. *Natrix natrix* (grass snake) was identified in areas where springs and ponds provide abundant amphibian prey. Two additional species were considered rare within the site: *Coronella austriaca* (smooth snake), was recorded only once inside forest habitats, and *Zamenis longissimus* (Aesculapian snake), a semi-arboreal species typically associated with forest interiors and edges.

Figure 9. The new reptile species recorded in the studied site

Comparison with regional studies indicates that while ROSCI0405 has stable forest habitats (91M0 and 91Y0 are currently in "Favourable" status), the herpetofauna faces increasing pressure. Human impacts identified during the study - such as heavy vehicle traffic causing road gullying, the distribution of illegal waste, and sheep/goat grazing - are degrading the fragile meadow-forest ecotones.

Several invertebrate species of community interest (Figure 10) have been recorded in the ROSCI0405 Dealurile Strehaia-Bâtlanele site, highlighting the ecological importance of its forest and edge habitats.

Thus, *Lucanus cervus* (stag beetle), listed in Annex II of the EU Habitats Directive, was identified here as a new locality in its Romanian distribution. This saproxylic species is closely associated with deciduous forests, particularly oak-dominated habitats such as 91M0 and 91Y0 within the site. Its presence depends largely on mature *Quercus* trees and the availability of dead wood, which provides essential breeding microhabitats.

Another species of conservation interest is *Cerambyx cerdo* (great capricorn beetle), which inhabits old deciduous forests and shows a strong preference for mature or declining oak trees such as *Quercus petraea*, *Quercus cerris*, and *Quercus frainetto*. The species was directly observed during field surveys conducted in 2018-2019, and its occurrence is linked to the presence of standing and fallen dead wood.

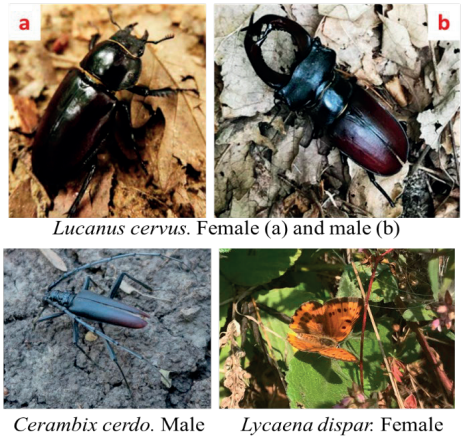

Figure 10. Invertebrate species of community interest

The site also hosts *Lycaena dispar* (large copper butterfly), typically found in humid grasslands, forest edges, and open clearings. In the area, it was recorded mainly in forest margins and glades, where herbaceous vegetation is well developed.

Conservation measures recommended for these invertebrates include maintaining native forest structure, preserving dead wood, and avoiding the use of insecticides in forest ecosystems.

Despite the relatively good conservation status of the forest habitats, the ecological integrity of the site is threatened by several anthropogenic pressures. One of the most significant threats is the spread of invasive plant species, which alters the structure and functioning of natural ecosystems. Species such as *Ambrosia artemisiifolia, Asclepias syriaca, Pteridium aquilinum*, and *Erigeron annuus* frequently colonise disturbed areas, especially along forest roads or degraded clearings. These plants can form dense stands that reduce floristic diversity and replace native vegetation communities. For example, *Ambrosia artemisiifolia* often forms monocultures that significantly degrade the tortoise's feeding grounds by replacing the diverse herbaceous flora required for its diet.

Another major ecological pressure is the expansion of the non-native tree species *Robinia pseudoacacia* (black locust). This species spreads aggressively from nearby plantations into natural forest habitats, where it alters soil conditions and promotes the dominance of nitrophilous plants such as *Urtica dioica*. As a result, the floristic diversity characteristic of oak and hornbeam forests is reduced, and open grassland areas necessary for thermophilous reptiles gradually disappear. Because *Testudo hermanni* depends on sunny habitats for thermoregulation and feeding, the spread of black locust represents a significant long-term threat to the survival of the species in the site.

Human activities also contribute to habitat degradation. The development of forest roads and uncontrolled access by off-road vehicles can damage vegetation, create erosion channels, and facilitate the spread of invasive species. In addition, illegal waste dumping and uncontrolled tourism can negatively affect the ecological quality of the habitats. Illegal collection of tortoises for the pet trade is considered one of the most serious direct threats to the species, as it primarily affects adult individuals that are essential for maintaining population stability.

Grazing activities also influence the ecological dynamics of the site. Sheep grazing is generally considered to have a relatively low impact on forest habitats, as animals mainly use the forest as a transit route toward surrounding grasslands. However, grazing may still cause trampling of vegetation and disturbance of tortoise feeding areas, particularly when herds are accompanied by dogs. Goat grazing is considered much more destructive, as goats selectively consume vegetation, promote soil erosion, and facilitate the spread of invasive plants through seed dispersal in their fur.

Another ecological issue affecting the site is the gradual closure of open glades due to natural vegetation succession. In the absence of traditional land management practices such as controlled grazing or selective clearing, shrubs and young trees gradually invade grasslands and forest clearings. This process leads to canopy closure and the transformation of sunny habitats into shaded forest environments that are unsuitable for thermophilous reptiles such as *Testudo hermanni*.

Because of these cumulative pressures, the conservation status of the Hermann's tortoise population in the site is currently assessed as "unfavourable-bad". Consequently, several management measures have been proposed in order to improve the conservation status of the species and protect the ecological integrity of the habitats.

One of the most important measures involves active habitat management, particularly maintaining open habitats suitable for the tortoise. This includes cutting shrubs and young trees that threaten to close forest clearings and grasslands, especially in the main observation areas. Maintaining these open areas ensures adequate sunlight exposure necessary for the species' thermoregulation and nesting behaviour.

Another recommended action is the modification and expansion of the site boundaries. Field observations revealed that several individuals of *Testudo hermanni* occur in adjacent south-facing grasslands located outside the current limits of the protected area. Expanding the site to include these habitats would improve the protection of the species and increase the ecological connectivity of the landscape (ANANP, 2020).

The control and eradication of invasive species also represent a major priority. Management plans propose regular monitoring and mechanical removal of invasive plants such as *Ambrosia artemisiifolia* and *Asclepias syriaca*, particularly along forest roads and disturbed areas that serve as dispersal corridors. In addition, the expansion of *Robinia pseudoacacia* should

be limited through removal of invasive stands and replacement with native tree species characteristic of the local forest ecosystems.
Regulation of human activities is another key component of conservation management. Measures proposed include restricting unauthorised vehicle access through the installation of barriers, controlling waste disposal, and prohibiting the collection of tortoises from the wild. Grazing activities should also be regulated by establishing sustainable stocking limits based on the ecological carrying capacity of the habitats.

## CONCLUSIONS

The Natura 2000 site ROSCI0405 Dealurile Strehaia-Bâtlanele, located in the hilly region of Mehedinți County, represents an important biodiversity reservoir despite its relatively small surface area. The field studies significantly expanded the knowledge of the site's biological diversity, demonstrating that its ecological value is considerably higher than previously documented in the official Standard Data Form. The research identified new occurrences of species of community interest and confirmed the presence of several rare plants and animals, emphasising the conservation importance of this protected area within Romania's Natura 2000 network.
One of the most important botanical findings was the identification of *Ruscus aculeatus*, a species listed in Annex V of the EU Habitats Directive. Its presence in the site represents a new distribution locality in Romania. The species occurs in both main forest habitats of the site - 91M0 (Pannonian - Balkanic turkey oak-sessile oak forests) and 91Y0 (Dacian oak-hornbeam forests) - where it forms part of the shrubs layer and, in some stands, reaches ground cover values of up to 50%.
The faunal component of the site also includes several species of European conservation interest. Among invertebrates, the presence of *Lucanus cervus* (stag beetle) was recorded as a new locality, further emphasising the importance of the site for saproxylic insect conservation. Other protected species observed during the surveys include *Cerambyx cerdo* (great capricorn beetle) and *Lycaena dispar* (large copper butterfly), all species listed in Annex II of the Habitats Directive. These species are closely associated with mature deciduous forests and structurally complex habitats containing old trees and dead wood, conditions that are still partially preserved in the forest ecosystems of the site.
Additional herpetofauna species not previously included in the official documentation of the site were also recorded: *Pelophylax kl. esculentus* (edible frog), *Lacerta viridis* (European green lizard), *Natrix natrix* (grass snake), *Coronella austriaca* (smooth snake), *Zamenis longissimus* (Aesculapian snake).
Long-term monitoring and research programs are essential for assessing the effectiveness of these conservation measures. Monitoring protocols should focus on key periods in the tortoise's life cycle, including migration to breeding areas, egg-laying, and movement toward hibernation sites. Cooperation between forest managers and protected area administrators is also necessary to ensure effective surveillance and protection of the habitats.
Public awareness and environmental education represent additional important tools for conservation. Informational panels and educational programmes for local communities and schools can help increase awareness of the ecological importance of the site and promote responsible behaviour within the protected area.
Overall, the results of this research demonstrate that the ROSCI0405 Dealurile Strehaia-Bâtlanele site has a much higher biological value than previously recognised. The discovery of new distribution localities for species of community interest such as *Ruscus aculeatus* and *Lucanus cervus*, together with the presence of numerous rare plants and vertebrates, highlights the importance of this area for regional biodiversity conservation. This increased knowledge as to the value of Dealurile Strehaia-Bâtlanele should contribute not only to the Natura 2000 network in Europe, but also to national biodiversity planning and implementation in Romania. These findings provide an important scientific basis for the implementation of the site's management plan and establish a baseline for the five-year monitoring cycles required under the EU Habitats Directive, ensuring that conservation actions can be effectively evaluated and adapted in the future.

## ACKNOWLEDGEMENTS

Our study was developed in the period 2018-2019 in the framework of the project "Elaboration of the management plan for the site of community importance ROSCI0405 Strehaia Hills - Bâtlanele", SMIS Code 102055. The present paper is written in the framework of the project RO1567-IBB01 from the Institute of Biology Bucharest, financed by the Romanian Academy. We kindly thank to J. Owen Mountford for his valuable comments on the article and for controlling the correctness of English.

***Abstract***

*A study of the state of atmospheric air and anthropogenic impact in a typical urban area of Bulgaria - the city of Plovdiv and its surroundings was conducted. The study is based on a specific incident - a fire at a solid waste landfill in the city of Plovdiv. The values of the main pollutants of the atmospheric air above the settlements were monitored (PM10, $SO_2$, $NO_2$, $O_3$, CO and benzene). The chemical and ecological state of the atmospheric air was assessed. Its quality was analyzed using the Air Quality Index (AQI) of the United States Environmental Protection Agency (US-EPA) and the European Air Quality Index (EAQI) of the European Environment Agency. Deviations from the permissible values are observed only for particulate matter (PM10) - irregular higher hourly values above the permissible value, which is for 24 hours. The results are compared with those of the two automatic stations in the city. The possible impact of the excessive values on human health, living organisms, and protected habitats is shown. Measures to improve air quality were discussed.*

***Key words****: air pollution, air quality index, anthropogenic impact, chemical state, particulate matter.*

## INTRODUCTION

Anthropogenic air pollution arises from human activities related to industrial and social development. The majority of the population exposed and affected by air pollution lives in the area of pollution sources. Obviously, attention is being directed towards the urban environment and industrial sites (Allegrini et al., 2023).

Any activity that leads to a deterioration or reduction in the quality of the natural environment is considered pollution. This is the biggest global problem facing humanity and a leading environmental cause of morbidity and mortality (WHO global air quality guidelines, 2021; Directive (EU) 2016/2284; Directive (EU) 2024/2881). Environmental pollution is more common in middle- and low-income countries than in developed countries. The likely reasons for this are poverty, poor legislation, and lack of awareness about forms of pollution. The population's daily encounter with pollution leads to habituation and dulling of attention. People often carry out activities that disrupt the stability and resilience of ecosystems and lead to environmental deformation - deforestation, deliberate arson, and unregulated disposal of agricultural, household, and electronic waste. Exponential population growth and urbanization are increasing this harmful pressure on the environment. Air pollution is well-studied and receiving increasing attention due to increased morbidity and premature mortality. It affects the most vulnerable groups in middle- and low-income countries. Greater awareness of the dangers of pollution and the subsequent limitation and prevention of activities leading to environmental pollution are needed so that the restoration of already affected nature becomes feasible (Ukaogo et al., 2020). Natural and

anthropogenic features and the interaction between them determine air quality in urban environments. Pollution is determined by incoming emissions, dispersion, and transport of pollutants. Factors contributing to the deterioration of air quality in cities include population growth, increased traffic, and the energy and industrial sectors. There is a typical annual, weekly and daily cyclicality (Mayer, 1999).

The harmful impact on human health from air pollution is expressed in the exacerbation of cardiovascular, airborne diseases, diseases of the gastrointestinal tract and endocrine system, an increase in the frequency of allergies and bronchial asthma (with increased dust content). The implementation of sustainable development policies is crucial for limiting emissions and reducing morbidity (Komilova et al., 2023).

Since 1950, the world population has more than doubled, with the urban population more than quadrupling. The number of cars has increased even faster, over ten times. This rapid urbanization is leading to environmental degradation. Urban activities are sources not only of local air pollution, but also have a significant share in transboundary pollution (Fenger, 1999).

Urban regions are the source of one third of anthropogenic greenhouse gases and the majority of air pollutant emissions worldwide. While climate change is a global problem, poor air quality is a local one. Joint action on both climate and air pollution is needed to limit the harmful effects of air pollutants on urban populations and ecosystems (Crippa et al., 2021).

Different countries and regions have different air quality systems. Each system uses its own harmfulness index, permissible pollution concentration, and measurement time. This makes it difficult for users to navigate between the different systems. The Air Quality Index (AQI) of the United States Environmental Protection Agency (US-EPA) and the European Air Quality Index (EAQI) of the European Environment Agency are widely popular and used.

The AQI is a number calculated based on measured levels of particulate matter (PM2.5 and PM10), ozone, nitrogen dioxide, sulfur dioxide, and carbon monoxide in ambient air. The values are divided into six levels of air pollution, each of which is in a different color and provides information about possible health effects (Horn & Dasgupta, 2024; Sheikh, 2019). The EAQI also takes into account the main pollutants - particulate matter (PM2.5 and PM10), ozone, nitrogen dioxide and sulfur dioxide, but the values are specific to each pollutant. The ranges of values are divided into six zones according to the impact and relative health risk, as defined by the World Health Organization and related to short-term exposure to the pollutants (European Air Quality Index, 2024).

Both indices should not be compared with the relevant air quality standards in individual countries. They can serve as a guide to the quality of ambient air when traveling, working, or in general for populated areas. At the same time, public awareness of the importance of clean air is being raised and broader support for air quality and emissions regulations is being built. As regulatory restrictions change, both indices change, keeping them current and timely (Sheikh A., 2019; European Air Quality Index, 2024).

Particulate matter is a major factor in air pollution and its harmful effects on human health and living organisms in recent decades. The negative effect is determined by the dispersion, chemical composition and, accordingly, the physicochemical properties of these particles. The presence of heavy metals in road dust in densely populated areas is mainly due to industrial, construction and transport activities (Lei et al., 2024; Ma et al., 2025).

Air quality standards in cities are frequently exceeded. This negatively affects the population and leads to reduced labor productivity, increased economic and medical costs, and shortened life expectancy. Pollutants such as particulate matter, nitrogen dioxide, and ground-level ozone have the most serious impact on human health. Compliance with the recommendations of the World Health Organization would lead to limiting the negative effects of urban air pollution (Air pollution quick country facts, 2024).

Air pollution negatively affects both terrestrial and aquatic ecosystems, thereby deteriorating the environment and reducing biodiversity. Each pollutant has a specific harmful effect.

Ozone, as a secondary air pollutant, damages plants and forest stands, reducing growth rates and yields. The release of ammonia (in agricultural activities) and nitrogen oxides (in combustion processes) leads to nitrogen deposition on land and in water bodies, respectively to eutrophication processes and ultimately to changes in the structure and function of the ecosystem (Impacts of air pollution on ecosystems in Europe, 2024).

Nearly three-quarters of European ecosystems are exposed to harmful levels of air pollution, according to the latest data. This leaves Europeans exposed to concentrations of air pollutants above WHO recommended levels (Health and environment impacts of air pollution exposure remain high across Europe, 2024).

The increase in public health incidents resulting from air quality, as well as environmental degradation, is prompting authorities and experts to improve and seek new ways of monitoring air quality and “adequately” deploying air quality sensors (Chaudhuri & Roy, 2024).

The subject of this study is a typical urbanized urban area, namely that of Plovdiv, the second largest city in Bulgaria. The high density of construction, intensive car traffic and industrial activity are characteristic. The main factors for air pollution in the area under consideration are combustion processes, transport, the condition of the road and adjacent infrastructure. Plovdiv is located in the central part of the Upper Thracian Lowland. The relief is mainly flat, and the hills form an arc along the border with the Rhodope Mountains. The climate is transitional-continental with moderate precipitation and prolonged summer droughts. The prevailing westerly and easterly winds are of relatively low speed. A characteristic feature is the high proportion of calm weather. The dispersion of pollutants is adversely affected by temperature inversions (on about 81% of the days during the year) and the large number of foggy days in winter (Report on the Influence of the Atmospheric Air on the Health of the Population of "Plovdiv Agglomeration" in 2024, 2025).

The air quality in the area is monitored through air monitoring stations, which are part of the National Environmental Monitoring System. There are two automatic measuring stations (AMS) (Regulation No. 12 of July 15, 2010 for standards for sulfur dioxide, nitrogen dioxide, fine dust particles, lead, benzene, carbon monoxide and ozone in atmospheric air):

– AMS "Kamenitsa", classified as an urban background station. It is located in the central part of the city of Plovdiv in an area with mainly residential buildings and medium-heavy car traffic;

– AMS "Trakia" - meets the conditions for a transport-oriented point. It is located in an area with heavy car traffic. The observed pollution is mainly formed by transport and individual heating systems.

## MATERIALS AND METHODS

The anthropogenic impact and potential pollution of the Plovdiv region was studied through a typical incident factor - a fire at the Regional Non-Hazardous Waste Landfill. The location of the air monitoring stations, the regional non-hazardous waste landfill and the protected areas in the study area are presented on the map in Figure 1.

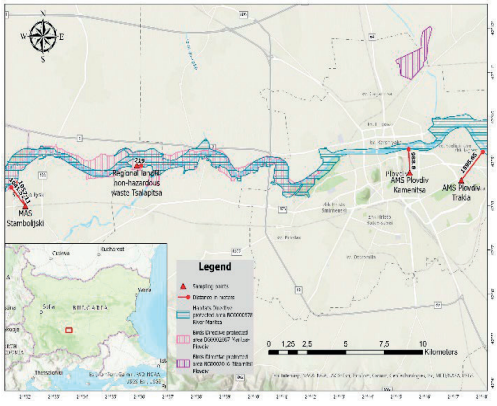

Figure 1. Locations of air monitoring stations, the regional non-hazardous waste landfill and protected areas in the study region

The main typical indicators of ambient air quality in populated areas were analyzed, namely - particulate matter (PM10), sulfur dioxide, carbon monoxide, nitrogen dioxide, nitrogen oxide, ozone, benzene. The indicators, together with their analysis methods and current permissible concentrations for Bulgaria, are presented in Table 1.

Table 1. Measured indicators and main characteristics

| Indicator | Unit of measure | Analysis method | Uncertainty | Standard |
|---|---|---|---|---|
| Particulate matter | μg/m$^3$ | BDS EN 16450:2017 | U=14.7% | ADN - 50 AAN - 40 |
| Sulfur dioxide | μg/m$^3$ | BDS EN 14212:2012 | U=3.70% | AHN - 325 AND - 125 |
| Carbon monoxide | mg/m$^3$ | BDS EN 14626:2012 | U=3.75% | HHPS - 10 |
| Nitrogen monoxide and Nitrogen dioxide | μg/m$^3$ | BDS EN 14211:2012 | U=3.74% | AHN - 200 AAN - 40 |
| Ozone | μg/m$^3$ | BDS EN 14625:2012 | U=3.60% | HHPS - 180 |
| Benzene | μg/m$^3$ | BDS EN 14662-3:2015 | U=4.5% | AAN - 5 |

Legend: ADN - Average daily norm for the protection of human health; AAN - Average annual norm for the protection of human health; AHN - Average hourly norm for protecting human health; HHPS - Human health protection standard (maximum eight-hour average value within 24 hours); Regulation No. 12 (2010).

Ambient air quality was analyzed using the Air Quality Index (AQI) of the United States Environmental Protection Agency (US-EPA) and the European Air Quality Index (EAQI) of the European Environment Agency. The values of the two indices AQI and EAQI and their corresponding air quality color scales are presented in Table 2 (Horn & Dasgupta, 2024; European Air Quality Index, 2024).

Table 2. Air Quality Index (AQI), European Air Quality Index (EAQI) and the corresponding condition color scale

| Air Quality Index (AQI) | | European Air Quality Index (EAQI), PM10 | |
|---|---|---|---|
| Values | Condition color scale | Values, μg/m$^3$ | Condition color scale |
| 0-50 | good | 0-20 | good |
| 51-100 | moderate | 20-40 | fair |
| 101-150 | unhealthy for sensitive individuals | 40-50 | moderate |
| 151-200 | unhealthy | 50-100 | poor |
| 201-300 | very unhealthy | 100-150 | very poor |
| 300+ | dangerous | 150-1200 | extremely poor |

The fire at the Regional Non-Hazardous Waste Landfill, Tsalapitsa, occurred on 1 August 2024 and was contained within a few days. The impact and potential contamination of the Plovdiv area were assessed through the readings of the Stambolijski MAS, Kamenitsa MAS - Plovdiv and Trakia MAS - Plovdiv for the period 1-6 August 2024. The mobile station in Stambolijski is temporarily located for the above-mentioned period in connection with the specific meteorological conditions and the dispersion of possible pollutants.

## RESULTS AND DISCUSSIONS

The impact and probable pollution of the surveyed region from the fire at the non-hazardous waste landfill was assessed through the readings of the MAS Stambolijski, AMS "Kamenitsa" - Plovdiv and AMS "Trakia" - Plovdiv for the period 1-6 August 2024. The interval of the measured hourly values for the controlled atmospheric pollutants for the time from 1 August 2024 to 6 August 2024 for the three stations is presented in Table 3.

Table 3. Interval of measured hourly values for controlled atmospheric indicators for the time from August 1, 2024 to August 6, 2024, for the three automatic stations

| Indicator | Value range | | |
|---|---|---|---|
| | AMS - Trakia | AMS - Kamenitsa | MAS - Stambolijski |
| Particulate matter, μg/m$^3$ | 12 ÷ 348 | 9 ÷ 139 | 7 ÷ 45 |
| Sulfur dioxide, μg/m$^3$ | 2 ÷ 14 | 8 ÷ 49 | 7 ÷ 35 |
| Carbon monoxide, mg/m$^3$ | 0.2 ÷ 0.7 | 0.1 ÷ 0.6 | 0.2 ÷ 0.6 |
| Nitrogen monoxide, μg/m$^3$ | 5 ÷ 13 | 0.5 ÷ 8 | 1 ÷ 5 |
| Nitrogen dioxide, μg/m$^3$ | 15 ÷ 56 | 4 ÷ 37 | 8 ÷ 40 |
| Ozone, μg/m$^3$ | - | 25 ÷ 160 | 31 ÷ 131 |
| Benzene, μg/m$^3$ | 0.01 ÷ 4.23 | 0.02 ÷ 0.16 | - |

Hourly values higher than the maximum permissible concentrations are observed only for the PM10 indicator - the deviations are present for the two automatic stations in the city of Plovdiv. The high maximum values (close to the permissible values according to legislation) for nitrogen dioxide, ozone and benzene should not be ignored.

The average daily concentrations of PM10 for the three measuring stations and the EAQI and AQI levels are presented in Table 4.

The reported values correspond to good status according to both indices, with the exception of the value reported for AMS Trakia on 02.08.2024 - moderate status according to EAQI.

The hourly exceedances of the 24-hour average limit for PM10 (50 μg/m$^3$) and the assessment of the condition according to EAQI and AQI are presented in Table 5.

Table 4. Average daily particulate matter concentration for the three measuring stations and EAQI and AQI levels

| Data | Value | | | | | |
|---|---|---|---|---|---|---|

As can be seen from the data in Table 5, hourly exceedances of PM10 are observed on August 2, 3 and 4, 2024 for AMS - Trakia and August 2 and 3, 2024 for AMS - Kamenitsa. For AMS - Trakia, the exceedances are a total of eight, while for AMS - Kamenitsa, there are a total of six. The highest and highest values were recorded in the first half of the day on August 2, 2024. Out of the total 14 exceedances obtained, 7 values indicate poor air quality (4 in AMS - Trakia and 3 in AMS - Kamenitsa); 5 values indicate very poor air quality (2 in AMS - Trakia and 3 in AMS - Kamenitsa), and 2 values indicate extremely poor air quality according to EAQI (both in AMS - Trakia).

What is the impact of elevated PM10 values on the flora, fauna and health of the population in the study region? This impact has been assessed based on the Law on environmental protection, the Atmospheric air purity law, the Law of Health and Regulation No. 12/2010 on the standards of harmful substances in the ambient air of populated areas (Law on environmental protection, 2002; Law of Health, 2005; Atmospheric air purity law, 1996; Regulation No. 12, 2010).

No exceedances of the standards for the protection of human health were registered for the measured indicators in the days from 01.08.2024 to 06.08.2024, according to the presented results for the controlled pollutants of the atmospheric air for the three monitoring stations - MAS - Stamboliyski, AMS - Kamenitsa - Plovdiv and AMS - Trakia - Plovdiv. Fourteen of the reported hourly PM10 values exceed the daily average (Tables 3 and 5).

The average daily values indicate good air quality according to the AQI - air pollution poses a low or low risk. According to the EAQI, the values obtained correspond to good (9 values), sufficient (24 values) and only one - to moderate condition.

The hourly values exceed the daily average in 14 of the 288 results (4.86%) obtained for the two stations AMS - Trakia and AMS - Kamenitsa. This excess is from 1.01 to 6.97 times. According to AQI, 11 values indicate a moderate state of ambient air quality with a risk for very sensitive people with respiratory diseases and only one value for an unhealthy state, in which everyone can begin to experience health consequences, and members of sensitive groups may have more serious health

consequences. Despite the fact that the relative share of the results for the most part indicates a good state of ambient air quality (according to AQI), the excesses obtained are not negligible.

Near the assessed sites are Protected Area BG0002016 "Ribarnici, Plovdiv"; Protected Area BG0000578 "Maritsa River" for the protection of natural habitats and wild flora and fauna; Protected Area BG0002087 "Maritsa, Plovdiv" for the protection of wild birds (Figure 1). The increase in particulate matter levels is expected to worsen the living conditions of species and their ability to inhabit the protected area (Biodiversity Law, 2002; NATURA 2000).

In the region of the city of Plovdiv and the surrounding area in 2024, according to the Regional Inspectorate for Environment and Water and the Regional Health Inspectorate, five more fires occurred requiring measurements with a mobile automatic station for atmospheric air quality. Summary information on the quality of ambient air in the studied region is presented in the annual reports of both organizations. Table 6 presents the calculated annual average value (AAV) and the registered number of exceedances of the permissible values for basic indicators for the two measuring stations in the city of Plovdiv - AMS - Trakia and AMS - Kamenitsa for a three-year period - from 2022 to 2024 (Regional Report on the State of the Environment in 2024, 2025; Report on the Influence of the Atmospheric Air on the Health of the Population of "Plovdiv Agglomeration" in 2024, 2025). Exceedances of permissible values are observed mainly for particulate matter (of the average daily values for all three years for both stations), as well as for nitrogen dioxide (of the average annual values for 2022 and 2023 for AMS - Trakia). The observed exceedances of the average daily norm for PM10 in the AMC - Trakia exceed the permissible number, according to the legislation, of 35 times within the calendar year. The recorded maximum hourly values for benzene also exceed the permissible annual average standard.

For the incident we investigated - a fire at a solid waste landfill, no daily average values for PM10 higher than the maximum permissible concentration were observed, but high hourly values exceeding the daily average norm.

According to the Regional Inspectorate for Environment and Water and the Regional Health Inspectorate, the origin of air pollution in the region should be sought primarily in the production of electricity and heat, domestic heating and motor vehicle transport. In recent years, a positive trend towards a decrease in the number of registered exceedances and high values of pollutants at monitoring points has been observed (Regional Report on the State of the Environment in 2024, 2025; Report on the Influence of the Atmospheric Air on the Health of the Population of "Plovdiv Agglomeration" in 2024, 2025).

Table 6. Summary results for exceedances of basic assessment indicators for ambient air quality for AMS - Trakia and AMS - Kamenitsa for the period 2022-2024

| AMS | AMS - Trakia | | AMS - Kamenitsa | |
|---|---|---|---|---|
| Indicator PM10<br>Standard: AAN - 40 μg/m³, ADN - 50 μg/m³<br>(exceeded no more than 35 times per calendar year) | | | | |
| year | AAV, μg/m³ | Number of exceedances of the ADN | AAV, μg/m³ | Number of exceedances of the ADN |
| 2022 | **37.20** | **64** | **28.36** | **32** |

The specific meteorological conditions in the region (a large number of days with calm weather - wind speed below 1.5 m/s, temperature inversions and fog on the rivers) are a prerequisite for the retention and accumulation of pollutants. The adverse climatic conditions in the region - more than 50% of the days in the year with calm weather and over 75% of the days in the year with inversion processes, lead to the retention of the formed relatively high background concentrations of PM10.

Particulate matter is a major air pollutant. It is emitted directly into the atmosphere by transport, energy and domestic activities (primary emissions) or is formed in the air from metal oxides, polyaromatic hydrocarbons, sulfur dioxide, nitrogen oxides, ammonia and other gases (secondary emissions). Its harmful effects on health depend mainly on the size and chemical composition of the suspended particulate matter, on other chemical compounds adsorbed on their surface and on the part of the respiratory system in which it is deposited. Particulate matter enters the body mainly through the respiratory system, with larger particles being retained in the upper respiratory tract, while finer particles reach the lower parts of the respiratory system, leading to tissue damage in the lung. Children, the elderly and people with chronic lung diseases, respiratory diseases or asthma are particularly sensitive to high PM10 values. The harmful effect of particulate matter pollution is more pronounced when sulfur dioxide is present in the ambient air. Their synergistic effect on the respiratory organs and exposed mucous membranes is manifested by irritation and depends on the duration of exposure.

There is a relationship between high PM concentrations and mortality, hospitalizations for respiratory diseases, and person-days of bronchodilator use. It is assumed that acidic particles with nanosizes smaller than 100 nm cause acute respiratory problems in sensitive people. Particles with a diameter smaller than 10 μm can pass into the thoracic airways of people. PM pollution can lead to the development of asthma, aggravate respiratory diseases, provoke and progress chronic diseases such as emphysema, lung cancer and others. Adverse effects on human health, flora and fauna occur not only at high concentrations, but also at values close to or even below the permissible norm (Chuturkova, 2015).

## CONCLUSIONS

High values, including exceedances of the maximum permissible concentrations of air quality indicators, have a negative impact on the health, lifestyle and work of the population. These high values and exceedances are a consequence of both single incidents (such as the fire in question) and permanent anthropogenic load from the energy and transport sectors. Reducing the harmful impact of particulate matter as a major pollutant requires taking adequate measures. These may include: modernization, quality maintenance and washing of road surfaces; control of construction activities; landscaping of open areas; construction of insulating plant belts on busy streets with intensive transport traffic; tolerating the replacement of solid fuels used for heating with central heating, electricity and natural gas; increased control over landfills and unregulated burning of solid waste.

In order to limit air pollution and, accordingly, the harmful effects of dust particles, specific actions are required on the one hand by administrative and control authorities, and on the other - by citizens.

## ACKNOWLEDGEMENTS

The authors express their gratitude to Plovdiv University "Paissii Hilendarski", Agricultural University - Plovdiv and National Institute of Geophysics, Geodesy and Geography, Research Center for Hydrology and Water Management, Bulgarian Academy of Sciences, Sofia, Bulgaria for their support in carrying out this study.

***Abstract***

*The present study aims to establish the potential similarity between airborne microorganisms and soil microorganisms. We analyse the percentage of similarity based on dominant types of soil microorganisms and their frequency of occurrence in ground air, as well as their association with specific fractions of fine dust particles. For the purpose of the study, eight sampling plots were selected, with different anthropogenic pressure. A six-stage cascade impactor was used to collect air samples. Soil samples were taken from a depth of 0-15 cm. The dominant types of microorganisms were determined. DNA identification was performed. The results show that bacteria predominate in the first levels of the cascade impactor. Fungi are concentrated at sieves 4.7-7.0 µm. Actinomycetes are most concentrated at sieves 3.3- 4.7 µm and 2.1-3.3 µm. The most common from Bacilli are B. megaterium and B. cereus. The amount of soil microorganisms, as a percentage similarity to the air microflora, increases with increasing anthropogenic pressure and reach up to 8%. The increased presence of opportunistic soil microorganisms in heavy construction areas in Sofia poses a significant risk to public health, which highlights the need for specific regulations related to minimizing dust generation.*

***Key words****: airborne microorganisms, DNA, soil microorganisms, urban environment, 16S rRNA.*

## INTRODUCTION

Surface air, although long considered only as a transit medium for microorganisms, is now defined as a dynamic and complex microbial habitat that plays a critical role in environmental quality. Airborne microorganisms are often defined as bioaerosols. According to this is important to point out that bioaerosols include not only bacteria, fungi, actinomycetes, viruses and their fragments, but also any type of biological components, such as pollen and other plant fragments, for example. There is evidence that bioaerosols constitute up to 25% of the total mass of atmospheric aerosols (Shammi et al., 2021). This data determines the important role of airborne microorganisms in the analysis of atmospheric air quality.

From this perspective, air pollution is one of the main causes of deterioration of human health, as well as the functioning of ecosystems. Increased levels of pollutants in the air lead to changes in naturally occurring processes in ecosystems. These changes lead to a decrease in the degree of air decontamination, carbon dioxide assimilation, soil acidification, etc. Particulate matter concentrations are indicators of complex mixtures of pollutants (Masselot et al., 2024). It has been found that air quality is worse in urban areas than in rural areas. The main sources of dust pollution are road transport, industry, as well as the use of solid fuels for heating and power generation, and construction and excavation human activities (Ketchman & Bilec, 2013; Khan & Strand, 2018; Sager, 2020). In recent years, several studies have highlighted the potential relationship between the concentration of fine particulate matter, of various origins, and the content of microorganisms in the air (Mansour et al., 2014; Palladino et al., 2021). Concentration of settled microorganisms on fine particulate matters has different significance for ambient air quality. Determining the content and predominant groups of microorganisms can serve as an indicator of air quality.

The main sources of atmospheric microorganisms are land and water surfaces, with soil being the most significant reservoir for airborne microorganisms above land. Soil microorganisms enter the atmosphere through processes of mechanical soil breakdown as a result of various human activities, wind erosion, etc. Research shows that airborne microbial communities often reflect the structure of communities in surrounding surface ecosystems

The data shows that 46.3% of airborne bacteria originating from the immediate ground environment (Zhao et al., 2022). When studying air quality, it is necessary to analyze the microbial load, including the presence of specific microorganisms generally present in soils. Such information can show the influence of anthropogenic activity - construction, excavation activities, maintenance of parks and gardens - on the quantity and specificity of microorganisms present in the air. Given that the main source of airborne microorganisms is soil (Ruiz-Gil et al., 2020), and it contains a number of pathogens (Pales, 2024), it is of key importance to analyze the percentage of major and commonly occurring soil microorganisms in the air, in order to prevent human health and increase environmental hygiene. While the microbiological characteristics of soil, aquatic habitats, etc. have been studied in detail, revealing specific and interconnected ecosystems, air often remains neglected as an independent habitat for microorganisms. The air environment is often considered only as a spreading factor for microorganisms. New analyses show that air is a real and specific ecosystem, inhabited by a microbiome that is vast in both number and diversity (Amato et al., 2023). Airborne microorganisms not only influence climate processes through the formation of ice nuclei and cloud condensation, but also have a direct impact on human health, agriculture, and ecosystem stability. In conditions of increasing urbanization and anthropogenic pressure, understanding the mechanisms by which microorganisms are transferred from land surfaces to the ground air layer becomes fundamental for protecting public health and optimizing urban hygiene (Chen et al., 2020).

The study of the entry and distribution of microorganisms into the air environment will provide important information about the microbiological load of individual ecosystems. This information will predict in the future the microbiological effect of air pollution resulting from the ever-increasing construction activities in urban areas.

The main goal of this study is to establish the degree of similarity between air and soil microflora in urban environments by analyzing the distribution of dominant types of soil microorganisms in individual fractions of fine dust particles under the influence of different anthropogenic pressures.

## MATERIALS AND METHODS

The study was conducted in early September 2025, on the territory of the municipality of Sofia, Bulgaria, covering four areas with intense anthropogenic pressure (Sample Plot (SP) 1-4) and four areas in parks and mountain regions with low anthropogenic pressure (Sample Plot (SP) 5-8).

SP1 - Formation of a green park area, flower beds (manually) in Geo Milev Park - with the presence of anthropogenic pressure. Coordinates: 42°41′12.18″N 23°21′50.37″ E.

SP2 - Reconstruction of sidewalks in the residential district of Geo Milev - with the presence of anthropogenic pressure. Coordinates: 42°42′51.73″N 23°21′33.37″ E.

SP3 - Reconstruction of the roadway on Vladimir Vazov Blvd. - with the presence of anthropogenic pressure. Coordinates: 42°42′31.95″N 23°22′17.73″ E.

SP4 - Construction of a residential complex in the residential district of Dragalevtsi - with the presence of anthropogenic pressure. Coordinates: 42°38′13.93″N 23°18′39.35″ E.

SP5 - Western Park, heavily forested inner part - without the presence of anthropogenic pressure, only recreational activity is established. Coordinates: 42°20′09.59″N 23°15′20.53″ E.

SP6 - Hunting Park, heavily forested inner part - without the presence of anthropogenic pressure, only recreational activity is established. Coordinates: 42°39′48.90″N 23°20′17.98″ E.

SP7 - Vitosha Nature Park, tourist trail - without the presence of anthropogenic pressure, only recreational activity is established. Coordinates: 42°36′54.66″N 23°17′35.10″ E.

SP8 - Plana Mountain, tourist trail - without the presence of anthropogenic pressure, only recreational activity is established. Coordinates: 42°30′38.53″N 23°21′39.25″ E.

The present study includes analysis of the quantity of the main microbiological groups of the air microflora and determination of the total microbial number of each sample. Analysis of the main groups of soil microorganisms

(bacteria, actinomycetes and micromycetes) and determination of the total microbial number. The study also includes determination of the species of the genus *Bacillus: Bacillus cereus, Bacillus subtilis, Bacillus megaterium* and *Bacillus mycoides*. For precise monitoring of ground-level air microflora, a 6-stage cascade impactor was used, operating on the principle of inertial sedimentation. Sampling was performed once from each of the surveyed points, with one cubic meter of air being passed through the impactor at a uniform speed. The device divides the air sample (with a volume of 1 $m^3$) into six fractions based on the aerodynamic diameter of the particles: 1st stage (> 7.0 μm); 2nd stage (4.7-7.0 μm); 3rd stage (3.3-4.7 μm); 4th stage (2.1-3.3 μm); 5th stage (1.1-2.1 μm); 6th stage (0.65-1.1 μm). A Petri dish with a specific medium was placed at each level of the impactor. Samples were taken at a height of 1.5 m (the breathing zone) at a temperature of 11°C and a humidity of 86%. The incubation process was carried out under the following parameters: total microbial number (bacteria) on meat peptone agar (MPA) - incubation at 28°C for 48 hours in an aerobic environment. Actinomycetes - dense plating on starch ammonia agar (SAA), incubation at 35°C for a period of 10 days. Micromycetes - plating on Capek Dox Agar medium, incubation at 30°C for 7 days. Soil samples were taken once, with a sterile probe from a depth of 10 cm. The samples were placed in sterile bags and analyzed within 24 hours. Each sample was pre-cleaned of impurities and prepared for analysis by serial dilutions. For counting of germinated colonies, dense plating on solid agar media was used. The media and incubation period were identical to those used for the study of air samples. To determine the representatives of the genus *Bacillus: Bacillus cereus, Bacillus subtilis, Bacillus megaterium* HiBacillus Identification Kit (HiMedia Laboratories, India, Mumbai) was used. The study is based on a colorimetric test. The test is based on the principle of pH change. *Bacillus* species show metabolic changes during incubation, for which the color change in the medium is an indicator. To perform the analysis, each of the samples was previously prepared and purified. Incubation was performed at 37°C for 48 hours. The data were read using a color scale based on the color change of the plate. Given the specific colonies that *Bacillus mycoides* forms, it was also reported. After performing the analysis, pure cultures were prepared to confirm the identity of the bacilli by DNA sequencing. Molecular genetic identification of the isolated strains was performed by determining 16S rRNA gene nucleotide sequences using primer pair 27F (5'-AGAGTTTGATCMTGGCTCAG-3') × 1492R (5'-GGTTACCTTGTTACGACTT-3'). PCR amplifications were performed using the MyTaq HS DNA Polymerase 2x Mix (Bioline Ltd., UK). The resulting PCR products were separated by agarose gel electrophoresis, stained with GelRed (Biotium, USA). The amplified DNA fragments were excised and purified from the agarose gel using the GeneJET Gel Extraction Kit (Thermo Scientific, USA). The purified DNA fragments were directly sequenced in both directions (forward and reverse) using the same primers employed for amplification. The evaluation and analysis of the resulting chromatograms and nucleotide sequences were carried out using CHROMAS v2.31 and Vector NTI v.11 software packages. Final taxonomic identification and alignment were performed by comparing the consensus sequences against the NCBI BLAST database (GenBank).

The numerical data were processed with StatSoft Statistica 12 software. For each sample, the mean value of three replicates and the standard deviation SD were calculated, at a statistical significance threshold of $p < 0.05$ (95% confidence interval).

## RESULTS AND DISCUSSIONS

In urban areas, anthropogenic activities such as road traffic, construction, and industrial processes significantly accelerate the transport of soil particles and their associated microbes into the ground air. The study by Chen et al. (2020), highlights that the soil environment is one of the main pathways for the emission of microorganisms into the air.

The results for the reported amounts of microorganisms for each of the fractions are shown in Table 1.

Table 1. Microbiological parameters of air samples (CFU*$10^2/m^3$)

| Total microbial number | | | | | | |
|---|---|---|---|---|---|---|

According to air analysis data, sample areas with construction activities have microbial abundance about twice as high as green areas. The results show that bacteria predominate in

the first levels of the cascade impactor, where larger particles settle. Fungi are also most concentrated in the upper levels of the impactor, with the main percentage of them in the second stage of sedimentation (4.7-7.0 µm). In the case of actinomycetes, we again observe a greater number of CFU/m$^3$ in the petri dishes of the larger sieves 3.3-4.7 µm and 2.1-3.3 µm. These data are very intriguing considering that these are the sieves that capture the main soil particles (Padoan et al., 2021). The results of the soil analyses are provided in Table 2.

Table 2. Microbiological parameters of soil samples (CFU*10$^4$/g soil)

| | TMN | Bacteria | Actinomycetes | Micromycetes |
|---|---|---|---|---|
| SP1 | 12.6 ± 2.63 | 7.6 ± 1.76 | 3.4 ± 1.04 | 1.6 ± 1.18 |
| SP2 | 10.14±2.63 | 5.9 ± 1.76 | 3.2 ± 1.04 | 1.04 ± 1.18 |
| SP3 | 6.2 ± 2.63 | 3.6 ± 1.76 | 1.4 ± 1.04 | 1.2 ± 1.18 |
| SP4 | 9.6 ± 2.63 | 4.4 ± 1.76 | 1.6 ± 1.04 | 3.6 ± 1.18 |
| SP5 | 12.78 ± 3.7 | 9.02 ± 2.5 | 2.73 ± 0.64 | 1.03 ± 1.45 |
| SP6 | 17.24 ± 3.7 | 12.18 ± 2.5 | 1.95 ± 0.64 | 3.11 ± 1.45 |
| SP7 | 20.73 ± 3.7 | 13.94 ± 2.5 | 2.27 ± 0.64 | 4.52 ± 1.45 |
| SP8 | 20.45 ± 3.7 | 14.63 ± 2.5 | 3.42 ± 0.64 | 2.4 ± 1.45 |

As expected, the data on the quantities of individual groups of microorganisms, as well as the total microbial number in the soil, are hundreds of times higher than the results for air samples. This is completely understandable, given that soil is one of the richest environments in microorganisms (Llado et al., 2017). However, in undisturbed green areas, the reported total microbial count is higher compared to anthropogenically loaded soils. The results for the percentage distribution of the individual microbiological groups without taking into account the individual level of the separator are presented in Figure 1. Respectively, the percentage ratio of the studied soil samples is presented in Figure 2.

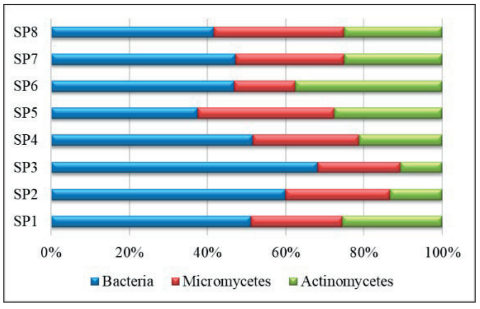

Figure 1. Percentage of the main microbiological groups in relation to the total microbial number of airborne microorganisms

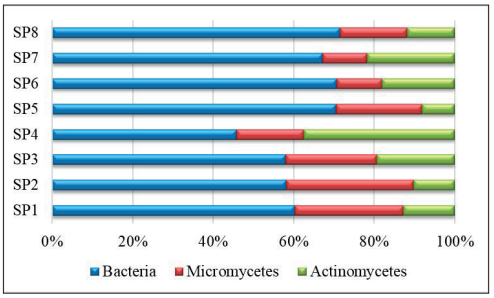

Figure 2. Percentage of the main microbiological groups in relation to the total microbial number of soil microorganisms

In both types of air and soil samples, a dominant presence of the group of bacteria is observed. However, there are certain specifics. Thus, in air samples, the participation of the groups of actinomycetes and fungi is noticeably greater compared to the percentage distribution in soil samples. These data once again prove that the air environment is not just a carrier of microorganisms, but a specific ecosystem, with specific characteristics and environmental conditions for the development of air microorganisms (Amato et al., 2023). The higher percentage of actinomycetes is probably related to the specificity of their spores and the way they spread, given their size and severity (Reponen et al., 1998).

The studied typical soil representatives of the genus *Bacillus: Bacillus cereus, Bacillus subtilis* and *Bacillus megaterium, Bacillus mycoides* were recorded both in all soil samples and in all air samples. When analyzing the data, over 69% of all CFU/m$^3$ of the studied bacilli developed in the petri dishes from the upper stages of the impactor, i.e. those that capture larger fractions. These data confirm the data that the soil particles fall mainly in the impactor range from 7 to 3.3 μm bacilli were also found in the remaining fractions, but in much smaller quantities.

The analysis revealed that soil samples were generally dominated by *Bacillus megaterium* and *Bacillus cereus*. In air samples, sequencing studies revealed that *Micrococcus luteus* and *Kocuria rosea* were dominant. Other studies also indicated that *Micrococcus luteus* and *Kocuria rosea* were common in the air (Fang et al., 2007; Turnbull et al., 2019). Other studies have found that the genus *Bacillus* constitutes a very large percentage of the microflora of outdoor air, while *Micrococcus* is part of the dominant airborne microorganisms in indoor spaces. Such data require in-depth studies on the mode of entry into the air and the distribution of airborne microorganisms (Fang et al., 2014).

The percentage of the studied bacilli (total) in the soil and air samples is presented in the Figure 3.

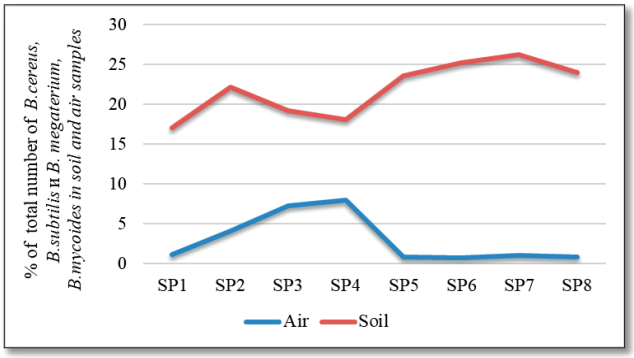

Figure 3. The percentage of the studied bacilli (total) in the soil and air samples

The results of the comparison of the distribution of typical soil microbial species in the air clearly show the influence of human activity. In samples from green areas, where there are no other anthropogenic activities except recreational ones, the percentage of the considered soil microorganisms is lower, compared to areas with some construction activities. Thus, the studied species of bacilli in these areas constitute only about one percent of the total microflora (SP5 - 0.83%; SP6 - 0.71%; SP7 - 1.1% and SP8 - 0.9%). In samples with different types of anthropogenic impact, the percentage of participation of typical soil microflora, represented by the four species of the genus Bacillus, increases. However, it is clearly seen that each of the considered above activities has a different impact on the distribution of typical soil microorganisms in the air environment. We conclude that with increasing anthropogenic load and the area of soil cover disturbance, the amount of typical soil microorganisms in the air increases. Thus, human activities with the most destructive nature of the soil layer (SP3 and SP4) show a much higher percentage of soil bacilli. In SP3, soil bacilli occupy 8.01% of the total microflora, and in SP2, respectively, 7.25%. This is over six times more than in samples without anthropogenic pressure. When we look at the data for SP1, it is impressive that the percentage of soil bacilli is almost similar to that of samples from the fields without anthropogenic pressure - SP1 - 1.2%. The results show that when manually treating the soil, sufficient amounts of soil particles are not generated at high to remain in the ground air and pose a threat to human health. It is important to note, however, that the current study was conducted at a height starting at 1.5 m. Given that garden workers are at a much lower height (around 0.5 m), we recommend that the activity be carried out while wearing protective masks, which minimize the risk of exposure to both fine dust particles and

pathogenic microorganisms. During the reconstruction of the sidewalk areas, given the use of mechanical equipment and the excavation of the peripheral soils, an increase in the percentage of the studied soil microflora in the air samples (4.07%) was observed. The results clearly show that with increasing anthropogenic pressure and increasing construction activities in the city, there is a real danger of increasing the amount of soil microflora in the air. The present study is a clear sign that it is necessary to increase the hygiene requirements during construction activities to minimize dusting. In general, we believe that it is necessary to pay serious attention to the overdevelopment of the city of Sofia, not only from an aesthetic point of view, but also in terms of the quality of the ground air around the construction sites.

## CONCLUSIONS

The present study aimed to investigate the similarity of soil and air microbial communities from eight sample areas (four with increased anthropogenic pressure and four without anthropogenic pressure, only with the presence of recreational activity). The present study found that all air samples contained the studied soil-typical microorganisms (Bacillus: *Bacillus cereus*, *Bacillus* subtilis, *Bacillus megaterium*, and *Bacillus mycoides*), but in different quantities. The results of the present study show that in activities with reduced levels of soil destruction and reduced machine activity, the amount of soil bacilli considered as part of the air microflora is lower (SP1 - 1.12%). With the use of equipment that excavates the soil, albeit at a shallow depth, as in the case of the sidewalk reconstruction of SP2, the amount of microorganisms studied in the air increases to 4.07%. These results confirm the strong negative impact of permanent construction activities in the capital of Bulgaria - Sofia. Such data indicate the need to minimize excavation and construction activities on huge areas covering tens of acres, which pose a real risk to the quality of ground air in the surrounding residential areas. The elevated percentage of soil bacilli, particularly potential opportunistic pathogens such as *B. cereus* in areas with heavy construction activities (SP3 and SP4), carries significant public health implications. Inhalation of these bioaerosols bound to fine particulate matter can penetrate deep into the human respiratory tract, potentially causing respiratory diseases, allergies, or systemic infections in immunocompromised individuals residing near construction zones. In terms of urban planning, these findings underscore the urgent need for local authorities to implement stricter regulations on dust management during large-scale construction. Urban planners should integrate compulsory dust-suppression protocols (such as continuous water spraying of disrupted soils) into municipal building permits to maintain ground air quality in rapidly developing urban areas in Sofia. As a pilot study, a key limitation of this research is its specific timeframe (early September). Therefore, future longitudinal and seasonal studies are highly needed to investigate how temporal and meteorological variations, such as humidity, temperature, and precipitation, affect the emission and persistence of soil microorganisms in the urban atmosphere over different seasons.

This pilot study can serve as a basis for in-depth analyses of the possibility of excavation and construction activities to change not only the quantity of airborne microflora, but also to sharply alter its qualitative composition.

## ACKNOWLEDGEMENTS

This research work was carried out with the support of Research Fund of Ministry of Education and Science in Bulgaria, project №: КП-06-Н74/5 “Relationships between the amount of fine particulate matter and airborne microorganisms in "hot spots", park areas, urban background areas and control forest areas”.

***Abstract***

*At the international level, current concerns of scientists have been observed, through which concerted actions are being taken, both in the spirit of developing the circular economy, and to reduce carbon dioxide emissions. To harness synergistically the potential of the two global challenges, our work has focused on developing innovative construction products by integrating rice husks and hemp stalks, two natural agro-industrial by-products. Biomaterials - based coatings with responsive potential have been obtained, characteristics that have been confirmed by verifying the innovative coatings through their indoor emission control properties by means of TVOC emission, $CO_2$ and/or CO absorption capacity. From the comparative analysis of the way in which the three responsive characteristics are correlated for each tested product, it is highlighted the importance that the distribution of the nature and size of the pores in the structure of the respective materials has on the mechanisms underlying the mentioned characteristics of the obtained products. Further research is necessary to specify and capitalize on the specific mechanisms of this type of innovative coatings.*

***Key words****: circular economy, climate change, indoor air quality, natural agro-industrial by-products.*

## INTRODUCTION

Indoor air quality (IAQ) is one of the essential concerns internationally recognized, the growing attention paid to it being based on the increase in the time people spend indoors (Klepeis et al., 2001; Hu et al., 2017; Yuan et al., 2023; Gonzalez-Martín et al., 2024), together with the higher level of pollutants found in indoor air compared to outdoor air (Montaluisa-Mantilla et al., 2023; Gonzalez-Martín et al., 2024).

This concern has grown significantly, especially as a result of the fact that the serious effects of indoor air pollution on human health range from allergies and asthma to high-morbidity diseases such as ischemic heart disease, respiratory diseases or cancer (Gonzalez-Martín et al., 2024; Hilly et al., 2024), with 3.8 million deaths recorded worldwide annually (World Health Organization, 2018).

One of the categories of pollutants with which indoor air pollution is associated is the class of volatile organic compounds (VOCs), a group that includes a wide variety of compounds, continuously growing as new sources of pollution are identified (Hu et al., 2017; Gonzalez-Martín et al., 2021). Poor degradability, severe toxicity and high volatility are the main characteristics of VOCs, having negative effects on the environment and human health. Long-term exposure to VOCs can have a wide range of consequences, from skin irritation, dizziness and fatigue, to impaired lung function (Morin et al., 2020; Caron et al., 2020), leukemia and symptoms related to sick building syndrome (Huang et al., 2021; Gan et al., 2023). Finishing products and furniture elements represent the most common and studied sources of VOCs indoors, the level of total volatile organic compounds (TVOC) constituting an element of the risk regarding the effects on the health of the occupants, used as a general indicator for assessing indoor air quality.

Another significant category of pollutants is the class of volatile inorganic compounds, carbon oxides (CO and $CO_2$), ozone ($O_3$), nitrogen oxides (NO and $NO_2$), sulfur dioxide ($SO_2$) being among the most relevant types of

pollutants in the indoor environment (Bernstein et al., 2008; Năstase et al., 2018).
In indoor spaces, CO can be present through transfer from outside air or from household activities such as combustion processes (cooking, heating with wood etc.). Among the harmful effects that CO can have on human health are headaches, dizziness, nausea, on pregnant women, young children, the elderly and people with heart and lung diseases being more sensitive to the effects of CO.
Carbon dioxide ($CO_2$) is an inorganic compound, naturally present in the earth's atmosphere, the predominant source, in non-industrial indoor environments, being human metabolism. Exhalation produces 37 g $h^{-1}$ per person (Yuan et al., 2023), studies showing that high levels of $CO_2$ can have a significant impact on both productivity and personality psychology (Azuma et al., 2018).
Therefore, large amounts of various categories of pollutants can accumulate in the indoor air of a building, and such dangerous substances pose a threat to human health, necessitating detailed research on how to eliminate them efficiently and economically (Hu et al., 2017).
The alarming increase in global $CO_2$ emissions, which represent 70% of the total volume of greenhouse gases (Khosrowshahi et al., 2023), constitutes a good premise for the development of a new research direction, through which the construction sector can contribute to the reduction of $CO_2$ and VOC emissions.
In this context, the paper presents the research carried out for the development of biomaterials-based coatings with responsive potential and verifying their indoor emission control properties. The products were designed through an approach that combines basic ideas, principles, materials and conditioning, as follows: integrating the principle of poly-ionic liquids and nano-fluids, by using a set of raw materials, considering that each of them activates a distinct possibility of increasing $CO_2$ absorption; the use of synthetic polyvinyl acetate binder, as a polymeric solvent for $CO_2$ absorption, and to improve the mechanical performance of responsive coatings; integration of solid materials in powder form, with micrometric-sized particles, namely lime, soda-lime (absorbent material, traditionally used in the medical field, in the present research acting as an alkaline solvent for $CO_2$ absorption), rice husks and chopped hemp stems, all creating in the presence of water a type of nano-fluid for $CO_2$ retention. The method used, the results obtained and the conclusions are described below.

## MATERIALS AND METHODS

Thirteen biomaterials - innovative coatings with compositionally responsive potential - were obtained and in terms of their response to specific requirements. This consisted of determining the indoor emission control property, by monitoring three characteristics, namely TVOC content emission, $CO_2$ absorption capacity and CO absorption capacity.
The components of the innovative products were: synthetic binder, lime, corn starch, soda-lime, rice husks and hemp stalks.
The products were designed considering the following criteria: different percentage content of synthetic binder; mixing time of the biomaterial, the products being mixed manually, and nature of the plant component, even, rice husks, hemp stalks or 1:1 rice husks: hemp stalks mixture.
The studied biomaterials-based coatings, noted EC1 - EC13, were composed of two successive layers, applied by brush on a plasterboard surface, with dimensions of 20 x 20 x 1 cm. Each bilayer biomaterial-based coating variant was subjected to emission monitoring, inside of S2 experimental stand (Figure 1, left), with DirectSense IQ-610 equipment (Figure 1, right), also used in other international studies (Canha et al., 2017; Johnson et al., 2018; Majd et al., 2019), according to the monitoring protocol described in Vasile et al. (2023), for 24 and 48 hours.

## RESULTS AND DISCUSSIONS

The interpretation of the experimental results obtained for the innovative products tested in terms of TVOC emissions was carried out by analysing and comparing the graphical representations of the TVOC emission profiles (Figure 2) and the average values of TVOC concentrations, presented in Table 1, all these results being compared after the same two time points, namely the first 24 hours and the 48 hours of monitoring.

The interpretation of the experimental results regarding $CO_2$ absorption, respectively CO absorption, was achieved by analysing and comparing the graphical representations regarding the variation of the $CO_2$/CO concentration (Figures 3 and 4), as well as the average values of the $CO_2$/CO concentrations presented in Table 1, for all tested products, all these results being compared according to the same time points, namely the first 24 hours and the 48 hours of monitoring.

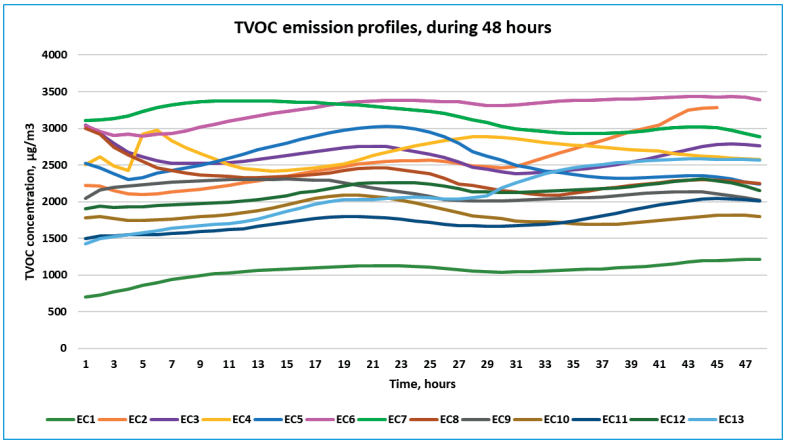

Figure 2. TVOC emission profiles for all monitored products, for 48 hours

Table 1. Average values of TVOC, $CO_2$ and CO concentrations, at 24 hours and 48 hours of monitoring

| Product | Average TVOC concentration values, µg m$^{-3}$ | | Decrease in TVOC concentrations µg m$^{-3}$ | Average $CO_2$ concentration values, ppm | | $CO_2$ absorption, ppm | Average CO concentration values, µg m$^{-3}$ | | CO absorption, µg m$^{-3}$ |
|---|---|---|---|---|---|---|---|---|---|
| | 24 h | 48 h | 48 h | 24 h | 48 h | 48 h | 24 h | 48 h | 48 h |
| EC1 | 999 | 1054 | - | 354 | 349 | 1.41 | 511 | 438 | 14.2 |

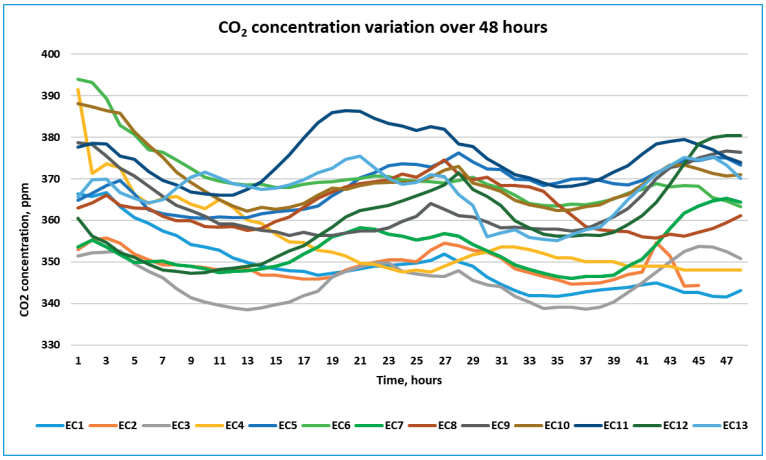

Figure 3. $CO_2$ concentration variation for all monitored products, for 48 hours

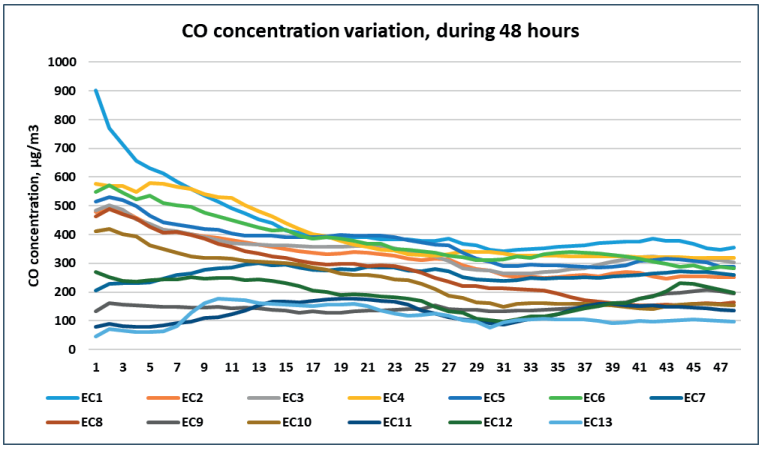

Figure 4. CO concentration variation for all monitored products, for 48 hours

Analysing the experimental results obtained as well as the different forms of their processing, regarding the TVOC emissions of the potentially responsive products tested, the following observations were made.

In general, the TVOC emission profiles are relatively similar to each other, especially in the first 24 hours of monitoring.

During the 48 hours of monitoring, it is observed that half of the products (EC3, EC5, EC7, EC8, EC9, EC10) have downward trends in TVOC emissions, while the others are slightly upward.

From the analysis of the recipes, it results that this evolution could be determined by structural changes in the biomaterials, in correlation with the mixing time, most of the products with a downward trend in emissions having 1 minute of mixing, comparing to those having 3 minutes of mixing.

Analysing the products both as a trend of emission profiles but especially as average values of TVOC concentrations, the product EC1 (with a low content of synthetic binder and rice husks) is particularly noteworthy, which, although with a slightly upward trend, maintains the lowest average values of TVOC concentrations emitted.

Regardless of the quantitative compositional particularities of the biomaterials, it is considered that, in situations where the concentrations of TVOC emitted are lower or decreasing, the favourable influence of three determinant factors are manifested synergistically: the low content of synthetic

binder, the highest possible content of rice husks or/and hemp stalks and the 3-minute mixing time of the biomaterial, before its application on the support surface.

The favourable influence of the presence of the plant component in the biomaterial, in terms of reducing TVOC emissions, is clearer in the case of incorporating the rice husks, or a 1:1 rice husks: hemp stalks mixture, it being desirable to incorporate as large a quantity of these natural materials as possible, within limits that do not affect the workability of the mixture.

Regarding the evolution of $CO_2$ concentrations, respectively their decrease as a result of the increase in $CO_2$ absorption by the tested coatings, the following were found:

Based on the individual profiles of $CO_2$ concentrations, respectively of the decreases in recorded concentrations, it results that the tested products have a certain responsive potential manifested through $CO_2$ absorption, a characteristic highlighted for seven of the products, especially in the first 14-19 hours of monitoring but also later, at the end of monitoring.

Given the general path of variation of $CO_2$ concentrations, with multiple irregularities, it is considered that the average values obtained are not quantitatively relevant at this stage of the research. It is noted that no obvious correlations can be established between the components/recipes of the biomaterials and the decrease in $CO_2$ concentrations during monitoring, and it is assumed that dimensional differences in the porous structure of the coatings could provide clarification, with future research being necessary in this regard.

It is appreciated that there are elements that could lead to an improvement in the responsive potential of the tested materials, regarding the increase in $CO_2$ absorption from the atmospheric air of the enclosure, mainly, mechanical mixing, increasing the mixing time, and applying protection to larger support surfaces.

The evolution of CO concentrations, respectively their decrease as a result of the increase in CO absorption by the tested coatings, showed the following:

Based on the individual profiles with a downward trend in CO concentrations and the variation in the average values of CO concentration, in the first 24 hours and during the 48 hours of monitoring, it results that the tested products also have a certain responsive potential manifested through CO retention.

The highest decrease in CO concentration (35%) was recorded for the EC12 product, with a content of 58.73% synthetic binder, 3.17% hemp stalks and 12.68% soda-lime, the latter two components supporting the responsive characteristic of the product in terms of CO absorption. Similarly, a significant decrease in CO concentration (24.12%) was recorded for the EC10 product, with a content of 50% synthetic binder, 3.57% hemp stalks and 14.28% soda-lime.

Contrary to expectations, a similar decrease in CO concentration (23.46%) was recorded for the EC8 product, a control product, therefore without soda-lime content, with a slightly higher content of synthetic binder (51.5%). It is considered that the effect observed was generated synergistically by the presence of lime and the 1:1 rice husks: hemp stalks mixture.

During the 48 hours of monitoring, seven of the thirteen tested products had CO concentration developments that indicated decreases between 11.99-15.61 $\mu g\ m^{-3}$ CO, values that indicated, from a compositional point of view, the synergistic effect of the presence of lime, the soda-lime product with a $CO_2$ absorbent role, and a plant component, mainly rice husks (1.85-3.47%), respectively only 1.75% hemp stalks. However, it is appreciated that the evolution of CO absorption phenomena, similarly to the case of $CO_2$, is based on the distribution of the nature and size of the pores in the structure of the resulting materials, but further research in this regard is necessary.

From the comparative analysis of the data in Table 1, regarding the way in which the three responsive characteristics (TVOC emission, $CO_2$ and/or CO absorption capacity) are correlated for each tested product, it is considered that this also highlights the importance of the distribution of the nature and dimensions of the pores in the structure of the respective materials, on the mechanisms underlying the emission and/or retention capacity of the responsive products obtained and studied.

Further research is needed to characterize and control the specific mechanisms of this type of innovative coatings.

## CONCLUSIONS

Thirteen innovative biomaterial-based coatings, composed of synthetic binder and two natural agro-industrial by-products, were studied in terms of their response to specific requirements that consisted of monitoring the emission of total volatile organic compounds (TVOC) content, carbon dioxide ($CO_2$) and carbon monoxide (CO) absorption capacity.

Based on the experimental results obtained, it is observed that most of the products have downward trends in TVOC emissions, while some profiles remain slightly upward, an evolution that could be determined by morphological and structural changes in the biomaterials.

Regardless of the quantitative compositional particularities of the biomaterials, it is considered that, in situations where the emitted TVOC concentrations are lower or decreasing, the favourable influence of the low content of synthetic binder and a significant content of vegetable component (rice husks, hemp stalks or 1:1 rice husks: hemp stalks mixture) is manifested synergistically.

Starting from the experimental results obtained regarding the evolution of $CO_2$ concentrations, based on individual profiles, it can be considered that some of the tested products have a responsive potential manifested through $CO_2$ absorption, especially in the first 14-19 hours of monitoring and subsequently, at the end of monitoring.

Based on the individual profiles with a downward trend in CO concentrations and the variation in the average values of CO concentration, in the first 24 hours and during the 48 hours of monitoring, it results that the tested products also have a certain responsive potential manifested through CO retention.

From the comparative analysis of the way in which the three responsive characteristics (TVOC content emission, $CO_2$ and/or CO absorption capacity) are correlated for each tested product, it is considered that this also highlights the importance that the distribution of the nature and size of the pores in the structure of the respective materials has on the mechanisms underlying the mentioned characteristics of the innovative responsive products obtained and studied. Further research is needed to customize, control and capitalize on the specific mechanisms of this type of innovative products/coatings.

## ACKNOWLEDGEMENTS

The research paper was carried out within Project PN 23 35 02 01 - Innovation and Digitalization Synergies in the Design of Eco-Materials and Multifunctional Products for Sustainable Construction, with Impact on the Environment and the Circular Economy, financed by the Ministry of Research, Innovation and Digitalization.

***Abstract***

*Natural agro-industrial by-products and the circular economy concept are closely interconnected, both being essential for promoting sustainability in various representative fields of the economy, such as agriculture, the food industry, the construction industry, etc. The establishment of circular practices in the agro-industrial and construction sectors leads to the minimization of deposits of such materials/natural waste, optimizes their use by increasing their value, and simultaneously creates economic, environmental and social benefits. The paper presents aspects of the experimental research carried out with the aim of the superior valorization of two local agro-industrial by-products, namely rice husks and hemp stalks, by obtaining cladding products usable in construction. It is recognized that due to their compositional and structural particularities, the two natural materials, integrated in different types of construction materials, give them mechanical resistance, thermal insulation properties and acoustic performance. The products resulting from this research were studied from physical and mechanical point of view, considering that additional, multi-criteria tests are necessary, to gain a complete evaluation regarding the field of use in constructions of this type of innovative products.*

***Key words****: agro-industrial by-products, circular economy, construction, sustainability, waste.*

## INTRODUCTION

Currently, humanity is faced with a complex set of problems that are mutually interrelated. On the one hand, construction industry is an important consumer of energy and a major source of waste and greenhouse gas emissions (Cintura et al., 2021). Along with these, the growth of the world population and, implicitly, the necessary built stock, together with the aggressive impact of the conventional building materials industry through air, soil and water pollution, represent current problems that require clear intervention measures (Maraveas, 2020). At a global level, a wide range of directions for the valorization of recyclable materials has been identified, in the form of different types of construction materials/ products. In this regard, examples can be given ranging from the use of rice husk ash as an additional material in concrete production, contributing to improving the strength and durability of concrete (Kumar et al., 2013), the use of biological waste specific to the Euro-Mediterranean area, to obtain construction products and implicitly solving some associated challenges (Cintura et al., 2021), to the development of innovative asphalt mixture recipes, by incorporating different recyclable materials, in order to improve the lifespan of road structures (Ionescu & Dobre, 2025).

On the other hand, as a result of the increased demand for food, the agricultural sector together with the processing industries generate significant quantities of vegetable waste and natural agro-industrial by-products which, unused and improperly stored, also contribute to environmental pollution (Maraveas, 2020; Capanoglu et al., 2022; Yaashikaa et al., 2022; Ufitikirezi et al., 2024; Carrillo-Rodriguez et al., 2025). In this context, it is increasingly necessary to identify ecological approaches for the construction industry, the application of circular economy principles demonstrating that the productive use of agro-industrial waste can constitute an efficient and sustainable solution (Carrillo-Rodriguez et al., 2025). The circular economy contributes to reducing environmental

pollution by minimizing generated waste, optimizing its use through viable processes, and establishing interconnected circular practices between the agri-food and construction sectors. By transforming natural waste into raw materials and creating alternative materials, at much affordable costs (Maraveas, 2020), mainly of organic origin and from recyclable natural materials (Gołębiewski et al., 2025), the circular economy promotes the conservation of the economic value of products and contributes to increasing the added value of the resulting product (Coelho Vianna et al., 2024). The purpose of this experimental research is to find a new possibility of superior utilization in construction for two natural agro-industrial by-products (S.A.N.), namely rice husk and industrial hemp stalks, by obtaining innovative cladding products.

Specialized literature confirms researchers' concern for the exploitation of these S.A.Ns, in various types of construction products.

For exemple, rice husks can be used in plasters and agglomerated composite boards, products characterized by thermal or acoustic insulation properties (Revelo-Cuarán et al., 2022; Marin-Calvo et al., 2023; Milawarni et al., 2023; Pradhan et al., 2024; Wan et al., 2024), in cement blocks as a partial replacement of sand or in fire clay bricks, in form of rice husk ash (Maraveas, 2020).

In turn, hemp stalks are integrated into numerous types of building materials, hemp-lime composites with pro-ecological characteristics (Gołębiewski, 2017). The role of hemp in improving thermal insulation properties is recognized, having one of the lowest thermal conductivity coefficients among commonly studied plant aggregates (Gołębiewski, 2025), while also contributing to the compressive strength and humidity regulation of the materials in which it is integrated. One of the best-known hemp-based construction materials is hemp concrete, obtained by mixing hemp pulp with a lime-based binder. Having good thermal insulation, significant breathability, hygroscopicity and a reduced carbon footprint, high permeability to water vapor, fire resistance, biodegradation, good acoustic properties, it can be used for roofs and floors, or for insulating walls on their exterior side (Gołębiewski, 2017; Demir & Doğan, 2020; Yadav & Saini, 2022; Gołębiewski, 2025). Hemp can also be used to obtain products such as: particleboard and fiberboard, by mixing hemp pulp with other lignocellulosic materials and binders, boards usable as floor and wall panels, as well as biocomposite materials, by combining hemp pulp with a matrix of synthetic or natural polymers, resulting in floors, cladding elements and interior finishes (Cigasova et al., 2015; Dhakal & Zhang, 2015; Requile et al., 2019; Maraveas, 2020).

## MATERIALS AND METHODS

Based on the documentation carried out on obtaining cladding products by integrating plant waste, a series of materials were selected to design products of this type, both in ecological and hybrid variants. Both types of recipes integrated rice husks (Figure 1), hemp stalks (hurd) chopped at lengths between 1-5 cm (Figure 2) or mixtures thereof, but different in the nature of the binders.

Figure 1. General appearance of rice husks

Figure 2. General appearance of chopped hemp stalks

In this approach, the eco-recipes had either a natural binder of plant origin, obtained from a mixture of corn starch, hydrated lime and water, or a natural binder of animal origin, based on bone glue (denoted COS). The hybrid recipes had a binder resulting from a mixture of COS

and a synthetic adhesive, based on polyvinyl acetate (denoted AD1) or polyurethane (denoted AD2), the last two materials having the role of improving the cohesion of the cladding product. All recipes have been designed to obtain organic products or products with organic characteristics, from a compositional point of view, with high cohesion and hardness. Thus realized, the recipes allow the comparative study of the influence that the different compositional factors have on the mechanical characteristics of the obtained products. The influencing factors studied were the following: type of binder (natural vs. hybrid binder, respectively its synthetic component); type of the S.A.N. integrated in the product (rice husks vs. rice husks+hurd vs. hurd); presence of the adhesive; type of adhesive (polyvinyl acetate vs. polyurethane). The cladding products were obtained by casting the biomaterials in a steel mold and applying an external pressure, using a press, to reduce excess moisture in the plate mass. The mould was designed and made for this purpose, with dimensions of 270 x 270 x 25 mm. The methodology for obtaining the cladding products consisted of the following sequence of main steps: Preparation of raw materials and binders simultaneously with heating the steel mold in the oven at 70°C, for aprox. 4 hours → Mixing the components according to the recipe and homogenizing them → Pouring the resulting biomaterial into the steel mold → Closing the mold with its lid → Placing the mold + biomaterial assembly in the press and applying an exterior force to it → Demoulding the sample from the mold → Natural drying of the obtained plate, in laboratory conditions (temperature of 23±2°C şi relative air humidity of 50% ± 10%). Regarding this work protocol, the following additions are necessary to be outlined: a. The S.A.N were dried in the oven at 70°C, for approx. 4 hours; b. While the preparation of the vegetable binder consisted only in mixing and homogenizing hydrated lime and corn starch with water, in the case of the COS binder, this was obtained by soaking the granules in water (mixing ratio 1:1 in mass units) for approx. 12 hours, then by heating the obtained gel in a Bain-Marie, up to a temperature of 50-70°C, resulting the bone glue in the colloidal phase; c. There was a slow and constant application of a force to the mold. The maximum value of the applied force varied, on the one hand depending on the moment when the binding liquid phase started to emerge from the mold and, on the other hand, on the values of the external force applied, in order not to affect the integrity of the mold under load. This thermoforming protocol proved to be functional, as the obtained plates showed stability and cohesion between the constituent elements, but required advanced drying. As a result, the plates were weighed every 24 hours, so that the condition of complete drying to constant mass could be reached. Depending on the thickness of the cladding products, drying of the plates continued for about 10 days, after which the cladding products were placed in a vertical position and were normaly dried, in laboratory conditions (temperature of 23±2°C şi relative air humidity of 50% ± 10%), for another about 20 days.

Based on considerations regarding the workability of the biomaterial, as well as the compact aspect of the material both after demolding and at the end of the drying period, four vegetable - bound, six hybrid - bound and three COS - bound cladding products were obtained and then studied by means of their main mechanical characteristics. From the point of view of the vegetable component: binder mixing ratios, compositional benchmarks of the obtained cladding products are presented in Table 1.

Table 1. Compositional benchmarks of the biomaterials obtained by integrating rice husks and hemp stalks

| Biomaterial/ Cladding product notation | Binder | S.A.N : binder mixing ratios (mass units) | Vegetable components |
|---|---|---|---|
| C4-1 | Vegetable | 3:25 | P[1] |
| C6-1 | Vegetable | 20:70 | P, H[2], P=H |
| C7-1 | Vegetable | 20:70 | P, H, P=H |
| C8-1 | Vegetable | 20:70 | P, H, P=H |
| PMI′ | COS, AD1 | 1:3.74 | P |
| PMI″ | COS, AD2 | 1:3.77 | P |
| PMIII′ | COS | 1:5.75 | P, H, P=H |
| PMIII‴ | COS | 1:5.75 | P, H, P<H |
| PMIII‴bis | COS | 1:3.50 | P, H, P<H |
| PMIV′ | COS, AD1 | 1:4,30 | P, H, P<H |
| PMIV″ | COS, AD2 | 1:3.50 | P, H, P<H |
| PMV′ | COS, AD1 | 1:4.03 | H |
| PMV″ | COS, AD2 | 1:4.20 | H |

[1]P=Husk rice.
[2]H=Hurd (Choped hemp stalks).

After drying, the general appearance of the obtained cladding products was different

depending on the incorporated S.A.N. but also on the binder (Figures 3, 4 and 5).

Figure 3. Examples of the general aspect of vegetable-bound cladding products based on rice husks (left), and on a mix of rice husks and choped hemp stalks (right)

Figure 4. Example of the general aspect of COS-bound cladding products based on rice husks

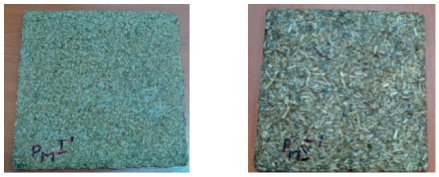

Figure 5. Examples of the general aspect of hybrid - bound cladding products based on rice husks (left), and on a mix of rice husks and choped hemp stalks (right)

The general appearance of the cladding products illustrates their cohesive, compact character.
In order to highlight the significant differences among all the materials with different compositions developed and presented in this research, a statistical analysis was applied, using a one-way analysis of variance (one-way ANOVA). The software used to perform the statistical analysis was Microsoft Excel.

## RESULTS AND DISCUSSIONS

The determination of physical and mechanical characteristics was performed on both eco- and hybrid-recipes cladding products. Each plate was measured to establish dimensional compliance, the nominal thickness and side length. After the end of the drying period of the cladding products, the measured values of the sides were between 255 mm (PMIII‴) and 267 mm (C4-1), and the average thickness values, between 8.23 mm (PMIII′) and 22.84 mm (PMV″). The modulus of elasticity in bending was determined by applying a constant speed load to the middle of the sample placed on two supports. For the calculation of the value, the slope of the rectilinear area of the load-deformation curve was used.
The bending load-deflection diagrams have a comparable appearance for all types of recipes, with a linear upward evolution on the first portion of the representation, followed by a threshold value, the maximum load, corresponding to the resistance of the base material.
Subsequently, the material failure occurred and the curve becomes descending, some examples being illustrated in Figure 6, for the two test pieces of C4-1 and PMIII‴ clading product. The results regarding the flexural strength and modulus of elasticity for all the obtained cladding products are graphically represented in the Figures 7 and 8.

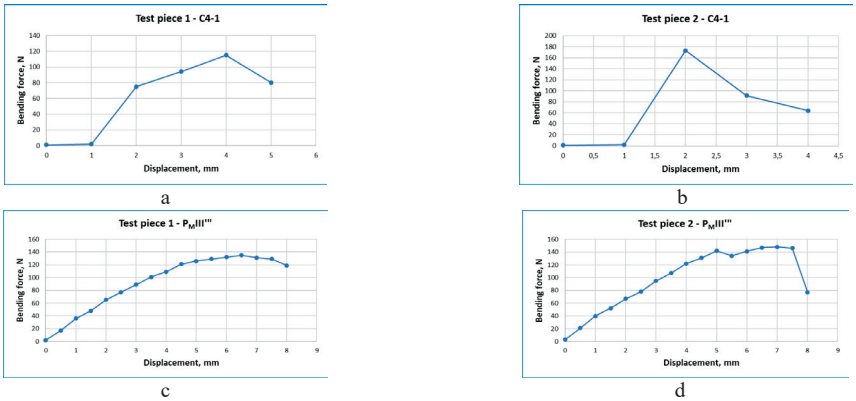

Figure 6. Load-deformation curves. Specific examples for C4-1 (a, b) and PMIII‴ (c, d) cladding product

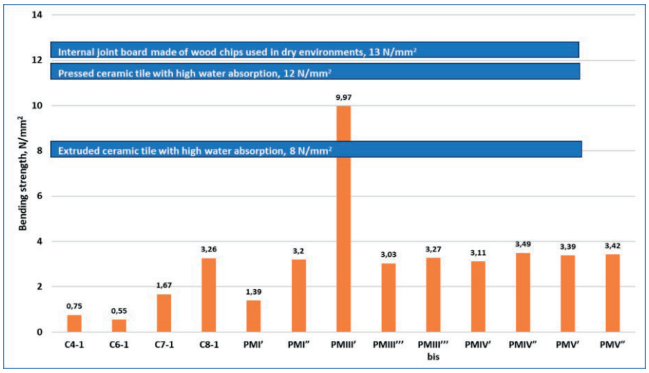

Figure 7. Bending strength of rice husk and hemp stalks based cladding products

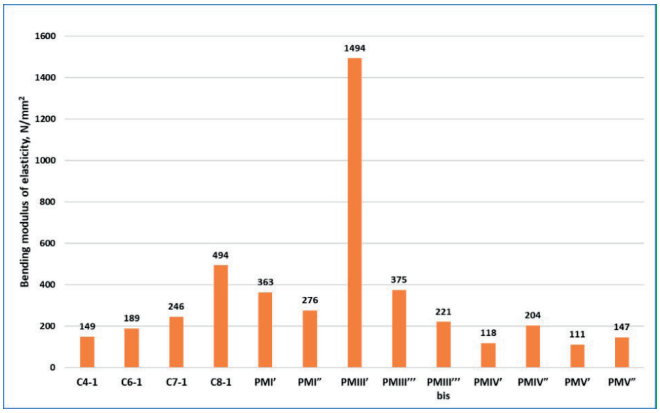

Figure 8. Bending modulus of elasticity for rice husk and hemp stalks based cladding products

Regarding eco - cladding products, the highest value for flexural strength was obtained for C8-1, of 3.26 N/mm$^2$ with a flexural modulus of elasticity of 494 N/mm$^2$ at an average board thickness of 8.30 mm. This value is comparable to that of PMI″, average plate thickness 12.68 mm (flexural strength 1.39 N/mm$^2$, flexural modulus 363 N/mm$^2$), of PMIII‴, average plate thickness 9.28 mm (flexural strength 3.03 N/mm$^2$, flexural modulus 375 N/mm$^2$) and of PMIII‴bis, average plate thickness 16.37 mm (flexural strength 3.27 N/mm$^2$, flexural modulus 221 N/mm$^2$), which contain COS with or without synthetic products for binding the vegetable fraction. This is why, the C8-1 recipe consisting of rice husks, hurd, lime and corn starch represents a compositional variant to be taken into account for further optimization.

The best bending strength was recorded for PMIII′, with a value of 9.97 N/mm$^2$ and a bending modulus of elasticity of 1494 N/mm$^2$, for an average thickness of 6.86 mm, the product having an eco-recipe based on rice husks, chopped hemp stalks and COS.The bending load-deflection diagrams have a comparable appearance for all types of recipes, the maximum load, corresponding to the strength of each material, reaching the value of 1110 N. The strength of PMIII' tends to reach the value of bending strength of boards based on wood chips intended for use in dry environments and may represent a premise for future compositional development.

From the analysis of these obtained results, the following aspects can be highlighted:

The best results from a mechanical point of view were obtained in the case of cladding products with eco-recipes having bone glue as a binder and those with hybrid recipes, especially with polyurethane adhesive.

Also noteworthy were the products with mixed vegetable content, regardless of the type of

binder, and in the case of the products with eco-recipes, the C8-1 board, with the highest corn starch content.

It is considered useful to highlight that this research is characterized by a certain limitation regarding the possibility of interpreting the obtained experimental results. The limitation is explained by the fact that the research is still in development, with the aim of identifying the field in which the obtained products could be classified, and subsequently studying the possibilities of their improvement. In this context, it is specified that the methodology applied for determining the bending strength and the bending modulus of elasticity was similar to that of SR EN 310, but the tests were performed on a small number of samples, the graphic representations of the mentioned characteristics being made based on the obtained average values.

To assess whether the flexural strength differs between the 13 cladding products (configurations), a one-way ANOVA analysis was applied, which revealed significant differences between groups ($F(12,13) = 8.84$; $p = 0.00021$), with a very large effect of configuration on flexural strength ($\eta^2 = 0.89$). The same analysis revealed significant differences in the flexural modulus of elasticity between the 13 cladding products ($F(12,13) = 7.99$; $p = 0.00035$), with the configuration explaining approximately 88% of the variation in the values ($\eta^2 = 0.88$). The value of the F statistic indicates greater variability between the 13 groups (recipes) of cladding products and less within the same group of specimens.

## CONCLUSIONS

Rice husks and industrial hemp constitute a category of S.A.N. with a high potential for valorization in the form of various types of construction products. Seven cladding products with natural binders and six with hybrid binders were studied in terms of mechanical characteristics, representing the first stage in evaluating their potential for use in construction. From a compositional point of view, the cladding products that had the mixed natural binder, of corn starch and hydrated lime had a more cohesive structure than those with a single vegetable binder, starch or lime.

The cladding products have mechanical characteristics higher than those of extruded ceramic tiles with high water absorption and relatively close to those of pressed ceramic tiles with high water absorption, characteristics that can still be improved.

Based on the experimental results obtained up to this stage of research on innovative cladding products containing rice husks and/or chopped industrial hemp stalks, it is considered that additional tests are necessary in order to achieve a more complete assessment of their potential for use in construction.

## ACKNOWLEDGEMENTS

This research work was carried out with the support of Ministry of Research, Innovation and Digitalization and also financed from Project PN 23 35 02 01 “Innovation and Digitalization Synergies in the Design of Eco-Materials and Multifunctional Products for Sustainable Construction, with Impact on the Environment and the Circular Economy”.

# CORRELATION BETWEEN THE PHYSICAL PROPERTIES AND NPK NUTRIENT CONTENT OF ORCHARD SOILS FOR THE SELECTION OF APPROPRIATE SOIL DECONTAMINATION TECHNOLOGIES

**Maria POPA**

Petroleum-Gas University of Ploiesti, 39 Bucharest Blvd, Ploiesti, Romania

***Abstract***

*The network of underground pipelines used to transport petroleum products may crack and lead to soil contamination. As these pipelines can be located near orchards, this study investigated soils from quince, plum, and pear orchards. The physical properties of the soils were analyzed comparatively, including density, texture and granulometry, capillarity and permeability. Capillarity, permeability and retention capacity were determined for both water and a petroleum product considered a potential soil pollutant. The analysis of physical properties, together with the NPK nutrient content of each soil type, was used to facilitate the selection of appropriate decontamination technologies. Two pollutant removal methods applicable to all three soil types were evaluated: thermal desorption at 400°C and successive extraction using two solvents, petroleum ether and benzene. Nutrient content was determined before and after each decontamination process.*

***Key words****: decontamination, nutrients, orchard soil, pollutant.*

## INTRODUCTION

Soil is a fundamental natural resource that sustains agricultural ecosystems and supports long-term food production. Orchard soils, in particular, require careful and continuous monitoring, as the specific physical properties of the soil, including texture, bulk density, granulometry, capillarity, and permeability, directly influence the growth requirements of fruit tree species such as quince, plum, and pear (Capri et al., 2023; Özdemir et al., 2022). Knowledge of these properties is essential not only for the appropriate selection of fruit tree species, but also for the efficient management of irrigation and fertilization practices. In this context, monitoring the NPK nutrient content of orchard soils plays a central role in achieving sustainable yields, as imbalances in nitrogen, phosphorus, and potassium directly affect tree physiology, flowering, and fruit quality (Sun et al., 2023; Rusu et al., 2025).

Since each fruit tree species has specific growth requirements, knowledge of the physical properties of the soil is essential. Furthermore, determining the nutrient content of orchard soils allows for the appropriate application of fertilizers. Recent studies show that orchard soils require constant and careful monitoring, with the recommendation including the use of sewage sludge with high nutrient content (Iorga et al., 2025) and fertilization with compost (Butcaru et al., 2024). Other authors conducted a comparative study between a conventional system based on herbicide use and a conservation system based on cover crops, evaluating nutrient content in a plum orchard (Rusu et al., 2025). The use of biofertilizers as alternatives to chemical fertilizers has also been investigated. Studies were conducted in an apple orchard over a period of five years (Ferreira et al., 2025) and in a pear orchard over a period of two years (Li et al., 2025). The combination of cover crops with legumes planted in orchards has been shown to improve the nutrient cycle (Raimundo et al., 2025). Other studies on nutrient uptake were carried out in cherry orchards (Karampatzakis et al., 2025) and pear orchards (Liu et al., 2025), with particular emphasis on tree age. Recent studies also highlight the importance of factors such as temperature, irrigation water, the use of biostimulants, and weed presence for ensuring good crop production in orchards (Lisek, 2023; Cara, 2025). The application of the electrokinetic decontamination method, with different types of electrodes, on agricultural soil led to different changes in NPK nutrients (Popa, 2025).

Nitrogen is responsible for leaf growth; its deficiency causes yellowing, while an excess can prolong the vegetation period. Phosphorus is important for the functioning of the immune system and stimulates the flowering process. Potassium is converted, through chemical reactions, into potassium hydroxide, which stores nutrients required by the plant. When potassium is deficient, the intensity of photosynthesis decreases.

Beyond agronomic challenges, orchard soils located in proximity to major petroleum product transport infrastructure face an additional risk: accidental contamination with hydrocarbons resulting from pipeline failures or leaks (Franchi et al., 2022; Adeniran et al., 2023). Such contamination events pose a serious threat to soil fertility and long-term agricultural productivity, as petroleum hydrocarbons alter the physical structure of the soil, disrupt nutrient availability, and suppress microbial activity (Ambaye et al., 2022; Ossai et al., 2020). The selection of an appropriate decontamination strategy is therefore critical, as it must balance the effective removal of the pollutant with the preservation of the soil's agronomic potential. Among the available remediation technologies, thermal desorption and successive solvent extraction have been evaluated as viable approaches for hydrocarbon-contaminated agricultural soils (O'Brien et al., 2024; Caetano et al., 2024). However, the impact of these methods on soil nutrient content, particularly NPK levels, remains an aspect that requires further investigation, especially in the context of orchard soils.

## MATERIALS AND METHODS

Major pipelines can be located very close to orchards; therefore, this study focuses on two neighboring counties in Romania where such risks may occur: Prahova and Dambovita (Figure 1). Although the main pipeline network in Romania is continuously monitored, rapid action is required if soil contamination with petroleum hydrocarbons occurs.

Soil samples used in this study were collected from quince and pear orchards in Dambovita County and from plum orchards in Prahova County. This study compares two methods for the decontamination of soils contaminated with hydrocarbons: successive extraction with solvents and thermal desorption.

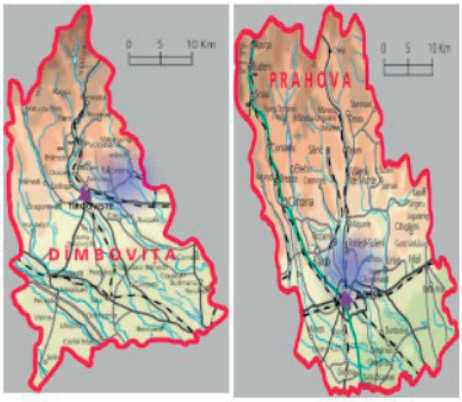

Figure 1. The orchard areas

Soil characterization involved determining the physical properties of the three samples. Additionally, for pollution control conducted in the laboratory, diesel oil was characterized by its density and viscosity. These properties of diesel oil help to understand how it penetrates the soil structure. The concentration of pollutants in soil was 7% by mass, a percentage deliberately chosen as it falls within the minor pollution range. All methods used to determine the physical properties of the analysed soil samples have been described in previous works (Popa, 2023; 2024).

Capillarity, defined as the maximum height a liquid can reach in the soil within one hour, represented by the ascent phenomenon, was established. Permeability, the property that ensures the penetration of liquid from top to the bottom of the soil, was calculated as the average permeability over one hour of exposure to the soil. This property depends on the free spaces between the solid aggregates of the soil, as well as the physicochemical interactions formed with the fluid molecules passing through the soil.

The liquid retention capacity of the soil was also determined and expressed in liters of liquid per $1m^3$ of dry soil. Both permeability and retention capacity were tested for water and diesel oil. Permeability could be determined for only a single measurement for diesel oil, at 15 minutes, due to a high pollutant consumption for the soil in the quince orchard. Granulometry was determined using the sieving method with four

different sieve diameters (1.6 mm, 1 mm, 0.5 mm and 0.25 mm).

Based on the laboratory determined grain size, soil texture was established, allowing for verification of differences between the two regions from which the soil originated. All physical properties were determined on dry soil samples (oven-dried at 105°C, for one hour), thus establishing the initial moisture content of the samples (% mass).

The NPK nutrient content was determined qualitatively. In orchards, monitoring nutrient content is essential to achieving good yields. The reagents used in the Hanna test kit (Popa, 2023) are pre-measured solutions specially formulated for colorimetric and turbidimetric reactions, which enable the rapid and accurate determination of essential NPK nutrients. The kit defines the following ranges: trace (0-5 ppm), low (5-15 ppm), medium (15-30 ppm), high (30-50 ppm).

Dry soils, pre-heated for one hour at 105°C, were contaminated with 7% diesel oil and immediately subjected to thermal decontamination. The process was carried out at 400°C, enabling both pollutant recovery and water removal at elevated temperatures.

The apparatus has been described in the literature (Popa, 2023). Decontamination by successive solvents extraction was performed using two solvents, petroleum ether and benzene, using a Soxhlet apparatus as described in the literature (Popa, 2024).

## RESULTS AND DISCUSSIONS

### *Characterization of clean soils*

The analyzed clean soils were characterised by their physical properties (Table 1), and nutrient values were estimated at the upper limit of the recommended range provided by the analysis kit.

Table 1. Characterization of clean orchard soil samples

| Property | Type of orchard soil | | |
|---|---|---|---|
| | Quince | Plum | Pear |
| Max. capillarity to water (cm) | 4.6 | 3.5 | 3.6 |
| Max. capillarity to diesel oil (cm) | 8.5 | 7.3 | 7.4 |
| Permeability to water ($cm^3/h$) | 8400 | 411.4 | 596.28 |
| Water retention capacity (kg water/$m^3$ soil) | 170.1 | 384.6 | 324.2 |
| Diesel oil retention capacity (kg diesel oil/$m^3$ soil) | 29 | 64 | 42 |
| Max nutrients content (mg/kg soil) | | | |
| N | 5 | 30 | 30 |
| P | 30 | 15 | 30 |
| K | 50 | 15 | 15 |
| pH | 6.5 | 6.5 | 5.5 |
| Moisture (% mass) | 18 | 20.1 | 18.3 |
| Granulometry (g) | | | |
| Sieve diameter | | | |
| 1.6 mm | 58 | 58 | 58.6 |
| 1 mm | 14.9 | 16.2 | 16.5 |
| 0.5 mm | 18 | 13.6 | 18.9 |
| 0.25 mm | 8.9 | 5.8 | 5.5 |
| losses on the sieve | 0.2 | 6.4 | 0.5 |
| Textural class | sandy | sandy loam | sandy |
| Conductivity (µS/cm) | 120 | 150 | 134 |
| Apparent density ($g/cm^3$) | 1.36 | 1.58 | 1.38 |
| Real density ($g/cm^3$) | 2.74 | 2.60 | 2.65 |
| Porosity (%) | 50.3 | 39.2 | 47.9 |

The physical properties of the three analyzed soils reveal significant differences related to their textural class and geographical origin. The quince orchard soil, classified as sandy, exhibited the highest capillarity to diesel oil (8.5 cm) and the highest permeability to water (8400 $cm^3/h$), indicating a very open pore structure that facilitates rapid fluid movement. Consequently, its water retention capacity was the lowest (170.1 $kg/m^3$), which suggests that this soil type is the most vulnerable to deep pollutant infiltration in the event of a petroleum spill. In contrast, the plum orchard soil, classified as sandy loam, displayed the highest water retention capacity (384.6 $kg/m^3$) and the lowest permeability, reflecting a denser, more cohesive structure with a lower porosity of 39.2%. The pear orchard soil presented intermediate values between the two, with a sandy texture and a porosity of 47.9%. Regarding nutrient content, notable differences were observed among the three soils: the quince soil was characterized by low nitrogen (5 mg/kg) and high potassium (50 mg/kg), the plum soil showed a balanced but moderate NPK distribution, while the pear soil presented elevated nitrogen and phosphorus content (30 mg/kg each). These differences reflect the distinct fertilization histories of each privately owned orchard and underline the importance of site-specific nutrient monitoring.

***Characterization of diesel oil***

To illustrate how the pollutant penetrates the soil structure through the soil's capillary and permeability properties, as shown in Table 1, it was necessary to characterize the pollutant in terms of density and viscosity. These are key properties for the pollutant - diesel oil - and are presented in Table 2.

The density of diesel oil (850.5 $kg/m^3$ at 20°C) is significantly lower than the real density of all three soil types (2.60-2.74 $g/cm^3$), which means that diesel tends to remain in the upper soil layers and within the pore spaces rather than sinking rapidly to deeper horizons.

However, its low kinematic viscosity ($3.57 \times 10^{-4} m^2/s$ at 40°C) facilitates mobility through the soil matrix, particularly in sandy soils with high permeability such as the quince and pear orchard soils. These properties are relevant for understanding the capillarity and permeability results observed in Table 1, where diesel oil consistently reached higher capillary heights than water, due to its lower surface tension and different wetting characteristics relative to the soil mineral surfaces.

Table 2. The physical properties of diesel oil

| Physical properties | Value |
|---|---|
| Density ($kg/m^3$ ) at 20°C | 850.5 |
| Kinematic viscosity·$10^4$ ($m^2/s$) at 40°C | 3.57 |

***Thermal desorption for soil decontamination***

The extent of decontamination achieved by thermal desorption as summarized (Table 3). Following thermal decontamination, the nutrient content of the soils was restored (Table 4).

Table 3. The degrees of decontamination established after thermal desorption

| Measured | Type of orchard soil | | |
|---|---|---|---|
| | Quince | Plum | Pear |
| Diesel oil volume (ml) | 4.76 | 3.64 | 3.59 |
| Volume of water desorbed (ml) | 3.7 | 5.25 | 2 |
| Volume of diesel oil desorbed (ml) | 3.1 | 3.25 | 3 |
| Degree of decontamination achieved (%) | 83.8 | 89.3 | 83.6 |

Table 4. Nutrient content after desorption decontamination

| Nutrient | Type of orchard soil (mg/kg) | | |
|---|---|---|---|
| | Quince | Plum | Pear |
| N | 5 | 5 | 30 |
| P | 50 | 15 | 15 |
| K | 30 | 5 | 15 |

***Successive solvents extraction for soil decontamination***

Clean samples were decontaminated to quantify the organic material extracted according to soil structure (Table 5).

Table 5. Extraction results for the clean sample

| Measured | Type of orchard soil | | |
|---|---|---|---|
| | Quince | Plum | Pear |
| Organic material with petroleum ether (%) | 0.08 | 0.41 | 0.55 |
| Organic material with benzene (%) | 0.16 | 0.27 | 0.39 |
| Total organic material extracted (%) | 0.24 | 0.68 | 0.94 |

Soil samples contaminated in labor with 7% diesel oil were subjected to successive solvents extraction. The results obtained for the clean sample were used as a reference. The final results establishing the degree of decontamination are presented (Table 6).
After solvents extraction, the nutrient content of the soils was re-established (Table 7).

Table 6. The degrees of decontamination established after extraction

| Measured | Type of orchard soil with 7% diesel oil | | |
|---|---|---|---|
| | Quince | Plum | Pear |
| Diesel oil with petroleum ether (%) | 46.18 | 49.8 | 49.7 |
| Diesel oil with benzene (%) | 11.18 | 23.9 | 40.8 |
| Degree of decontamination achieved, (%) | 57.36 | 73.7 | 90.5 |

After the application of the decontamination methods, the soil pH values increased, except for the plum orchard soil, which showed a lower pH value after extraction (Table 8).
At 400°C, the acidic organic fractions in the soil and in the pollutant suffer degradation and volatilization, leading to an increase in basic mineral compounds and, consequently, to a rise in pH.

Table 7. Nutrient content after extraction decontamination

| Nutrient | Type of orchard soil, (mg/kg) | | |
|---|---|---|---|
| | Quince | Plum | Pear |
| N | 50 | 50 | 30 |
| P | 50 | 15 | 30 |
| K | 30 | 30 | 30 |

Changes in soil composition and buffering capacity can cause the pH to shift toward more alkaline values during successive solvent extraction.

Table 8. Variation of soils pH

| pH | Type of orchard soil | | |
|---|---|---|---|
| | Quince | Plum | Pear |
| pH for clean soil | 6.6 | 6.5 | 5.5 |
| pH of soil after desorption | 8.5 | 5.5 | 6 |
| pH of soil after extraction | 7.5 | 8 | 7 |

The application of decontamination methods highlights changes in nutrients content (Figure 2).

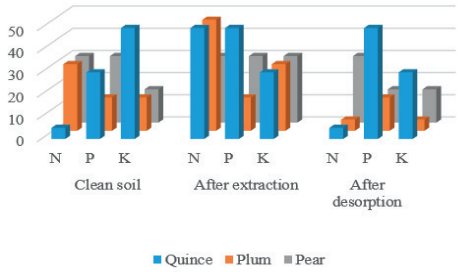

Figure 2. Variation of nutrients content

It should be noted that the orchards from which the samples were collected are privately owned and relatively small in size, each having received organic amendments. The fertilizers applied were not consistently monitored; therefore, different nutrient contents were observed in the clean soil samples (Table 1). The orchards are located in areas vulnerable to pollution due to accidental leaks from main petroleum product transport pipelines.

Thermal desorption at 400°C proved effective for all three soil types, achieving decontamination degrees ranging from 83.6% (pear orchard soil) to 89.3% (plum orchard soil). The plum orchard soil, which had the highest diesel oil retention capacity (64 kg/m³), also yielded the largest volume of desorbed water (5.25 ml), suggesting that its higher moisture content and denser structure required more energy for complete pollutant volatilization. The quince orchard soil, despite its high permeability, achieved a decontamination efficiency of 83.8%, likely due to the high initial pollutant mobility within its open pore structure. Overall, the results confirm that thermal desorption at 400°C is a reliable method for recovering petroleum hydrocarbons from all three soil types, with recovery rates consistently above 83%. The present study was based on the assumption that variations in nutrient content (NPK) in orchard soils may influence the selection of an appropriate decontamination technology. At the same time, soil pH was found to play an important role.

Following thermal desorption, notable changes in NPK nutrient content were recorded compared to the initial clean soil values (Table 1). In the quince orchard soil, phosphorus increased significantly (from 30 to 50 mg/kg), while nitrogen remained stable (5 mg/kg) and potassium decreased (from 50 to 30 mg/kg). In the plum orchard soil, all three nutrients decreased markedly, with nitrogen dropping from 30 to 5 mg/kg and potassium from 15 to 5 mg/kg, suggesting that the high treatment temperature caused volatilization or transformation of nitrogen compounds and leaching-like redistribution of potassium. The pear orchard soil showed an increase in nitrogen (from 30 to 30 mg/kg - unchanged) and stable phosphorus and potassium values. These results indicate that thermal desorption, while highly effective for pollutant removal, exerts a heterogeneous influence on nutrient content depending on the soil's initial composition and texture.

A comparison of the two decontamination approaches reveals that successive solvents extraction exerts a relatively mild impact on soil structure and nutrient content, while inducing minimal changes in pH. This method is predominantly linked to the mobilization of nutrients associated with organic matter. Conversely, desorption primarily interacts with the mineral fraction of contaminated soils, leading to a more pronounced increase in pH. When performed at 400 °C, desorption facilitates the determination of available nutrient content through mineralization. An advantage of the desorption method lies in its ability to recover and reuse the pollutant in relatively high proportions (over 83%), but the application of desorption can affect long-term fertility. For orchard soils, permanent irrigation is necessary (permeability is high), as is the controlled use of organic amendments, possibly alternating them, and nutrient supplements.

Successive solvent extraction with petroleum ether and benzene yielded decontamination efficiencies ranging from 57.36% (quince orchard soil) to 90.5% (pear orchard soil). The pear orchard soil achieved the highest removal efficiency, with both solvents contributing substantially (49.7% with petroleum ether and 40.8% with benzene). In contrast, the quince orchard soil showed the lowest overall efficiency despite its high permeability, which may be attributed to strong adsorption interactions between the diesel oil and the sandy soil matrix at the concentration used. The plum orchard soil achieved an intermediate efficiency of 73.7%. Notably, petroleum ether consistently outperformed benzene in the first extraction step across all soil types, suggesting that the lighter, non-polar diesel oil fractions are more readily mobilized in the initial extraction phase, with benzene recovering the heavier residual fractions in the second step. Successive solvent extraction had a generally positive or neutral effect on nutrient content compared to the initial clean soil values. The quince orchard soil showed significant increases in nitrogen (from 5 to 50 mg/kg) and maintained its phosphorus level (50 mg/kg), while potassium remained stable (30 mg/kg). The plum orchard soil similarly showed a marked increase in nitrogen (from 30 to 50 mg/kg) and potassium (from 15 to 30 mg/kg), with phosphorus unchanged (15 mg/kg). The pear orchard soil maintained stable nitrogen and phosphorus levels (30 mg/kg each) and showed an increase in potassium (from 15 to 30 mg/kg). These results suggest that solvent extraction, unlike thermal desorption, does not destroy nutrient compounds and may even

mobilize organically bound nutrients, making it a more agronomically favorable option with respect to post-treatment soil fertility. Changes in nutrient content before and after remediation were also observed in agricultural soil when the electrokinetic remediation method was used (Popa, 2025).

The results obtained are similar to the literature on the properties of orchard soils (Tkaczyk et al., 2018).

The application of both decontamination methods induced measurable changes in soil pH. Following thermal desorption, the pH increased substantially in the quince orchard soil (from 6.6 to 8.5) and moderately in the pear orchard soil (from 5.5 to 6.0), while the plum orchard soil experienced a decrease (from 6.5 to 5.5). The pronounced alkalinization observed in the quince soil after desorption can be attributed to the thermal degradation and volatilization of acidic organic fractions, combined with the formation of basic mineral compounds at 400°C. After solvent extraction, pH values generally shifted toward slightly alkaline conditions in the quince (7.5) and plum (8.0) soils, while the pear soil showed a moderate increase (from 5.5 to 7.0). The exception was the plum soil after thermal desorption, which showed a slight acidification, possibly linked to the selective volatilization of alkaline compounds or the release of acidic intermediates during the process. Overall, both methods tend to increase soil pH, which should be considered when planning post-treatment agronomic management, particularly for species sensitive to alkaline conditions.

## CONCLUSIONS

The selection of appropriate technologies for the decontamination of hydrocarbon-polluted soils represents a challenging task. Methods that allow the recovery of the pollutant to the greatest possible extent are generally preferred. In the case of the orchard soils investigated in this study, slight differences in the determined decontamination efficiencies were observed.

Both thermal desorption at 400°C and successive solvent extraction with petroleum ether and benzene proved effective for the removal of diesel oil from all three soil types. Thermal desorption achieved decontamination efficiencies above 83% for all samples, while solvent extraction yielded efficiencies ranging from 57.36% to 90.5%, with the highest performance recorded for the pear orchard soil. With respect to nutrient content, successive solvent extraction demonstrated a milder and generally more favorable impact on NPK levels, in some cases even increasing the available nutrient content through the mobilization of organically bound compounds. Thermal desorption, while highly efficient for pollutant recovery, produced more variable and in some cases more pronounced changes in nutrient content, particularly for nitrogen and potassium, and led to a significant increase in soil pH, factors that may affect long-term soil fertility.

The results confirm that the selection of an appropriate decontamination technology for petroleum-contaminated orchard soils cannot be based solely on removal efficiency, but must also account for the post-treatment agronomic status of the soil, including nutrient availability and pH. For this study, a comparison of the decontamination methods used leads to the conclusion that, although the degree of decontamination achieved by the successive solvent extraction method is lower than that achieved by the thermal desorption method, the change in nutrient content is more favorable for extraction.

The use of soil amendments must be carefully monitored so that, in the event of accidental pollution with hydrocarbons, this factor is taken into account when selecting a decontamination method.

Future research should explore additional decontamination methods, such as soil washing with environmentally friendly surfactants and electrokinetic decontamination, and assess their impact on a broader range of soil fertility indicators, in order to support the development of integrated and sustainable remediation strategies for orchard soils affected by accidental hydrocarbon contamination.

***Abstract***

*Hazardous organic compounds are organic chemicals characterized by toxicity, persistence, and bioaccumulation potential, as well as their ability to distribute across environmental compartments such as soil, water, and air. This study aims to evaluate the contamination levels of soils from industrial areas with polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), and organochlorine insecticides (OCPs) in order to establish a database for the development of a soil emission inventory. For this purpose, 40 soil samples were collected from industrial sites in the southern region of the country, extracted using hexane-like solvents, and analyzed by gas chromatography (GC) and high-performance liquid chromatography (HPLC). The results indicate that soil concentrations of PCBs ranged between 0.002 mg/kg and 0.326 mg/kg, whereas PAH concentrations ranged from 0.044 mg/kg to 12.022 mg/kg. Among OCPs, lindane and DDE - the main metabolite of DDT - were the most frequently detected OCPs in soil.*

***Key words****: contamination, OCPs, PAHs, PCBs, soil.*

## INTRODUCTION

Polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), and polycyclic aromatic hydrocarbons (PAHs) are environmentally persistent organic contaminants that share several physicochemical and toxicological characteristics. These compounds are hydrophobic and lipophilic, exhibiting low water solubility and a strong affinity for organic matter and biological lipids, which promotes their accumulation in soils, sediments, and living organisms (Rissato et al., 2006). Due to their chemical stability and resistance to degradation, they persist in the environment and can undergo long-range atmospheric transport, leading to global distribution. The Stockholm Convention on Persistent Organic Pollutants (POPs) was adopted in 2001 to eliminate or restrict chemicals that are persistent, bioaccumulative, toxic, and capable of long-range environmental transport (UNEP, 2001). Both PCBs and OCPs were included among the initial substances targeted for global control. PCBs were listed in Annex A (Elimination) at the Convention because of their extensive industrial use and widespread environmental contamination. Parties were required to cease production and new uses, identify and label PCB-containing equipment, and ensure environmentally sound management and disposal. The Convention set a goal of eliminating the use of PCBs in equipment by 2025 and achieving environmentally sound waste management by 2028. Several OCPs were also classified as POPs, reflecting decades of evidence linking them to ecological damage and human health risks (Jones & Voogt, 1999). Pesticides such as aldrin, dieldrin, endrin, heptachlor, chlordane, toxaphene and mirex were included in Annex A (Elimination), while DDT was additionally placed in Annex B (Restriction) to allow limited use for malaria vector control under specific condition (Lallas, 2001). PAHs are organic pollutants composed of two or more condensed rings. The US Environmental Protection Agency (USEPA) declared 16 compounds from the PAHs category as priority pollutants in 1983, due to their presence in the environment at high concentrations, their recalcitrant nature, and toxicity (Barathi et al., 2023). Many high-molecular-weight PAHs display similar persistence and bioaccumulative behavior as PCBs and OCPs. All three groups are associated with significant health risks, including carcinogenic, mutagenic, endocrine-disrupting,

and immunotoxic effects, making them important targets for environmental monitoring and risk assessment (La Merrill et al., 2020). These compounds originate primarily from anthropogenic activities, although some natural sources exist. PCBs were intentionally manufactured for use in electrical equipment, hydraulic fluids, plasticizers, and other industrial applications, and their release occurred through production, usage, disposal, and leakage from contaminated materials (Rubin, 1999; Hannah et al., 2022; Sandu et al., 2025). OCPs were widely applied in agriculture and public health programs for pest control, with environmental contamination resulting from large-scale application, improper handling, and long-term persistence in soils (Jones & Voogt, 1999). In contrast, PAHs are mainly formed as by-products of incomplete combustion of organic matter, including fossil fuels, biomass burning, industrial processes, and vehicular emissions; however, they can also originate from natural events such as wildfires and volcanic activity (Ravindra et al., 2008). Overall, industrialization, agricultural practices, and combustion-related processes represent the principal sources of these contaminants in the environment.

This study aims to evaluate the contamination levels of soils from industrial areas with these compounds, providing baseline data that may contribute to the future development of a soil emission inventory supporting the implementation of Regulation (EU) 2019/1021 regarding persistent organic pollutants. The originality of this study consists in providing an up-to-date picture of soil contamination correlated with the current profile of industrial activity in southern Romania.

## MATERIALS AND METHODS

40 topsoil samples (0-20 cm) were collected in spring of 2024 from areas potentially affected by industrial activities, as follows (Table 1):

- Pitești (P1-P5) and Mioveni (P8-P11)

In the vicinity of the city was located one of Romania's largest oil refineries, which may have contributed to the local environmental contamination through the historical use of PCB-containing equipment and the release of PAHs from oil processing. Additionally, historical agricultural practices in the surrounding area may have left residues of OCPs in soils. Mioveni also hosts industrial facilities. PCBs could originate from older industrial and electrical equipment, including facilities associated with automotive manufacturing. PAHs could be released through vehicle emissions, local industrial activity, and fuel combustion.

Table 1. Sample locations of the soil samples

| Sample code | Sampling location | Latitude (N) | Longitude (E) |
|---|---|---|---|
| P1 | Pitești 1 | 44°48'05" | 24°56'19" |

- Ploiești (P6, P7)

Soil contamination with PCBs in the vicinity of the refinery is mainly associated with facilities and equipment that were in operation before the regulatory phase-out of PCBs. In addition, PAHs may be released into the environment through incomplete combustion processes related to petroleum refining activities, fuel combustion, and vehicle emissions

- Câmpulung, Râmnicu Vâlcea, Brașov (P12-P17, P28, P29)

Soil samples were collected from three former industrial sites: an industrial park in Câmpulung, an area in the vicinity of an industrial platform in Râmnicu Vâlcea and Brașov.

- Slatina

From Slatina, an important industrial center in southern Romania with a long history of manufacturing and heavy industry, were collected 10 soil samples (P18-P27) situated in industrial area.

- Bucharest and Ilfov county

The sampling points were located near industrial platforms (P 30, P31, P34, P35), pharmaceutical manufacturing facilities (P32, P33), tire and rubber material factories (P 38, P39), two concrete mixing plants (P36, P37) and an electrical transformer station (P40) (Figure 1).

Figure 1. A sampling point located near electrical transformers

Samples were collected in March when air temperatures averaged 15°C. Each sample consisted of a composite of five subsamples collected from the four corners and the center of a 5 × 5 m² plot. Representative soil samples weighing approximately 500 g were stored in glass containers, protected from light, and refrigerated until analysis.

PCBs analysis in soil was performed in accordance with SR EN 17322:2020, PAHs analysis followed SR EN 17503:2022, and OCPs determination was carried out according to ISO 23646:2022. Accordingly, in compliance with these standards for the extraction of PCBs, OCPs, and PAHs from soil, an automated Soxhlet extractor was employed. Ten grams of air- dried soil samples were extracted for 2 hours using a 1:1 mixture of hexane:acetone. The extract is then washed with water for chromatography to remove acetone, passed over anhydrous sodium sulfate to remove water and evaporated to the appropriate volume. The PCBs determination (seven isomers indicated by Order 756/1997): PCB 28, PCB 52, PCB 101, PCB 118, PCB 138, PCB 153, PCB 180 and the OCPs determination (α, β, γ, δ HCH, pp'-DDE, pp'-DDD and pp'-DDT) were performed on an Agilent gas chromatograph (GC) equipped with an electron capture detector (ECD), operated at 300 °C and a capillary column (30 m x 0.32 mm x 0.25 mm) with a nonpolar stationary phase (DB-5) (Preda et al., 2025).

The determination of PAHs was carried out using a Knauer ultrahigh-performance liquid chromatograph (UHPLC) equipped with an UV-VIS detection at a wavelength of 254 nm. Order 756/1997 stipulates the quantification of the following priority PAHs: anthracene, benzo(a)anthracene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[a]pyrene, benzo[ghi]perylene, chrysene, fluoranthene, indeno(1,2,3)pyren, naphthalene, phenanthrene, pyren. The pair of compounds benzo[ghi]perylene and indeno(1,2,3)pyrene cannot be resolved using this type of detector. The separation of the remaining compounds was carried out on a C18 column (2.1 mm × 100 mm, 1.8 µm) maintained at 40°C. The mobile phase consisted of water and acetonitrile, applied under gradient elution conditions (Preda et al., 2025).

For calibration of the PCBs, OCPs and PAHs were used mixed standard solutions (PCB Calibration Mixture 10 µg/ml, PAH-Mix 100 µg/ml, Organochlorine Pesticide Mix 1000 µg/ml). To minimize contamination, all glassware was rinsed with solvents. To guarantee the representativeness and reliability of the results obtained, QA/QC procedures

included duplicate samples, blanks, and the analysis of a certified reference material.
The limit of quantification in soil is 0.001 mg/kg for each PCB and OCP isomers and 0.01 mg/kg for each PAH compounds. All the results are expressed as dry matter.

## RESULTS AND DISCUSSIONS

### *PCBs content in soil*

The total concentration of PCB compounds ranged from 0.002 mg/kg to 0.326 mg/kg. The highest content exceeds the alert threshold of 0.25 mg/kg, it was observed at sampling point P33, collected from the former site of a chemical manufacturing company specializing in the production of solvents, thinners, and other industrial chemical products (Figure 2). Schuhmacher et al. (2004) considered that in a chemical plant, PCBs may have been generated unintentionally as by-products of industrial processes.
20% of the analyzed samples showed normal values of concentration (<0.01 mg/kg), 77% had concentrations between the upper limit of the normal value and the alert threshold, and the remaining 3% exceeded the alert threshold.
Regarding the contribution of the seven isomers to the total PCB content, it can be observed that, at most sampling points, highly chlorinated compounds (PCB 138, PCB 153, and PCB 180) are predominant (Figure 3). Numerous studies have documented the presence of highly chlorinated PCBs such as PCB 138, PCB 153 and PCB 180 in soils from industrialized or urbanized areas, reflecting their persistence and historical contamination patterns (Nadal et al., 2007; Li et al., 2023; Sandu et al., 2025). For example, Li et al. (2023) reported hexachlorinated and heptachlorinated congeners among the dominant PCB profiles in soils around an industrial park. There are several sampling points (P8, P15, P29, P30, P35, and P36) where, in contrast, low-chlorinated compound, specifically PCB 28 and PCB 52, are predominant. The investigated sites are located in Mioveni, within the industrial area of Brașov and Râmnicu Vâlcea, on the industrial platform in Bucharest, and in areas situated in the vicinity of tire and rubber manufacturing facilities. Thus, in point P15, collected from a chemical plant from Râmnicu Vâlcea, the major omologue is PCB 52 (41%), the tetra-chlorinated isomer. In this point the PCB 52 concentration (0.034 mg/kg) exceeds the intervention limit (0.01 mg/kg).

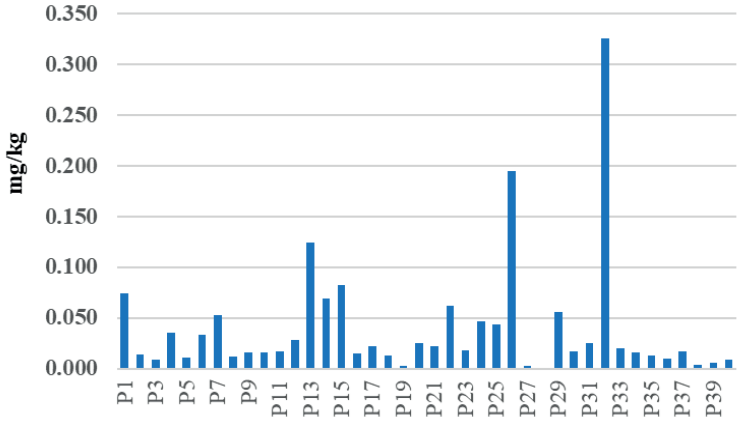

Figure 2. The total content of PCBs in soil samples collected from industrial areas

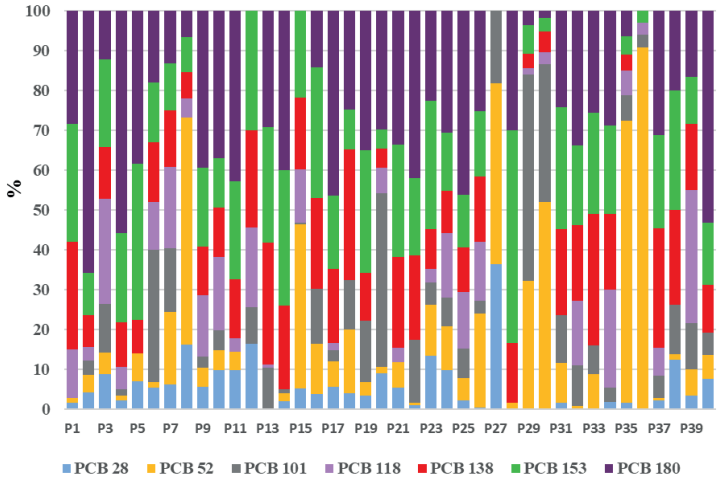

Figure 3. The contribution of the isomers to the total content of PCBs

Similar findings were reported by Zhang et al. (2014), who found that tetra-CBs (31%) and tri-CBs (19%) were the dominant PCB homologs in soils collected from an industrial area. The predominance of low-chlorinated congeners (PCB 28 and PCB 52) at several sampling sites may indicate the influence of local industrial emissions. Tri- and tetra-chlorinated PCBs are frequently associated with unintentional industrial releases and urban/industrial activities, including metal processing and the manufacture or use of polymer- and rubber-based materials (Sandu et al., 2025). Their presence may also be caused by dechlorination of higher chlorinated PCBs which break down over time in the environment (Tolefe et al., 2025). Salihoglu et al. (2011) have shown that intense industrial activity is the main source of high levels of PCB contamination in soil.

***PAHs content in soil***

The total concentration of polycyclic aromatic hydrocarbons (PAHs) in soils collected from the industrial areas ranged from 0.044 mg/kg to 12.022 mg/kg, with a mean value of 0.636 mg/kg. According to Order 756/1997, the normal values for total PAH concentrations in soil must be below 0.1 mg/kg. These results indicate that 10.91% of the analyzed soil samples were within the normal concentration range, 87.20% exceeded the normal threshold but remained below the alert level, and 1.89% surpassed the alert threshold of 7.5 mg/kg. The highest value (12.022 mg/kg) was recorded in the soil sample collected from Slatina industrial area (P32). Elevated concentrations were also recorded at sampling points P39 (1.505 mg/kg), P28 (1.342 mg/kg), and P35 (1.336 mg/kg); however, at these points, the alert threshold for sensitive land uses of 7.5 mg/kg was not reached. Similar results were reported by Wang et al. (2010) who found PAH concentrations ranging between 0.031 mg/kg and 1.475 mg/kg in soil collected from an industrial city. Regarding the individual compounds it was observed that the highest average concentrations in soil corresponded to chrysene, benzo[b]fluoranthene, and benzo[a]anthracene (Figure 4). These substances belong to the category of high molecular weight polycyclic aromatic hydrocarbons (HMW PAHs), containing more than four aromatic rings per molecule. Chrysene and benzo[b]fluoranthene exceeded the alert threshold for sensitive land uses of 2 mg/kg (2.210 mg/kg and 2.874 mg/kg, respectively), while benzo[a]anthracene was very close to this threshold (1.890 mg/kg). These concentrations were measured in soil sample P32 collected in the vicinity of a facility engaged in the production of graphite electrodes, refractory materials, and other coal-derived products - industrial activities that involve high-temperature processing and the use of petroleum-derived feedstocks. Among the low molecular weight compounds (LMW PAHs, with fewer than four aromatic rings per

molecule), the highest average soil concentration, 0.064 mg/kg, was observed for phenanthrene - which is also the most thermodynamically stable.

Examining the compound profile, it can be observed in Figure 4 that the decreasing order of concentrations in the studied soils is as follows: chrysene > benzo[b]fluoranthene > benzo[a]anthracene > phenanthrene > fluorene > benzo[a]pyrene > benzo[k]fluoranthene > anthracene > fluorene > naphthalene.

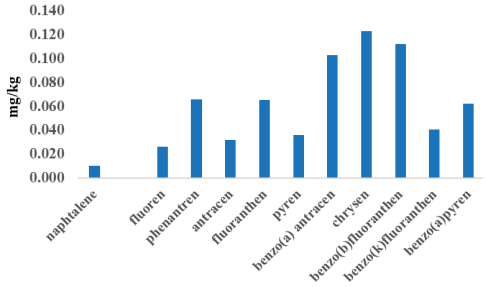

Figure 4. Average concentration of the individual PAH compounds in soils collected from industrial areas

It was observed that low molecular weight (LMW) hydrocarbons have a lower total concentration than high molecular weight (HMW) hydrocarbons, which may indicate a pyrogenic source (combustion-related processes). The ∑LMW/∑HMW PAH ratio can be used to distinguish petrogenic from pyrogenic sources (Zhang et al., 2008). Values of this ratio below 1 indicate pyrogenic sources, while values above 1 suggest petrogenic sources. Petrogenic sources include crude oil and petroleum-derived products such as kerosene, gasoline, lubricating oils, and asphalt. Pyrogenic sources result from combustion processes, including the burning of fossil fuels (coal, wood, oil) or biomass (forests, grasslands, crop residues).

In this study, the ∑LMW/∑HMW ratio ranged from 0.046 to 2.102. These values indicate the presence of pyrogenic sources in approximately 94% of the analyzed soil samples. Ratios above 1 were observed in samples collected from the Pitești refinery area (all samples), in one sample from the pipe manufacturer area in Slatina, and in the soil sample from the pharmaceutical factory in Bucharest.

***Organochlorine insecticides in soil***

OCPs have been widely used in agriculture on a global scale for several decades. Montory et al. (2017) showed that various organochlorine compounds, including hexachlorocyclohexanes (HCHs) and dichlorodiphenyltrichloroethanes (DDTs), remain widely present in the environment due to their persistence, despite their production and use having been banned in developed countries during the 1970s and 1980s. In Romania OCPs have been banned since 1985 (Dirtu et al., 2006). However, in our country too, studies show the presence of these residues in the soil (Ene et al., 2012; Tarcau et al.; 2013).

The total concentration of HCHs in collected soil samples ranged between 0.011 mg/kg and 0.291 mg/kg with an average concentration of 0.085 mg/kg. Lindane is present in 84% of the analyzed samples, although in concentrations around normal values (< 0.001). A particular case is observed for the samples collected near the Râmnicu Vâlcea plant (P14-P17), which are contaminated with all four HCH isomers. In this industrial area, the β-HCH isomer exceeds the alert threshold for less sensitive sites (0.15 mg/kg), as defined by Order 756/1997, and lindane reaches and even exceeds the alert threshold for sensitive uses of 0.02 mg/kg (Figure 5).

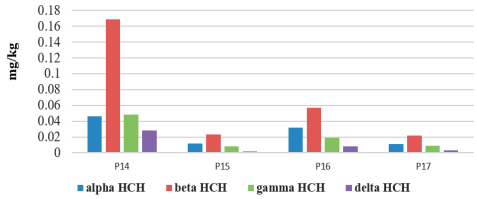

Figure 5. HCH isomer ratio in soil samples collected from Râmnicu Vâlcea

The concentrations of the other HCH isomers (α- and δ-HCH) exceed the upper limit of the normal range (< 0.002 mg/kg and < 0.001 mg/kg, respectively) but remain below their respective alert thresholds (0.1 mg/kg and 0.005 mg/kg, respectively). As illustrated in Figure 5, β-HCH exhibits the highest concentration in this area. Since β-HCH is the most persistent isomer, its predominance relative to the other isomers suggests that the contamination is of historical

origin (Wohrnschimmel et al., 2012). Regarding the total content of DDTs, the mean value of concentration is 0.015 mg/kg, ten times lower than the upper limit of normal values (<0.15 mg/kg). Similar observations were made by Tarcau et al. (2013), who reported that p,p′-DDE and p,p′-DDT were the major contributors to sum DDTs accounting for 54% and 38% of the total concentration, respectively.

## CONCLUSIONS

Regarding PCB contamination, 20% of the analyzed soil samples exhibited normal value of concentrations (<0.01 mg/kg), while 77% showed levels between the normal value and the alert threshold, and 3% exceeded the alert threshold. The highest concentration (0.326 mg/kg) was recorded in a soil sample collected from the former site of a chemical manufacturing facility producing solvents, thinners, and other industrial chemicals.

For PAHs, 10.91% of the analyzed soil samples were within the normal range, 87.20% exceeded the normal level but remained below the alert threshold, and 1.89% surpassed the alert level (7.5 mg/kg). The maximum concentration (12.022 mg/kg) was observed in a soil sample collected from the Slatina industrial area. Chrysene, benzo[b]fluoranthene, and benzo[a]anthracene were the dominant PAH compounds detected.

Lindane and p,p′-DDE were the predominant organochlorine pesticide residues in the analyzed soils. The predominance of β-HCH in soils collected from the Râmnicu Vâlcea industrial platform suggests legacy contamination associated with historical industrial activities.

The distribution and the concentrations of PCBs, PAHs, and OCPs observed in this study confirm the strong influence of historical and current industrial activities and provide valuable input for the development of a soil emission inventory under Regulation (EU) 2019/1021.

## ACKNOWLEDGEMENTS

This research work was financed with the support of the Project PN 23 29 01 01- “Research on the soil emissions inventory of some persistent organic pollutants - an important stage of the national implementation of EU Regulation 1021/2019”.

***Abstract***

*This study focuses on the origins of particulate matter (PM), an important air pollutant with significant effects on the environment and human health. PM comes from a variety of sources, including anthropogenic ones such as industrial emissions, traffic, and construction activities, as well as natural processes like wildfires and volcanic eruptions. The paper also examines how these particles are released into the atmosphere and how their behaviour is influenced by their size and chemical composition. In addition, the study discusses the transport and dispersion of particulate matter in the atmosphere, highlighting the factors that affect its concentration and persistence. Understanding these processes is essential for improving air quality management, reducing pollution levels, and protecting both ecosystems and public health.*

***Key words****: air pollution, environmental health, monitoring, particulate matter (PM), PM sources.*

## INTRODUCTION

Air pollution is a major environmental concern, with particulate matter (PM) being one of the most significant atmospheric pollutants due to its complex origin and widespread presence. PM originates from both natural processes and anthropogenic activities, including traffic emissions, industrial processes, construction activities, biomass burning, and secondary atmospheric formation.

This study focuses on the characterization of PM sources and the importance of source identification for air quality management and emission control strategies.

Understanding PM source contributions is essential for the development of effective air pollution mitigation policies. This topic has been widely addressed in the scientific literature, particularly in studies focusing on source apportionment and atmospheric pollution dynamics (Durbacă, et al., 2020).

This review is based on peer-reviewed articles indexed in ISI Web of Science and Scopus databases, published mainly over the last 10-15 years (2010-2025), including systematic reviews and source apportionment studies of particulate matter.

The aim of this study is to identify and analyse the main natural and anthropogenic sources of particulate matter based on recent scientific literature, to provide an overview of their relative contributions and environmental relevance.

## MATERIALS AND METHODS

This study is based on a narrative review of scientific literature regarding particulate matter (PM) sources and origins. Relevant peer-reviewed articles were selected from ISI Web of Science and Scopus databases, focusing on publications from 2010 to 2025.

The literature search included studies addressing PM source identification, source apportionment, and emission characterization. The collected information was critically analysed and synthesized to provide an overview of the main natural and anthropogenic sources of particulate matter and their environmental significance.

## RESULTS AND DISCUSSIONS

This section synthesizes findings from recent literature on particulate matter (PM) sources and source apportionment studies. The reviewed studies consistently identify both natural and anthropogenic contributions to ambient PM levels, with variability depending on location, seasonality, and local emission profiles.
Anthropogenic sources, particularly traffic emissions, industrial activities, construction processes, and biomass burning, are generally reported as the dominant contributors in urban and industrial areas, while natural sources such as dust resuspension and sea salt are more relevant in rural or coastal environments.

## SOURCES OF PARTICULATE MATTER (PM)

Particulate matter (PM) is divided into primary and secondary sources. Primary PM originates directly from natural events such as marine aerosols, volcanic activity, wildfires, and bioparticles, as well as anthropogenic sources including transport, industry, construction, and domestic practices.
Secondary PM forms in the atmosphere from chemical reactions involving precursors gases.
As shown in Figure 1, the main sources of PM pollution are presented. This study also highlights the main sources of PM in Bucharest, where urban and traffic-related emissions are dominant.

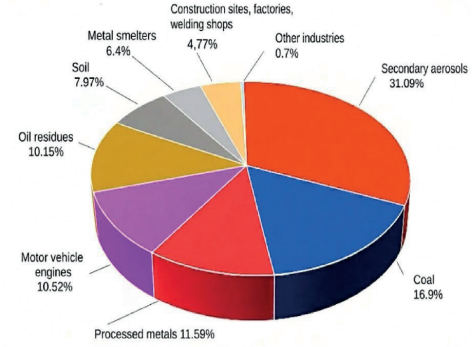

Figure 1. Sources of PM pollution (Lee et al., 2023)

### Natural sources of particulate matter (PM)

Aeolian dust and soil erosion **r**elease fine mineral particles into the atmosphere, contributing significantly to PM10 and PM2.5 concentrations. These processes are driven by wind action over exposed or disturbed soils, where the breakdown of soil aggregates facilitates particle detachment and suspension. Emissions increase strongly in dry, bare or agricultural lands, especially under high wind speeds and low soil moisture conditions. Once uplifted, particles can remain suspended for extended periods and be transported over long distances, influencing air quality at both local and regional scales (Katra, 2020).
Marine aerosols are a major natural source of $PM_{2.5}$ and $PM_{10}$ in coastal regions, formed mainly from sea spray processes. They consist predominantly of sodium ($Na^+$), chloride ($Cl^-$) and other sea-derived ions such as magnesium, which are commonly used as chemical tracers for marine origin. In atmospheric measurements, these ions are also used in source apportionment studies to distinguish marine contributions from anthropogenic inputs and to assess aerosol aging processes in coastal environments (Wu et al., 2024).

**Shipping emissions from maritime transport** represent an important source of particulate matter, particularly in coastal and port areas. Ship engines, often using heavy fuel oil, emit $SO_2$ and primary PM2.5, while also contributing to secondary particle formation in the atmosphere through oxidation processes. These emissions can significantly affect air quality in major ports and coastal urban zones, making maritime transport a relevant contributor to regional PM pollution in Europe (Thunis et al., 2015).
Volcanic activity is a major natural source of particulate matter, releasing ash, fine particles, and gases that affect aerosol chemistry. These emissions vary in intensity and composition and can impact air quality at local, regional, and global levels. Volcanic particles contain silica, aluminium and iron oxides, and sulphides, and can be transported over long distances (Wu et al., 2023).
Figure 2 illustrates volcanic emissions including solid particles (ash and dust) and secondary aerosols formed from gas condensation.

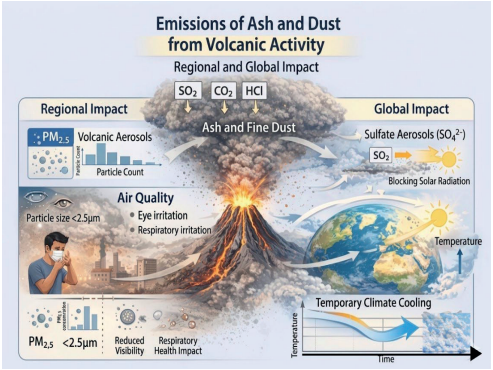

Figure 2. Emission of Ash and Dust from Volcanic Activity (image generated with AI)

Fine particles ($PM_{2.5}$) can remain in the atmosphere and travel long distances, increasing PM levels. At a global scale, volcanic aerosols, especially sulphates from $SO_2$, can reflect solar radiation and temporarily cool the climate (Zhang et al., 2022).

Wildfires release a complex mixture of gases and particulate matter, including $PM_{2.5}$, $PM_{10}$, VOCs, CO, and NOx. Fine particles can travel long distances and significantly increase PM concentrations, often exceeding air quality limits. This leads to large-scale air pollution and impacts both local and distant regions, as shown in Figure 3 (Hadiwijoyo et al., 2025).

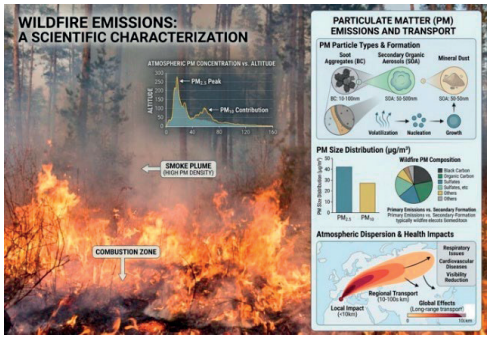

Figure 3. Wildfire emissions (image generated with AI)

Wildfire smoke acts as an atmospheric aerosol, affecting solar radiation and cloud formation. As a result, $PM_{2.5}$ and $PM_{10}$ can influence weather patterns and climate at regional and global scales (Vaezi et al., 2025).

Recent studies show that pollen and fungal spores are dispersed in the atmosphere as part of bioaerosols and can contribute to particulate matter, particularly in the PM10 fraction and, in some cases, in the fine fraction below 10 µm. These particles are of biological origin and can become incorporated into airborne particulate matter through mechanical release and atmospheric transport processes. Bioaerosols also contribute to the organic fraction of PM, highlighting their relevance in the overall composition of atmospheric particulate matter in both indoor and outdoor environments (Sikoparija et al., 2025).

Vegetation reduces wind-driven soil erosion by stabilizing the soil structure and limiting the detachment of fine particles through root systems and surface cover. In contrast, exposed or bare lands act as important sources of dust emissions, with the number of resuspended particles strongly dependent on wind speed, soil texture, and moisture content. Under dry conditions and high wind intensity, these surfaces can significantly contribute to atmospheric PM10 levels through enhanced dust emission and transport processes (Labiadh et al., 2023).

Seasonal variability and meteorological conditions significantly influence the concentration, transport, and spatial distribution of marine aerosols. Wind speed plays a key role in the generation and emission of sea spray particles, while atmospheric humidity and temperature affect their hygroscopic growth and chemical evolution in the atmosphere. Atmospheric stability conditions determine the vertical mixing and dispersion of these particles, controlling how efficiently they are transported from coastal zones towards inland continental areas. As a result, marine aerosol concentrations can vary considerably depending on seasonal weather patterns and large-scale atmospheric circulation, which modulate both their intensity and persistence in the atmosphere (Zhu et al., 2025).

Particulate matter emissions and PM10 and PM2.5 concentrations exhibit significant seasonal variability, with higher levels typically observed during dry and warm periods. In these conditions, soils are more exposed and susceptible to wind-driven resuspension, while reduced moisture content increases the ease of particle detachment from surfaces. In contrast, during wet seasons, precipitation and higher humidity contribute to the removal of airborne

particles through wet deposition and limit dust generation from soils. Seasonal dynamics therefore affect both natural emissions from soil surfaces and ambient PM levels in urban environments, leading to higher concentrations during dry, stagnant atmospheric conditions compared to rainy periods. This variability highlights the importance of meteorological factors and seasonal climate patterns in assessing particulate matter emissions and identifying periods of increased environmental risk (de Souza et al., 2025).

Lightning is a natural source of nitrogen oxides (NOx) in the atmosphere, produced during high-temperature electrical discharges. These emissions contribute to the formation of ozone and secondary particulate matter through atmospheric oxidation processes involving NOx-derived compounds. Although lightning-induced emissions are episodic and spatially variable, they represent an important natural pathway for atmospheric chemical reactions that can influence the formation of secondary aerosols, including PM2.5, at regional scales (Bender et al., 2006).

Table 1 presents the main environmental factors influencing PM emissions and their effects on $PM_{10}$ and $PM_{2.5}$ concentrations.

Table 1. Factors which influence PM emissions
*Source: compiled by the author based on literature data*

| Factor | Effect on PM emissions |
|---|---|
| Arid- semi-arid climate | Increases PM10 and PM2.5 concentrations |
| Exposed soil/intensive agriculture | Increases PM10 concentration (>10%) |
| Low humidity | Increases particle mobilization and intensifies turbulence |
| Precipitation | Reduces PM (through particle deposition) |
| Reduced vegetation | Increases the risk of PM10 and PM2.5 emissions |
| Green zones/tree shelterbelts | Reduces PM10 and PM2.5 concentrations |

**Anthropogenic sources of particulate matter (PM)**

Vehicle exhaust emissions are a major anthropogenic source of $PM_{2.5}$ and $PM_{10}$ in urban environments, originating mainly from incomplete combustion of fossil fuels in internal combustion engines. These emissions are characterized by high concentrations of carbonaceous particles, particularly organic carbon (OC) and elemental carbon (EC), which significantly influence both the mass and toxicity of particulate matter. Diesel engines generally produce higher particulate emissions compared to gasoline engines due to differences in combustion efficiency and fuel composition. In addition to exhaust emissions, non-exhaust sources such as brake wear, tire abrasion, and road surface wear also contribute substantially to urban PM levels through mechanically generated particles. Elevated OC and EC fractions are typically associated with inefficient or incomplete combustion processes and varying operating conditions (Shi et al., 2023).

Aviation contributes to particulate matter emissions mainly in airport areas, especially during landing and take-off cycles. Aircraft engines emit PM2.5 and ultrafine particles, including black carbon and sulphate-related particles formed during fuel combustion. Although its global contribution to PM mass is relatively limited compared to road traffic and industry, aviation can significantly affect local air quality near airports due to concentrated emissions at low altitudes (Dadvand et al., 2011).

Residential heating is an important anthropogenic source of particulate matter, with emissions strongly dependent on the energy system used. Domestic heating systems based on solid fuels (wood, coal, biomass) generate significantly higher PM10 and PM2.5 emissions due to incomplete combustion, especially in older and low-efficiency installations. In contrast, centralised district heating systems generally show lower specific emissions because of higher combustion efficiency, better fuel control, and the use of emission abatement technologies. However, in urban areas where individual heating systems still dominate, domestic combustion remains a major contributor to wintertime PM levels, often exceeding emissions from transport in cold seasons (Cincinelli et al., 2019).

Table 2 summarizes the main sources of particulate matter (PM), their predominant particle fractions, and their key characteristics.

Table 2. Main sources of particulate matter (PM)
*Source: compiled by the author based on literature data*

| Source Type | Main PM Fraction | Key characteristics / examples |
|---|---|---|
| Natural sources | PM10, 2.5 | Marine aerosols, wildfires, volcanic ash |
| Traffic | PM2.5 | Combustion (OC, EC), non-exhaust wear |
| Construction | PM10 | Dust from excavation, demolition |
| Residential burning | PM2.5 | Biomass and waste combustion |
| Agriculture | PM10 | Soil dust, crop residue burning |
| Industry | PM2.5, PM10 | Metal particles, combustion, chemical PM |

## CONCLUSIONS

The literature review highlights that particulate matter originates from a wide range of natural and anthropogenic sources, with significant spatial and temporal variability. Anthropogenic activities, particularly traffic, industrial processes, and construction, are consistently identified as major contributors in urban environments, while natural sources such as dust and marine aerosols play a more important role in rural and coastal areas.

The reviewed studies emphasize that source apportionment is essential for understanding PM distribution and for supporting effective air quality management strategies.

Overall, the findings underline the importance of targeted emission control measures adapted to local emission profiles.

***Abstract***

*The paper presents an experimental analysis of the influence of partially replacing natural aggregates with ceramic waste on the permeability of concrete. The use of recycled materials in concrete aims to reduce environmental impact and promote the reuse of waste from the construction industry. In this study, concrete samples were prepared with different substitution levels of aggregates (0%, 50% of 0-4 mm aggregates, 50% of 4-8 mm aggregates, and 50% of 8-16 mm aggregates), and permeability characteristics were determined using standardized methods. The chemical composition of the ceramic waste aggregates was determined by X-ray fluorescence (XRF) analysis to characterize their oxide content and potential influence on concrete behaviour. The results indicate that the addition of ceramic waste affects the pore structure of concrete, having an impact on the permeability coefficient and the material's durability. Water permeability tests according to EN 12390-8 showed an increase in water penetration depth from 700 mm in the control concrete to 850-1300 mm in concretes with ceramic aggregates, depending on the replaced fraction. The conclusions highlight the potential of using ceramic waste in concrete as a sustainable solution with positive effects on the circular economy and technical performance.*

***Key words****: ceramic waste, circular economy, concrete permeability, durability, recycled aggregates, sustainable construction.*

## INTRODUCTION

In the context of sustainable development and the circular economy, the construction industry is under increasing pressure to reduce the consumption of natural resources and the volume of generated waste (Glevitzky et al., 2025; Javed et al., 2025). Concrete production, one of the most widely used construction materials worldwide, relies heavily on natural aggregates and cement, whose extraction and processing contribute to environmental degradation and $CO_2$ emissions (Ahmad et al., 2024; Jwaida et al., 2024). On the other hand, the ceramic industry (which includes floor and wall tiles, bricks, and household ceramic products) generates significant amounts of waste annually, originating from production residues, rejected products, or materials resulting from demolition activities (Jiang & Cheng, 2020). These wastes are generally disposed of in uncontrolled areas, increasing pressure on landfill capacity and the risk of environmental pollution (Medina et al., 2012). From this perspective, the reuse of ceramic waste in concrete represents a promising solution for reducing the current environmental impact (Zong et al., 2014). Recent studies have highlighted the potential of using ceramic waste as both fine and coarse aggregate, as well as an auxiliary cementitious component (powder), with significant effects on the durability, microstructure, and mechanical performance of concrete (Elemam et al., 2023).

An essential aspect of concrete durability is permeability - an indicator of structural integrity and resistance to external aggressive actions (such as the penetration of water and aggressive

ions). Although numerous studies have investigated the mechanical strength of concrete incorporating ceramic aggregates, there is increasing interest and a clear need for a more in-depth understanding of how these materials influence the permeability and microstructure of the final concrete product (Semmana et al., 2025; Tokareva & Waldmann, 2025).

Durability studies have shown that concrete incorporating ceramic waste may exhibit an improved microstructure due to the pozzolanic activity of the ceramic material, which contributes to pore filling and strengthening of the cement-aggregate interfacial transition zone (Ahmad et al., 2024). At the same time, experimental investigations involving partial replacement of aggregates (either fine or coarse) have reported mixed results: moderate replacement levels (up to approximately 20-50%) may enhance strength, whereas higher replacement rates tend to increase porosity and permeability (Al-Fakih, 2025; Ngayakamo, 2025). Despite the increasing number of publications on the use of ceramic waste in concrete, the scientific literature highlights a lack of consensus regarding its effect on permeability (Jwaida et al., 2024). While some studies report a reduction in permeability due to the densification of the microstructure and improvement of the interfacial transition zone, others indicate adverse effects, associated with increased capillary porosity and water absorption, particularly in the case of coarse ceramic aggregates or high replacement rates (Zhou et al., 2025). These contradictory findings suggest that the influence of ceramic waste on permeability is not determined solely by the replacement percentage, but also by the particle size fraction used - an aspect insufficiently investigated in existing studies (Ahmad et al., 2023).

This article aims to help address this knowledge gap through a systematic experimental analysis of the permeability of concrete in which 50% of natural aggregates are separately replaced with ceramic waste from the 0-4 mm, 4-8 mm, and 8-16 mm fractions. The originality of the study lies in the comparative evaluation of the influence of each particle size class on the permeability coefficient, using the same concrete mix and identical testing conditions, which allows for a coherent and reproducible interpretation of the results. The findings provide valuable experimental benchmarks for optimizing the use of ceramic waste in durable concrete and for supporting construction solutions compatible with the principles of the circular economy (Sălcudean & Popa 2025).

## MATERIALS AND METHODS

Table 1 presents the main materials used in the preparation of the concrete mix, as well as their characteristics.

Table 1. Characterization of the materials used in the composition of the concrete mix

| Material | Type | Grading | Origin | Role in the mix |
|---|---|---|---|---|
| Cement | Hydraulic binder | - | Industrial (manufactured by Heidelberg Materials, Chișcădaga Cement Plant, Hunedoara) | Binds the aggregates through hydration and provides strength to the mix |
| River aggregate | Fine aggregate | 0-4 mm | Natural, Mureș River, Elis Quarry, Balomiru de Câmp, Sibot commune, Alba | Fills the voids between larger particles and ensures workability |
| | Coarse aggregate | 4-8 mm | | Contributes to the mechanical strength of concrete |
| | | 8-16 mm | | Provides the load-bearing skeleton of the mix |
| Ceramic aggregate | Lightweight aggregate | 0-4 mm | Artificial, ceramic waste from Reciclare Moloz SRL, Vințu de Jos, Alba | Reduces the self-weight of concrete and improves insulation properties |
| | | 4-8 mm | | Contributes to obtaining lightweight concrete |
| | | 8-16 mm | | Reduces concrete density and improves thermal behavior |
| Water | Active component | - | Natural (SC APA CTTA SA, Alba Iulia, Alba) | Activates cement hydration and enables workability |

Using the materials previously characterized, four experimental specimens (P1-P4) and one control specimen were produced, corresponding to a C16/20 concrete class. Table 2 presents the adopted concrete mix designs, expressed in terms of the quantities of the constituent materials.

Table 2. The concrete mix designs used for producing the experimental specimens and the control specimen

| Material | Quantity (kg) | | | | |
|---|---|---|---|---|---|
| | C16/20 concrete - control sample | P1 | P2 | P3 | P4 |
| Cement | 1.475 | 1.475 | 1.475 | 1.475 | 1.475 |
| River aggregate 0-4 mm | 3.945 | 1.9725 | 3.945 | 3.945 | 1.9725 |
| River aggregate 4-8 mm | 1.835 | 1.835 | 0.9175 | 1.835 | 0.9175 |
| River aggregate 8-16 mm | 3.395 | 3.395 | - | 1.6975 | 1.6975 |
| Ceramic aggregate 0-4 mm | - | 1.9725 | - | - | 1.9725 |
| Ceramic aggregate 4-8 mm | - | - | 0.9175 | - | 0.9175 |
| Ceramic aggregate 8-16 mm | - | - | 3.395 | 1.6975 | 1.6975 |
| Water | 0.85 | 0.85 | 0.85 | 0.85 | 0.85 |
| Water/Cement ratio | 0.57 | 0.57 | 0.57 | 0.57 | 0.57 |

The concrete resulting from the preparation of the experimental recipes is poured into standard molds, cubes with sides of 150 mm to determine the permeability of the concrete, then it is kept in these molds for 24 hours, after which it is removed and placed in the sample storage tank, for 28 days, at a constant temperature of 20 degrees Celsius (Figure 1).

Figure 1. Prepared samples and their storage

Table 3 shows the density values of the recipes used, both in the fresh and hardened state.

Table 3. Density values

| Concrete type | Density of fresh concrete sample (kg/m3) | Density of hardened concrete sample (kg/m3) |
|---|---|---|
| C16/20 | 2,310 | 2,235 |
| P1 | 2,256 | 2,149 |
| P2 | 2,277 | 2,206 |
| P3 | 2,267 | 2,157 |
| P4 | 2,262 | 2,105 |

Chemical composition of waste aggregates by X-ray fluorescence (XRF). The sample was first dried and finely ground to a uniform powder with a particle size of approx. 70 µm. The chemical composition of this powdered material was then determined using X-ray fluorescence (XRF) spectrometry, performed on a Quant'X ARL energy-dispersive XRF analyzer (Thermo Fisher Scientific, Waltham, MA, USA).

The control specimen was produced exclusively using natural river aggregates, serving as a reference element for evaluating the behavior of the experimental concretes. Specimens P1-P4 were obtained by the partial or total replacement of natural aggregates with ceramic aggregates, across different granulometric fractions, in order to analyze their influence on the concrete properties. The quantities of cement and water were kept constant for all specimens to ensure identical comparative conditions. According to NE 012/1-2022 "Standard for the production of concrete and the execution of works made of concrete, reinforced concrete and prestressed concrete - Part 1: Production of concrete", for concrete class C16/20, the optimal water/cement ratio (W/C) is 0.50-0.60 (m water/m cement). In the case of the recipes used in this work, the water/cement ratio is approximately 0.57.

The duration of the permeability tests was 3 days for all specimens, from the start date to the completion of the test. Concrete impermeability was determined using the Impermeability Test Set - UTC-1090 (Turkey, Sincan-Ankara). The matured concrete specimens were mounted and sealed in the test cells and then subjected to progressively applied water pressure in accordance with the testing procedure. After completion of the test, the specimens were split, and the depth of water penetration into the concrete mass was measured using a caliper and used to evaluate impermeability. All determinations were performed in triplicate (EN 12390-8, 2009).

## RESULTS AND DISCUSSIONS

Table 4 presents the major oxides, their approximate weight percentages, and relevant notes on their contribution to the properties of the aggregates and their potential impact on concrete behaviour.

Table 4. Chemical composition of ceramic waste aggregates (Vințu de Jos) determined by XRF

| Oxide | wt.% | Notes |
|---|---|---|
| $SiO_2$ | 58.37 | Main component, contributes to hardness and chemical stability |
| $Al_2O_3$ | 22.03 | From clay minerals; affects density and thermal behavior |
| $Fe_2O_3$ | 6.10 | Gives reddish color; minor impact on durability |
| CaO | 2.98 | Minor lime or cement contamination; affects alkalinity slightly |
| $K_2O$ | 1.31 | Alkali from clay; small influence on cement hydration |
| $Na_2O$ | 2.10 | Usually low; minor effect |
| MgO | 2.04 | Minor, stable in concrete |
| $TiO_2$ | 0.59 | Inert, minor contribution |
| $ZrO_2$ | 0.17 | Minor, inert. |
| LOI (Loss on ignition) | 3.82 | Organic residues and bound water; contributes to porosity |

The XRF analysis of the ceramic waste aggregates indicates a high content of $SiO_2$ and $Al_2O_3$, characteristic of clay-based ceramics, along with moderate $Fe_2O_3$ and minor CaO and alkalis. This composition suggests that while the aggregates provide structural stability and thermal resistance, the relatively high LOI may increase porosity, potentially affecting the permeability and water absorption of the concrete in which they are incorporated.
Specimens for testing the permeability of concrete were obtained, with dimensions of 150 × 150 mm, as shown in Figure 2.

Figure 2. The four specimens obtained for testing the permeability of concrete

To determine the depth of water penetration, the concrete specimens were split longitudinally, in accordance with the procedure specified in standard SR EN 12390-8, 2009 (Figure 3).

Figure 3. Testing of specimens according to SR EN 12390-8:2009

This operation allows a clear visualization of the water's path inside the specimen and enables precise measurement of the penetration depth (Figure 4).

Figure 4. Splitting of the concrete specimens and longitudinal sections of the samples

After splitting the specimens, the depth of water penetration was determined using a calliper, by measuring the distance from the water-exposed surface to the point of maximum observed penetration (Figure 5).

Figure 5. Performing measurements of water penetration depth in the specimens

Table 5 presents the results of the concrete permeability tests for the specimens used, including the control specimen and four experimental variants (P1-P4). All permeability tests were conducted over a period of 72 hours, starting from the preparation date of the specimens and continuing until the completion of the test for each specimen.
The results of the permeability tests highlight the differences between the control specimen and the experimental specimens made with ceramic aggregates. The control specimen, produced exclusively with natural river aggregates, recorded a water penetration depth of 700 ± 8 mm, serving as the standard reference for evaluating concrete behaviour. This value

reflects the characteristic permeability of C16/20 concrete obtained according to the traditional mix.

Table 5. Results of the tests for determining concrete permeability

| Sample | Concrete type / Observations | Water penetration depth (mm ± SD)* | Difference vs control (%) | Significance vs Control |
|---|---|---|---|---|
| Control sample | Standard C16/20 concrete mix | 70 ± 0.8 | - | - |
| P1 | Experimental variant 1 | 124 ± 1.5 | +77.1 | $p < 0.05$ |
| P2 | Experimental variant 2 | 130 ± 1.0 | +85.7 | $p < 0.05$ |
| P3 | Experimental variant 3 | 85 ± 0.5 | +21.4 | $p < 0.05$ |
| P4 | Experimental variant 4 | 97 ± 0.7 | +38.6 | $p < 0.05$ |

*Values are means ± SDs (n = 3).

The experimental specimens P1 and P2 exhibited much higher penetration depths, 124 ± 1,5 mm and 130 ± 1 mm, respectively, indicating a significant increase in permeability. This is primarily attributed to the partial or total replacement of natural aggregates with ceramic aggregates in certain fractions, resulting in a more porous matrix and reduced cement-aggregate cohesion.

For specimens P3 and P4, the water penetration depth was lower compared to P1 and P2, measuring 85 ± 5 mm and 97 ± 7 mm, respectively. This suggests that a more balanced combination of ceramic and natural aggregates can more effectively control the permeability, mitigating the negative impact on watertightness.

The results demonstrate that the use of ceramic aggregates directly affects the impermeability properties of concrete, with the effect varying depending on the granulometric fraction and replacement proportion. Specimens P1 and P2, which showed the greatest water penetration, emphasize the need to optimize the mix composition and material proportions to maintain adequate performance for concrete intended for applications where impermeability is critical. Specimens P3 and P4 suggest that a balance between natural and ceramic aggregates can produce moderately permeable concrete, suitable for situations where slightly increased permeability is acceptable.

Comparing these findings with those reported in the literature, a similar trend is observed regarding the influence of alternative materials on concrete permeability (Glevitzky et al., 2026). Recent studies on the use of ceramic and recycled aggregates in concrete generally indicate a negative impact on concrete transport properties, particularly permeability and water penetration resistance (C. Li et al., 2025).

Research conducted by Xu et al. in 2023 demonstrated that the use of recycled ceramic aggregates in high-performance concrete leads to an increase in permeability, attributing this effect to increased porosity and changes in the pore distribution within the concrete matrix. Furthermore, chloride ion penetration analysis revealed a tendency for enhanced fluid transport behaviour in materials containing a significant proportion of recycled ceramic aggregates. This finding is consistent with the results of experimental specimens P1 and P2 in the present study, where the partial or total replacement of natural aggregates with ceramic aggregates resulted in higher water penetration depths (124 mm and 130 mm) compared to the control specimen.

On the other hand, some literature results suggest that low levels of ceramic substitution and optimized mix proportions can limit the increase in permeability or even improve certain durability properties. A study published by L. Li et al. (2025), on mortars with fine ceramic aggregates showed that moderate substitutions can reduce water absorption and permeability by filling voids and improving the microstructure of the matrix. This observation can be correlated with the results of specimens P3 and P4, where the lower permeability values compared to P1 and P2 (yet still higher than the control) suggest that a balanced replacement of natural aggregates with ceramic aggregates can mitigate the negative effects on watertightness.

A review of the literature (Paul et al., 2023) on the use of ceramic waste as aggregates in concrete confirms that concrete incorporating such materials exhibits permeability and other durability characteristics that are comparable to or acceptable relative to conventional concrete, depending on the replacement proportions and the optimization treatments applied (Ray et al., 2021). Thus, although most studies show a general trend of increased permeability with higher ceramic aggregate content (particularly at high replacement levels), they also emphasize

the importance of optimizing the granulometry and the mix design to maintain durable performance.

These results can be interpreted within the broader context of sustainability and the circular economy in construction. The use of recycled ceramic aggregates contributes to reducing the consumption of natural resources and valorizing waste; however, the higher permeability may affect concrete durability, including resistance to freeze–thaw cycles and the penetration of aggressive agents (Murali et al., 2025).

From the perspective of future research, it is recommended to investigate the use of additives or pozzolans to reduce the porosity of concrete with ceramic aggregates and to evaluate the effects of different types of recycled aggregates on mechanical and durability properties. Additionally, the development of predictive models correlating the proportions of alternative aggregates with permeability and other durability characteristics could support the design of sustainable and eco-friendly concretes. Implementing long-term studies under real exposure conditions to water and aggressive agents could further confirm the performance of these concretes in practice.

Thus, this study not only confirms the trends observed in the specialized literature but also provides insights for optimizing durable concrete mixes, highlighting that a balance between natural and ceramic aggregates is essential for maintaining impermeability and durability properties while promoting the use of recycled materials.

***Statistical analysis of concrete permeability***

A statistical analysis was conducted to evaluate the influence of ceramic aggregate replacement on the impermeability of concrete. For each concrete mixture, three specimens were tested, and the mean water penetration depth ± standard deviation is reported (Cojocaru et al., 2018).

Comparisons between each experimental mixture (P1-P4) and the control concrete were performed using the t Student test for unequal variances (Welch t-test). The water penetration depth of all experimental mixtures was significantly higher than that of the control concrete ($p < 0.05$), confirming that partial or total replacement of natural river aggregates with ceramic aggregates increases concrete permeability (Gluck, 1971; Aloman, 1998; Senedecor & Cochran, 1980).

The differences in penetration depth relative to the control concrete are also expressed as percentages, highlighting the impact of aggregate replacement. Mixtures P1 and P2, which contained ceramic aggregates in the fine and medium fractions, exhibited the highest increases (+77.1% and +85.7%, respectively), while mixtures P3 and P4 showed moderate increases (+21.4% and +38.6%), corresponding to partial replacement in coarser fractions (Popa et al., 2022).

The relatively low standard deviations (±5-15 mm) indicate good repeatability and uniformity of the specimens, confirming the reliability of the testing procedure. The statistical analysis demonstrates a clear correlation between the granulometric fraction of ceramic aggregates and concrete permeability, with finer fractions causing a greater increase in water penetration depth.

## CONCLUSIONS

The study shows that replacing natural aggregates with ceramic aggregates generally increases the permeability of concrete, due to their higher porosity and the modification of the matrix microstructure. However, the effect depends on the proportion and granulometry of the ceramic aggregates; moderate substitution levels can keep permeability close to that of conventional concrete and may improve matrix density.

The results suggest that concrete with ceramic aggregates can be used as a sustainable solution by valorizing waste materials, but optimizing the mix design and controlling the microstructure are essential to ensure durability and watertightness. Thus, ceramic aggregates represent a promising alternative, but concrete performance depends on how they are integrated into the composition.

***Abstract***

*The paper presents an experimental study on the production and testing of bricks that incorporate brick waste and sawdust as a sustainable solution for the construction industry. The aim of the research is to reduce environmental impact by reusing recycled materials and wood processing residues. Samples were manufactured using brick waste fractions (0-4 mm, 4-8 mm, 8-16 mm) and sawdust of different particle sizes, with cement as a binder, and tests focused on physical and mechanical properties (compressive strength), density, water absorption, and drying behaviour. Brick waste was analyzed using X-ray fluorescence (XRF) spectroscopy in order to determine its chemical composition and elemental distribution. The results indicate that the addition of sawdust influences density and porosity, while ceramic waste helps maintain structural strength. Data show a reduction in dry density by 5.8%, saturated density by 7.2%, water absorption by 13.8%, and compressive strength by 55.6%, indicating that the incorporation of brick waste and sawdust produces lighter, less porous bricks with significantly reduced mechanical strength. The conclusions highlight the potential of these materials for producing eco-friendly masonry elements.*

***Key words****: brick waste, compressive strength, experimental bricks, recycled materials, sawdust.*

## INTRODUCTION

In recent decades, the circular economy has become a central principle in global sustainable development strategies (Velenturf & Purnell, 2021). The construction industry, being one of the largest consumers of natural resources and generators of waste, is under increasing pressure to adopt more responsible and innovative practices (Cudecka-Purina et al., 2024). In this context, the reuse of ceramic waste-originating from both manufacturing processes and demolition activities - offers an opportunity to valorize materials previously considered unusable, thereby reducing the environmental impact of construction activities (Gajzler et al., 2025).

Ceramic waste includes broken bricks, tiles, ceramic floor and wall coverings, and other ceramic products that can no longer be used in their original form (Sarner & Guillon, 2025). Recycling these materials not only reduces the amount of waste disposed of in landfills but can also partially replace natural aggregates, thereby contributing to lower production costs and the conservation of limited natural resources. Furthermore, products manufactured using recycled materials can exhibit performance comparable to that of conventional materials, provided that the proportions and manufacturing processes are carefully controlled (Chen et al., 2024). The use of ceramic waste also presents significant challenges. From a technical perspective, variability in particle size, composition, and porosity of recycled materials can substantially affect the mechanical and physical properties of the final product (Murali et al., 2025). From an operational standpoint, the collection, sorting, and processing of waste require specific infrastructure and involve additional costs (Olawade et al., 2024). From an environmental perspective, improper handling

of ceramic waste may generate dust and pollution, raising further health and safety concerns (Huseien et al., 2025).

Scientific literature shows a diversity of results and opinions regarding the optimal amount of ceramic waste that can be incorporated into construction mixes without compromising performance (Sălcudean & Popa, 2025). Some studies indicate that up to 30% of natural aggregate can be replaced with ceramic waste without significant strength loss (Silvestre et al., 2013), while other research warns about increased porosity and water absorption at higher proportions, generating discussions and controversies within the scientific community (Furszyfer Del Rio et al., 2022). This lack of consensus highlights the need for studies that simultaneously investigate the physical, mechanical, and durability properties of materials produced from ceramic waste. Combining ceramic waste with other recycled materials, such as sawdust, opens new perspectives for the production of eco-friendly bricks and masonry elements (Vidak Vasić et al., 2024). Sawdust, as an organic residue, can influence the porosity and weight of the material while providing a solution for valorizing waste from the wood industry (Adegoke et al., 2022). Investigating these mixtures requires a careful approach, simultaneously analyzing density, water absorption, porosity, and compressive strength in order to establish practical limits and assess their application potential.

The aim of this article is to evaluate the efficiency of using ceramic waste in combination with sawdust for the production of eco-friendly bricks, providing experimental data on the physical and mechanical behavior of these materials. The original contribution lies in offering comprehensive information on density, porosity, water absorption, and compressive strength, thereby complementing the existing literature and supporting the development of sustainable construction practices.

## MATERIALS AND METHODS

For the evaluation of the influence of using brick waste and sawdust on the behaviour of bricks, a comparative experimental study was conducted. The analysis was based on two types of mixtures: a reference mixture, without any added recycled materials, and one that includes brick waste and sawdust, according to the recipe presented in Table 1.

Table 1. Composition of the mixture for the experimental brick

| Material used | Quantity (kg) | Source |
|---|---|---|
| Cement 42.5 R | 0.25 | Heidelberg Materials, Chișcădaga, Romania |
| Brick waste 0-4 mm | 0.27 | Reciclare Moloz SRL, Vintu de Jos, Alba, Romania |
| Brick waste 4-8 mm | 0.30 | |
| Brick waste 8-16 mm | 0.50 | |
| Fine sawdust | 0.2 | Remarcabil Mobila, Ocna Mureș, Alba, Romania |
| Coarse sawdust | 0.2 | |
| Natural aggregates 4–16 mm | 0.2 | Elis Agregate, Cariera Jidovu – Pătrângeni, Alba, Romania |
| Water | 0.7 | APA CTTA SA, Alba Iulia, Alba, Romania |

For the preparation of the experimental mixtures, processed brick waste with various granulometric sizes was used, as shown in Figure 1.

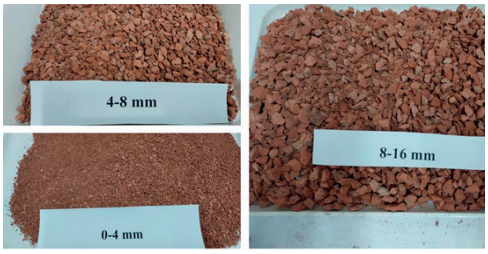

Figure 1. Brick waste with different granulometries

Additionally, fine and coarse sawdust was employed, presented in Figure 2.

Figure 2. Sawdust used in the composition of the mixtures: fine and coarse

Chemical composition determined by XRF. The brick waste aggregates were first dried at 105°C to remove moisture and then ground to a fine, homogeneous powder with a particle size of approximately 60-70 µm. The chemical composition of the brick waste was determined using X-ray fluorescence (XRF) spectrometry in accordance with SR EN 15309:2007

(Characterization of waste and soil. Determination of elemental composition by X-ray fluorescence n.d.). Measurements were performed with a Quant'X ARL energy-dispersive XRF spectrometer (Characterization of waste and soil. Determination of elemental composition by X-ray fluorescence n.d.) (Thermo Fisher Scientific, Waltham, MA, USA), following standard operating procedures for powdered ceramic materials. The analysis provided the content of major oxides ($SiO_2$, $Al_2O_3$, $Fe_2O_3$, etc.) and the Loss on Ignition, allowing characterization of the brick waste for potential reuse or recycling applications.

Brick waste is separated into granulometric fractions (0-4 mm, 4-8 mm, 8-16 mm) and crushed/sieved as necessary to achieve uniformity. The sawdust is dried and sieved to ensure it does not contain excessive moisture, which could cause cracking during firing. Natural aggregates are cleaned of impurities (stones, dust) and sorted to the 4-16 mm size range. Cement is kept dry and added to improve the cohesion of the mixture.

All fractions of brick waste are combined with the natural aggregates and sawdust into a homogeneous mixture. Cement is added to bind the materials. Water is gradually incorporated while continuously mixing to achieve a plastic, uniform consistency that is easy to shape. The objective is to ensure an even distribution of sawdust and waste particles to prevent segregation.

The mixture is molded using molds or by manual/mechanical pressing with UTEST UTC-0900E-T vibrating table, made in Turkey (Figure 3). The dimensions and shape are maintained in accordance with the experimental standard. Fine sawdust contributes to uniform porosity, while coarse sawdust creates a more aerated internal structure, reducing the overall weight.

The bricks are placed in drying chambers or in the open air for 3-7 days to reduce the moisture content to 5-7%. Drying must be gradual to prevent cracking, as the sawdust creates internal porosity. The amount of sawdust directly influences the density and thermal insulation properties. The proportions of brick waste and natural aggregates affect the compressive strength and durability. It is recommended to document in detail each fraction and to perform testing for optimizing the mixture. Homogeneous brick samples were obtained, free of visible defects, ready for subsequent mechanical and physical testing. The adopted method proved to be simple, reproducible, and efficient, providing a solid foundation for further research.

(a) (b) (c)

Figure 3. Preparation of the experimental bricks: (a) mixture prepared according to the recipe; (b) pouring into the mold; (c) brick after drying

The dry state mass is determined at the end of the slow drying period by weighing, expressed in grams.

The saturated state mass is determined after the brick has been immersed in water and left for 24 hours at a temperature of 20 ± 5°C. The brick is then removed and weighed in grams (EN 772-21, 2011).

The volume of the bricks was calculated by measuring the dimensions (length L = 230 mm, width l = 115 mm, and height h = 63 mm). Then, using the formula for the volume of a rectangular parallelepiped, the volume of the bricks was determined as $V = L \times l \times h = 230 \times 115 \times 63 = 1666.35$ cm³.

Dry state density/Saturated state density. Knowing the mass and volume of the standard solid brick and the experimental brick, the density was calculated for each using the density formula $\rho = m/V$, both in the dry state and in the saturated state: $\rho_{\text{dry standard}} = 2592.97/1666.35 = 1.556$ g/cm³; $\rho_{\text{dry experimental}} = 2441.35/1666.35 = 1.465$ g/cm³; $\rho_{\text{saturated standard}} = 3111.57/1666.35 = 1.867$ g/cm³; $\rho_{\text{saturated experimental}} = 2888.42/1666.35 = 1.733$ g/cm³.

The water absorption is determined after immersing the bricks in water for 24 hours. The samples are removed from the water, superficially wiped to remove excess surface moisture, weighed, and the water absorption is calculated using the formula $A = (M_1 - M_0)/ M_0$

× 100 [%], where $M_0$ represents the mass of the brick in the dry state (g), and $M_1$ represents the mass of the brick after immersion (g). For the experimental brick, the absorption was $A_{cex}$ = (2888.42 − 2441.35)/ 2441.35 × 100 = 18.31 %, while for the standard brick $A_{csp}$ = (3111.57 − 2592.97)/ 2592.97 × 100 = 20 %.

The compressive strength of the brick samples was determined using the Matest Cyber Plus Evolution static materials testing machine (model CO7gPN191, Matest, Italy), a specialized device for measuring the compressive strength of construction materials, with a measurement range between 25-250 kN and 20-3000 kN. The samples were subjected to a gradually and uniformly applied axial compressive load, under controlled temperature conditions (+5…+40 °C) and relative humidity (30-70%), until the state of failure by crushing was reached, at which point the maximum force sustained was recorded (EN 12390-4, 2009; EN 772-1, 2001).

The sample was subjected to a gradually applied axial compressive load until the state of failure by crushing was reached (Figure 4).

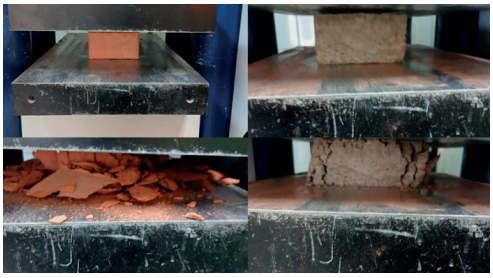

Figure 4. Experimental and standard brick samples under axial compression until failure

The compressive strength is determined as the ratio between the maximum force recorded at failure and the cross-sectional area of the specimen.

## RESULTS AND DISCUSSIONS

The average chemical composition of the brick waste aggregate determined by X-ray fluorescence (XRF) analysis is presented in Table 2.

The chemical composition of brick waste determined by XRF shows that the material is rich in $SiO_2$ (55%) and $Al_2O_3$ (15%), the main constituents that provide hardness and stability.

Table 2. Chemical Composition of Brick Waste Aggregate (XRF Analysis)

| Compound | Value (wt.%) | Interpretation |
|---|---|---|
| $SiO_2$ | 55.04 | Contributes to mechanical strength and potential pozzolanic reactivity. |
| $Al_2O_3$ | 15.11 | Enhances ceramic stability and may support secondary hydration reactions. |
| $Fe_2O_3$ | 7.65 | Contributes to thermal stability |
| CaO | 8.07 | May influence hydraulic reactivity |
| MgO | 4.83 | It is associated with carbonate or clay minerals and can affect durability |
| $SO_3$ | 1.08 | Related to sulfate phases; excessive amounts may influence durability. |
| $K_2O$ | 1.03 | Alkali oxide from clay minerals; may affect alkali–silica reactivity. |
| $TiO_2$ | 0.28 | Associated with accessory minerals; limited structural impact |
| BaO | 0.22 | From mineral impurities; negligible effect on overall performance. |
| MnO | 0.10 | May slightly influence coloration |
| Loss on Ignition | 6.40 | Indicates volatiles, residual carbonates, and unburned material affecting thermal behavior and durability. |

The relatively high $Fe_2O_3$ content (7.65%) explains the characteristic red color of the bricks, while CaO (8%) may originate from lime or calcareous sand additives, influencing the material's strength and durability. $K_2O$ (1%) and $SO_3$ (1%) are alkaline oxides that can affect chemical behavior during hydration or other reactions, whereas $TiO_2$, BaO, and MnO are minor components with minimal impact but useful for identifying the source of the raw material. The Loss on Ignition value of 6.4% indicates the presence of organic matter or moisture released during firing. Overall, the material is suitable for recycling as aggregate or as a raw ceramic material due to its balanced chemical composition.

Table 3 presents the mass, volume, density, water absorption, and compressive strength of the bricks, comparing the experimental values with the standard ones and highlighting the absolute and percentage differences.

Table 3. Physical and mechanical properties of experimental and standard bricks

| Parameter | Brick type | | Difference | |
|---|---|---|---|---|
| | Experimental | Standard | Absolute | % |
| Dry mass (g) | 2441.35±4.0 | 2592.97±2.1 | 151.62 | 5.85 |
| Saturated mass (g) | 2888.42±0.9 | 3111.57±3.4 | 223.15 | 7.17 |
| Volume ($cm^3$) | 1666.4±0.0 | 1666.4±0.0 | 0 | 0 |
| Dry density ($g/cm^3$) | 1.465±0.1 | 1.556±0.1 | 0.091 | 5.84 |
| Saturated density ($g/cm^3$) | 1.733±0.1 | 1.867±0.1 | 0.134 | 7.17 |
| Water absorbed (g) | 447.07±0.8 | 518.6±1.2 | 71.53 | 13.8 |
| Compressive strength ($N/mm^2$) | 16.7±0.1 | 37.6±0.1 | 20.9 | 55.6 |

Values are means ± SDs (n = 3).

The compressive strength of the experimental brick decreases dramatically, by approximately 56%, indicating that the inclusion of waste significantly affects the mechanical performance of the material. At the same time, water absorption decreases by about 14%, a potentially positive effect if the goal is to obtain less porous bricks. Density and mass decrease slightly, by around 6-7%, suggesting that the brick's structure becomes lighter without changing its volume, so the observed differences are strictly due to changes in the internal material.

The experimental results illustrate both the potential and the limitations of using recycled materials in the production of construction elements, contributing to a deeper understanding of the possibilities for transitioning toward a circular economy in the construction sector. The incorporation of brick waste and sawdust as additives in brick production results in a distinct balance between reduced density, decreased mechanical strength, and improvement in certain porosity-related aspects, when compared to the reference mixture (Lewo Nkondi, 2025).

In the European Union, the technical specifications for masonry units, including fired clay bricks, are regulated by the harmonized series of standards SR EN 771 (SR EN 771-1+A1:2015 n.d.). The standard defines the characteristics, performance requirements, and conformity criteria for clay masonry units (dimensions, tolerances, strength, density, etc.), providing a clear framework for the evaluation of both industrially and experimentally produced materials (Affan et al., 2025). Furthermore, the design and calculation of masonry structures incorporating such units are governed at the European level by Eurocode 6 (EN 1996-1-1, 2022), which establishes general rules for reinforced and unreinforced masonry structures, including the properties of constituent materials and their behaviour under load.

In line with the results reported in the scientific literature (Meng et al., 2022; Hu et al., 2024), the incorporation of brick waste into the mixture contributes to the valorization of recycled materials and can influence the internal structure of the bricks, affecting their density and mechanical strength (Abdullah, 2021). If the obtained properties (e.g., density, compressive strength, or water absorption) fall within the limits required by SR EN 771-1, the respective materials may be considered compliant or close to technical compliance for certain masonry applications. Compliance with these requirements is essential for the acceptance of experimental samples as construction materials, particularly in projects adhering to European standards (Oyguc, 2025). The use of sawdust, due to its organic nature and variable granulometry, can lead to changes in the material's porosity, an aspect that is reflected both in the volumetric mass (density) and in the behaviour under mechanical loading (Robert et al., 2024).

As noted by Ludovice et al. (2025), the interpretation of the experimental results in the context of normative requirements provides a solid foundation for assessing the practical viability of the materials studied, opening pathways for the optimization of compositions and the continuation of research aimed at achieving or surpassing the performance levels required by international standards. Comparison of the obtained results with those of previous studies indicates that the proportion and type of recycled materials play an essential role in the final performance of the bricks. Thus, a controlled content of brick waste and sawdust can represent a viable solution for producing materials with reduced environmental impact, without significantly compromising their functional characteristics (Benjeddou, 2025; Jwaida & Di Sarno, 2025).

The experimental study highlighted several key lessons regarding the use of brick waste and sawdust in brick production. First, the integration of recycled materials leads to a significant reduction in compressive strength, underscoring the importance of controlling the proportions and granulometry of the components (Akbulut, 2025). At the same time, the addition of sawdust was found to contribute to a decrease in density and mass, offering an advantage in producing lighter materials with a certain level of thermal insulation (Esakki Priya, 2025). Water absorption can be positively influenced, indicating the possibility of obtaining less porous bricks, which provides benefits for durability in certain masonry applications (Raimondo et al., 2009).

In the long term, the use of brick waste and sawdust can have a significant impact on sustainability in construction (Rabiu & Damdelen, 2023). The adoption of these materials reduces pressure on natural resources, limits the amount of waste disposed of in landfills, and can lead to cost savings in production (Zhang, 2024). Long-term success depends on optimizing mix designs to maintain adequate mechanical properties and on compliance with international technical standards, so that the materials can be used in real structures without compromising safety and durability (Soave & Ferrara, 2025). Expanding research on long-term behaviour and resistance to environmental factors will be essential for the large-scale adoption of these technologies.

From a broader perspective, the results of this study support current research directions focused on the development of sustainable construction materials through the integration of industrial waste and natural by-products into manufacturing processes. Moreover, they highlight the potential of using recycled materials in brick production as an alternative to conventional raw materials (Popa et al., 2025; Anbarasu & Karuppusamy, 2025).

The statistical analysis of the experimental results was carried out in order to highlight the differences between the experimental brick and the standard brick with respect to the analyzed physico-mechanical properties. Given the small number of determinations performed for each type of material (n = 3) and the impossibility of robustly verifying the normality assumption of the distributions, data comparison was conducted using the nonparametric Mann-Whitney U test, applied to independent samples, at a significance level of $\alpha = 0.05$.

The obtained results indicated the existence of statistically significant differences between the two types of bricks, particularly in terms of compressive strength, for which the standard brick exhibited significantly higher values compared to the experimental brick ($U = 0$, $p \leq 0.05$). Similar trends were also observed for density and water absorption parameters, suggesting superior physico-mechanical performance of the standard material.

The application of the Student's t-test for independent samples, used for indicative purposes, also revealed the existence of a statistically significant difference between the two types of bricks with regard to compressive strength ($|t| \gg t_{(crit)}$, $\alpha = 0.05$), thereby confirming the results obtained using the nonparametric Mann–Whitney U test.

Table 4 presents the results of the t-test applied to all analyzed parameters, including the values of the t statistic and the corresponding significance levels (*p*-values) obtained for the comparison between the two types of bricks.

Table 4. Results of the t-test for the comparison of the physical and mechanical properties of the experimental and standard brick

| Parameter | t-statistic | p-value | Interpretation |
|---|---|---|---|
| Dry mass | -58.13 | $1.04\times10^{-5}$ | Highly significant difference – the experimental brick is much lighter in the dry state |
| Saturated mass | -109.89 | $2.71\times10^{-5}$ | Highly significant difference |
| Volume | 0.0 | 1.0 | No difference observed |
| Dry density | -1.11 | 0.33 | Statistically non-significant difference |
| Saturated density | -1.64 | 0.18 | Statistically non-significant difference |
| Amount of absorbed water | -85.90 | $6.39\times10^{-7}$ | Highly significant difference – the experimental brick absorbs much less water |
| Compressive strength | -255.97 | $1.40\times10^{-9}$ | Highly significant difference – the experimental brick exhibits nearly half the compressive strength of the standard brick |

The statistical analysis indicates highly statistically significant differences between the experimental brick and the standard brick with respect to dry mass, saturated mass, amount of absorbed water, and compressive strength ($p < 0.001$), highlighting a major impact of waste incorporation on these properties. The experimental brick is significantly lighter (both dry and saturated mass are significantly lower) and absorbs significantly less water, which suggests a lower porosity or a different structure (possibly more compact or with closed pores). Dry and saturated densities do not differ statistically significantly (although the mean values are slightly lower for the experimental brick) - the variability between measurements makes the difference non-significant with only three repetitions. Compressive strength is dramatically lower for the experimental brick (approximately 44% of the standard value), representing the most important practical difference.

## CONCLUSIONS

The study confirms that the combination of brick waste and sawdust can be used for the production of eco-friendly bricks with physical and mechanical properties different from those of conventional bricks. Compressive strength decreases significantly, while density and water absorption can be adjusted depending on the proportions of recycled materials. The results suggest that, through careful optimization of mix designs, these experimental bricks may represent a sustainable alternative in construction, contributing to the circular economy and to the reduction of environmental impact. The study also opens opportunities for future research aimed at improving durability, environmental performance, and the long-term evaluation of the mechanical and functional behaviour of recycled materials.

***Abstract***

*This study investigates the influence of incorporating ceramic waste into paving block mixtures on their splitting tensile strength. The use of recycled ceramic materials aims to reduce environmental impact and promote sustainable construction practices. The aggregates were characterized in terms of particle size, shape, bulk density, porosity, water absorption, hardness, and chemical composition, with X-ray fluorescence (XRF) analysis used to determine the main oxides present in the ceramic waste. Experimental tests were conducted on paving blocks with varying percentages of ceramic waste replacing natural aggregates, including partial (50%) and full (100%) replacement. Splitting tensile strength was determined according to standardized procedures. The results indicate that ceramic waste affects the mechanical performance of paving blocks, with partial replacement slightly reducing tensile strength, while full replacement improves performance beyond the control mix. These findings highlight the importance of aggregate characterization for understanding mechanical behavior and support the potential of ceramic waste as an alternative aggregate in paving block production, contributing to circular economy objectives, particularly in low- to moderate-traffic applications.*

***Key words****: splitting tensile strength, paving blocks, ceramic waste, recycled aggregates, sustainable construction, durability.*

## INTRODUCTION

In the global context of increasing urbanization and infrastructure development, the construction industry faces growing pressure to reduce its environmental footprint while maintaining adequate mechanical performance and durability of construction materials (Alghamdi, 2025; Glevitzky et al., 2026). The transition from a linear economic model toward a circular economy has become a strategic priority, emphasizing waste minimization, material reuse, and resource efficiency (Hasibuan et al., 2025). Within this framework, the reuse of industrial and construction waste in road infrastructure and paving applications represents a promising solution for reducing landfill disposal and conserving natural aggregates (Kuttah, 2024). Among the various waste materials investigated, recycled ceramic waste - originating from demolished structures, ceramic tiles, sanitary ware, and industrial rejects - has gained attention due to its high availability, chemical stability, and favourable mechanical properties (Meena et al., 2022). Ceramic materials are characterized by high hardness, resistance to abrasion, and durability, which makes them potential candidates for partial or total replacement of natural aggregates in paving blocks. Their reuse not only contributes to sustainable construction practices but also supports waste recovery and resource efficiency strategies (Jwaida et al., 2024).

Life cycle assessment research has shown that incorporating ceramic waste into various construction materials, such as paving blocks, reduces greenhouse gas emissions and energy consumption throughout their life cycle, making them more sustainable (Azam et al., 2024; Kiran et al., 2024).

The incorporation of ceramic waste into paving blocks aligns with the principles of sustainability, particularly by reducing the consumption of virgin raw materials and lowering the environmental impact associated with aggregate extraction (Torkittikul and Chaipanich, 2010). From a circular economy perspective, paving blocks represent an ideal construction product for waste valorization due to their modular nature, standardized manufacturing processes, and widespread use in pedestrian areas, parking zones, and low-traffic roads (Barbhuiya et al., 2025).

The incorporation of ceramic waste in paving blocks presents technical challenges, including variations in particle characteristics and bonding with the cement matrix. These factors can affect mechanical properties, particularly splitting tensile strength, which influences cracking resistance and long-term performance (Lin et al., 2023). Additionally, paving blocks containing ceramic waste may exhibit different behavior under high traffic loads, freeze–thaw cycles, or moisture variations, limiting their application in heavy-duty pavements (Famewo and Shokouhian, 2025).

From the perspective of the circular economy and waste recovery, various types of waste have been investigated for paving block production, including ceramic waste, recycled concrete aggregates, glass waste, rubber particles, and industrial by-products such as fly ash or slag (Wattanasiriwech et al., 2009). Each waste type offers specific benefits but also introduces technical limitations that must be carefully assessed to ensure compliance with performance requirements (Glevitzky et al., 2025). The use of ceramic waste, in particular, offers advantages such as improved abrasion resistance and reduced environmental impact, but may result in reduced tensile performance at higher replacement levels (Meena et al., 2022).

The technological process of manufacturing paving blocks containing ceramic waste generally follows conventional procedures, including material selection, mix proportioning, compaction, curing, and quality control (Dehghani et al., 2024; Poon, et al., 2002). Nevertheless, the presence of ceramic aggregates may require adjustments to mixture design, water–cement ratio, and compaction parameters to achieve optimal mechanical performance. Ensuring consistency and reproducibility in production is essential for large-scale implementation (Silveira et al., 2025).

The use of recycled materials in paving blocks must comply with construction standards and regulations. The key reference is EN 1338:2003 (EN 1338, 2003), which sets essential requirements for mechanical strength, durability, and conformity assessment of concrete paving blocks. Standardized testing methods, including splitting tensile strength, ensure consistent performance evaluation and safe application in infrastructure (Iduwin et al., 2024).

This study aims to evaluate the influence of ceramic waste incorporation on the splitting tensile strength of paving blocks and to identify suitable replacement levels that maintain acceptable mechanical performance. The findings support the application of circular economy principles in paving systems, particularly for low to moderate traffic conditions.

## MATERIALS AND METHODS

The use of recycled materials in paving blocks must comply with a set of technical standards and regulations that ensure mechanical performance, durability, and operational safety. At the international and European levels, the most relevant requirements are defined by standards for precast concrete products, testing methods, and the use of recycled aggregates.

One of these is EN 1338 - Concrete paving blocks - Requirements and test methods, which establishes requirements regarding mechanical strength, freeze-thaw resistance, water absorption, abrasion resistance, and dimensional tolerances of concrete paving blocks. This standard is essential for assessing the conformity of products intended for use in road and pedestrian infrastructure.

The determination of splitting tensile strength is carried out in accordance with EN 12390-6 (EN 12390-6, 2009), which describes the standardized testing method applicable to both conventional concrete and concrete containing recycled aggregates, including ceramic waste.

Regarding the materials used, EN 12620 – Aggregates for concrete regulates the

requirements for natural and recycled aggregates, including permissible limits for impurities, physical properties, and durability characteristics (EN 12620, 2002). This standard allows the use of aggregates derived from waste, provided that quality requirements are met.

At the international level, ASTM standards are also frequently used for comparison and experimental validation. Among the most relevant is ASTM C496/C496M - Standard Test Method for Splitting Tensile Strength of Cylindrical Concrete Specimens, which provides an alternative method for determining splitting tensile strength (ASTM C496/C496M, 2017).

From a sustainability and circular economy perspective, European policies such as Waste Framework Directive (Directive 2008/98/EC) and the European Union Circular Economy Action Plan encourage the reuse of construction and demolition waste, including ceramic waste, in construction materials, provided that applicable technical standards are respected.

Compliance with these main standards and regulations is essential for the market acceptance of paving blocks containing ceramic waste and for ensuring safe use in infrastructure applications, especially in areas with low or moderate traffic.

To demonstrate the feasibility of using ceramic waste in the manufacturing process of paving blocks, experimental concrete mixes were developed in which natural aggregates were partially replaced with ceramic fragments. Tile and ceramic waste originating from construction and demolition activities were used, with a particle size of 4-8 mm (Figure 1), obtained through crushing and granulometric sorting.

Figure 1. Aggregates from ceramic waste size 4-8 mm

***Granulometry***. 500 g of dried aggregate are weighed and sieved through a standard set of 4-8 mm sieves, and the percentage retained on each fraction is determined (EN 933-1, 2003).

***Bulk density and porosity***. The dry mass of the aggregate is determined, then it is submerged in water for 24 hours. The saturated mass is weighed, and the bulk density and porosity are calculated (EN 1097-6, 2010).

***Water absorption***. Similar to the bulk density method; absorption is calculated as a percentage: $(m_{saturated}-m_{dry})/m_{dry}\times 100$ (EN 1097-6, 2010).

***Hardness/abrasion resistance***. Los Angeles test. The aggregate and steel balls are placed in a rotating drum, rotated for a standard number of cycles, and then the aggregates are sieved to determine the percentage loss due to wear (EN 1097-2, 2010).

***Chemical composition***. The aggregates are dried, then ground to a fine, homogeneous powder of 65 μm and then analyzed. The chemical composition of the aggregate from ceramic waste was determined by X-ray fluorescence (XRF) spectrometry using a Quant'X ARL energy-dispersive X-ray fluorescence spectrometer (Thermo Fisher Scientific, Waltham, MA, USA).

The specimens were prepared manually by homogenizing the components according to the experimental mix design, then cast into standard molds, kept for 24 hours, and subsequently cured for 28 days at 20°C. The testing was performed using a Matest universal testing machine for static material testing, whose technical characteristics are presented in Table 1.

Table 1. Characteristics of the MATEST Static Material Testing Machine

| | |
|---|---|
| Model | CYBER PLUS EVOLUTION / CO7gPN191 |
| Usage | Measurement of the compressive strength of hardened concrete (cylinders, cubes, and prisms) |
| Measurement Range | From 25 to 250 kN and from 20 to 3000 kN |
| Force Application Method | Compression |
| Testing Conditions | Temperature from +5 °C to +40 °C; Humidity from 30% to 70% |
| Standards Compliance | EN 12390-4, SR EN 772-1 |

For the control sample (R1), the standard concrete mix C16/20 (Table 2), also known as B250, was used, which is one of the most commonly used concrete mixes in Romania. For the two experimental mixes, 50% of the natural 4-8 mm aggregate was replaced with ceramic

waste aggregate for R2, and 100% replacement of natural 4-8 mm aggregate with ceramic waste aggregate was used for R3 (Table 2).

Table 2. Composition of the concrete mixes used

| Material | R1 (kg) | R2 (kg) | R3 (kg) | Material Source |
|---|---|---|---|---|
| Cement | 0.7375 | 0.7375 | 0.7375 | Heidelberg Materials, Chișcădaga Cement Plant, Hunedoara |
| Aggregate 0-4 mm (quarry) | 1.9725 | 1.9725 | 1.9725 | Elis Aggregates, Jidovu Quarry, Zlatna, Alba |
| Aggregate 4-8 mm (quarry) | 0.9175 | 0.45875 | - | Elis Aggregates, Jidovu Quarry, Zlatna, Alba |
| Aggregate 4-8 mm (ceramic waste) | - | 0.45875 | 0.9175 | Planodom Construct SRL, Cugir, Alba |
| Aggregate 8-16 mm (quarry) | 1.6975 | 1.6975 | 1.6975 | Elis Aggregates, Jidovu Quarry, Zlatna, Alba |
| Water | 0.65 | 0.65 | 0.65 | SC APA CTTA SA, Alba Iulia, Alba |

Figure 2 shows the manual preparation of the experimental mixes by incorporating ceramic waste, which partially (R2) or completely (R3) replaces the natural aggregates. For the control mix (R1), standard concrete from the SC Elis Pavaje batching plant in Petrești was used.

Figure 2. Composition of the experimental concrete mixes

All determinations and experiments were performed in triplicate.

## RESULTS AND DISCUSSIONS

The key physical and mechanical properties of the ceramic waste aggregate used in the study are summarized in Table 3. The average chemical composition of the ceramic waste aggregate determined by X-ray fluorescence (XRF) analysis is presented in Table 4.

Table 3. Properties of ceramic waste aggregate

| Property | Value | Remarks / Implications |
|---|---|---|
| Particle size | 4-8 mm | According to experimental description; promotes good compaction in concrete |
| Particle shape | Irregular, angular | Increases mechanical adhesion with cement paste; may affect workability |
| Bulk density | 2.2-2.6 g/cm³ | Similar to natural aggregates; allows correct proportioning |
| Porosity | Moderate (≈15-25%) | Higher water absorption than natural aggregates; influences water/cement ratio |
| Water absorption | 6-10% | Requires pre-wetting or adjustment of mixing water |
| Mohs hardness | 6-7 | Hard surface; contributes to mechanical strength |
| Color | Red-brown and whitish | Indicates a mixture of gres and faience |

Table 4. Chemical Composition of Ceramic Waste Aggregate

| Compound | Value (wt.%) |
|---|---|
| $SiO_2$ | 70.93 |
| $Al_2O_3$ | 15.21 |
| $Fe_2O_3$ | 4.70 |
| CaO | 3.04 |
| $K_2O$ | 1.33 |
| MgO | 1.25 |
| $Na_2O$ | 0.60 |
| $TiO_2$ | 0.41 |
| $ZrO_2$ | 0.17 |
| Loss on Ignition | 2.06 |

The XRF results indicate that the ceramic waste aggregate is predominantly composed of silica (70.93%) and alumina (15.21%), characteristic of clay-based ceramics. Minor amounts of $Fe_2O_3$, CaO, alkalis ($K_2O$, $Na_2O$), and other oxides are present, while the low loss on ignition (2.06%) suggests minimal organic or moisture content. This composition indicates a stable, mostly inert material suitable for partial replacement of natural aggregates, with limited impact on the chemical behavior of concrete but potential effects on porosity and permeability.

Tensile strength tests by splitting were performed on the concrete samples 28 days after casting (EN 12390-3, 2002). The tests were carried out for both the standard mix and the experimental mixes (Figure 3).

As a result of the splitting tensile strength tests (Figure 3), the obtained results are presented in Table 5.

The results obtained for the three studied mixes demonstrate a significant influence of replacing natural aggregates with ceramic waste on the mechanical behavior of pavers.

Figure 3. Specimens tested in splitting tension

Table 5. Results of the splitting tensile strength tests.

| Mix | Sample 1 | Sample 2 | Sample 3 |
|---|---|---|---|
| R1 (control concrete) | 2.663 | 2.222 | 2.198 |
| R2 (50% ceramic aggregate) | 1.737 | 1.910 | 2.010 |
| R3 (100% ceramic aggregate) | 2.672 | 2.360 | 2.850 |

These observations align with current trends in the scientific literature, which highlight the high potential of recycled ceramic materials for use in precast concrete products (Wattanasiriwech et al., 2009).

The test values obtained for the standard C16/20 mix (R1) are consistent with the characteristic strengths of this type of concrete and confirm the reliability of the preparation and testing procedures. The performance of the control mix provides a solid baseline for comparison and is also in accordance with European standards for evaluating splitting tensile strength according to EN 12390-6.

The mix with 50% replacement of the 4-8 mm aggregate with ceramic waste (R2) shows greater variability in results, as well as a decrease in average tensile strength compared to the control mix. This reduction can be explained by the physical and structural properties of the ceramic particles, such as increased roughness and high-water absorption, which may compromise the quality of the cement-aggregate interface. Recent studies indicate that such heterogeneities can significantly affect mechanical behavior, particularly in regions subjected to tensile stresses (Dehghani et al., 2024; Silveira et al., 2025).

The R3 mix, with 100% replacement of the 4-8 mm aggregate, exhibited superior results compared to both the control concrete and R2. This behavior suggests that a fully homogeneous mix composed entirely of ceramic aggregates can produce a compact internal structure. The characteristics of ceramic particles, such as angular shape and hard surface, contribute to more efficient stress transfer in the splitting zone, a phenomenon also reported in other studies on the use of ceramics as recycled aggregates (Wattanasiriwech et al., 2009).

**Statistical analysis**

To evaluate the influence of replacing natural aggregates with ceramic waste on the splitting tensile strength of concrete blocks, the experimental data obtained for the three mixes (R1, R2, R3) were statistically analyzed (Aloman, 1998; Gluck, 1971). The objective of the analysis was to identify differences between the mixes, as well as to assess the variability and stability of their mechanical behavior (Popa et. al, 2022). The values were summarized in Table 6 using the arithmetic mean, standard deviation (SD), median, and coefficient of variation (CV).

Table 6. Descriptive statistics for splitting tensile strength

| Mix | Mean (MPa) | SD (MPa) | Median (MPa) | CV (%) |
|---|---|---|---|---|
| R1 | 2.361 | 0.242 | 2.222 | 10.2 |
| R2 | 2.082 | 0.362 | 1.960 | 17.4 |
| R3 | 2.605 | 0.345 | 2.605 | 13.2 |

Variability ranged from low to moderate among the three mixes. While R1 and R3 exhibited coefficients of variation below 15%, R2 showed a slightly higher coefficient of variation (17.4%), indicating a greater dispersion of the experimental results.

To evaluate the differences between the three concrete mixes, a one-way analysis of variance (ANOVA) was applied to the experimental data. The statistical analysis revealed significant differences in the mean splitting tensile strengths among the three compositions, with the most pronounced variations observed between R2 and R3, as well as between R2 and R1. In particular, the mix with partial replacement (R2) exhibited a clear reduction in mechanical performance compared to both the control concrete and the fully substituted mix (R3), highlighting the influence of partial substitution on the integrity of the cement–aggregate interface and the overall stress transfer within the specimens.

The statistical evaluation indicate that the percentage of natural aggregate replacement has a decisive effect on the splitting tensile strength of the concrete. While partial replacement at 50% results in a noticeable decrease in average

strength, complete replacement at 100% leads to an increase in average strength relative to the control mix, suggesting that a fully homogeneous mix composed entirely of ceramic aggregates can provide a more compact internal structure and improved stress distribution under tensile loading. Additionally, all three mixes exhibited low variability, as indicated by the coefficients of variation, which demonstrates good experimental stability and reproducibility of the testing procedures. The homogeneous structure of the R3 mix, in particular, promotes superior mechanical behavior, confirming the potential of recycled ceramic aggregates as a viable alternative to natural aggregates.

## CONCLUSIONS

The experimental results demonstrate that the substitution of natural aggregates with recycled ceramic aggregates significantly influences the mechanical performance of paving blocks. Partial replacement tends to reduce splitting tensile strength, primarily due to the heterogeneous particle shape, increased roughness, and higher water absorption of ceramic aggregates, which can affect the quality of the cement–aggregate interface. Complete replacement, however, leads to improved tensile performance, indicating that a fully homogeneous mix of ceramic aggregates can form a compact internal structure that enhances stress transfer under tensile loading. Despite the promising mechanical behavior, the brittle nature and water absorption characteristics of ceramic aggregates should be carefully considered for applications subject to heavy or repeated dynamic loading. These findings underscore the potential of ceramic waste as a sustainable alternative to natural aggregates, providing environmental benefits by reducing construction and demolition waste, conserving natural resources, and supporting circular economy principles. Further investigations are recommended to evaluate additional properties such as abrasion resistance, freeze-thaw durability, water absorption, and long-term performance, in order to validate the applicability of recycled ceramics in diverse paving block applications.

## ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support of Elis Pavaje SRL, Romania, a paving block manufacturer that actively incorporates construction and demolition waste into its products, promoting sustainable and circular construction practices.

***Abstract***

*Hydrocarbons are widely recognized as the most important class of persistent and toxic environmental pollutants. Moreover, bacteria from the genus Pseudomonas play a key role in the biodegradation of these compounds, and their remarkable metabolic versatility enables them to adapt to a wide range of contaminated environments, enhancing their effectiveness in pollutant removal. Although many species in this genus have already been identified, new Pseudomonas strains with significant relevance for environmental bioremediation continue to be reported each year. This study investigated hydrocarbon-tolerant and hydrocarbon-degrading bacteria in sediment samples from the Danube Delta collected during summer and autumn. Additionally, the ability of four Pseudomonas strains, individually and as a consortium, to tolerate and degrade paraffin (a mixture of saturated petroleum hydrocarbons) was evaluated. The tested strains demonstrated promising potential for paraffin biodegradation, particularly when applied as a consortium, likely due to functional complementarity and enhanced metabolic interactions. These findings provide valuable insights for environmental applications, including land reclamation and ecological engineering, and contribute to the development of effective strategies to mitigate petroleum hydrocarbon pollution and restore contaminated ecosystems.*

***Key words:*** *biodegradation, paraffin, Pseudomonas, tolerance.*

## INTRODUCTION

Pollution caused by petroleum and petroleum-based products, including paraffinic oils, is widely recognized as a major environmental issue due to the widespread use and extensive distribution of hydrocarbon-based materials in natural ecosystems. As industrial activities and urbanization intensify, hydrocarbon contamination in water bodies has become increasingly problematic, contributing substantially to the degradation of aquatic habitats. Although numerous strategies and technologies are currently employed to prevent and control global contamination by petroleum and petroleum-based products, the increasing frequency of accidents in aquatic environments continues to make hydrocarbon pollution a significant challenge in the coming decades. In this context, biodegradation is considered a key process, as it represents one of the primary and most cost-effective processes for removing hydrocarbons from polluted environments (Das & Chandran, 2011; Xu et al., 2018; Xu et al., 2022; Duarte et al., 2024; Al Haj Chehadeh et al., 2025; Samsuria et al., 2025).

Petroleum and petroleum-based products are highly complex mixtures composed of thousands of individual compounds, which are generally grouped into four classes based on their structural characteristics and physicochemical properties: saturated (aliphatic) hydrocarbons, aromatic hydrocarbons, resins, and asphaltenes (Das & Chandran, 2011; Pandolfo et al., 2023). Each class is characterized by distinct yet interrelated physicochemical properties – particularly toxicity, volatility, solubility, molecular weight, and biodegradability – which collectively influence its environmental fate, transport, and transformation in aquatic systems. When petroleum and its derivatives enter these systems, they act as environmental stressors, with toxic effects extending across trophic levels, affecting phytoplankton, zooplankton, fish, birds, mammals, and benthic communities. Beyond immediate ecological disruption, such releases alter biodiversity, degrade water quality, and generate long-term socio-environmental consequences for surrounding human populations (Perhar &

Arhonditsis, 2014; Duarte et al., 2024; Sharma et al., 2024; Samsuria et al., 2025).

In aquatic environments, the lightest and most volatile hydrocarbon fractions tend to volatilize rapidly into the atmosphere. In contrast, amphipathic and hydrophilic components dissolve or disperse in the water column, while more lipophilic fractions preferentially associate with suspended particulate matter and organic colloids (Pandolfo et al., 2023). These hydrophobic constituents further bind to particulates and sediments, promoting their accumulation and facilitating exposure in benthic species (Perhar & Arhonditsis, 2014; Pandolfo et al., 2023). The accumulation of hydrocarbons in sedimentary matrices can alter microbial community structure, suppress the metabolic activity of sensitive sediment bacteria, and disrupt key biogeochemical processes such as nutrient cycling and organic matter degradation. These sediments may also harbor bacterial taxa capable of degrading hydrocarbons, thereby contributing to natural attenuation in contaminated benthic environments. At the same time, hydrocarbons can eliminate or inhibit susceptible microbial taxa, thereby altering key ecosystem functions. The selective pressure exerted by these compounds often reduces microbial diversity and shifts community composition toward bacterial populations that use hydrocarbons as carbon and energy sources. Given this dual role of hydrocarbons in both constraining susceptible microorganisms and selecting for specialized microbial communities, the characterization of bacteria capable of hydrocarbon degradation is essential for assessing natural attenuation potential in aquatic sediments (Das & Chandran, 2011; Pandolfo et al., 2023; Al Haj Chehadeh et al., 2025; Samsuria et al., 2025).

This study investigated hydrocarbon-tolerant and hydrocarbon-degrading bacteria in sediment samples from the Danube Delta collected during summer and autumn. Additionally, the tolerance and biodegradation capacity of four *Pseudomonas* strains, tested individually and as a consortium, were evaluated using paraffin, a mixture of saturated petroleum hydrocarbons characterized by high chemical stability and low biodegradability.

## MATERIALS AND METHODS

### Quantification of bacteria in sediments

Sediment samples from the Danube Delta (Roșu, Roșuleț, and Puiu lakes, Tulcea County, Romania), part of the southern lacustrine complex within the Danube Delta Biosphere Reserve, were used for the development of enrichment cultures. The experimental setup was based on a modified minimal medium (Stancu, 2023), supplemented with petroleum (5%, v/v) as the sole carbon and energy source. Cultures were maintained at 30°C under constant agitation (200 rpm) for 21 days to promote the growth of hydrocarbon-adapted microorganisms. The abundance of hydrocarbon-tolerant and hydrocarbon-degrading bacteria was determined using two culture-dependent quantification methods: the most probable number (MPN) and colony-forming unit (CFU) counts (Stancu, 2025).

### Paraffin tolerance and biodegradation by *Pseudomonas* strains and consortium

Four *Pseudomonas* strains (IBBDt2, IBBDt4.2, IBBDt1, and IBBDt8), previously isolated and identified (Stancu, 2023), were cultured in LB medium at 30°C under shaking conditions (200 rpm) for 24 h. Subsequently, the antagonistic interactions among the four strains were assessed using the cross-streak method (Hossain, 2024). In this assay, one strain was initially streaked onto LB agar and incubated at 30°C for 24 h, after which the remaining strains were spot-inoculated in proximity to the primary streak.

Tolerance to paraffin and biodegradation potential of the four bacterial strains, both individually and as a consortium (CnP), were further evaluated. Standardized overnight cultures ($OD_{660}$ = 0.08) were inoculated into fresh LB and MM media supplemented with paraffin (5%, v/v) and incubated at 30°C under shaking conditions (200 rpm) for 7 days. Uninoculated MM supplemented with paraffin (5%, v/v) served as an abiotic control.

Bacterial growth was assessed through optical density measurements at 660 nm ($OD_{660}$), using a SPECORD 200 UV-Vis spectrophotometer (Analytik Jena). Biomass accumulation was further estimated by determining dry cell weight. Bacterial viability was evaluated by

spotting paraffin-exposed cultures onto LB and MM agar media, both in the presence and absence of a paraffin overlay. To assess growth dynamics, paraffin-exposed cultures were transferred into fresh LB medium and incubated at 30°C under controlled conditions. Changes in optical density ($OD_{660}$) were monitored at hourly intervals over a 24 h period using a SpectraMax ABS Plus microplate reader (Molecular Devices).

Paraffin biodegradation was evaluated using a combination of complementary approaches, including observation of paraffin film fragmentation, gravimetric determination of residual paraffin recovered from cell-free supernatants after chloroform extraction, and high-performance thin-layer chromatography (HPTLC), following a previously described method (Stancu, 2023) with modifications for paraffin analysis. Chromatographic analyses were performed using a CAMAG TLC system, and 3D profiles were processed using visionCATS software (CAMAG). Samples were applied to silica gel plates and developed in a pre-saturated chamber with an n-hexane–ethyl acetate (92:8, v/v) mobile phase. Plates were then treated with iodine vapors and analyzed under visible light (Vis, 500 nm).

Biosurfactant production was assessed using several complementary assays, including the hydrocarbon overlay agar plate method, drop-collapse test, CTAB assay, and the emulsification index ($E_{24}$), as previously described (Satpute et al., 2008). In addition, biosurfactant yield was quantified gravimetrically after extraction from cell-free culture supernatants using a chloroform–methanol mixture (2:1, v/v), and subsequent solvent evaporation (Gesheva et al., 2010).

The presence of alkane-degrading genes (*alkB* and *alkM*) and the rhamnosyltransferase gene (*rhlAB*) was investigated by polymerase chain reaction (PCR). Genomic DNA was isolated using the PureLink Genomic DNA Kit (Invitrogen). Amplification reactions were performed in a Mastercycler Pro S thermocycler (Eppendorf) with gene-specific primers (alkB-f/alkB-r, Whyte et al., 1996; alkM-f/alkM-r, Márquez-Rocha et al., 2005; rhlA-f/rhlB-r, Medina et al., 2003) and GoTaq G2 Flexi DNA Polymerase (Promega). PCR amplification included an initial denaturation at 94°C for 10 min, followed by 35 cycles (94°C for 1 min, 50-62°C for 30 s, and 72°C for 2 min) and a final extension at 72°C for 10 min. Amplified fragments were resolved by electrophoresis on 1.5% (w/v) agarose gels (Sambrook & Russell, 2001) and visualized using SYBR Safe DNA gel stain (Invitrogen).

Changes in genomic fingerprinting profiles were analyzed by repetitive extragenic palindromic PCR (REP-PCR) using the $(GTG)_5$ primer (Versalovic et al., 1994) and GoTaq G2 Flexi DNA Polymerase (Promega). Amplification was performed in a Mastercycler Pro S thermocycler (Eppendorf).

PCR conditions included an initial denaturation at 94°C for 10 min, followed by 35 cycles (94°C for 1 min, 52°C for 1 min, and 65°C for 8 min) and a final extension at 65°C for 16 min. The resulting fragments were separated on 2.0% (w/v) agarose gels and visualized as described above.

Reagents used in this study were obtained from Merck and Sigma-Aldrich.

## RESULTS AND DISCUSSIONS

### Quantification of bacteria in sediments

Petroleum and petroleum-based products frequently contaminate aquatic ecosystems, entering through industrial activities, shipping activities, accidental spills, and urban wastewater. In the Danube Delta, a protected wetland of high ecological value, hydrocarbon accumulation in sediments poses a long-term threat to biodiversity and ecosystem processes.

The abundance of hydrocarbon-tolerant and hydrocarbon-degrading bacteria in sediment samples collected in summer (July) and autumn (September) from the Danube Delta was assessed after enrichment in petroleum-amended minimal medium (MM). Bacterial populations were quantified using MPN and CFU approaches (Figure 1), providing insights into the sediment microbial community's natural attenuation potential and seasonal variations. Regardless of the quantification method, hydrocarbon-tolerant bacteria were consistently present at higher levels ($10^4$-$10^6$ cells $mL^{-1}$, $10^3$-$10^6$ CFU $mL^{-1}$) than hydrocarbon-degrading bacteria ($10^2$-$10^3$ cells $mL^{-1}$, $10^1$-$10^3$ CFU $mL^{-1}$). Seasonal differences were also observed for both groups. Sediment

samples collected in July showed higher levels of hydrocarbon-tolerant bacteria ($10^5$-$10^6$ cells $mL^{-1}$, $10^4$-$10^6$ CFU $mL^{-1}$) than those collected in September ($10^4$-$10^5$ cells $mL^{-1}$, $10^3$-$10^4$ CFU $mL^{-1}$). Similarly, hydrocarbon-degrading bacteria were more abundant in July samples ($10^3$ cells $mL^{-1}$, $10^3$ CFU $mL^{-1}$) than in September samples ($10^2$ cells $mL^{-1}$, $10^1$ CFU $mL^{-1}$). These patterns likely reflect seasonal temperature effects on bacterial growth and hydrocarbon metabolism. The predominance of hydrocarbon-tolerant heterotrophs over specialized degraders aligns with previous studies, where metabolically versatile degraders represented a smaller fraction of the microbial community in hydrocarbon-exposed sediments (Xu et al., 2022

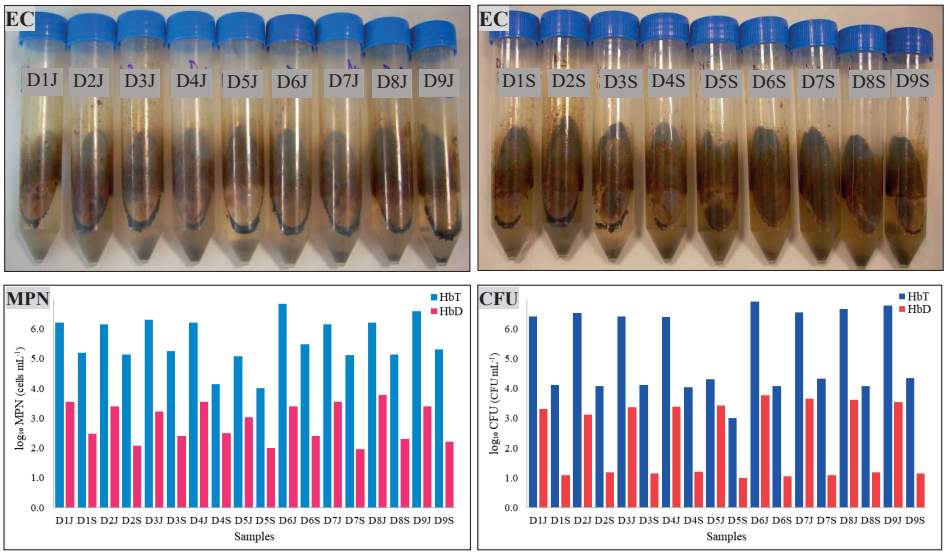

Figure 1. Quantification of bacteria in sediments
Sediment samples collected in July (D1J-D9J) and September (D1S-D9S) were analyzed after enrichment (EC) for hydrocarbon-tolerant (HbT) and hydrocarbon-degrading (HbD) bacteria using MPN and CFU methods ($log_{10}$ scale)

**Paraffin tolerance and biodegradation by *Pseudomonas* strains and consortium**

The *Pseudomonas* strains IBBDt2, IBBDt4.2, IBBDt1, and IBBDt8, previously identified as *P. aeruginosa*, *P. nitroreducens*, *P. aeruginosa*, and *P. multiresinivorans*, respectively (Stancu, 2023), were evaluated for paraffin tolerance and biodegradation, both individually and in consortium. *Pseudomonas* species produce secondary metabolites, such as pyocyanin, pyoverdine, and biosurfactants, which affect microbial interactions through redox reactions, iron chelation, and membrane destabilization (Chong & Li, 2017; Butaitė et al., 2018; Abdelaziz et al., 2023). Consequently, strain compatibility was assessed before the experiments, given the selected bacteria's capacity to produce metabolites, such as pyocyanin and/or pyoverdine, and biosurfactants (Stancu, 2023). No antagonistic interactions were detected among four *Pseudomonas* strains (Figure 2), consistent with reports that metabolite production does not necessarily induce inhibition under all growth conditions.

**Bacterial growth.** All four *Pseudomonas* strains IBBDt2, IBBDt4.2, IBBDt1, and IBBDt8, grown individually and as a consortium in LB broth supplemented with 5% paraffin, presented high tolerance, as indicated by optical density at 660 nm ($OD_{660}$ = 1.06-1.45) and dry biomass measurements (3.54-5.17 g $L^{-1}$) (Table 1). In addition, both the individual strains and the consortium grew in MM broth supplemented with 5% paraffin as the sole carbon and energy source ($OD_{660}$ = 0.63-0.87, dry biomass = 1.22-3.34 g $L^{-1}$).

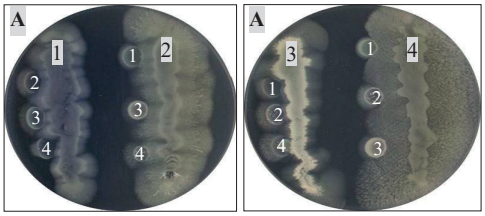

Figure 2. Antagonistic interactions among *Pseudomonas* strains
Antagonistic activity (AA) of strains IBBDt2 (1), IBBDt4.2 (2), IBBDt1 (3), and IBBDt8 (4), evaluated by testing each strain against the other three on LB agar

In tolerance (LB) and biodegradation (MM) experiments, the *Pseudomonas* consortium exhibited enhanced growth in the presence of paraffin ($OD_{660}$ = 1.45 and 0.87, respectively) compared to the individual strains ($OD_{660}$ = 1.06–1.36 and 0.63–0.83, respectively). Although differences in OD and dry biomass values were observed among the experimental variants, viability assays performed after 7 days of growth in LB or MM with 5% paraffin revealed confluent growth of all cultures on LB agar, with or without paraffin overlay (Figure 3). In contrast, reduced viability was observed on MM agar overlaid with paraffin, suggesting metabolic stress under nutrient limitation (Márquez-Rocha et al., 2005). Although reduced viability was observed under nutrient-limited conditions, the individual strains and the consortium maintained growth in the presence of paraffin, suggesting adaptability to hydrocarbon substrates, likely through alkane catabolic pathways (Whyte et al., 1996; Das & Chandran, 2011).

*Pseudomonas* strains cultivated for 7 days as individual cultures or as a consortium in LB and MM broths supplemented with 5% paraffin, and subsequently reinoculated into fresh LB broth, showed a lag phase of approximately 3-4 h (Figure 3). In all cases, this initial adaptation period was followed by an exponential growth phase occurring between 4 and 18 h. After approximately 15-19 h of incubation, the cultures entered a stationary (plateau) phase. The onset and duration of these phases varied across individual strains and the consortium. This observation was further supported by the determined growth rates and generation times (Table 1). Cultures previously grown for 7 days in LB broth with 5% paraffin showed growth rates (μ) ranging from 0.61 to 0.87 $h^{-1}$ and generation times (g) between 0.80 and 1.13 h, whereas cultures grown in MM broth with 5% paraffin had lower growth rates (μ = 0.55-0.72 $h^{-1}$) and longer generation times (g = 0.96-1.25 h) when transferred to fresh LB. Cultivation under nutrient-rich conditions favors faster adaptation and enhanced growth kinetics, while minimal media impose metabolic constraints, reducing growth rates and prolonging generation times (Hall et al., 2014).

**Paraffin biodegradation.** *Pseudomonas* strains IBBDt2, IBBDt4.2, IBBDt1, and IBBDt8, cultivated individually and as a consortium in MM broth supplemented with 5% paraffin, disrupted the paraffin film, indicating emulsification and degradation (Table 1). Gravimetric analyses confirmed the capacity of tested bacteria to biodegrade paraffin, with degradation efficiencies ranging from 60.88% to 85.45%. The highest biodegradation efficiency was achieved for the *Pseudomonas* consortium (85.45%), exceeding that noticed for the individual strains (60.88-77.70%), suggesting a synergistic interaction within the consortium that enhances paraffin biodegradation. Among the individual strains, IBBDt1, IBBDt2, and IBBDt4.2 exhibited comparatively higher biodegradation efficiencies (77.70%, 75.64%, and 69.25%, respectively), whereas strain IBBDt8 showed the lowest efficiency (60.88%). Previous studies have reported that bacterial consortia display superior hydrocarbon-degrading performance compared to pure cultures due to complementary metabolic pathways, synergistic enzymatic activities, and biosurfactant production, which enhance hydrocarbon bioavailability and overall biodegradation efficiency (Das & Chandran, 2011; Varjani, 2017; Xu et al., 2018).

Following the gravimetric evaluation of paraffin degradation, residual paraffin samples were subjected to HPTLC analyses. These analyses indicated the presence of a single spot migrating close to the solvent front, with retardation factor ($R_f$) values ranging from 0.82 to 0.86 (Figure 3). Three-dimensional chromatographic (3DC) profiles confirmed differences in peak intensity among the samples. In the abiotic control, the $R_f$ value was 0.84. Similar $R_f$ values (0.82-0.83) were recorded for extracts obtained from *Pseudomonas* strains IBBDt2, IBBDt1, IBBDt8, and the consortium, whereas the extract from strain IBBDt4.2 showed a slightly higher $R_f$ value (0.86). For this strain, the detected spot was of low intensity and markedly smaller than the other chromatographic spots. Although the *Pseudomonas* consortium and strains IBBDt1 and IBBDt2 presented higher gravimetric biodegradation efficiencies, their HPTLC profiles showed minor differences compared to the abiotic control, consistent with the semi-quantitative nature of HPTLC. In contrast, strain IBBDt4.2, despite its moderate biodegradation efficiency (69.25%), displayed a reduced spot intensity, suggesting preferential degradation of the paraffin fraction corresponding to this chromatographic spot. These results indicate that different strains may target distinct paraffin fractions. Genomic DNA extracted from paraffin-exposed cultures was used for PCR detection of the *alkB* and *alkM* genes, which encode alkane hydroxylases responsible for the initial step of alkane oxidation (Table 1, Figure 4). The *alkB* gene (≈870 bp) was detected in strains IBBDt2, IBBDt1, IBBDt8, and in the consortium, whereas strain IBBDt4.2 produced a slightly smaller amplicon (~850 bp). The *alkM* gene (≈870 bp) was present in strains IBBDt2, IBBDt4.2, and IBBDt8, while only weak amplification was observed in the consortium, and no amplification was detected in strain IBBDt1. Together, these results confirm the alkane-degrading potential of the individual *Pseudomonas* strains and the consortium, in agreement with previous studies reporting a strong correlation between the presence of *alkB*/*alkM* genes and efficient alkane biodegradation in hydrocarbon-degrading bacteria (Whyte et al., 1996; Márquez-Rocha et al., 2005; Das & Chandran, 2011; Pandolfo et al., 2023).

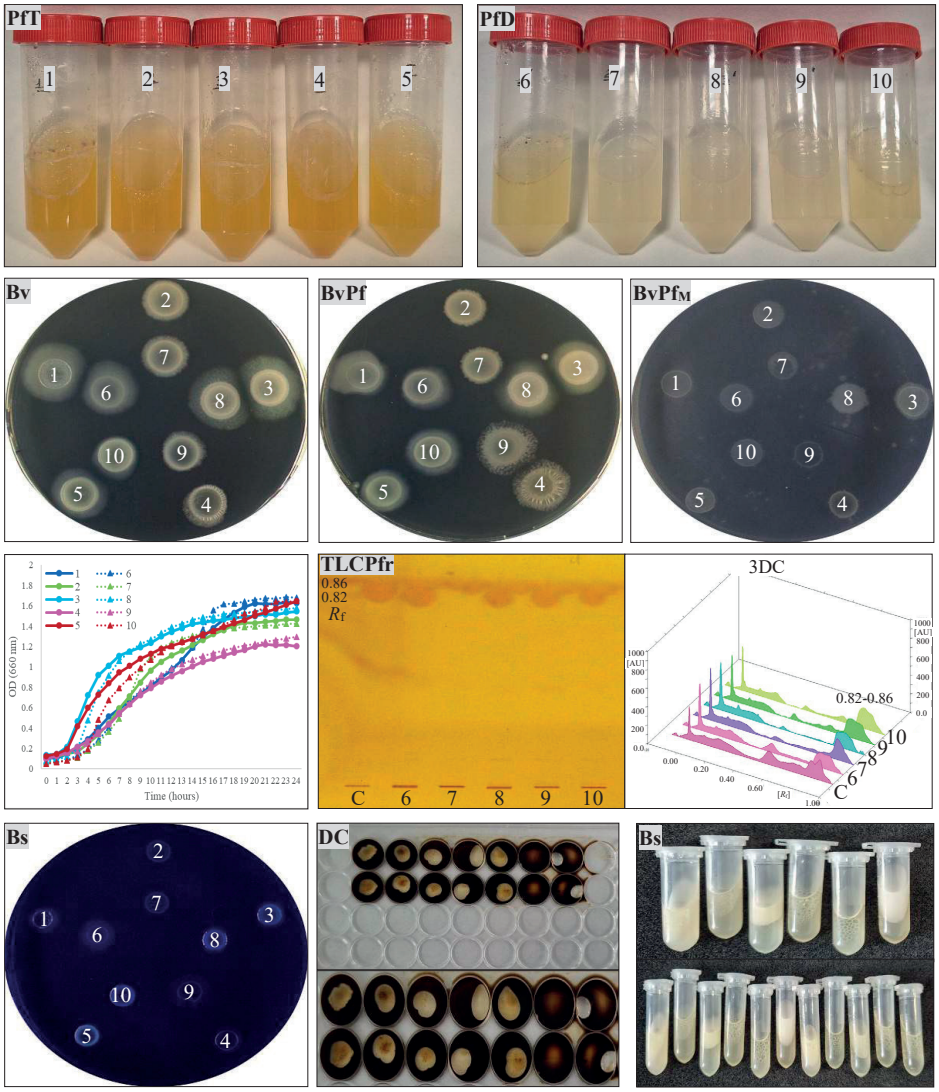

Figure 3. Paraffin tolerance and biodegradation by *Pseudomonas* strains and consortium
Paraffin tolerance (PfT, 1–5) and biodegradation assays (PfD, 6–10) performed for strains IBBDt2 (1, 6), IBBDt4.2 (2, 7), IBBDt1 (3, 8), IBBDt8 (4, 9), and the consortium (CnP, 5, 10). Bacterial viability on LB agar (Bv) and LB or MM agar overlaid with paraffin (BvPf, BvPf$_M$). Growth curves of the tested strains and consortium (Gc). HPTLC analysis of residual paraffin (TLCPfr, $R_f$ 0.82–0.86) compared with abiotic control (C), including TLC plate and 3D chromatogram (VIS). Biosurfactant production on CTAB agar (Bs); drop-collapse assay (DC); and emulsification assay (Es).

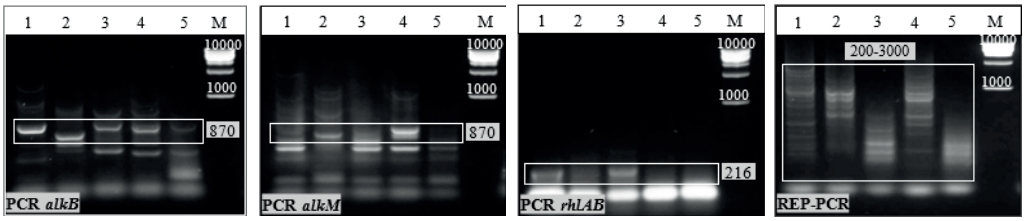

Figure 4. Molecular characterization of *Pseudomonas* strains and consortium
PCR detection of *alkB* (870 bp), *alkM* (870 bp), and *rhlAB* (216 bp) genes using DNA from strains IBBDt2 (1), IBBDt4.2 (2), IBBDt1 (3), IBBDt8 (4), and the consortium (CnP, 5); 1 kb DNA ladder (M). REP-PCR fingerprinting profiles of the same strains (1–4) and consortium (5).

**Biosurfactant production.** *Pseudomonas* strains IBBDt2, IBBDt4.2, IBBDt1, and IBBDt8, cultivated individually and as a consortium in the presence of 5% paraffin, presented biosurfactant production, as evidenced by positive results in the hydrocarbon overlay and drop-collapse assays (Table 1, Figure 3). All tested strains, as well as the consortium, produced a blue halo on CTAB agar when paraffin-grown cultures were spotted, indicating the synthesis of glycolipid or other anionic biosurfactants. The produced biosurfactants presented strong emulsification activity, with emulsification index ($E_{24}$) values ranging from 30% to 100% (Table 1). Maximum $E_{24}$ values (100%) were observed for the *Pseudomonas* strains IBBDt1 and IBBDt2, as well as for the consortium containing all four strains, followed by strains IBBDt4.2 (50%) and IBBDt8 (30%). Biosurfactant production by the individual *Pseudomonas* strains and the consortium ranged from 0.31 to 1.89 g $L^{-1}$. The *Pseudomonas* consortium presented the highest biosurfactant yield (1.89 g $L^{-1}$), followed by strains IBBDt1 (1.22 g $L^{-1}$) and IBBDt2 (0.92 g $L^{-1}$), whereas lower yields were recorded for strains IBBDt8 (0.41 g $L^{-1}$) and IBBDt4.2 (0.31 g $L^{-1}$). This enhanced biosurfactant production (1.89 g $L^{-1}$) by the consortium could be attributed to synergistic interactions among its constituent strains, which likely contribute to their superior paraffin biodegradation efficiency (85.45%). *Pseudomonas* spp. efficiently utilizes petroleum and petroleum-based products as carbon and energy sources and produce biosurfactants that facilitate hydrocarbon emulsification and biodegradation in contaminated environments (Chong & Li, 2017; Cui & Dörmann, 2025).

PCR amplification targeting the *rhlAB* genes encoding rhamnosyltransferase I detected the expected 216 bp fragment exclusively in the paraffin-exposed individual strains IBBDt2 and IBBDt1, both identified as *P. aeruginosa* (Table 1, Figure 4). These genes encode key enzymes involved in the biosynthesis of mono- and di-rhamnolipids, glycolipid biosurfactants that facilitate hydrocarbon solubilization and uptake. Previous studies indicate that *rhlAB* genes are predominantly associated with *P. aeruginosa* and play a central role in rhamnolipid production (Medina et al., 2003; Chong & Li, 2017; Wongsirichot & Winterburn, 2025). In contrast, no amplification products were obtained from *P. nitroreducens* IBBDt4.2, *P. multiresinivorans* IBBDt8, or from the consortium, despite the presence of the two *P. aeruginosa* strains. The absence of detectable *rhlAB* amplification in the consortium may be attributed to a lower relative abundance of *P. aeruginosa* genomic DNA, dilution effects during DNA extraction, or preferential amplification of dominant genomic templates in mixed bacterial communities, as reported in PCR-based analyses of complex microbial communities (van Dorst et al., 2014).

REP-PCR fingerprinting revealed distinct banding patterns (ranging from 200 to 3000 bp) for the four tested *Pseudomonas* strains when cultivated individually, confirming their genomic heterogeneity (Figure 4). In contrast, the consortium displayed a simplified REP-PCR profile, characterized by fewer bands predominantly between 200 and 400 bp. Several bands observed in the consortium overlapped with those detected in strain IBBDt1. The reduced complexity of the consortium fingerprint may indicate a shift in

population structure during incubation in 5% paraffin, possibly reflecting the numerical predominance of IBBDt1 under these conditions. Despite this apparent structural simplification, the consortium maintained superior paraffin biodegradation efficiency compared to the individual strains.

Our results demonstrate the promising potential of the tested *Pseudomonas* strains for paraffin biodegradation, particularly when combined in a consortium, likely due to functional complementarity and enhanced metabolic interactions. Collectively, these findings highlight their potential applicability in environmental biotechnology, including land reclamation and ecological engineering strategies aimed at mitigating petroleum hydrocarbon pollution and restoring contaminated ecosystems.

## CONCLUSIONS

Hydrocarbon-tolerant and hydrocarbon-degrading bacteria exhibited higher abundances during summer, with hydrocarbon-tolerant bacteria consistently dominating, indicating a clear seasonal influence on their distribution.

The tested *Pseudomonas* strains, both individually and as a consortium, demonstrated good ability to tolerate and degrade paraffin, indicating high metabolic versatility and suggesting their potential applicability in the bioremediation of sediments contaminated with saturated petroleum hydrocarbons.

Overall, this study enhances the understanding of the functional diversity and ecological role of hydrocarbon-degrading bacteria in natural sediments and provides a scientific basis for the development of environmentally friendly monitoring and bioremediation strategies in sensitive ecosystems such as the Danube Delta.

## ACKNOWLEDGEMENTS

The study was funded by project no. RO1567-IBB05/2026 from the Institute of Biology Bucharest of Romanian Academy.

# SEASONAL VARIATION OF $CO_2$ SOIL FLUX AND VEGETATION RESPONSE AT BODOC AND BĂILE LĂZĂREȘTI

**Lia STELEA[1, 2], Alexandra-Constanța DUDU[1], Corina AVRAM[1], Marius-Bogdan BĂRĂITĂREANU[1, 2], Andrei-Gabriel DRAGOȘ[1, 2], Gabriel IORDACHE[1]**

***Abstract***

*Bodoc and Lăzărești were chosen as test sites to assess an environmental monitoring methodology that combines soil $CO_2$ flux and vegetation surveys. Field campaigns conducted in September 2024 and April 2025 enabled a comparative assessment of spatial and seasonal variability. The two sites display very different patterns. Bodoc exhibits low $CO_2$ fluxes with limited seasonal change, likely driven by shallow biological processes. In contrast, Lăzărești displays high, naturally sourced $CO_2$ fluxes with high spatial and seasonal variability, probably also influenced by hydrological conditions and soil biological activity. Vegetation patterns also differ: at Bodoc, elevated $CO_2$ fluxes are associated with higher cover of healthy plants, whereas at Lăzărești, high fluxes correspond to reduced vegetation cover, changes in community composition and an increased monocot/angiosperm ratio.*

***Key words****: soil $CO_2$ flux, natural analogue, environmental monitoring, vegetation response, seasonal variability, Bodoc, Lăzărești.*

## INTRODUCTION

Carbon capture and storage (CCS) is widely regarded as an important mitigation strategy for reducing greenhouse gas emissions. According to the IPCC Sixth Assessment Report (IPCC, 2023), the observed increase in global average temperatures since the industrial era is very likely driven by anthropogenic greenhouse gas emissions. The deployment of CCS has been recommended as part of the portfolio of solutions needed to achieve global climate targets outlined in recent IPCC assessments (IPCC, 2022). However, one of the key challenges associated with this technology is the potential risk of $CO_2$ leakage and its possible impacts on surrounding ecosystems.

Several studies describe the relationship between increased $CO_2$ concentration in soils and the state of vegetation. The effect of $CO_2$ can be direct on plants or indirect through pH changes and mobilization of nutrients and potentially toxic elements (Noble et al., 2012). These effects are typically investigated using controlled leakage at experimental field sites or by using natural analogues where there are significant $CO_2$ releases.

It is important to state that the changes reported are due to $CO_2$ leaking towards the surface from the underground sources, not due to an increase of $CO_2$ concentration in the air. The latter often has a fertilizing effect on above-ground organs (Norby & O'Neill, 1991; Dahlman, 1993; Huxman & Smith, 2001; Veteli et al., 2002; Hymus et al., 2003; Schäfer et al., 2003) and underground organs (Idso & Kimball, 1992; Rogers et al., 1992; Schäfer et al., 2003) in some species.

It can also have little to no effect on physiology, growth or productivity on some ecosystems (Dahlman, 1993; Kirschbaum, 1999) or even be detrimental to some species, such as *Rumex obtusifolius* and *Cardamine flexuosa*, where it introduces pronounced discolouration of the leaves and premature senescence of the foliage, as well as a decrease in yield (Diaz et al., 1993). Previous research has shown that botanical changes caused by the presence of $CO_2$ in soil are site and species specific. Usually, plants show no significant response at moderate concentrations of $CO_2$ (Bouma et al., 1997). At high concentrations, plants can have decreased height, root respiration and depth of rooting (Nobel & Palta, 1989; Vodnik et al., 2006). They can also present signs of stress such as yellowing or browning of leaves due to a rapid flux of $CO_2$ (West et al., 2009; Pfanz et al., 2011). There is a predominance of grasses in the proximity of

$CO_2$ vents (Beaubien et al., 2008; West et al., 2009). Vegetation dieback (Bergfeld et al., 2006) or absence of vegetation (Beaubien et al., 2008) can also be due to high fluxes of $CO_2$.

There have been sites where certain species acted as potential bioindicators of high $CO_2$ concentrations or fluxes. These have been genus *Polygonum* with the species *P. arenastrum* (Krüger et al., 2009) and *P. aviculare* (West et al., 2015), as well as the species *Minuartia glomerata* (Ziogou et al., 2013).

Another finding from some studies has been concentric vegetation zonation around well-defined $CO_2$ vents, with the more resistant taxa growing increasingly closer to the vent and often with absence of vegetation at the vent core (Beaubien et al., 2008; Krüger et al., 2009; 2011).

Romania hosts several sites suitable as natural laboratories for the study of the effects of a potential leakage from an anthropogenic $CO_2$ storage site (sites with natural $CO_2$ emissions) as well as background conditions representative of safe storage environments (natural $CO_2$ fields). In the framework of a nationally funded research project that aims to develop an environmental monitoring methodology, two sites have been selected as natural laboratories: Bodoc for safe storage (Covasna County) and Băile Lăzărești for leakage (Harghita county). Gas flux measurements and vegetation surveys were conducted at both sites in September 2024 and April 2025.

## MATERIALS AND METHODS

### Study areas

The Bodoc site is located on a cattle pasture situated on the outskirts of Bodoc commune, along the Borviz Brook, above a carbonated mineral water reservoir. Geographically, the Bodoc site can be found at: 45°57'57.47"N; 25°52'21.19"E and an average altitude above sea level of 586.35 m (Figure 1). Geologically, Bodoc is located at the western limit of the intensely folded and faulted Cretaceous flysch deposits.

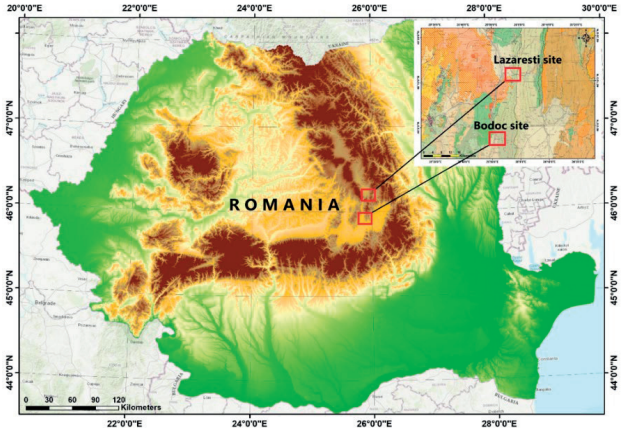

Figure 1. Location of Bodoc and Lăzărești sites in Romania and on geological map (the smaller image)

The Sânmartin-Bodoc strata are an alternation of sandstones, marls, shales and conglomerates. Aquifers are present at medium depth in the basement rock and also at shallow depth, in post tectonic deposits of the sedimentary cover. The conglomerate facies, found in a synclinal, is strongly affected by a series of transverse faults through which mineral waters migrate to the surface (Mutihac, 1990). These mineral waters are well-known, on the left bank of Borviz brook is the F1 SNAM Talomir well, with the aquifer in Upper Pliocene-Quaternary deposits and on the right bank is the oligomineral water well F2 SNAM in Quaternary deposits (SNAM, 2025).

Băile Lăzărești site, also known as Lăzărești, is situated next to the village of Lăzărești in the Cozmeni commune, being renowned by highly concentrated $CO_2$ emissions which can exceed 85% in volume (Dudu et al., 2024). Geographically, Băile Lăzărești is found at 46°11'00.17"N; 25°57'11.72"E and an average altitude above sea level of 743.29 m (Figure 1).

From a geological perspective, Băile Lăzărești is situated on a succession of geological deposits which starts with the Cretaceous flysch at the base (Sânmartin-Bodoc, of Barremian-Albian age) to the terrace deposits at the top. A fault system dominates the deep geological structure of the area, which facilitates the migration and distribution of post-volcanic emissions, like mofettas and mineral springs (Mutihac, 1990).

**Study campaigns**

The measurements were conducted at Bodoc and Lăzărești sites in September 2024 and April 2025. These included soil flux and vegetation surveys.

Soil flux measurements were performed using the West Systems portable fluxmeter equipped with $CO_2$, $CH_4$ and $H_2S$ sensors. FluxRevision 4.11 software provided by West Systems was used to process the data.

The September 2024 campaign included 244 soil flux measurements and 107 points for vegetation assessment at Bodoc site, divided in two perimeters, one along a brook valley and one on a cattle pasture (Stelea et al., 2025). At Lăzărești site, gas measurements were done also on two perimeters, one in the area with the most important touristic features and one on a recently landscaped hill with three terraces. The sampling points were 5 m apart, with 52 sampling points for soil flux measurements and vegetation assessment.

The April 2025 campaign took place between 23-29 April 2025. The April campaign in Bodoc 2025 consisted of 131 points of variable distance and the campaign in Lăzărești 2025 consisted of 250 points, 5 m apart, all of which were assessed for gas flux and vegetation.

**Vegetation surveys**

The vegetation surveys for Bodoc and Băile Lăzărești for the September 2024 campaign are similar to those conducted in April 2025. The quantitative vegetation surveys were done in the same place or the immediate vicinity of the measurement points for soil gas flux and concentration, using a 50 × 50 cm quadrat placed at the locations where gas measurements were conducted.

The interior of every quadrat was digitally photographed with the camera of a mobile phone (Xiaomi Poco M3 for the 2024 campaign, Motorola Edge 50 Neo for the 2025 campaign). Using GIMP software (version 2.6 for the 2024 campaign, version 3.0.60.0 for the 2025 campaign), a grid of 25 points situated at equal distance was created inside the quadrat (Figure 2). The category corresponding to each grid intersection was recorded at the intersection or immediately above, in case it falls on multiple elements at once.

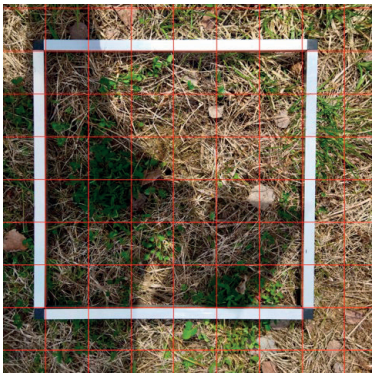

Figure 2. The grid used to calculate the relative abundance of vegetation and soil coverage categories

For the survey we performed a quantitative evaluation through the presence and dominance of categories of soil cover or plant types, also considering their state of health. Where possible, the main taxa of herbaceous plants were identified using the mobile platform iNaturalist (iNaturalist, 2024, 2025), with the observations georeferenced and published through the GBIF network (GBIF 2024; 2025).

The soil coverage categories used are similar for September 2024 and April 2025 assessments. The categories are as follows:

1. dicotyledonous angiosperms (dicots) not known as indicators - healthy organs;
2. monocotyledonous angiosperms (monocots) - healthy organs;
3. herbaceous angiosperms - withered, yellowed or browning organs;
4. herbaceous angiosperms - dried organs;
5. mosses;
6. pteridophytes;
7. external (tree leaves, twigs, litter etc.) or unidentified (shaded) elements;
8. bare ground;
9. known “indicator” taxa from other studies: *Polygonum* sp., *Minuartia glomerata*.

The criteria for selecting categories 1-2 come from scientific literature, where it was found that monocots are generally more frequent than dicots in areas with high levels of $CO_2$ (Krüger et al., 2009; West et al., 2009; Krüger et al., 2011; Noble et al., 2012). Categories 3 and 4 were selected because very high $CO_2$ emissions can lead to the yellowing or browning of leaves (West et al., 2009) or can lead to plant death (Bergfeld et al., 2006). Mosses and pteridophytes (categories 5 and 6) can be dominant in certain places although it is unknown whether their presence is related to given $CO_2$ concentrations. Category 7 is neutral, although external elements often mask bare ground. Categories 8 (bare ground) and 9 ("indicator" taxa) can appear at the highest $CO_2$ fluxes or concentrations. Using the photographs, mapping techniques and data analysis functions of Microsoft Excel relationships were analysed between the composition of soil coverage categories and the $CO_2$ flux, for both Bodoc and Lăzărești and both campaigns.

## RESULTS AND DISCUSSIONS

### Flux measurements of soil $CO_2$

The minimum, maximum, median and mean values for the two campaigns (2024 and 2025) at Bodoc and Lăzărești are written in Table 1 and the distribution is illustrated in Figure 3.

At Bodoc, during the September 2024 campaign the values obtained for flux measurements are relatively low. During April 2025 campaign the measured flux values are slightly higher.

The values obtained at Lăzărești in September 2024 are much higher than at Bodoc, due to known $CO_2$ seepage.

Table 1. $CO_2$ summary statistics for Bodoc and Lăzărești

| Campaign | Minimum [mol/ $m^2$/ day] | Median [mol/ $m^2$/ day] | Mean [mol/ $m^2$/ day] | Maximum [mol/ $m^2$/ day] |
|---|---|---|---|---|
| Bodoc Sep 2024 | 0.042 | 0.272 | 0.291 | 1.382 |
| Bodoc Apr 2025 | 0.233 | 0.604 | 0.693 | 2.736 |
| Lăzărești Sep 2024 | 0.2 | 3.479 | 13.039 | 322.3 |
| Lăzărești Apr 2025 | 0.1383 | 2.99 | 16.420 | 601.4 |

A Mann-Whitney U statistical test was performed between pairs of the four sites – campaigns: Bodoc 2024, Bodoc 2025, Lăzărești 2024, Lăzărești 2025 and the result, for all but one of six combinations, was that the rank sums are significantly different. This means that most sites, even the same site at different campaigns, has flux values that, as groups, are also significantly different from each other; Lăzărești site has values that are not statistically different in 2024 and 2025.

### Vegetation survey at Bodoc

As described in Stelea et al. (2025), the herbaceous vegetation consists of a cattle pasture next to an oak forest, slightly sloped in the upper, northern area and flat in the lower, southern area, separated by a steeper slope with ungrazed vegetation. The upper sector is oriented NE–SW and shaped like a wide stripe.

Due to grazing, plants are generally no taller than 5 cm from the ground surface, except for some unpalatable taxa and plants found near shrubs. Grazing makes plants hard to identify, especially those from order Poales.

In September 2024, plants were generally affected by drought, with withered, yellowed and dried organs due to an unusually hot and dry summer and autumn. More vigorous plants were in the ungrazed parts, close to the Borviz brook or in the shade of the taller vegetation (shrubs and trees).

In April 2025 plants were green and vigorous, unaffected by drought, although some had dried organs, probably left over from last year. The trees and shrubs from the middle part of the study area were removed.

Mosses are present, without being identified by genus or species. Pteridophytes are represented by genus *Equisetum*. Dicots are dominated (as number of identified species) by families Asteraceae, Lamiaceae and Plantaginaceae. Monocots are mostly represented by order Poales, family Poaceae, with *Poa pratensis*, *Agropyrum repens* and other species which cannot be identified due to the lack of reproductive elements. Moist areas have *Luzula* sp., *Carex* sp., *Juncus* sp. One species of orchid was found, *Neotinea (Orchis) ustulata*.

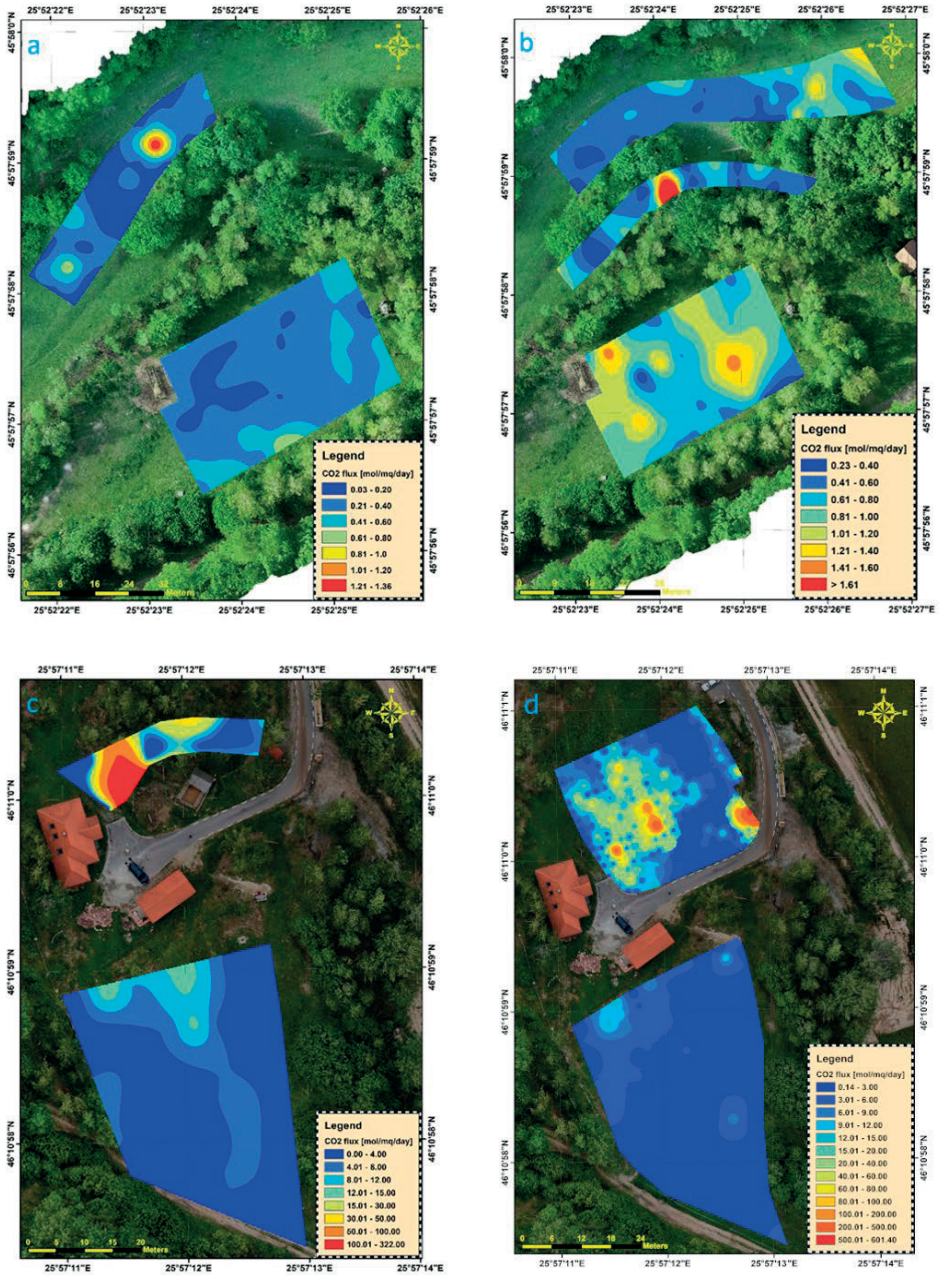

Figure 3. Flux maps at Bodoc 2024 (a), Bodoc 2025 (b), Lăzărești 2024 (c) and Lăzărești 2025 (d)

**Vegetation survey at Lăzărești**

The study area was also described in Stelea et al. (2025). It is a vegetated enclosure with built structures for balneotherapy and some terracing works. The area has a marked, but not steep slope, with Northern exposure. Vegetation is represented by trees (dominated by birches – *Betula pendula*, with hornbeams – *Carpenus betulus* and spruces – *Picea abies*), shrubs (*Salix capraea*, *Juniperus communis*) and herbaceous vegetation. Unlike for Bodoc, Lăzărești vegetation reaches its typical growth height, but

may be prevented to grow by anthropic intervention such as treading, mulching and by the presence of balneotherapy constructions. Herbaceous plants are generally vigorous although some are yellowed in appearance.
Mosses are present but they were not identified. Among pteridophytes are present *Lycopodium clavatum*, *Equisetum* sp., *Pteridium aquilinum* and *Athyrium filix-femina*. Dicotyledonous angiosperms are dominated as a number of species by the families Asteraceae, Caryophyllaceae, Fabaceae, especially genus *Trifolium*. Monocotyledonous angiosperms are dominated by order Poales, with families Poaceae, Cyperaceae and Juncaceae. Other monocots found were autumn crocuses (*Colchicum autumnale*), as well as unidentified orchids (missing reproductive elements at the time of the survey).

**Quantitative survey - comparison**

For the quantitative survey there were processed for Bodoc 107 points in 2024 and 131 in 2025. For Lăzărești 52 points in 2024 and 250 in 2025 were processed. By analysing the data from spring 2025, a new category of vegetation coverage has been identified in the form of dried plant organs, which can be an indicator of extreme stress or just a remnant from previous year. This identification leads to the reinterpretation of the autumn 2024 data, previously presented in Stelea et al. (2025).
Comparing the two surveys (Table 2, Figure 4) from the two separate campaigns, we can see that at Bodoc there is a similar proportion of healthy dicots and monocots in autumn 2024 but not in spring 2025, when there are more healthy dicots. At Lăzărești there are more healthy monocots than dicots in both campaigns.
Bodoc in the autumn of 2024 has plants with more dried organs than either Lăzărești or Bodoc in the spring 2025 campaign. The explanation for this phenomenon is the 2025 drought.
At Lăzărești in the spring of 2025 there are more dried plant organs than in the autumn of 2024, because they probably died during the cold season and had not yet decomposed or covered by new growth.
External elements, such as leaves, twigs, roots or unidentified and shaded elements are poorly represented at Bodoc in 2024. There are more external elements at Lăzărești in the spring of 2025 (mostly birch leaves) than in autumn 2024 or at Bodoc in both campaigns.
As minor elements there are mosses and pteridophytes. The percentages of bare ground are similar in 2025 in both Bodoc and Lăzărești, slightly higher in Lăzărești 2024 campaign and lower in Bodoc 2024 campaign.
"Indicator" plants were lacking from all studied points.
Based on soil coverage we calculated two indicators – "Healthy plants coverage" and "Monocots/Total angiosperms ratio".
"Healthy plants coverage" (Figures 5 and 6) represents the proportion of plants with healthy organs from the sample – monocots, dicots and pteridophytes. We excluded mosses from the calculation, because they were mostly dehydrated.
Typical values for Bodoc in spring 2025 are around the average of 65.5% with a standard deviation of 18.3%. Typical values for Lăzărești in the same campaign are around the average of 42.3% with a standard deviation of 23.7%. These values and the distribution show us that at Bodoc healthy vegetation generally covers a much higher proportion that at Lăzărești, but considering the results from the autumn of 2024, we consider that things can change with the influence of climatic factors and vegetation succession.

Table 2. Comparison between soil coverage categories at Bodoc and Lăzărești

| | Campaign | Dicots (%) | Monocots (%) | Stressed organs (%) | Dried organs (%) | Moss (%) | Pteridophytes (%) | Other (%) | Bare ground (%) |
|---|---|---|---|---|---|---|---|---|---|
| Bodoc | 2024 | 17.27 | 17.38 | 6.5 | 46.43 | 2.58 | 0 | 7.07 | 2.77 |
| | 2025 | 36.61 | 28.67 | 0.82 | 3.48 | 1.44 | 0 | 22.66 | 6.32 |
| Lăzărești | 2024 | 22.62 | 44 | 3.08 | 7.77 | 0.08 | 0.38 | 12.92 | 9.15 |
| | 2025 | 9.42 | 30.4 | 1.49 | 15.54 | 2.37 | 0.11 | 34.56 | 6.11 |

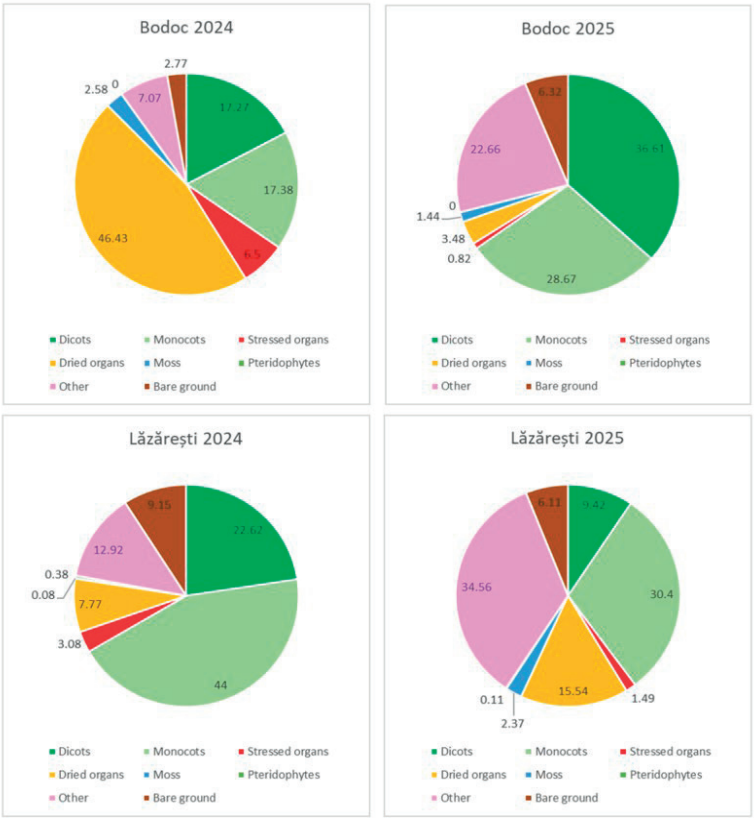

Figure 4 Comparison between soil coverage categories for Bodoc and Lăzărești in 2024 and 2025

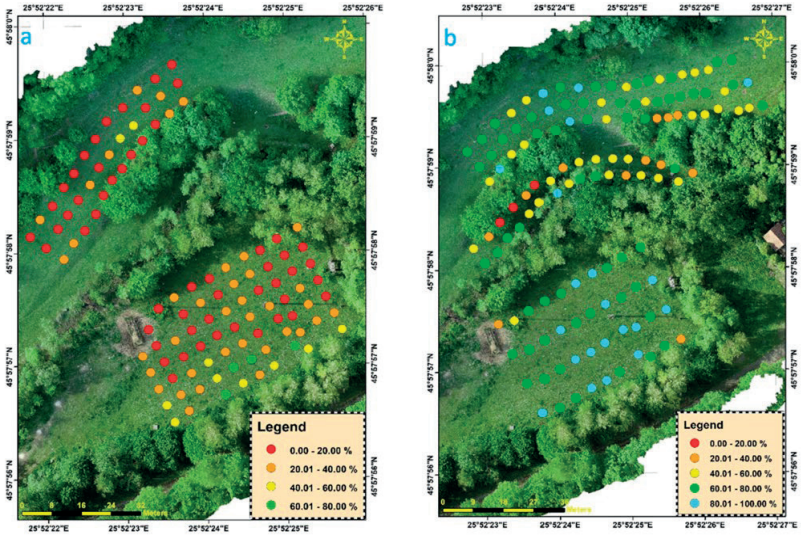

Figure 5. Healthy plant coverage at Bodoc in the 2024 campaign (left - a) and 2025 campaign (right - b)

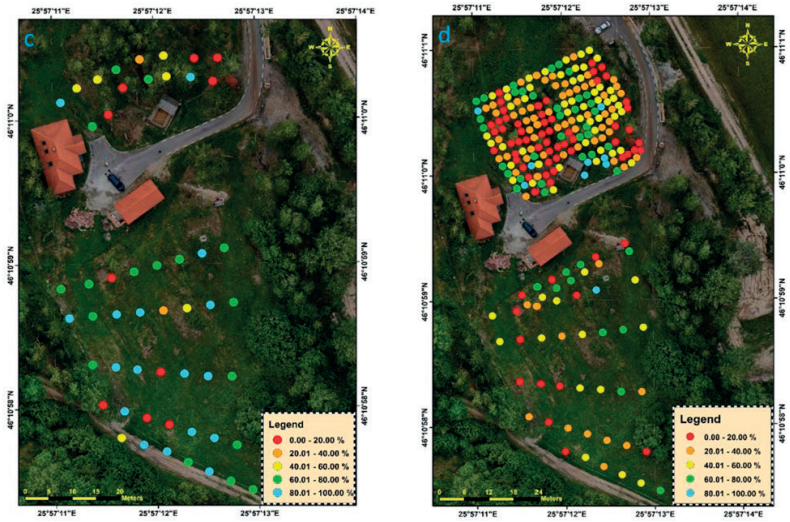

Figure 6. Healthy plant coverage at Lăzărești in the 2024 campaign (left - c) and 2025 campaign (right - d)

The monocots/Total angiosperms ratio represents the proportion of apparently healthy organs (leaves, stems, flowers, fruits) of monocots divided to the total of healthy angiosperms. The higher the value, the higher the chances of species substitution due to high fluxes of $CO_2$.

Typical values for Bodoc in 2025 are around the average of 43.3% with a standard deviation of 22.1%. Typical values for Băile Lăzărești are much higher, with an average of 72.6% but the distribution shows a strong increase of the values up to the maximum. These values and their distribution show us that at Lăzărești is a higher proportion of monocots, which is to be expected, but it is possible that with vegetation succession over the year these values and proportions can change.

**The relationship between the vegetation survey and the flux measurements at Bodoc and Băile Lăzărești in 2025**

We attempted to highlight quantitative relationships between the composition of soil coverage categories and the flux of $CO_2$. We have done this by identifying three categories of flux (high, intermediate and low) for both Bodoc and Băile Lăzărești. At first, we have tried a correlation analysis of individual samples with $CO_2$ flux but it did not give any significant results due to samples being too small and too variable. However, if summed up together we can observe some trends.

For Bodoc we established three categories – under 0.5 mol/m$^2$/day (relatively low flux), between 0.5 and 1 mol/m$^2$/day (relatively average flux), over 1 mol/m$^2$/day, up to 2.7 mol/m$^2$/day (relatively high flux) of $CO_2$ (Figure 7).

It can be observed at the three flux categories that with the increase of the $CO_2$ flux also increases the prevalence of healthy plants, especially monocots, and the bare ground percentage decreases. The neutral elements percentage is higher at a flux of $CO_2$ under 0.5 mol/m$^2$/day and approximately equal at higher fluxes (~21%). The dicot percentage is almost 31% at the relatively low flux and approximately equal at the relatively intermediate and high fluxes.

Higher $CO_2$ fluxes are associated with more plant coverage, especially of monocots. It is necessary, though, to repeat the measurements to see if these results were not due to chance.

Also, for Băile Lăzărești we established three categories – 0-10 mol/square meter/day (low flux), 10-49.(9) mol/square meter/day (intermediate flux), 50+ mol/square meter/day (high flux) (Figure 8). These categories are not the same as the ones used at Bodoc, because we have different orders of magnitude for the $CO_2$ flux.

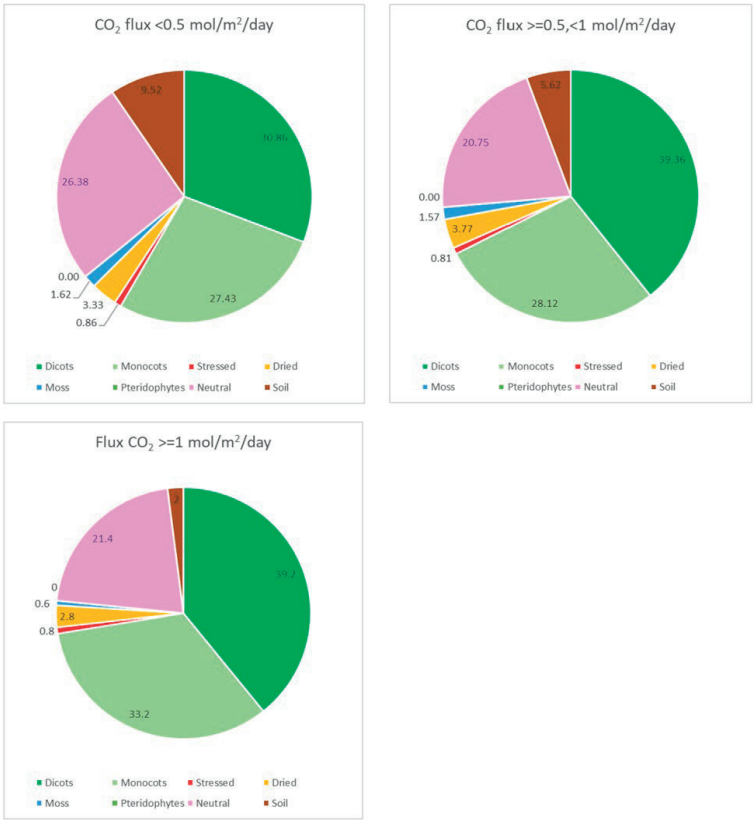

Figure 7. Soil coverage categories function of CO2 flux at Bodoc, 2025

We have analysed three subcategories of the low flux – under 0.499 mol/m$^2$/day, 0.5-0.999 mol/m$^2$/day and 1-3 mol/m$^2$/day to compare with results from Bodoc, but it was inconclusive, probably due to the small number of samples with such values.

Analysing the data and graphs with the soil covering categories coupled with $CO_2$ flux categories for Lăzărești we can see the following trends:

- A decrease of the ratio of healthy plants – monocots, dicots and pteridophytes. The indicator "Healthy plant coverage" decreases from the average of 43.7% for low flux, to 35.2% for intermediate flux and 12% for high flux.
- No change for the ratio of monocots/total angiosperms; even though the average values slightly decrease, a Mann-Whitney test performed on pairs reveals that the samples are statistically similar.
- A decrease of pteridophyte ratio.
- A decrease of dried plant organs ratio.
- A slight increase of moss coverage.
- A high increase of the surface covered by external elements and bare ground.
- Absence of "indicator" taxa.

As interpretation, it is considered that the decrease of surface covered by healthy plants is due primarily to soil and water acidification produced by $CO_2$ and associated gases. Differently from what we observed at Bodoc, higher values of $CO_2$ are not associated with richer vegetation, but poorer.

The decrease of the ratio of dried plant organs is related to the decrease of the ratio of healthy-looking plant organs. In the present case, we consider that dried organs are not primarily due to the toxic effect of $CO_2$ and other gases but represent a normal plant response to the cold season.

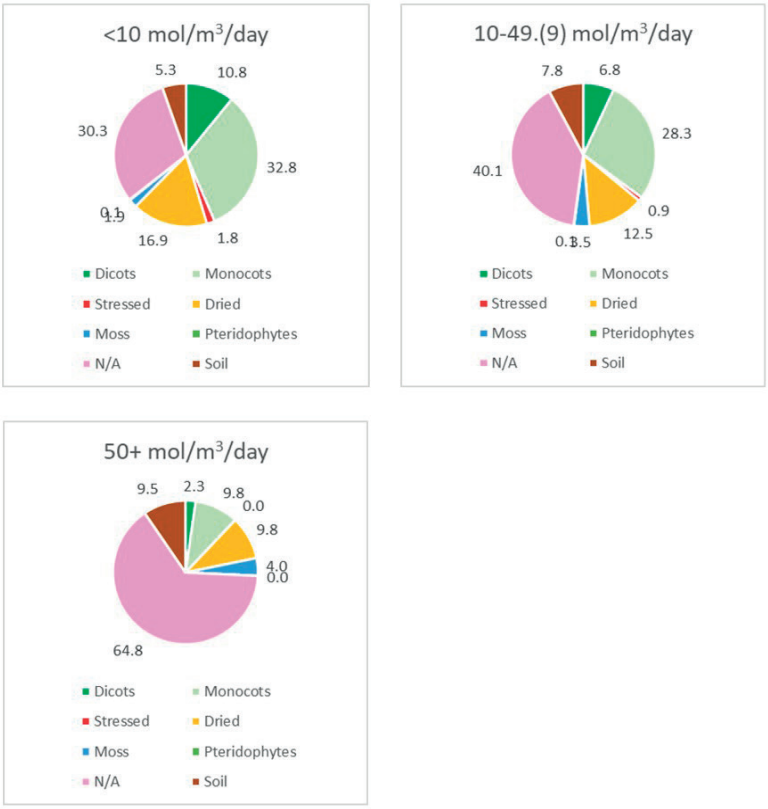

Figure 8. Soil coverage categories function of $CO_2$ flux at Lăzărești, 2025

Because the $CO_2$ flux did not start suddenly, like for the case of experimental grounds, but represented more or less a constant presence, we consider that the vegetation at Lăzărești is adapted to the high $CO_2$ fluxes, having relatively few organs with signs of stress (apart from the dried ones).

The lowering of the ratio of pteridophytes and the increase of mosses must be considered with caution, due to the small values of their presence and dominance. The increase of the surface occupied by external elements and bare ground is a good indication for the $CO_2$ flux, both directly, due to the toxic effects of the mofetta gases, as well as indirectly (the closeness to the mofettas with high concentrations of $CO_2$ can lead to a higher anthropic impact in those areas, which would affect the vegetation).

Lastly, the study areas did not contain known "indicator taxa" like the genus *Polygonum* or the species *Minuartia glomerata*. This does not mean that there aren't areas with abundant $CO_2$, but that the presence of "indicator" plants which are tolerant to high fluxes of $CO_2$ is not necessary. Other plant taxa strongly associated with high fluxes of $CO_2$ were not identified.

## CONCLUSIONS

The study evaluated the potential of vegetation surveys as an environmental monitoring tool for $CO_2$ geological storage and the presence of bioindicators that could be used as early signs of $CO_2$ leakage. In order to meet these objectives, vegetation surveys were conducted in two natural analogues relevant for geological $CO_2$ storage monitoring and representing different storage scenarios (one for safe storage and one for a leaking site) aiming to compare vegetation characteristics and to correlate where possible with different categories of $CO_2$ fluxes. Another aim of the study was to assess whether vegetation responses to increase $CO_2$ fluxes

described in the international literature are observable in the Romanian sites.

From the start, one conclusion is that the study areas are floristically too different to be readily compared. Bodoc area is a cattle pasture surrounded by an oak forest. Băile Lăzărești represents an ecosystem lacking large herbivores, but anthropically modified. There are biotope differences which are reflected in the species composition, with taxa which prefer higher humidity and colder climate present at Lăzărești.

The higher fluxes of $CO_2$ in the area of Bodoc, still close to the normal values, are associated with a higher prevalence of healthy plants, particularly monocots. In the area of Băile Lăzărești the higher fluxes of $CO_2$, significantly above normal, are associated with a decrease of the coverage by healthy and dried plants, and in the areas with the highest fluxes, vegetation is almost absent and bare ground is often found, which can also be due to anthropic factors.

The observed relationships between vegetation cover, plant functional groups, and soil $CO_2$ flux suggest that herbaceous vegetation may provide a useful complementary indicator for identifying areas affected by elevated $CO_2$ emissions at $CO_2$ geological storage sites. However, vegetation responses are strongly influenced by local ecological conditions and anthropogenic disturbance, limiting the use of vegetation alone as a qualitative monitoring tool.

As a limitation of the study, the observed trends appear at the sums of categories but not at the individual samples, which are too varied in composition and cannot be used for a correlation analysis. Vegetation monitoring should therefore be considered as a complementary component of integrated CCS monitoring strategies, to be used together with geophysical and geochemical methods rather than as a standalone indicator of $CO_2$ leakage.

An important limitation of the methodology is that soil flux measurements required the removal of inventoried vegetation at the sampling points, in order to achieve the airtightness required for the measuring chamber of the fluxmeter. This disturbance modifies the local plant assemblages over time by favouring opportunistic colonizing species, making long-term monitoring of identical points unreliable. For this reason, future studies should either establish adjacent non-destructive monitoring plots or periodically relocate sampling points.

Comparing this study to others performed on natural analogues in other countries has revealed the lack of potential "indicator species" for higher $CO_2$ values. Because of the random placement of the high, mid and low flux $CO_2$ points and their possibly inconsistent emission patterns as revealed by the flux maps, the concentric vegetation zonation present in places with well-individualized $CO_2$ vents is absent at Lăzărești.

## ACKNOWLEDGEMENTS

The research leading to these results was conducted within the project PN 23300404 “Development of an environmental monitoring methodology for potential $CO_2$ storage sites in Romania (Dezvoltarea unei metodologii de monitorizare de mediu pentru potențialele situri de stocare de $CO_2$ din România)”, financed by the Ministry of Research, Innovation and Digitalization of Romania through the Core Program (“Programul Nucleu”).

The authors also thank for the support of town halls of Cozmeni and Bodoc, who eased the access to the site and the proper running of the campaigns.

We are also thanking the reviewers for the suggestions provided to improve the manuscript.

***Abstract***

*This study aimed to evaluate the performance of several winter wheat (Triticum aestivum L.) varieties cultivated under the minimum tillage system in the semi-arid pedoclimatic conditions of Săcele, Constanța County (Romania) during the 2021-2024 agricultural years(October-July cropping cycles). The experimental design included four varieties: Avenue, Katarina, Rubisko, and Sorrial, monitored under variable rainfall regimes (330 mm in 2021-2022, 380 mm in 2022-2023, and <290 mm in 2023-2024). Morpho-productive parameters such as tillering capacity, plant height, grain number per spike, grain mass per spike, thousand kernel weight (TKW), and test weight (TW) were analyzed. The results represent the mean values of three consecutie agricultural years, highlighting varietal stability and adaptability under drought stress.*

*Among the tested varieties, Rubisko showed the highest productivity (5.9 t/ha), followed by Avenue (5.5 t/ha), Sorrial (5.0 t/ha), and Katarina (4.3 t/ha). Strong positive correlations were recorded between yield and TKW ($r = 0.94$), yield and TW ($r = 0.91$), and yield and NDVI ($r = 0.97$). The linear regression analysis confirmed a significant relationship ($R^2 = 0.93$, $p < 0.05$) between NDVI and yield, demonstrating that vegetation indices derived from multispectral UAV imagery and Sentinel-2 satellite data provide reliable and complementary information for predicting wheat yield under the studied conditions.*

*The study demonstrates that combining minimum tillage with precision agriculture technologies ensures sustainable and resilient wheat production in arid regions. The results support the integration of digital monitoring, biofertilization, and site-specific management as key components of climate-smart agriculture for southern Romania and similar environments.*

***Key words****: drought, minimum tillage, NDVI, precision agriculture, Triticum aestivum.*

## INTRODUCTION

Wheat (*Triticum aestivum* L.) is one of the most important field crops worldwide, playing a fundamental role in human nutrition due to its high nutritional value and technological versatility. In recent decades, adapting wheat cultivation to increasingly variable and often extreme environmental conditions has become a global agricultural priority (Xiong et al., 2024; Arif et al., 2025). Under the current climate change context: characterized by prolonged drought, heat stress, and large thermal fluctuations, enhancing wheat resilience through variety selection and sustainable technologies represents a strategic direction for agricultural development (Nyaupane et al., 2024; Shaheen et al., 2025). In the current context of accelerated climate change, the increase in land surface temperatures and the intensification of aridization processes are exerting growing pressure on agricultural systems, particularly in regions with high climatic vulnerability. Recent global-scale analyses highlight that changes in thermal and hydrological regimes directly affect agricultural productivity, ecosystem stability, and food security, generating significant economic and social impacts (Buzatu et al., 2024). At the same time, at the national level, the dynamics of land resources and the progressive degradation of soils require the adoption of sustainable conservation strategies aimed at reducing the negative effects of intensive agricultural practices on soil structure and fertility. In Romania, the implementation of conservative technologies and soil protection practices is considered essential for preventing physical and chemical soil degradation and for

adapting agricultural production systems to the new climatic conditions (Buzatu et al., 2023).

In Romania, winter wheat holds a significant share in the cropping structure, being cultivated across all agricultural regions. In the Dobrogea area, particularly around Săcele, Constanța County, the pedoclimatic conditions are distinctive, with low annual precipitation (350-450 mm), high summer temperatures frequently exceeding 35°C, and frequent dry winds factors that necessitate adapting cultivation technologies (Pascu, 2012; Partal et al., 2023). The dominant soils are cambic and leached chernozems, with medium to high natural fertility but prone to water loss through evaporation and structural degradation if excessively tilled.

In this context, the minimum tillage system, based on reducing soil disturbance and maintaining crop residues on the surface, has become a modern and sustainable technological solution for conserving soil water and fertility (Leonte et al., 2024; Dinuta et al., 2025). By decreasing the number and depth of tillage operations, this system helps preserve soil moisture, protect beneficial microorganisms, and reduce fuel and labor costs. Furthermore, it provides a favorable framework for the implementation of precision agriculture technologies, enabling optimized sowing, fertilization, and plant protection through the use of sensors and satellite data (Raza et al., 2025a; Haseeb et al., 2025).

Recent research conducted in southern Romania has demonstrated that conservative soil management systems such as minimum tillage, no-tillage, and strip-tillage practices, do not significantly reduce yields when adapted and resilient wheat varieties are used (Gheorghe & Nicolae, 2023; Nita et al., 2024). Studies performed at the Albota and Brăila research stations revealed that modern cultivars such as Izvor, Ursita, and Glosa maintain high productivity even under limited rainfall conditions (Ghiorghe et al., 2024; Dinuta et al., 2025). Moreover, the application of effective disease control treatments adapted to new climatic conditions plays a key role in ensuring yield stability (Grigoraș et al., 2012; Cioineag & Cristea, 2015; Iosub et al., 2022).

The integration of precision agriculture elements, such as UAV-based crop monitoring and remote sensing approaches (satellite-based observations), opens new perspectives for optimizing wheat crop management (Joshi et al., 2024; Qosimov & Imomov, 2025). Comparative analyses of conventional and organic systems, based on field experiments and long-term assessments, further indicate that conservative technologies such as: minimum tillage, no-tillage, and strip-tillage, as well as residue retention, reduce environmental impact while improving the sustainability of agricultural production (Kheiralipour et al., 2024; Zorovski, 2024).

Considering these aspects, the present study aims to evaluate the performance of several wheat varieties under the minimum tillage system in the pedoclimatic conditions of Săcele, Constanța County, during the 2021-2024 period corresponding to three consecutive agricultural years (October 2021 - July 2022, October 2022 - July 2023, and October 2023 - July 2024). The main objective is to identify the most adaptable varieties and the optimal technological practices within the minimum tillage system for achieving high, stable, and sustainable yields under the arid and variable climatic conditions characteristic of southern Dobrogea where Săcele is located. The results will contribute to the scientific foundation of regional strategies promoting sustainable agricultural practices and efficient use of local pedoclimatic resources, by supporting variety selection, optimizing minimum tillage management, and improving data-driven decision-making under arid conditions.

## MATERIALS AND METHODS

The present research was carried out within an agricultural holding located in Săcele, Constanța County, an area representative of southern Dobrogea, characterized by pedoclimatic conditions specific to the semi-arid regions of southeastern Romania (Stroe et al., 2025; Stroe et al., 2026). The area is distinguished by a moderately continental climate with marine influences, hot and dry summers, and relatively mild winters, where the annual rainfall is low, generally ranging between 350 and 450 mm. Under such conditions, the choice of cultivation technology and the selection of suitable varieties are essential for ensuring production stability.

The study area is located in the southern part of Constanța County, near the locality of Săcele, at an average altitude of 25-30 m, within the Dobrogea Coastal Plain. The relief is slightly fragmented, predominantly flat, and favorable for intensive mechanization and precision agriculture practices. The proximity to the Black Sea creates a distinct climatic influence, with very hot and dry summers, frequent winds, and high evapotranspiration rates, making this region one of the most vulnerable agricultural areas in Romania to the process of aridization.

The regional climate is continental-excessive with Pontic influences, characterized by large thermal amplitudes and a low rainfall regime. The multiannual mean air temperature is approximately 11.3°C, but recent years have shown a steady warming trend, consistent with regional climatic observations reported by Shi et al. (2025) and Xiong et al. (2024). During the analyzed period, the annual mean temperature ranged between 11.8°C and 12.9°C, with clear positive deviations from the long-term average, particularly in the 2022-2023 and 2023-2024 agricultural years, when maximum summer temperatures frequently exceeded 35°C.

The rainfall regime of the Săcele area is among the lowest in the country, and the 2021-2024 agricultural years further emphasized this trend: in 2021-2022, total annual precipitation was below 330 mm, with a pronounced deficit in September, March, April and June, leading to uneven emergence and weak tillering. In 2022-2023, the total rainfall reached approximately 380 mm, yet it was the warmest agricultural year of the entire period, with extended heat stress during stem elongation and grain formation. In 2023-2024, the recorded precipitation dropped below 290 mm, making it the fifth driest year in Romania's modern meteorological history. The absence of rainfall during the critical months of April and May coincided with the spike formation stage, intensifying water stress and reducing both grain weight and the number of fertile tillers.

The average annual wind speed ranges between 4.8 and 5.5 m/s, with prevailing northeasterly winds that further accelerate evapotranspiration and soil moisture loss, especially between April and August. These conditions strongly justify the adoption of minimum tillage systems, which, by reducing soil disturbance and maintaining crop residues on the surface, significantly decrease evaporation, preserve soil moisture, and protect soil structure (Leonte et al., 2024; Dinuta et al., 2025).

From a pedological perspective, the agricultural lands in the Săcele area are dominated by cambic and leached chernozems, developed on loess deposits, with a medium texture (from sandy-loam to loam-clay). The humus content varies between 2.8 and 3.5%, and the soil reaction is slightly alkaline (pH 7.7-8.0). These soils have moderate to good natural fertility but are highly susceptible to moisture loss and structural degradation under conditions of repeated deep tillage and prolonged drought. The water-holding capacity is moderate, estimated at 55-60% of field capacity, which limits the availability of soil water for plants during periods of intense hydric stress.

The experimental activity was conducted over three consecutive agricultural years: 2021-2022, 2022-2023, and 2023-2024, during which the influence of climatic variability on the behavior of several winter wheat varieties cultivated under the minimum tillage system was assessed. The collected data were processed by calculating mean values across the three experimental years to evaluate the overall performance and stability of the tested varieties under variable environmental conditions.

The minimum tillage system applied consisted of performing a reduced number of soil operations, limited to shallow loosening at 10-15 cm depth, partial retention of crop residues on the surface, and seedbed preparation using a light combinator, followed by direct sowing. This method helps conserve soil moisture, reduce wind erosion, and lower energy consumption, in line with the findings reported by Leonte et al. (2024) and Dinuta et al. (2025).

For the purpose of this study, four winter wheat varieties were selected: Avenue, Katarina, Rubisko, and Sorrial, each characterized by a high yield potential and different levels of adaptability to thermal and water stress. The variety Avenue is known for its good drought tolerance and stable performance under variable conditions; Katarina shows rapid autumn development and high winter hardiness; Rubisko stands out for its superior grain quality and high protein content; and Sorrial is

appreciated for its resistance to major foliar diseases and strong tillering capacity.

The wheat crop was established annually in October, during the optimal sowing period for southern Dobrogea, on land previously cultivated with rapeseed, considered one of the best preceding crops for wheat due to its positive effects on soil structure and reduction of disease and pest pressure in cereals (Georgiev et al., 2024). The sowing density ranged between 400 and 450 viable seeds per square meter, with a row spacing of 12.5 cm and a sowing depth of 5 cm, using a seeder compatible with the minimum tillage system.

Fertilization was applied according to crop development stages and climatic conditions in each year. Balanced NPK doses were used, supplemented with foliar fertilizers and biostimulants, which enhanced root development and increased resistance to abiotic stress (Cioineag & Cristea, 2015; Iosub et al., 2022). Specifically, basal fertilization consisted of NPK complex fertilizers (18-46-0) applied at sowing at a rate of 200 kg/ha, followed by nitrogen top-dressing (ammonium nitrate) applied in early spring (BBCH 21-25) at 100 kg N/ha. Foliar fertilizers and biostimulants based on micronutrients and humic substances were applied during stem elongation (BBCH 30–32). Weed control was achieved through selective herbicides applied post-emergence at recommended doses during early growth stages (BBCH 12–16), while disease management was ensured by modern fungicides adapted to warm and dry climatic conditions applied at key phenological stages (BBCH 31–39 and BBCH 51–59), as recommended by recent research (Nita et al., 2024).

Throughout the growing season, the crop was systematically monitored to capture the influence of climatic and technological factors on plant development. Observations focused on plant density at emergence and tillering, average height at maturity, spike formation, and crop uniformity. Before harvest, representative samples were collected to determine the main morpho-productive indicators: number of grains per spike, grain weight per spike, thousand-kernel weight (TKW), test weight, and average yield per hectare. For the assessment of fertile tillers per plant, measurements were conducted using a systematic sampling approach based on 1 m² observation areas (eight adjacent rows over a length of 1 m), with three replicates per variety. Within each sampling unit, plants were randomly selected and the number of fertile tillers per plant was recorded. Observations were performed at key phenological stages: after emergence (first true leaf stage, BBCH 11), before winter dormancy, after winter recovery, and prior to harvest. The collected data were averaged across replicates and subsequently across the three experimental years to reflect the overall performance and stability of the varieties under the studied conditions.

Crop monitoring was carried out using both multispectral UAV imagery and Sentinel-2 satellite data (10 m spatial resolution). For satellite-based monitoring, a total of 12 Sentinel-2 images were used, acquired during the three agricultural years (2021-2024) at key phenological stages, specifically during stem elongation and peak vegetation (BBCH 30–59). UAV-based data were collected through 6 flight campaigns conducted during the same phenological stages, with flights performed in each experimental year to capture crop development under different climatic conditions. The term “different climatic conditions” refers to the inter-annual variability in key environmental factors, including air temperature, precipitation, and soil moisture availability. These variables were characterized based on recorded meteorological data for each agricultural year and were considered when interpreting crop development and vegetation index dynamics, particularly in relation to drought intensity and water stress conditions. The acquisition dates corresponded to periods of maximum vegetative activity, ensuring comparability between years. To ensure transparency and reproducibility, the exact acquisition dates of the Sentinel-2 images used in the analysis are provided in Table 1. The images were selected based on cloud-free conditions and their correspondence to key phenological stages of crop development (BBCH 30–59), allowing consistent inter-annual comparison of vegetation dynamics.

Table 1. Sentinel-2 image acquisition dates and phenological stages (2021-2024)

| Year | Platform | Acquisition date | BBCH stage | Phenological description |
|---|---|---|---|---|
| 2022 | Sentinel-2A | 12-04-2022 | BBCH 31 | Beginning of stem elongation |
| 2022 | Sentinel-2B | 05-05-2022 | BBCH 37 | Flag leaf visible |
| 2022 | Sentinel-2A | 28-05-2022 | BBCH 55 | Heading |
| 2022 | Sentinel-2B | 15-06-2022 | BBCH 69 | End of flowering |
| 2023 | Sentinel-2A | 10-04-2023 | BBCH 30 | Start of stem elongation |
| 2023 | Sentinel-2B | 02-05-2023 | BBCH 39 | Flag leaf stage |
| 2023 | Sentinel-2A | 25-05-2023 | BBCH 55 | Heading |
| 2023 | Sentinel-2B | 12-06-2023 | BBCH 65 | Full flowering |
| 2024 | Sentinel-2A | 08-04-2024 | BBCH 30 | Stem elongation |
| 2024 | Sentinel-2B | 30-04-2024 | BBCH 37 | Flag leaf |
| 2024 | Sentinel-2A | 22-05-2024 | BBCH 55 | Heading |
| 2024 | Sentinel-2B | 05-06-2024 | BBCH 61 | Beginning of flowering |

Multispectral images acquired from both platforms were processed to derive the Normalized Difference Vegetation Index (NDVI) and other vegetation parameters, including canopy cover, vegetation vigor, and spatial variability of crop development. The combined use of UAV and satellite data allowed for a complementary assessment of crop conditions, integrating the high spatial resolution of UAV imagery with the temporal consistency of Sentinel-2 observations. For each UAV flight campaign, multiple overlapping images were acquired, with the number of images varying depending on the size of the monitored area and flight configuration. The acquired imagery was processed using a standard photogrammetric workflow, including image alignment, dense point cloud generation, and orthomosaic production, resulting in a georeferenced orthomosaic for each campaign.

Flights were performed under controlled acquisition parameters, with relatively constant flight altitude and overlap to ensure data comparability, resulting in high spatial resolution imagery (centimeter-level ground sampling distance, GSD). The main acquisition parameters and flight characteristics are summarized in Table 2.

Table 2. UAV flight campaigns and acquisition parameters (2021-2024)

| Campaign | Year | Date | No. images | Flight altitude (m) | GSD (cm/pixel) | Output | Climatic conditions |
|---|---|---|---|---|---|---|---|
| Flight 1 | 2022 | 14-04-2022 | 280 | 100 | 3.2 | Orthomosaic | Moderate temperature, low rainfall |
| Flight 2 | 2022 | 30-05-2022 | 310 | 100 | 3.1 | Orthomosaic | Warm, increasing water stress |
| Flight 3 | 2023 | 12-04-2023 | 290 | 100 | 3.2 | Orthomosaic | Favorable moisture conditions |
| Flight 4 | 2023 | 28-05-2023 | 320 | 100 | 3.0 | Orthomosaic | Optimal growth conditions |
| Flight 5 | 2024 | 10-04-2024 | 275 | 100 | 3.3 | Orthomosaic | Low soil moisture |
| Flight 6 | 2024 | 25-05-2024 | 300 | 100 | 3.2 | Orthomosaic | Severe drought conditions |

Harvesting was performed mechanically between June 25 and 30 of each experimental year, when grain moisture dropped below 15%. Samples were processed and analyzed following standard agricultural research methodologies. The data obtained were statistically analyzed using the analysis of variance (ANOVA) to identify significant differences among varieties and years, while Pearson correlation analyses were conducted to determine the relationships between yield components and environmental factors. The statistical processing of results ensured the accuracy and reliability of the interpretations, in accordance with the principles stated by Panaitescu et al. (2014).

The applied methodology was designed to assess the combined effects of the minimum tillage system, combined with appropriate variety selection and optimal crop management, contributes to achieving high and stable yields under the pedoclimatic conditions specific to the Dobrogea region. The data obtained were

comparatively analyzed and correlated with the climatic and pedological parameters of the Săcele area, in order to formulate practical conclusions applicable to modern farming practices, consistent with the principles of sustainable and precision agriculture (Haseeb et al., 2025; Raza et al., 2025b).

The cultivation technology applied in the Săcele area was designed to integrate principles of conservative soil management with elements of precision agriculture, through the use of digital tools for crop monitoring and resource optimization. The minimum tillage system consisted of reducing the intensity of soil operations and maintaining crop residues on the surface, thereby limiting water losses through evaporation and preserving soil structure. This approach is particularly suitable under the restrictive pedoclimatic conditions of Dobrogea, contributing to improved moisture conservation and reduced soil compaction (Leonte et al., 2024; Dinuta et al., 2025).

## RESULTS AND DISCUSSIONS

Under the pedoclimatic conditions of the Săcele area, the application of the minimum tillage system was associated with yield values ranging between 4.3 and 5.9 t/ha across the three experimental years. Despite pronounced interannual variability in rainfall, the system supported relatively stable crop development, as reflected by consistent morpho-productive parameters and strong correlations between NDVI and yield. These results indicate that minimum tillage contributed to maintaining wheat performance under drought-prone conditions.

The results further highlight that under increasingly restrictive climatic conditions characterized by rainfall deficits and thermal stress, conservative tillage technologies such as minimum tillage play an important role in ensuring yield stability and agroecosystem sustenability (Kheiralipour et al., 2024; Raza et al., 2025a; Shi et al., 2025).

To further characterize crop development under these conditions, vegetation indices such as canopy cover, vegetation vigor and spatial variability of crop development. Image aquisition was performed at key phenological stages particularly during stem elongation and peak vegetation (BBCH 30-59). These measurements provided essential information regarding crop density, uniformity of emergence, the degree of water stress, and nutrient use efficiency. The NDVI values recorded during the peak vegetation stage were correlated with yield using pooled data across all varieties, establishing a clear positive relationship between higher NDVI values and increased productivity, as also observed by Haseeb et al. (2025) and Joshi et al. (2024).

Complementary to these monitoring activities, a biofertilization program was implemented, based on natural formulations rich in beneficial microorganisms and humic acids. These products were used to stimulate soil microbial activity and enhance nutrient availability, contributing both to agronomic efficiency and to maintaining the ecological balance of the soil system, in line with the findings of Kheiralipour et al. (2024).

Disease and pest management were carried out through integrated plant protection strategies, tailored to the local climatic conditions and phytosanitary status of the crop. During years with high thermal stress and limited rainfall, foliar disease pressure: particularly powdery mildew (*Blumeria graminis f. sp. tritici*) and septoria leaf blotch (*Zymoseptoria tritici*), remained moderate, but preventive treatments were applied using systemic, broad-spectrum fungicides at calibrated doses according to phenological observations. Weed control was gererally low to moderate during the growing season, with dominant dicotyledonous species such as *Galium aparine* and *Stellaria media.* The applied control measures were effective in maintaining a low level of infestation without significant competition effects on crop development.

In the driest years (2021-2022 and 2023-2024), an increased presence of coleopteran pests: especially *Zabrus tenebrioides*, was observed, confirming findings reported by Talmaciu et al. (2024). This trend highlights the influence of drought and high temperatures on pest dynamics, which can intensify crop vulnerability under arid conditions.

The integration of precision agriculture tools, including Global Positioning Systems (GPS) and Geografic Information Systems (GIS), together with UAV-based monitoring,

contributed to a better identification of spatial variability in crop vigor and pest-affected areas. This approach supported more efficient crop management and improved the overall response to biotic and abiotic stress factors, in accordance with the principles of site-specific management (Raza et al., 2025b).

Overall, the technological package implemented under the minimum tillage system contributed to improved crop performance, as reflected by the obtained yield values (4.3-5.9 t/ha) and the strong positive correlations between yield and key indicators such as NDVI (r = 0.97), thousand kernel weight (r = 0.94). And test weight (r = 0.91). Under the restrictive pedoclimatic conditions of Dobrogea, the application of precision technologies and biofertilization supported efficient resource use and enhanced crop stability, as also indicated by the consistent performance of adaptable varieties such as Rubisko and Avenue (Gheorghe & Nicolae, 2023; Kheiralipour et al., 2024; Nita et al., 2024).

The average NDVI values recorded for the four analyzed wheat varieties (Avenue, Katarina, Rubisko, and Sorrial) show a distinct interannual variation across the growing seasons, closely related to the climatic and rainfall patterns of each year (Figure 1). The highest average NDVI values were recorded in the 2022-2023 agricultural year (with approximately 380 mm of annual rainfall and a mean temperature of 12.5°C), when the index ranged between 0.72 and 0.78, indicating a vigorous vegetative growth and high photosynthetic activity.

In contrast, during 2021-2022 and especially 2023–2024, NDVI values decreased significantly (0.58-0.68), which may be associated with prolonged pedological drought and thermal stress affecting green biomass development. The 2023-2024 season, with rainfall below 290 mm, was the most restrictive, leading to a reduction in active leaf area and irregular crop density, as also reflected by the lower NDVI values derived from UAV multispectral imagery (Figure 1).

Among the tested varieties, Rubisko consistently exhibited the highest NDVI values, indicating higher vegetation vigor and suggesting a better adaptability to the given environmental conditions, followed by Avenue and Sorrial. These differences are consistent with previous studies reporting stable performance of modern wheat varieties under conservative soil management systems, supporting the observed varietal differences in this study (Gheorghe & Nicolae, 2023; Dinuta et al., 2025).

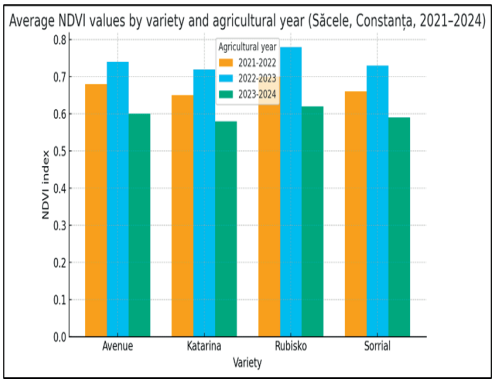

Figure 1. Average NDVI values by wheat variety and agricultural year (Săcele, Constanța, 2021-2024)

The correlation analysis between mean NDVI values and wheat yield across the three experimental years revealed a strong positive relationship (r = 0.97), confirming the reliability of NDVI as an early indicator of crop performance under precision agriculture systems (Figure 2). Higher NDVI values were directly associated with higher yields, reflecting the beneficial effect of a dense and healthy canopy on dry matter accumulation and grain filling.

The 2022-2023 agricultural year, characterized by relatively favorable rainfall distribution and moderate temperatures during grain filling, recorded the highest average yield (6.4 t/ha), corresponding to the maximum NDVI value (0.74). Conversely, the 2023-2024 season, marked by extreme drought and heat stress, showed the lowest NDVI (0.59) and an average yield of 4.1 t/ha, illustrating the strong sensitivity of winter wheat to hydric stress in arid environments. The close NDVI–yield relationship confirms the potential of multispectral imagery and vegetation indices as powerful tools for yield modeling and site-specific resource management. These results are in line with studies by Haseeb et al. (2025) and Raza et al. (2025a), which demonstrated that the

integration of optical sensors and remote sensing algorithms in agricultural monitoring systems allows optimized fertilization and phytosanitary treatments, reducing yield losses under extreme climatic variability.

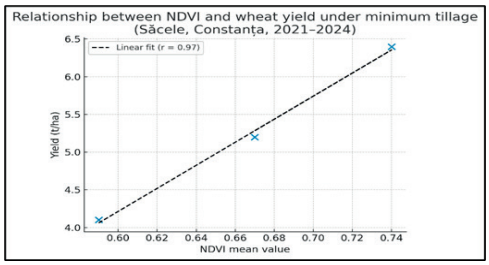

Figure 2. Relationship between average NDVI values and wheat yield across the three experimental years (inter-annual analysis) under the minimum tillage system (r = 0.97)

Under such pedoclimatic constraints, the implementation of the minimum tillage system in the Săcele area represents a well-adapted technological approach. By minimizing soil disturbance and maintaining crop residues on the surface, this system contributes to improved water-use efficiency, reduced fuel consumption, and erosion control, without significant yield penalties. These findings are consistent with results reported in other parts of Dobrogea (Ghiorghe et al., 2024; Nita et al., 2024).

Tillering represents one of the most important phenological stages in the development of wheat, having a decisive role in determining the yield potential by establishing the number of fertile tillers that contribute to the final spike density. This process is strongly influenced by soil moisture and temperature conditions during autumn and early spring, as well as by soil fertility and the cultivation technology applied (Panaitescu et al., 2014; Dinuta et al., 2025).

Under the pedoclimatic conditions of the Săcele area, characterized by low annual rainfall and mild winters, tillering occurred more slowly but uniformly, especially under the minimum tillage system, where crop residues retained higher moisture levels in the upper soil layers. The measurements revealed moderate differences between varieties, with average values ranging between 2.8 and 3.5 fertile tillers per plant, and a general mean of 3.1. The varieties Rubisko and Avenue showed the highest tillering capacity (3.5 and 3.3 fertile tillers per plant, respectively), due to their strong vegetative vigor and well-developed root systems, which allowed for better utilization of soil moisture. The variety Katarina exhibited a moderate tillering capacity (2.8 tillers per plant), typical for short-stature genotypes, while Sorrial recorded an intermediate value (3.0 tillers per plant), demonstrating balanced adaptation to both thermal and hydric stress.

The results confirm that the minimum tillage technology promotes more uniform tillering compared to conventional systems, due to better moisture conservation and reduced thermal fluctuations in the germination layer. Overall, the behavior of the analyzed varieties indicates a good adaptive capacity, with clear genetic differences among genotypes, an important advantage when selecting varieties suited to the pedoclimatic conditions of Dobrogea.

Plant height is a fundamental morphological indicator, reflecting each variety's ability to utilize available water and nutrient resources and to adapt to the pedoclimatic conditions specific to the cultivation area. Plant stature is influenced by both genetic characteristics and cultivation technology, as well as by soil fertility and climatic factors (Axinte et al., 2006; Panaitescu et al., 2014).

The measurements conducted in the agricultural area of Săcele, Constanța County, within the experiment carried out under the minimum tillage system during the 2021-2024 agricultural years, revealed notable differences among the analyzed varieties. The reported values represent multi-year means calculated across the three experimental years. The average plant height ranged between 83 cm and 92 cm, with a general mean of 88 cm for the entire experimental period. Among the four studied varieties, Rubisko exhibited the greatest height (92 cm), followed by Avenue (89 cm), Sorrial (87 cm), and Katarina, which showed the lowest height (83 cm) (Figure 3). These differences reflect both the genetic distinctiveness of each variety and their variable adaptive capacities to the restrictive conditions of the Dobrogea region, where rainfall is limited and thermal stress is frequent. The greater height of Rubisko can be associated with strong vegetative growth and enhanced ability to exploit deep soil moisture, an advantage conferred by its robust root structure and adaptability to semi-arid

conditions (Nita et al., 2024; Georgiev et al., 2024).

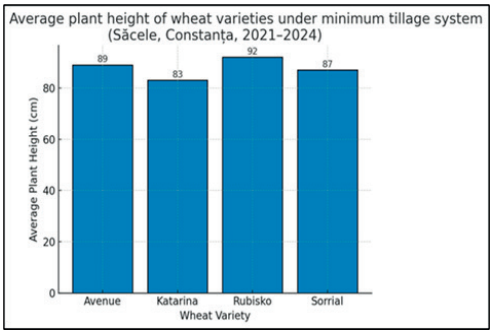

Figure 3. Average plant height of wheat varieties under minimum tillage system (Săcele, Constanța, 2021-2024, mean values across three experimental years)

The Avenue variety, although slightly shorter, displayed constant growth and high morphological stability, which was accompanied by elevated NDVI values recorded in the 2022-2023 season. In contrast, Katarina's shorter stature represents a genetically designed trait, offering increased lodging resistance and metabolic efficiency during dry years, when plants with extensive leaf area are more susceptible to excessive evapotranspiration. Sorrial exhibited intermediate behavior, showing balanced and uniform growth, well adapted to the minimum tillage system, which better preserves soil moisture in the active layer. The general mean height of 88 cm is slightly below the values reported for more humid regions of Romania, such as the Pecica-Arad area where higher plant heights have been observed under more favorable water conditions (Pop et al., 2024) a difference explained by the pedoclimatic characteristics of southern Dobrogea, where water stress limits vegetative growth (Leonte et al., 2024; Dinuta et al., 2025). Nevertheless, the relatively uniform values recorded for key morpho-productive parameters, such as plant height and tillering capacity, across experimental plots demonstrates a good adaptability of modern wheat varieties to local environmental conditions and confirms the efficiency of the minimum tillage system in maintaining balanced plant development. The results indicate that Rubisko performed best in terms of morphological development, followed by Avenue and Sorrial, while Katarina, despite its shorter height, stood out through stability and stress tolerance. The comparative analysis confirms that variety selection, combined with the application of conservative technologies, represents a key factor in ensuring uniform growth and a high productive potential under the pedoclimatic conditions of the Dobrogea region. The grain mass per spike and the number of grains per spike are key morpho-productive indicators of the agronomic value of wheat, being closely correlated with the final yield. Under the restrictive pedoclimatic conditions of the Săcele area: characterized by low annual rainfall (below 330 mm in 2021-2022, approximately 380 mm in 2022-2023, and below 290 mm in 2023-2024), these two traits reflected both the genetic differences among varieties and the influence of annual climatic variability on grain formation and filling processes.

The yield results showed clear differences among the analyzed wheat varieties across the three experimental years (Figure 4). In 2021-2022, the average yield was 5.2 t/ha, with higher values recorded for Rubisko and Avenue, while Katarina showed the lowest performance. In 2022-2023, the most favorable year, the average yield increased to 6.4 t/ha, maintaining the same varietal ranking. In contrast, during the driest year (2023-2024), the average yield decreased to 4.1 t/ha, although Rubisko and Avenue continued to exhibit better adaptability under drought conditions compared to Sorrial and Katarina. These differences were supported by statistical analysis (ANOVA, $p < 0.05$), confirming the significant effect of varietal characteristics and climatic conditions on yield performance.

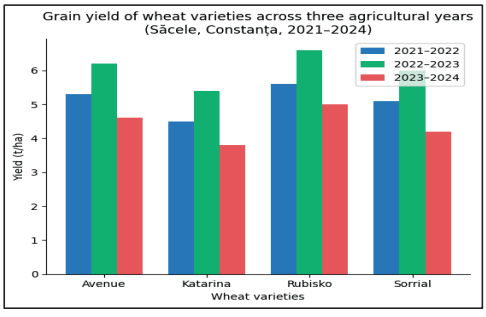

Figure 4. Grain yield of wheat varieties across three agricultural years (Săcele, Constanța, 2021-2024).

On average, Rubisko recorded 48 grains per spike and a grain mass per spike of 2.08 g, ranking first; Avenue registered 47 grains per spike and 2.02 g; Sorrial had 46 grains per spike and 1.98 g; while Katarina, despite its shorter stature and good stress resistance, reached 45 grains per spike and 1.93 g (Figure 5). The results show a positive relationship between the number and the mass of grains per spike across all varieties. Rubisko recorded the highest values (48 grains/spike and 2.08 g), confirming its superior fertility and adaptability under drought-prone conditions. Avenue and Sorrial exhibited stable intermediate performances, while Katarina had the lowest averages, consistent with its shorter and more conservative growth type. The data indicate that vigorous varieties achieved better grain filling under the minimum tillage system due to improved soil moisture conservation, and the observed differences were statistically significant (ANOVA, $p < 0.05$). The hierarchy correlates with both NDVI values and average plant height, suggesting that vegetative vigor and efficient water use under the minimum tillage system contributed to better grain filling and superior spike fertility. The differences among varieties were statistically confirmed through ANOVA, while positive correlations between the number and mass of grains per spike and yield were supported by correlation analyses, in agreement with previous studies reporting similar relationships between spike fertility, components and yield performance, where higher grain number and grain weight per spike were associated with increased productivity (Nita et al., 2024; Pop et al., 2024).

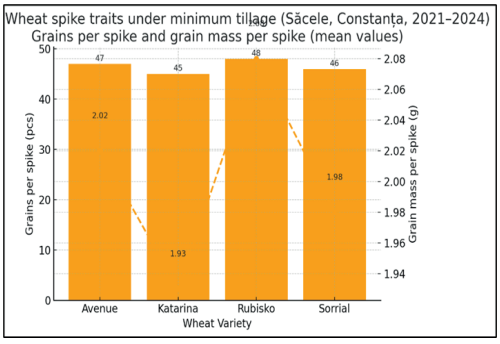

Figure 5. Wheat spike traits under minimum tillage (Săcele, Constanța, 2021–2024): grains per spike and grain mass per spike (mean values)

The thousand kernel weight (TKW) values recorded in this study ranged between 40.8 g and 44.1 g, reflecting differences in grain filling and varietal performance under pedoclimatic conditions of Săcele area. These variations indicate the influence of both genetic characteristics and environmental factors, particularly water avaibility and nutrient use efficiency during the grain filling period (Roman et al., 2013; Stroe & Panaitescu, 2025). Under the restrictive climatic conditions of the Săcele area, where the annual rainfall was below the multiannual average (≈330 mm in 2021-2022, ≈380 mm in 2022-2023, and below 290 mm in 2023-2024), TKW values ranged between 40.8 g and 44.1 g, with a general mean of 42.6 g. Among the tested varieties, Rubisko recorded the highest value (44.1 g), confirming its superior grain-filling capacity and resistance to water stress. Avenue (43.2 g) and Sorrial (42.5 g) showed intermediate values, while Katarina (40.8 g) had the lowest kernel weight, correlated with its shorter stature and more conservative growth rate (Figure 6).

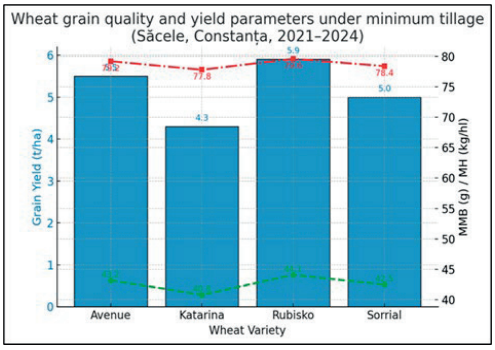

Figure 6. Wheat grain quality and yield parameters under minimum tillage (Săcele, Constanța, 2021-2024)

The test weight (TW), an indicator of grain density and physical quality, ranged between 77.8 and 79.6 kg/hl, with an average of 78.7 kg/hl. The high values recorded for Rubisko (79.6 kg/hl) and Avenue (79.2 kg/hl) indicate a complete grain filling and good physiological condition of the crop, even under drought conditions. Sorrial (78.4 kg/hl) and Katarina (77.8 kg/hl) showed slightly lower quality, but still within the standards for bread wheat.

Regarding grain yield, the average values obtained over the three agricultural years (2021-

2024) ranged between 4.3 and 5.9 t/ha, showing similar trends to NDVI and test weight (TW). The most productive variety was Rubisko with an average of 5.9 t/ha, followed by Avenue (5.5 t/ha), Sorrial (5.0 t/ha), and Katarina (4.3 t/ha).

The results confirm that the interaction between genotype and the minimum tillage technology, under accentuated drought conditions, significantly influences both the quality and productivity of the crop. Varieties with higher vegetative vigor and deeper root systems, such as Rubisko and Avenue, were more efficient in utilizing residual moisture and nutrients, maintaining good yield stability during dry agricultural years. The differences among varieties were statistically significant (ANOVA, $p < 0.05$), and correlation analyses revealed positive relationships between TKW, TW, and average yield, confirming that these indicators can serve as reliable predictors of yield performance in the arid climate of Dobrogea. The results highlight a clear positive relationship between grain yield, thousand kernel weight (TKW), and test weight (TW) across the studied wheat varieties. The variety Rubisko showed superior performance for all parameters, confirming its high adaptability and physiological efficiency under drought-prone conditions. Avenue also maintained stable yield and grain quality, while Sorrial and Katarina achieved slightly lower values, consistent with their more conservative growth patterns. The data demonstrate that varieties combining strong vegetative vigor with efficient resource use achieve both higher yield and better grain quality under the minimum tillage system in semi-arid regions.

The results revealed strong and relationships between morpho-productive parameters and agronomic performance particularly, between average yield, thousand kernel weight (TKW), test weight (TW), and the NDVI index.

The results revealed strong positive correlations between yield and TKW (r = 0.94), as well as between yield and TW (r = 0.91), confirming that well-developed grains and high endosperm density are key determinants of yield performance under drought conditions. Furthermore, the correlation between NDVI and yield (r = 0.97) suggests that NDVI can serve as reliable predictive indicator for estimating yield potential and supporting data-driven crop management decisions. The regression analysis indicated a significant linear relationship ($p < 0.05$) between NDVI and yield ($R^2 = 0.93$), demonstrating that variations in active biomass can explain over 90% of the yield variability under the climatic conditions of the study area. A strong positive linear relationship was observed between NDVI values and average grain yield across the studied wheat varieties ($R^2 = 0.93$). Varieties with higher NDVI, such as Rubisko and Avenue, achieved greater productivity, reflecting their superior vegetative vigor and efficient resource utilization under drought-prone conditions. The regression model indicates a strong relationship between NDVI and yield performance ($R^2 = 0.93$), suggesting the potential of NDVI as an indicator for yield estimation under minimum tillage systems (Figure 7). The NDVI values used in this analysis are higher than those presented in Figure 2, as they represent varietal averages derived from peak vegetation stages, reflecting maximum canopy development. The correlations between yield and other parameters such as thousand kernel weight (TKW) and test weight (TW), are presented based on numerical statistical analysis in the text, without additional graphical representation. While Figure 2 illustrates the NDVI–yield relationship based on inter-annual variability, the following analysis focuses on the varietal-level relationship, highlighting differences in crop performance among the studied wheat varieties.

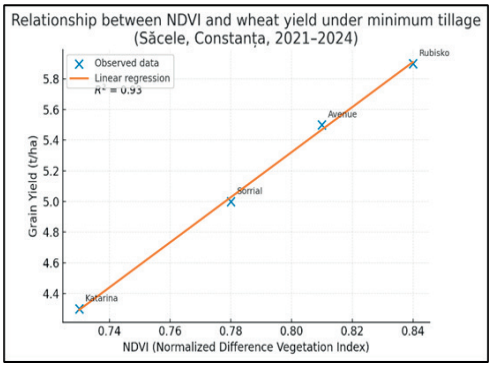

Figure 7. Relationship between average NDVI values and grain yield at the varietal level under minimum tillage (Săcele, Constanța, 2021-2024).

Within the experiment conducted in the Săcele area, the minimum tillage technology was

complemented by the application of precision agriculture tools aimed at optimizing crop management and monitoring plant development. Vegetation monitoring was carried out using both UAV multispectral imagery and Sentinel-2 satellite data, from which NDVI was derived to assess canopy uniformity and crop vigor across different phenological stages. Based on these data, fertilizer rates and phytosanitary treatments were adjusted accordingly, reducing over-application and improving cost efficiency. Variable-rate applications were performed using GPS-guided equipment and spatial data derived from UAV and satellite monitoring, ensuring precise and uniform distribution, thereby enhancing input efficiency and minimizing environmental impact. The integration of these digital tools demonstrated significant benefits in managing abiotic stress and maintaining a balance between productivity and sustainability, confirming the potential of precision agriculture in optimizing wheat cultivation under the arid climatic conditions of Dobrogea.

## CONCLUSIONS

The results obtained from the study conducted in the Săcele area, Constanța County, during 2021-2024, highlight the adaptability of the wheat varieties Rubisko and Avenue to the restrictive pedoclimatic conditions of Southern Dobrogea, as reflected by their higher yield performance and NDVI values under low rainfall and frequent thermal stress. The application of the minimum tillage system contributed to soil moisture conservation, structural stability, and reduced energy consumption in field operations.

Among the tested varieties, Rubisko consistently achieved the highest morpho-productive performance, with superior values for grain weight, test weight, and average yield (5.9 t/ha), confirming its enhanced efficiency in resource use and strong drought tolerance. The varieties Avenue and Sorrial demonstrated good yield stability and grain quality, making them suitable for conservative farming systems, while Katarina, though more moderate in growth, showed stable performance and can be recommended for areas facing pronounced water stress.

Statistical analyses revealed strong positive correlations between yield, thousand kernel weight, test weight, and NDVI ($r = 0.91$-$0.97$), while the linear regression analysis ($R^2 = 0.93$) indicated a strong association between NDVI and yield. These findings highlight the value of integrating precision agriculture tools, such as multispectral imaging and variable-rate input application, to support improved wheat management under drought-prone conditions.

In conclusion, combining minimum tillage practices with digital monitoring and the selection of locally adapted varieties contributes to stable wheat production under the pedoclimatic conditions of southern Dobrogea. It is recommended to expand future research through multi-location and long-term trials, focusing on the cumulative effects on soil fertility and resource efficiency, as well as on the integration of AI-based predictive models to improve climate risk forecasting and adaptive management strategies.

***Abstract***

*Key areas located in the northernmost part of Romania, within the Maramureș Mountains along the northern border with Ukraine, represent agro-mountain ecosystems of high value for environmental stability and regional ecological security. This cross-border area is exposed to increased anthropogenic pressures in the context of the armed conflict in Ukraine, which amplifies the vulnerability of environmental components, biodiversity, and ecosystem functionality. The study addresses the assessment of environmental impacts on soil, water resources, biodiversity, and habitat fragmentation through an integrated approach specific to environmental science and engineering. The methodology is based on environmental quality indicators, pedological and hydrological analyses, ecosystem condition assessment, multi-criteria evaluation methods, and GIS tools for the spatial analysis of pressures and impacts. The results highlight the need to implement preventive-oriented environmental protection measures aimed at biodiversity conservation and the reduction of ecological degradation risks in border regions. Romania–Ukraine cooperation is essential for the sustainable management of environmental impacts in transboundary areas affected by conflict-induced regional instability.*

***Key words****: environmental impact, key-areas, transboundary area.*

## INTRODUCTION

The Maramureș Mountains constitute a fundamental pillar of ecological stability in the northern part of Romania, representing a transboundary agro-montane ecosystem with a biodiversity of European importance. The importance of protecting environmental factors in this key area is emphasized by the status of a protected area (Maramureș Mountains Natural Park) and by the need to maintain the ecological security of the border with Ukraine (Ilieș et al., 2010). In the context of 2026, anthropogenic pressures on this ecosystem have diversified, being amplified by regional instability that generates additional risks for soil, water and habitats (Ukraine conflict environmental briefing: Nature, 2024). The degradation of environmental factors in border areas is not only a regional problem, but a systemic one, because habitat fragmentation and transboundary pollution can affect ecological connectivity across the entire Carpathian chain (Kuemmerle et al., 2011). The use of modern technologies, such as Geographic Information Systems (GIS) and remote sensing, has become imperative for monitoring these hard-to-reach areas, providing precise data on land use dynamics and ecosystem health (McGarigal, 2015; ESA, 2026). This paper analyzes these vulnerabilities and proposes preventive measures based on a multi-criteria environmental impact assessment.
The hydrographic structure of the Vișeu basin is defined by a series of lotic systems with sources in the Maramureș Mountains, among which the right tributaries Ruscova (39 km), Socolău (13 km) and Bardi (11 km) stand out (Curtean-Bănăduc et al., 2008; Bănăduc et al., 2011a, Curtean-Bănăduc et al., 2017). There are three administrative-territorial units (Poienile de Sub Munte, Repedea, Ruscova) with approximately 19,343 inhabitants in 2021 (National Institute of Statistics, 2023). As can be seen in Figure 1, this cross-border area is exposed to increased anthropogenic pressures, which amplifies the vulnerability of soil and water resources (Kucsicsa & Popovici, 2016), biodiversity and ecosystem functionality.
Among the monitored taxonomic units, fish present a heightened vulnerability to pressures

exerted by human activities, being directly affected by habitat changes and anthropogenic stressors (Năvodaru & Năstase, 2006; Bănăduc et al., 2011b; Florea, 2017; Khoshnood, 2017).

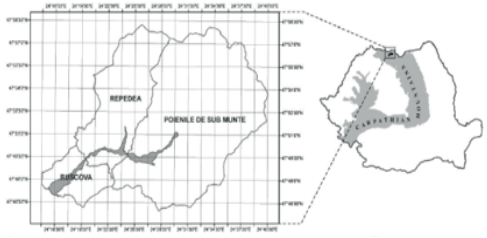

Figure 1. Valea Ruscova Depression (processing after) (Kucsicsa & Popovici, 2016)

## MATERIALS AND METHODS

The methodology uses GIS tools for spatial analysis of pressures (Kłapyta et al., 2024) and quality indicators related to environmental standards (Ministry of Water, Forests and Environmental Protection, 1997). The assessment of anthropogenic pressures on the ichthyofauna in the Vișeu basin must be carried out in accordance with national environmental quality standards (Ministry of Water, Forests and Environmental Protection, 1997). At the same time, given the transboundary nature of the watercourses in the region, their management is subject to international agreements for the protection of common water resources (Parliament of Romania, 1995), within the broader framework of environmental protection legislation (Parliament of Romania, 2005). The current configuration of the agro-montane landscape and the state of habitats in the Poienile de Sub Munte sector, observed during the field monitoring stages, are presented in Figure 2.
Spatial analyses carried out in the watersheds of the Maramureș Mountains (e.g. Ruscovei Valley) indicate a high vulnerability of water quality to anthropogenic influences, especially through increased nitrate concentrations from agricultural and domestic activities (Kucsicsa & Popovici, 2016). The use of Geographic Information Systems (GIS) allows the identification of critical areas where environmental factors and population density converge, generating risks of pollution of water resources essential for local biodiversity (Kucsicsa & Popovici, 2016).

Figure 2. Panoramic view of the study area in the Poienile de Sub Munte administrative unit; the mosaic of forest and agricultural habitats is observed (Source: Author's personal archive, 2024)

Monitoring environmental factors involves the use of status indicators that reflect the degree of anthropization and the risk of ecological degradation of protected areas (Coman, 2010). Mountain ecosystems are highly vulnerable to human interventions, degradation processes often being irreversible in the absence of well-structured conservation measures (Coman, 2010). Natural resource management in the Ruscova Corridor must align with the principles of sustainable development specific to Maramureș County, where the protection of fragile ecosystems is inextricably linked to the economic viability of local communities (Coman, 2006).
Digitalization of the management of resources involved in environmental protection facilitates superior team coordination in difficult areas, such as the Ruscova Corridor, ensuring clear traceability of field activities and interventions in vulnerable areas (Thira et al., 2025). This digital infrastructure allows for rigorous data collection necessary for the assessment of ecological security, which must take into account the transfer capacity of pollutants from soil to vegetation. The use of transfer indices similar to those analyzed in recent studies in the Maramureș region is essential to prevent risks of bioaccumulation in the food chain and to ensure food security for local communities (Filip & Coman, 2024; 2025).

## RESULTS AND DISCUSSIONS

The forests of Maramureș are under double pressure: on the one hand human activity/conflict, on the other hand drought and increasing temperatures in recent years, which

limit tree growth (Popa et al., 2024). The forests of Maramureș not only produce wood, but also provide ecosystem services (soil protection, water regulation, biodiversity) valued at impressive amounts. The study shows that the "conservation" scenario offers a much higher total value in the long term than intensive timber exploitation (Popa et al., 2016).

Sustainable management of mountain ecosystems must recognize soil not only as an agricultural resource, but as a strategic asset capable of providing vital ecosystem services (carbon storage, water filtration, biodiversity), fundamental for the ecological security of the region (Cioruta & Coman, 2022). Early studies on ciliates in the Tisza basin (Kovalchuk, 1997) established a baseline state of aquatic biodiversity. Comparing these data with recent monitoring (e.g. Bitušík et al., 2025) allows identifying the cumulative impact of pollution and climate change on the mountain lotic ecosystems of the Maramureș Mountains.

The sustainable management of the Ruscova Corridor must take into account the adaptability of forest species to climate change, given the high sensitivity of spruce and fir to thermal and water stress identified in the region (Popa et al., 2024). The protection of juniper habitats in the subalpine floor of the Maramureș Mountains is critical, given their role in stabilizing slopes and the presence of specific insect communities, such as Retinia rosinella, which require undisturbed habitats to maintain biological balance (Olenici & Semeniuc Fecioru, 2021).

It is not just a matter of visible pollution, but of a biological collapse: soil fauna can no longer mediate litter decomposition (Dou & Lin, 2026), while the main forest species are already at the limit of resilience due to thermal stress (Popa et al., 2024). Regional ecological security can be supported by integrating varieties improved for productivity and resistance into the local agricultural circuit, thus ensuring a stable fodder base, without resorting to excessive chemical fertilization, protecting biodiversity and water resources (Schitea, 2010).

Environmental protection in the Ruscova Corridor can be supported by encouraging local entrepreneurship in rural tourism. Digitalization of services and promotion of authentic cultural heritage reduce pressure on natural resources by offering a sustainable economic alternative to intensive forestry (Ciolac et al., 2022). Environmental protection in Maramureș must go hand in hand with the preservation of the historical and cultural testimonies of the communities, as these form the local identity that underpins any sustainable regional development initiative (Cioruță et al., 2023).

Climate change in the Eastern Carpathians is leading to earlier snowmelt, a process that, while initially increasing carbon sequestration capacity, drastically alters ecosystem dynamics throughout the growing season (Vought et al., 2025). Deforestation in the Ruscova Corridor not only reduces woody mass, but also destroys the ecosystem's ability to moderate maximum temperatures. This phenomenon, combined with earlier snowmelt (Vought et al., 2025) and the sensitivity of spruce to heat (Popa et al., 2024), creates a "cascade" effect that threatens regional ecological security (Abera et al., 2025).

The ecological security of the Pop Ivan transboundary area depends on the integrity of its peatlands, which function as critical carbon reservoirs. Retrospective studies (Deyl et al., 2023) establish a historical purity standard (pH 3.8-5.5 and conductivity below 40 µS/cm), any deviation from these values being indisputable evidence of anthropogenic or military pollution at the border. Alteration of this bio-chemical balance, corroborated with early snowmelt (Vought et al., 2025), risks transforming these bogs from carbon stores into massive sources of greenhouse gas emissions, accelerating the degradation of the mountain ecosystem.

Although current genetic diversity is robust, habitat fragmentation through massive logging or border infrastructure can isolate conifer populations. Curtu et al. (2009) emphasize the importance of maintaining gene flow; the isolation of these forest 'islands' would lead to a decrease in genetic resilience precisely at the moment when climatic stress (Popa et al., 2024) is at its highest. Given the unique genetic structure identified in Maramureș (Curtu et al., 2009), any ecological reconstruction effort must use exclusively local genetic material in order not to alter the evolutionary adaptability of these transboundary ecosystems.

Sustainable management is not a luxury, but an economic necessity. The loss of water regulation services through excessive logging in the border area will generate flood repair costs much higher

than the profit obtained from the sale of logs (Popa et al., 2016). Knowledge of the spatio-temporal evolution trends of forest resorts in the Maramureș Mountains is essential for local authorities. Herman et al. (2026) emphasize that tourism development is discontinuous and uneven, which requires specific ecological security policies for sensitive areas such as the Ruscova Corridor, to avoid landscape degradation that constitutes the very basis of tourist attractiveness.

The discovery of new species for the Romanian fauna in the Maramureș Mountains (Bitušík et al., 2025) imposes a more severe restriction of tourist activities near glacial lakes, in order to maintain the chemical and biological balance of these fragile ecosystems. Monitoring populations of endemic earthworms (e.g. Octodrilus species) is essential for assessing the health of alpine ecosystems. Soil degradation through intensive grazing or transboundary pollution (metallic or chemical) directly threatens these endemic species, endangering decomposition processes and nutrient cycling in the Pop Ivan meadows (Csuzdi & Pop, 2008).

International experience suggests that the success of conserving alpine landscapes, such as those on Pop Ivan, depends on increasing the resilience of local communities. The integrated development model proposed for Asian mountain regions can be adapted in Maramureș through green financing mechanisms and cross-border ecological education programs (Nasrullah, 2024). As Cioruta & Coman (2022) point out, any anthropogenic intervention in the Ruscova Corridor must be preceded by an analysis of soil functions correlated with meteorological factors. Soil degradation through mining or forestry activities (previously studied by Cioruță in a philatelic/historical context) irreparably alters water storage capacity, amplifying flood risks downstream.

The literary and spiritual heritage described in particular by Pop (2009) provides a solid basis for cross-border collaboration. In this context, protecting biodiversity on Pop Ivan Peak and in the Ruscova Basin should be a joint effort, based on the shared cultural heritage that unites the two banks of the Tisza. The protection of natural heritage, such as the Beech Forest (included in the UNESCO heritage), must overcome political barriers. Academic cooperation, as exemplified by the collaboration between the "Ștefan cel Mare" University of Suceava and Ukrainian partners (Coșofreț, 2017), represents the "keystone" for the ecological security of the entire Maramures area.

Recent studies conducted in the cross-border region of Ukraine emphasize the importance of constant monitoring of chemical elements in soil and plants, using vegetation as an indicator of nutritional conditions and the presence of toxic substances (Karbivska et al., 2025). Ecological reconstruction in the Maramureș Mountains highlights the importance of cross-border collaboration in monitoring high mountain ecosystems sensitive to climate change (Kłapyta et al., 2024). The Maramureș Mountains represent the northernmost area of the Romanian Carpathians that preserves traces of glaciation, offering unique habitats formed by complex geomorphological processes on the border between Romania and Ukraine (Kłapyta et al., 2024).

In Romania, the correlation between investments in environmental protection and the perception of quality of life is significant, highlighting the fact that a healthy ecosystem is the foundation of social well-being (Gheorghe, 2024b). The integration of digital solutions in the monitoring of environmental indicators facilitates a more efficient management of natural resources and allows a rapid assessment of the impact of anthropogenic activities on vulnerable habitats (Gheorghe, 2024b).

The harmonization of legislation and the increase in the number of operators in organic agriculture reflect a growing concern for sustainability in Romania, providing a favorable framework for the protection of protected natural areas (Gheorghe, 2023). The assessment of the pressure exerted by human consumption on the biosphere through the ecological footprint reveals the need for immediate measures to reduce the negative impact on natural resources and maintain the balance of ecosystems (Gheorghe, 2024a).

The rural region of the Maramureș Mountains possesses a vast natural and cultural heritage, the exploitation of which through the concept of Smart Tourist Village can ensure balanced development, while protecting local ecosystems from uncontrolled anthropogenic pressure (Ciolac et al., 2022). In order to ensure the conservation of habitats on the Ruscova

Corridor, we consider, based on the analyzed data, that it would be necessary to transition to a Smart Village development model, which would integrate sustainable tourism and organic agriculture, protecting the natural resources of the localities of Poienile de sub Munte, Repedea and Ruscova (Ciolac et al., 2022; Gheorghe, 2023).

According to the regulations of Order 756/1997, the area of the localities of Poienile de sub Munte, Repedea and Ruscova is classified as a sensitive use area, which imposes strict environmental quality standards to protect the health of the population and the integrity of the ecosystems. Even in the absence of large industrial centers, domestic activities and the historical use of fungicides can lead to local increases in Zn and Cu concentrations in the soil, a phenomenon that needs to be carefully monitored in the Ruscova Corridor to protect both terrestrial and aquatic ecosystems (Bošković-Rakočević et al., 2014; Kucsicsa & Popovici, 2016).

Combating the high-intensity anthropogenic pressure in the Ruscova Corridor requires an approach based on sustainable solutions, where landscape architecture plays a crucial role in the regeneration of degraded ecosystems and in the creation of natural barriers against pollutants (Ciobanu & Cebotari, 2025). The implementation of sustainable landscape projects in border areas can reduce the vulnerability of these agro-montane ecosystems, contributing to regional ecological security by utilizing the environmental cleaning function of selected vegetation (Ciobanu & Cebotari, 2025).

The continuous transformations of trade flows and the adaptation of customs legislation in the context of regional instability (Bahnă, 2026) also require increased vigilance in terms of monitoring environmental factors, in order to prevent the degradation of agro-mountain ecosystems on Romania's northern border. Although the economic development of the Ruscova Corridor is based on the exploitation of mountain potential, the relationship between tourism and environmental law remains tense (Bocancea & Braşoveanu, 2026). It is imperative that tourism activities do not ignore ecological regulations, in order to avoid transforming this natural refuge into an area degraded by excessive and unregulated tourism.

## CONCLUSIONS

Transboundary ecosystems in the Maramureș Mountains face heightened risks due to pressures induced by the armed conflict in Ukraine, requiring immediate preventive protection measures for soil, water and biodiversity. GIS and multi-criteria analyses reveal critical vulnerabilities in habitat fragmentation and pollution, underlining the economic superiority of conservation over ruthless resource exploitation.

Romania-Ukraine cooperation, based on shared cultural heritage and international agreements, is vital for sustainable management and regional ecological security. In this sense, the strategic framework provided by the joint operational programs (Ministry of Development, 2021) constitutes the necessary administrative pillar for the implementation of these measures.

Digital tools and local genetic resources must guide reconstruction efforts to maintain evolutionary adaptability and in the face of climate stress.

***Abstract***

*This study analyses the interaction between geotechnical risk, GIS-based territorial analysis, soil management, and the Romanian legal framework governing earthworks and environmental protection. The Borhanci area of Cluj-Napoca was selected as a case study due to recent large-scale grading operations associated with urban development. The methodology combined GIS analysis, urban planning documentation, field observations, photographic surveys, and legislative review. Field observations identified longitudinal and transversal fissures with depths ranging from 0.20 m to 1.30 m. Landslide susceptibility maps classified neighbouring slopes as medium, high and very high risk. The results indicate that extensive grading works may influence slope stability and drainage conditions in adjacent undeveloped terrain. The study highlights the need for integrated geotechnical assessment, territorial planning, and regulatory clarity regarding grading and levelling works.*

***Key words****: geotechnical engineering, GIS, landslide susceptibility, soil management, urban planning.*

## INTRODUCTION

Geotechnical and civil engineering activities, which involve interventions on the soil and subsoil, are governed by a complex legal framework in Romania. Ensuring the stability and quality of construction requires strict adherence to regulations pertaining to construction quality (Law No. 10/1995, republished; Order No. 27/2023), authorization procedures (Law No. 50/1991, republished), land improvement works (Law No. 138/2004, republished), and environmental protection measures (OUG No. 92/2021 and OUG No. 195/2005). The objectives pursued in this paper involve identifying legislative problems with geotechnical implications and examining the specific normative regulations regarding the authorization of earthworks, particularly land improvements and site grading and levelling works.

A major challenge constantly analysed is legislative insufficiency regarding the regulation of site grading and levelling works. While technical documentation requires geotechnical investigations and the inclusion of descriptions of external works, site grading and levelling works, the legislation governing building permits does not explicitly classify or regulate standalone works involving modifications to land elevation.

The significance of this issue is particularly evident in rapidly developing urban areas such as Cluj-Napoca, where hillside development frequently requires extensive terrain modification and grading operations. Previous studies conducted in the region have shown that urban expansion on sloping terrain requires careful consideration of slope stability, groundwater management and landslide risk assessment in order to ensure sustainable development and reduce geotechnical hazards (Mureșan, 2011; Farcaș et al., 2021).

Geotechnical engineering increasingly relies on Geographic Information Systems (GIS) for the integration, visualization and interpretation of spatially referenced data. GIS supports the assessment of geotechnical hazards, territorial planning and risk management by enabling the analysis of complex interactions between geological, geomorphological, environmental and anthropogenic factors (Player, 2006; Singh et al., 2018).

The emerging field of Urban Geosciences highlights the importance of combining geotechnical engineering, geology,

hydrogeology and land-use planning in order to support sustainable urban development. Within this framework, GIS-based analysis provides local authorities with an effective instrument for identifying landslide-prone areas, evaluating territorial constraints and supporting informed planning decisions (Azougay et al., 2020; Campagna and Deplano, 2002).

Modern geotechnical practice should integrate not only analytical knowledge but also information-based approaches, interdisciplinary decision-support tools and risk management strategies. Such an approach is increasingly considered necessary for addressing complex environmental and territorial challenges (Arciszewski, 2006; Chowdhury & Flentje, 2007).

The objective of this study is to analyse the interaction between geotechnical risk, GIS-based territorial analysis, soil management and the Romanian legal framework governing earthworks and environmental protection.

## MATERIALS AND METHODS

The present study focuses on the Borhanci district of Cluj-Napoca, Romania, an area that has undergone significant land-use changes through urban planning procedures enabling the development of educational, healthcare, sports and public infrastructure facilities. Borhanci was selected as a case study due to the presence of extensive grading works, slope modification activities and documented landslide susceptibility conditions.

The analysis was based on multiple data sources, including the Cluj-Napoca GIS platform, the General Urban Plan (PUG), the Local Urban Planning Regulation (RLU), PUZ documentation, landslide susceptibility maps, field observations, photographic documentation and Romanian legislation regarding construction, environmental protection and land improvement works.

GIS analysis was used to evaluate the spatial relationship between planned urban development areas and landslide susceptibility zones. Official GIS layers and planning documentation were analysed in order to identify territorial constraints and risk-prone sectors. Previous studies have demonstrated that GIS represents an efficient framework for integrating geotechnical, geological and environmental information into a common decision-support system, supporting hazard identification, risk evaluation and territorial planning processes (Chowdhury & Flentje, 2007; Singh et al., 2018). The GIS platform of Cluj-Napoca provides valuable spatial information supporting urban planning and geotechnical risk assessment and is increasingly regarded as an essential component of digital governance and smart city initiatives (Campagna & Deplano, 2002). The integration of GIS-based spatial analysis, planning documentation and field observations provides an effective framework for identifying areas exposed to geotechnical hazards. Similar multidisciplinary approaches have been successfully applied in studies addressing slope instability and urban development in the hilly areas surrounding Cluj-Napoca (Ilieș et al., 2016; Farcaș et al., 2021). Figure 1 illustrates the planning framework applicable to the study area through the General Urban Plan (PUG).

Figure 4 presents fissures and instability indicators identified during field observations within the Borhanci study area.

A legislative review was conducted in order to analyse the legal framework governing construction activities, land improvement works, environmental protection and waste management. The analysis included Law No. 50/1991, Law No. 138/2004, Government Emergency Ordinance No. 92/2021, Government Emergency Ordinance No. 195/2005, as well as relevant urban planning regulations applicable to the study area. The legislative review was performed in parallel with the GIS analysis and field investigations in order to evaluate the interaction between geotechnical risk, territorial planning and environmental governance.

## RESULTS AND DISCUSSION

### 1. Legal Framework of Land Improvements

The regulation of land improvements is governed by Law No. 138/2004, with methodological norms approved by Government Decision No. 1.872/2005. Land improvement works are indispensable for the sustainability of agricultural land and soil quality, as well as for overall territorial protection.

Land improvements have several crucial objectives:

- Territorial Protection: Providing protection for lands of any kind and any categories of structures against floods, landslides, and erosion. This goal also includes regulating water courses and protecting accumulation lakes against silting.
- Soil Management: Ensuring an adequate level of soil moisture and the improvement of acidic, saline, and sandy soils (soil improvement), as well as providing protection against pollution.

These activities must be performed in compliance with environmental protection standards (Law No. 138/2004).

Land improvements consist of complex hydrotechnical, and soil improvement works that require a construction permit according to Law No. 50/1991. These works include:

- Irrigation and Rice Paddies: Including water catchment, pumping, transport, distribution, and evacuation works, and, where appropriate, site grading works.
- Desiccation and Drainage: Networks of structures, pumps, canals, and pipes used to prevent and remove excess water. The infrastructure includes components like canals and pumping stations.
- Erosion Control and Landslide Mitigation: Works aimed at preventing, reducing, or halting land degradation processes. These include soil protection measures, regulation of surface runoff on slopes, torrent control, and stabilization of loose sandy soils. Land improvement organizations may be established specifically for erosion control purposes.
- Soil improvement works: Works on saline, acidic, or sandy soils, including land levelling and modelling, scarification, deep loosening, and water drainage channels.

– Embankments and regulation of water courses.

The scope of these works clearly indicates that they involve significant earth moving and geotechnical interventions (Law No. 138/2004).

The infrastructure assets of land improvements, such as the secondary irrigation network in the private domain of the state, are administered by the National Agency for Land Improvements (ANIF) and can be transferred to legally constituted Land Improvement Organizations (OIFs) (Law No. 138/2004).

Law No. 138/2004 prescribes sanctions for unauthorized activities in these areas:

– Executing constructions, or modifying or extending constructions within land improvement facilities, without the prior authorization of the ANIF, organizations, or federations.
– Carrying out excavations, borrow pits, or trenches in embankments or their protection zones, or extracting materials from defence works, without the Agency's prior consent.

**2. Soil Management and Environmental Considerations**

The management of soil and excavated materials represents a key component of geotechnical risk prevention and environmental protection. Modern approaches increasingly emphasize the integration of geotechnical engineering, territorial planning and environmental governance in order to minimize the impact of earthworks on slope stability and land-use sustainability (Chowdhury & Flentje, 2007; Azougay et al., 2020).

The regulation of waste is critical in geotechnical projects involving earth movement. The framework aims to ensure a high level of protection for the environment and public health.

OUG No. 92/2021 excludes certain soil categories from the waste regime:

– Soils (in situ), including uncontaminated excavated soils and buildings permanently attached to the ground.
– Uncontaminated soils and other natural geological materials excavated during construction activities, provided there is certainty that the material will be used for construction in its natural state and on the site from which it was excavated.

If soil is moved off-site or utilized for uncontrolled filling (site grading works), its status can change, potentially classifying it as waste.

From a geotechnical perspective, the management of excavated materials is directly linked to slope stability, drainage conditions and the prevention of environmental degradation. GIS-based territorial analysis can support the identification of risk-prone sectors and contribute to more sustainable land management practices (Player, 2006; Singh et al., 2018).

Backfilling is explicitly defined as a recovery operation (R5 or R12 in the recovery operations list - OUG No. 92/2021), which is one of the preferred options in the waste hierarchy, above elimination. Backfilling involves the use of adequate non-hazardous materials for site restoration or landscaping purposes. The waste used for backfilling must replace non-waste materials and be limited to the strictly necessary quantity.

However, materials that no longer hold waste status and are used for backfilling are not considered towards meeting recycling objectives. Furthermore, placing waste (D1) in or on the ground (e.g., landfills) or burying any kind of waste is an offense (OUG No. 92/2021).

The environmental framework establishes principles such as the preventive action principle and the "polluter pays" principle. Holders of activities have the obligation to manage waste without endangering public health or damaging the environment, particularly without generating risks of contamination of air, water, soil, fauna, or flora (OUG No. 92/2021).

The lack of explicit authorization for site grading and levelling works in Law 50/1991 is particularly critical because unauthorized or uncontrolled deposits of soil, especially if classified as waste, violate fundamental environmental obligations and pose a direct threat of geotechnical stability. This directly contradicts the objective of land improvements to provide territorial protection against landslides. Failure to implement proper technical solutions for backfilling or slope

alterations results in a significant risk of landslides, a specific natural risk addressed in urban planning regulations.

The findings presented above demonstrate that soil management cannot be analysed solely from a legal perspective. The geotechnical consequences of uncontrolled filling activities include changes in drainage patterns, increased loading on slopes, and the potential activation of instability processes. Therefore, the integration of environmental legislation, geotechnical assessment and GIS-based territorial analysis is essential for sustainable land management and risk prevention (Chowdhury & Flentje, 2007; Singh et al., 2018).

## 3. Legislative Gaps and Proposed Solutions

Based on practical experience and the findings presented in this study, one of the most debated issues concerns the insufficient regulation of site grading works.

Although Law No. 50/1991 requires permits for "land improvement works" (which implicitly cover land levelling and modelling), it fails to explicitly include or sanction "site grading and levelling works involving changes in land elevations". This omission in the construction law framework creates disparate applications across local authorities and inconsistencies in permitting practices.

From a geotechnical perspective, insufficient regulation of grading and levelling works may lead to inconsistent implementation practices and difficulties in evaluating long-term impacts on slope stability. Similar concerns have been highlighted in studies addressing the integration of engineering practice, risk management and territorial planning (Arciszewski, 2006; Player, 2006).

In the case of general construction, the technical documentation must show the measures taken for the protection of neighbouring buildings' foundations, demonstrating that changes in site conditions (including site grading and levelling works) inherently impact structural stability.

The draft Code of Spatial Planning, Urbanism, and Construction aims to address this regulatory shortfall. This proposed legislation (which would eventually repeal Law No. 50/1991 and Law No. 10/1995) explicitly classifies land development works, including earthworks and external works, as requiring authorization. Under the proposed code, land arrangement operations, including demolitions, deforestation, site grading and levelling works, access roads, retaining walls, and drainage, are clearly listed as works that must be authorized.

In the light of the above analysis, the adoption of the new Code of Spatial Planning, Urbanism, and Construction may be considered necessary, particularly in view of its explicit regulation of external works and land development operations. Furthermore, the provision of clear and consistent solutions to divergent interpretations in practice is essential to ensure a coherent understanding and effective enforcement of the legal framework. Such clarification would contribute to addressing existing regulatory gaps concerning the aforementioned works and would facilitate both the proper application of the law by inspectors and local authorities, as well as its consistent interpretation and implementation by architects, engineers, and construction professionals.

## 4. Case Study: Implementation of Local Urban Planning Regulations in the Municipality of Cluj-Napoca (General Urban Plan (PUG) analysis)

Within the context of national legislative deficiencies regarding the explicit authorization of site grading and levelling works, the Local Urban Planning Regulation (RLU) related to the Cluj-Napoca General Urban Plan (PUG), Figure 1, institutes a set of strict constraints for specific intra-urban and extra-urban zones, aimed at territorial protection and slope stability.

The analysis of functional sub-zones highlights a systematic concern for the preservation of natural soil conditions and the mitigation of geotechnical risks, having selected all functional zones within the extra-urban area (Agricultural land - arable land, pastures, hayfields, tree nurseries, etc. (TDA), Agricultural land - orchards (TDA_L), Forested land (TDF)), while specifically focusing on agricultural lands, green spaces, and forests for the intra-urban area (Non-urbanized agricultural land (A), Non-urbanized and non-developable agricultural land - orchards (AL), Area designated for recreational activities

carried out in a natural setting, in proximity to forests located within or outside the intra-urban area (Aapp), The area includes sections of the corridors of the Someșul Mic River and the Morii Channel, comprising minor riverbeds, hydrotechnical works, riverbank arrangements, green strips or spaces, pedestrian and bicycle circulation routes, urban furniture, as well as protection strips along secondary watercourses (streams) located on the slopes (Ve), The area includes - green spaces with a protective function in relation to major infrastructure; main electricity and natural gas transmission networks, railway and road corridors; green spaces with a sanitary protection role for active or closed landfills and wastewater treatment plants; green areas designated for the ecological restoration of degraded land; plantations intended to stabilize steep slopes resulting from anthropogenic interventions or affected by natural landslide risks (VPr), Forested land located within the intra-urban area, introduced through urban planning documentation prior to the revision of the Romanian Forestry Code (2008). Subzone of forests designated for recreational use and subzone of pastures / hayfields within forested areas (VP)).

GIS-based territorial analysis provides an effective framework for integrating urban planning restrictions with geotechnical risk assessment. Such approaches enable the identification of environmentally sensitive sectors and support sustainable land-use management (Campagna & Deplano, 2002; Singh et al., 2018).

The analysis of intra-urban functional zones highlights a systematic concern for the preservation of natural soil conditions and the mitigation of geotechnical risks:

- A, AL: The preservation of the existing land-use structure is mandatory to maintain ground stability. Permitted uses include crops and land improvement works, while conditional works allow for greenhouses (>1 ha) and agricultural annexes (max. 10% Land Occupancy Percentage (P.O.T.) for A; 5% for AL). The discharge of wastewater and rainwater into natural watercourses is strictly prohibited, requiring on-site management solutions to prevent erosion processes. Additionally, all categories of waste must be managed in accordance with applicable regulations, to avoid the formation of uncontrolled deposits of excavated material.
- Aapp: Earthworks and, site grading and levelling works interventions that may affect public infrastructure or adjacent parcels are explicitly prohibited. Furthermore, a significant proportion of green space on natural soil (60–80%) is required, thereby limiting anthropogenic intervention.
- Ve, VPr: Permitted works include plantations and hydrotechnical works. The VPr zone is designated for afforestation and vegetation-based interventions aimed at stabilizing slopes with inherent landslide risk, as well as for the ecological restoration of degraded land. Within these areas, the P.O.T. is set at 0%, effectively prohibiting any construction activities involving alterations to ground morphology.
- VP: The RLU explicitly prohibits all forms of earthworks and site grading and levelling works interventions within forested areas. Only forestry exploitation and essential infrastructure are permitted, maintaining the P.O.T. at 0%.

In the extra-urban territory, the PUG focuses on maintaining ecological balance and preventing land degradation:

- TDA, TDA_L: Like intra-urban rules, it is forbidden to discharge water into slope watercourses, mandating on-site management to avoid soil transport. Permitted annexes are strictly limited to a maximum P.O.T. of 10% of the designated area (5% for orchards), while the remainder of the land must retain its natural state.
- TDF: To ensure "land stabilization" near the city, the PUG imposes severe restrictions, prohibiting all earthworks and site grading and levelling works, as well as any permanent constructions.
- The P.O.T. is strictly maintained at 0%.

A compelling example of how land-use modifications and large-scale site grading works can influence the morphological stability of adjacent terrains is provided by the Borhanci

area, located in the south-eastern part of the Cluj-Napoca municipality, near the Apahida-Vâlcele bypass road. This case study illustrates the geotechnical challenges encountered in rapidly developing urban areas where significant interventions occur on sensitive slopes.

The Borhanci development area represents a relevant example of the interaction between urban expansion, terrain modification and geotechnical risk. GIS-based analysis facilitates the assessment of territorial constraints and provides decision-makers with spatial information regarding landslide susceptibility and environmental vulnerability (Azougay et al., 2020).

According to the analysed documentation, this sector was initially classified under the General Urban Plan (PUG) of Cluj-Napoca as non-urbanized agricultural land incorporated into the intra-urban area (A). This status was subsequently modified through a Zonal Urban Plan (PUZ), Figure 2, approved by Local Council Decision (HCL) No. 510/2022 (later amended by HCL No. 645/2025), redesignating the area as Institutional and Public Interest Services Zone (Is Borhanci). This legal transition facilitated the development of a major infrastructure project, including an educational hub, healthcare and sports facilities, and a forest park.

The comparison between the planning documentation and the GIS-based territorial analysis indicates that significant grading operations were implemented in an area surrounded by sectors presenting varying degrees of landslide susceptibility.

While the construction platforms for the educational hub are being executed based on rigorous geotechnical investigations field observations indicate increased vulnerability in the adjacent terrains. GIS analyses and official risk maps classify the slopes in this area as having medium, high, and very high landslide susceptibility, Figure 3.

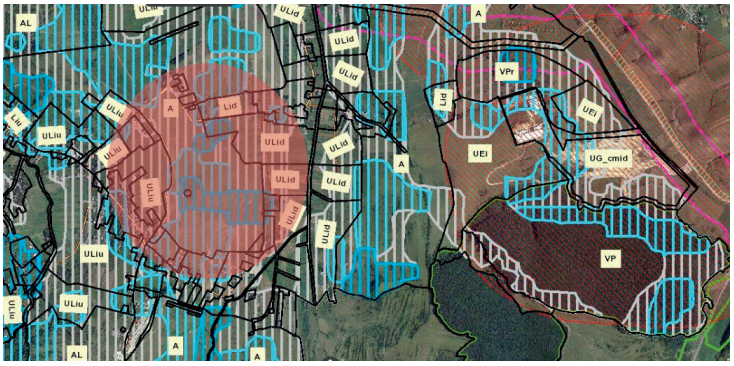

Figure 3. Studied area showing landslide susceptibility zones identified through GIS analysis: medium to high risk (grey), high risk (light blue), and very high risk (dark blue)

The GIS results demonstrate the importance of integrating landslide susceptibility information into urban planning decisions. Previous studies have shown that GIS-based risk mapping represents one of the most efficient tools for identifying sectors requiring enhanced monitoring and geotechnical investigation prior to the implementation of major earthworks (Bezerra et al., 2020; Singh et al., 2018).

At present, on the southern slope directly bordering the sites, where extensive site grading works have been carried out, active soil instability is evident. As this adjacent land has remained undeveloped (retaining the characteristics of the former agricultural Zone A), it serves as a natural indicator of the geotechnical stresses affecting the area (Table 1):

– Structural soil manifestations: Transversal and longitudinal fissures have developed within the non-homogeneous and uncompacted soil mass, with significant depths ranging from 0.20m to 1.30m, indicating structural failure within the soil mass, Figure 4.

- Morphological deformations: Multiple rupture zones and so-called *"slip surfaces"* (natural step-like terraces) have been observed, indicating that the shear strength of the soil has been exceeded under the influence of natural and anthropogenic factors.
- Hydrological indicators: The presence of hygrophilous vegetation confirms water stagnation or inadequate drainage, with excess moisture acting as a primary trigger for landslide processes.

Figure 4. Field photograph highlighting longitudinal and transversal soil fissures, suggesting active deformation processes

Table 1. Main geotechnical observations identified in the Borhanci study area

| Indicator | Observation |
|---|---|
| Minimum fissure depth | 0.20 m |
| Maximum fissure depth | 1.30 m |
| Fissure orientation | Longitudinal and transversal |
| Landslide susceptibility classes | Medium, High, Very High |
| Hydrological indicators | Hygrophilous vegetation |
| Morphological indicators | Rupture surfaces and local deformation |

The field observations indicate active deformation processes affecting adjacent undeveloped terrain. The identified fissures, rupture surfaces and hydrological indicators are consistent with instability phenomena commonly reported in areas affected by slope modification and inadequate drainage conditions. The integration of field observations with GIS-based analysis provides a more comprehensive understanding of local geotechnical risk conditions (Player, 2006; Azougay et al., 2020).

The Borhanci case highlights the critical importance of water management and controlled drainage, as well as the continuous monitoring of adjacent areas, in accordance with the principles set out in Land Improvement Law No. 138/2004. Although the authorized works benefit from dedicated geotechnical studies, the current lack of a unified national regulation under Law No. 50/1991 regarding the explicit authorization of ground elevation changes (site grading) makes it difficult to enforce preventive measures across the entire Territorial Reference Unit (UTR).

## CONCLUSIONS

The legal framework governing geotechnical engineering requires a coherent correlation between construction authorization (Law No. 50/1991), land improvement regulations (Law No. 138/2004), and environmental protection legislation (OUG No. 195/2005 and OUG No. 92/2021).

Land improvement works, such as irrigation systems and erosion control measures, constitute essential infrastructure and are explicitly subject to construction permit requirements. Their primary role is territorial protection, particularly in mitigating landslide risks.

A major practical challenge lies in the omission of site grading and levelling works, specifically those involving changes in land elevation, as a distinct category requiring authorization under the current Law No. 50/1991. The uncontrolled execution of such works generates significant geotechnical risks and may lead to illegal waste management practices, as deposited materials can be classified as waste. In this context, the law strictly prohibits the embedment of any type of waste in the ground.

The findings of this study further demonstrate that major earthworks, even when technically adequate at the site level, can alter the overall equilibrium of slopes and generate indirect geotechnical effects in adjacent areas. The Borhanci case study provides clear evidence of such impacts, highlighting the vulnerability of neighbouring terrains in the absence of coordinated measures at the territorial scale.

The analysis of the General Urban Plan of Cluj-Napoca shows that local authorities partially compensate for this legislative gap through Local Urban Planning Regulations. By restricting site grading and levelling works and earthworks in sensitive zones (VPr, VP, TDF, Aapp) and imposing a 0% P.O.T. in high-risk areas, the local framework actively contributes to preventing geotechnical instability and the improper management of excavated soil as waste.

In this context, the adoption of a consolidated Code of Spatial Planning, Urbanism, and Construction, explicitly including site grading and levelling works among the categories subject to authorization is both necessary and justified. Such a framework would ensure a consistent legal basis for the application of sanctions, improve the protection of neighbouring properties, and reinforce the fundamental environmental principle of preserving soil and subsoil quality.

The Borhanci case study demonstrates the importance of integrating geotechnical assessment, GIS analysis, environmental protection and territorial planning. The identified fissures, rupture surfaces and landslide susceptibility zones highlight the need for continuous monitoring and risk-informed decision making in areas affected by extensive grading operations.

The GIS-based territorial analysis performed in this study complements the legal and geotechnical assessment by providing spatial information regarding environmental constraints and landslide susceptibility. Such interdisciplinary approaches are increasingly recognised as essential tools for sustainable urban development and territorial risk management.

The results support the integration of geotechnical engineering, GIS technologies, environmental governance and urban planning in order to improve the management of earthworks and reduce long-term geotechnical risks.

Future research should include detailed geotechnical monitoring, GIS-based temporal analysis and quantitative assessment of slope stability in rapidly developing urban areas.

## ACKNOWLEDGEMENTS

This research was conducted within the Doctoral School of the Technical University of Cluj-Napoca, within the Structures Department of the Faculty of Civil Engineering. The author gratefully acknowledges the institutional support provided during the development of this work.

***Abstract***

*Public health concerns related to nitrate accumulation in vegetables are increasing, as nitrate can be converted to nitrite, which can form harmful N-nitroso compounds. Due to its high capacity to accumulate nitrate, lettuce represents a suitable crop for monitoring the effects of fertilization practices on environmental quality in greenhouse systems. This study evaluated nitrate, nitrite, and ammonium contents in greenhouse-grown lettuce from two sources: supermarkets and local producers. Three samples were collected from supermarkets, four from local producers. Samples were separated into leaves, roots, and growing medium (soil), yielding 21 representative samples. Differences were observed in concentrations and distribution patterns. Supermarket lettuce showed higher leaf nitrate content than local-producer samples. Supermarket samples also exhibited higher nitrite content, particularly in roots, suggesting active nitrate-reduction processes. Leaves were the primary site for nitrate accumulation, followed by roots and soil, whereas nitrite and ammonium were mainly associated with roots and soil. Notably, local producer samples exhibited higher ammonium concentrations in roots and soil compared to supermarket samples, suggesting differences in fertilization practices and nitrogen conversion efficiency. These findings support closer monitoring of fertilization practices to assess environmental quality in protected agriculture and to limit consumer exposure to nitrogen-related compounds.*

***Key words:*** *nitrate residue, greenhouse cultivation, lettuce, environmental quality.*

## INTRODUCTION

The nitrogen (N) sources are represented by inorganic forms ($NH_4^+$, $NO_2^-$, and $NO_3^-$), which are formed naturally in crops, soil, and water through the N cycle (Gidurus et al., 2012; Martín Leon & Luzardo, 2020). Thus, $NH_4^+$ and $NO_3^-$ constitute the most important forms of N, as they support plant growth and, when taken up in large quantities, achieve maximum production yields (Colla et al., 2018).

Complex interactions among plant root systems promote efficient N transfer within the soil-plant system, enabling optimal use of available nutrients (Hao et al., 2022). N residues from previous crops also serve as an important energy source for soil bacteria, supporting microbial activity, reducing the need for chemical inputs, and promoting N immobilization processes (Assémien et al., 2019).

N is vital for plant growth, and it circulates between soil and plants, often as an anion (Butnariu, 2018). N fertilizers are the primary artificial N source, with usage rising rapidly. About 50% of applied N is lost via leaching, contaminating surface and groundwater by increasing $NO_3^-$ content. After pesticides, nitrates are the second most concerning water contaminant for environmental and public health protection (Singh et al., 2022).

Plants need enough N to make amino acids, which are vital for cell and tissue formation. Without amino acids, plants can't produce proteins for growth, which harms development. Too much N, however, causes excess biomass, such as stems and leaves, and immature roots (Brady & Weil, 2010). Farmers use N fertilizers to boost crop growth; without them, about a third of food production could be lost. Yet, finding the optimal N level is crucial, as excess N pollutes water and threatens ecosystems (Aczel, 2019). Maintaining the right balance of essential life support elements is crucial. N deficiency in plants causes chlorosis and stunted growth (Britto et al., 2002). Proper N management prevents ecological problems such

as water pollution and soil degradation. Excess N can contaminate groundwater or other water bodies, causing eutrophication that harms aquatic ecosystems and biodiversity (Chislock et al., 2013).

Vegetables are a valuable source of minerals, vitamins, carbohydrates, and biologically active compounds. Adopting a diet rich in vegetables is one of the most effective ways to prevent numerous diseases, including obesity, which is becoming a major public health problem (Luetic et al., 2023). To support a healthy lifestyle that lowers the risk of various diseases and boosts immunity, the World Health Organization (WHO) advises consuming 400-500 g of vegetables daily as part of a balanced diet (Pennington et al., 2010).

Lettuce is a highly nutritious vegetable, abundant in vitamins C, A, K, and B9 (folate). Additionally, it is used medicinally for its high content of flavonoids, tocopherols, and carotenoids, compounds known for their high antioxidant properties. Another advantage is its global use and the fact that it is consumed raw in most cases, thereby retaining its full nutritional value (Popa et al., 2021).

Consequently, consumer exposure to nitrate ($NO_3^-$) varies depending on the types and amounts of vegetables consumed. In this context, leafy vegetables occupy a central place, as they have a high capacity for $NO_3^-$ accumulation, favored by both the accelerated growth rate specific to these species and the concentration of nitrogen ions predominantly in the leaves, the edible parts of these plants (Martín Leon & Luzardo, 2020).

In leafy vegetable cropping systems, such as lettuce, a shallow root system limits access to N in deeper soil layers, resulting in low N use efficiency, estimated at an average of only 25% (Pujol et al., 2017). This inefficiency contributes to excessive N accumulation in the soil. Unabsorbed N can be leached as $NO_3^-$ into groundwater, contaminating drinking water resources, or emitted into the atmosphere as nitrous oxide ($N_2O$), a particularly potent greenhouse gas (Cassman et al., 2002). Lettuce crops respond positively to N fertilization by increasing yields and improving product quality. In practice, high N fertilizer rates are often used to maximize production, but this can cause negative effects such as excess $NO_3^-$ in leaves, which impacts food security, and N leaching, which harms the environment. Lettuce's response to N depends on variety, soil, and climate, and thus requires tailored fertilization to improve N efficiency and minimize risks (de Barros Sylvestre et al., 2019).

In lettuce, shallow roots, frequent high-rate N fertilizers, and intensive irrigation increase N leaching, raising environmental loss risks and reducing sustainability (Korsaeth, 2008). A strategy to reduce N leaching is to lower N fertilizer rates in lettuce. This reduces $NO_3^-$ leaching with minimal impact on yield, while maintaining water quality and vegetable standards (Aragão et al., 2012).

Excessive N in vegetables poses ecological and health risks. Increased $NO_3^-$ intake from vegetables is a primary dietary source. The type, dose, and application method of N fertilizers affect $NO_3^-$ buildup in edible tissues. Rational N management is crucial to safeguard health and the environment (Coimbra et al., 2012).

The maximum allowable limit for $NO_3^-$ in lettuce is set by both the European Union and Romanian national regulations. Thus, the maximum levels in raw greenhouse-grown lettuce are as follows: for lettuce harvested from October 1 to March 31, the limit must not exceed 5,000 mg $NO_3^-$/kg; for lettuce harvested from April 1 to September 30, the limit must not exceed 4,000 mg $NO_3^-$/kg (EU No 915/2023).

This study aimed to assess $NO_3^-$ content in greenhouse lettuce, emphasizing the plant's tendency to accumulate $NO_3^-$ under intensive fertilization. Additionally, it focused on the identification and quantification of related inorganic nitrogen species, like nitrite ($NO_2^-$) and ammonium ($NH_4^+$), which pose higher toxicity risks. The analysis facilitates the assessment of safety, quality, and potential environmental impact.

## MATERIALS AND METHODS

### *Lettuce sampling*

To determine nitrate content and related inorganic nitrogen species (nitrite and ammonium), greenhouse lettuce was sampled in May 2025 from two sources: supermarkets and local producers. Three lettuce samples were collected from supermarkets (SP), and four from local producers (LP). The samples were divided

into the plant's components and the growing medium (leaves, roots, and soil). This resulted in a total of 21 representative samples.

***Extraction assessment of nitrate and related inorganic nitrogen species***

After sampling, the lettuce samples were frozen and then lyophilized. Following lyophilization, the lettuce samples were ground to a fine powder. Nitrate and related inorganic nitrogen species were extracted using microwave-assisted extraction (MAE), with ultrapure water as the solvent (Novaes et al., 2009). This method is effective for releasing nitrate and related inorganic nitrogen species from leaves, roots, and soil samples (Hao et al., 2015; Zandvakili et al., 2024). From each sample type, 1.5 g was weighed, and 60 mL of ultrapure water was added (plant-to-solvent ratio of 1/40). The extraction parameters were set as follows: extraction power of 500 W for 15 minutes at 100°C. After extraction, the samples were allowed to cool to room temperature for about 10 minutes. The mixture was centrifuged at 10000 rpm for 20 minutes, then filtered through a 0.45 µm cellulose acetate (CA) syringe filter to obtain a clear extract, as shown in Figure 1. The extracts were carefully stored at 4°C, ready for analysis. This step helps ensure everything stays fresh and accurate for the results. The extraction parameters and results are presented in Table 1.

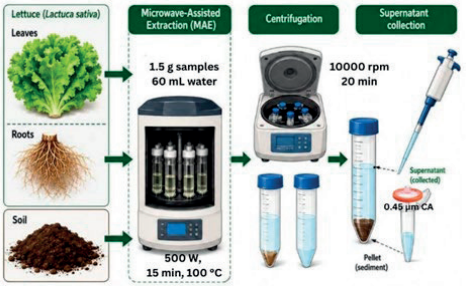

Figure 1. Procedure for extracting nitrate and related inorganic nitrogen species from lettuce samples

***Assessment of nitrate content in lettuce samples***

The nitrate content assessment of the extracts was performed using a modified ISO 7890-1:1986 spectrophotometric protocol based on 2,6-dimethylphenol (DMP) reagent (ISO, 1986). To 100 µL of each extract, 50 µL of DMP reagent and 100 µL of a mixture of sulfuric and phosphoric acids (9/1) were added. The resulting mixture was incubated at room temperature in the dark for 30 minutes. After incubation, the absorbance of the samples was measured at 345 nm. As a control, the extract was replaced with ultrapure water under the same conditions. The calibration curve was prepared using sodium nitrate ($NaNO_3$) at concentrations ranging from 0 to 20 mg/L. The results were expressed as milligrams of $NO_3^-$ per kilogram of sample (mg $NO_3^-$/kg).

***Assessment of nitrite content in lettuce samples***

The nitrite content assessment of the extracts was performed in the presence of the Griess reagent according to a modified spectrophotometric protocol (ISO 6777:1984; Moorcroft et al., 2001). 50 µL of Griess reagent was added to 150 µL of each extract. Griess reagent was a 1:1 mixture of sulfanilic acid and α-naphthylamine acetic solutions. The resulting mixture was incubated at room temperature, in the dark, for 30 minutes. After the incubation period, the absorbance of the samples was read at 520 nm. As a control, the extract was replaced with ultrapure water under the same conditions. The calibration curve was performed using sodium nitrite ($NaNO_2$) in concentrations ranging from 0 to 10 mg/L. The results were expressed as milligrams of $NO_2^-$ per kilogram of sample (mg $NO_2^-$/kg).

***Assessment of ammonium content in lettuce samples***

The ammonium content assessment of the extracts was determined using a modified ISO 7150-1:1984 spectrophotometric protocol in the presence of two reagents (ISO, 1984). Reagent A was a mixture of trisodium citrate, sodium salicylate, and sodium nitroprusside, and reagent B was a mixture of sodium hydroxide and sodium dichloroisocyanurate. 25 µL of reagent A and 25 µL of reagent B were added to 200 µL of each extract. The resulting mixture was incubated at room temperature, in the dark, for 60 minutes. After the incubation period, the absorbance of the samples was read at 650 nm. As a control, the extract was replaced with ultrapure water under the same conditions. The calibration curve was performed using ammonium chloride ($NH_4Cl$) in concentrations

ranging from 0 to 25 mg/L. The results were expressed as milligrams of $NH_4^+$ per kilogram of sample (mg $NH_4^+$/kg).

Table 1. Extraction parameters of nitrate and related inorganic nitrogen species

| Sampling site | Sample cod | Sample type | Sample/ volume ratio | Sample mass (g) | Initial volume (mL) | Final volume (mL) |
|---|---|---|---|---|---|---|
| Super-market 1 | SP1L | leaves | 1/40 | 1.50 | 60 | 53 |
| | SP1R | roots | 1/160 | 0.06 | 10 | 7.5 |

| | LP4R | roots | 1/40 | 0.80 | 33 | 31 |
| | LP4S | soil | 1/40 | 1.50 | 60 | 59 |

### *Assessment of dietary exposure and chronic health risk*

The Estimated Daily Intake (EDI, mg $NO_3^-$ /kg BW/day) and Hazard Quotient (HQ) were calculated according to European Food Safety Authority (EFSA) risk assessment guidelines in order to evaluate the consumer safety implications of nitrate accumulation in edible lettuce leaves (EFSA, 2008):

$$EDI = (C_{leaf} \times FIR) / BW$$
$$HQ = EDI / ADI$$

Where $C_{leaf}$ is the measured nitrate concentration in edible lettuce leaves (mg $NO_3^-$ /kg fresh weight), FIR is the daily consumption rate of leafy vegetables (0.06 kg/day for adults), and BW is the standard adult body weight (70 kg, EFSA, 2012). The Acceptable Daily Intake (ADI) established by EFSA for nitrate is 3.7 mg $NO_3^-$ /kg BW/day. An HQ < 1.0 indicates that chronic exposure remains within safe limits, whereas an HQ > 1 indicates potential chronic health risk.

### *Statistical analysis*

Statistical analysis of the results was performed using GraphPad (version 11.0.2). The correlation between nitrate, nitrite, and ammonium contents was determined using the Pearson correlation coefficient.

## RESULTS AND DISCUSSIONS

### *Nitrate content in lettuce samples*

Limited research has investigated the influence of source of origin on $NO_3^-$ content in lettuce. In this study, a quantitative analysis of greenhouse lettuce samples from different sources, including supermarkets and local producers, was conducted. The results showed significant differences based on source, plant parts, and growing medium (soil).

$NO_3^-$ distribution was uneven among leaves, roots, and soil, with higher concentrations accumulating mainly in the leaves. Comparing supermarket and local producer samples, notable differences emerged: supermarket lettuce had $NO_3^-$ content ranging from 73.99 ± 2.87 mg $NO_3^-$/kg (soil) to 5340.81 ± 80.95 mg $NO_3^-$/kg (leaves), while local producer samples ranged from 71.02 ± 1.45 mg $NO_3^-$/kg (soil) to 3212.92 ± 50.89 mg $NO_3^-$/kg (leaves) (Figure 2). Notably, leaves, roots, and soil samples differed, with leaves showing the highest absorption because they are the primary tissues that store $NO_3^-$.

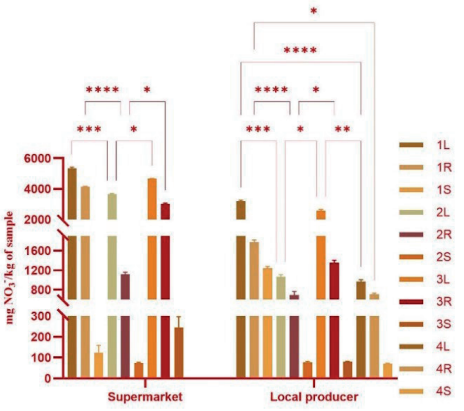

Figure 2. Nitrate content in different lettuce samples collected from supermarkets and local producers. Significant differences were noted at the following levels: * = $p < 0.05$, ** = $p < 0.01$, *** = $p < 0.001$, and **** = $p < 0.0001$

Regarding European standards for leafy vegetables, the higher $NO_3^-$ content in

supermarket samples raises food safety concerns. EU No 915/2023 sets a maximum limit of 4000 mg/kg for $NO_3^-$ in greenhouse-grown lettuce from April 1 to September 30. Conversely, local producer samples are significantly lower; thus, exposure to high concentrations of $NO_3^-$ from food is a major risk factor for human health. In the analyzed samples, the high values in lettuce leaves suggest increased accumulation of these compounds in the plant's edible parts. Because lettuce is often consumed raw in large quantities, even a moderate exceedance of the limit can lead to significant exposure, especially when combined with other dietary risk factors.

Therefore, the results underscore the importance of rigorous monitoring of agricultural inputs and compliance with the maximum permissible limit for $NO_3^-$ in fresh vegetables.

***Nitrite content in lettuce samples***

The evaluation of $NO_2^-$ content in lettuce samples revealed significant variation between supermarket and local producer samples. The supermarket samples showed much higher concentrations, especially for SP1R (roots), where content exceeded 2500 mg $NO_2^-$/kg, followed by SP3R (roots) at approximately 2000 mg $NO_2^-$/kg. In contrast, local producers' samples recorded considerably lower values, ranging from approximately 10 to 55 mg $NO_2^-$ /kg, with the highest in the LP4R (root) sample (Figure 3).

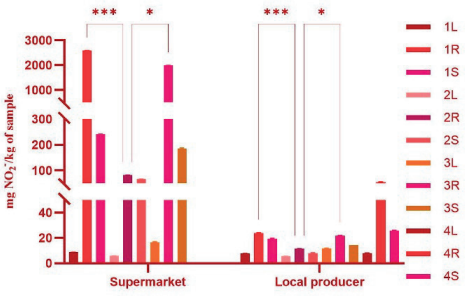

Figure 3. Nitrite content in different lettuce samples collected from supermarkets and local producers. Significant differences were noted at the following levels: * = $p < 0.05$, and *** = $p < 0.001$

The data show an opposite trend compared to $NO_3^-$. $NO_2^-$ is significantly accumulated in the roots, whereas $NO_3^-$ is accumulated mainly in the leaves. This may indicate a partial enzymatic conversion of $NO_3^-$ to $NO_2^-$. At the same time, soil samples (SP1S, SP4S) indicate a notable presence of $NO_2^-$, which may suggest the presence of specific microorganisms that favor the conversion of $NO_3^-$ to $NO_2^-$.

This uneven distribution suggests a significant difference between the two types of sources in post-harvest stages. Thus, lettuce collected from supermarkets is susceptible to the biochemical conversion of $NO_3^-$ to $NO_2^-$, a process favored by long-term storage, temperature fluctuations, and local anaerobic conditions in closed packaging. This process is significantly less pronounced in lettuce grown and sampled directly from local producers, which explains the lower $NO_2^-$ values.

The presence of $NO_2^-$ at high concentrations in lettuce samples, especially those from trade, represents a significant health risk. $NO_2^-$ are directly involved in the formation of nitrosamines, compounds with carcinogenic potential that can also induce methemoglobinemia, a serious condition in infants and vulnerable people (Popa et al., 2021).

Unlike $NO_3^-$, for which there are clear legislative thresholds in leafy vegetables, there are no maximum permitted limits for $NO_2^-$ in lettuce, but any high concentration is concerning. The concentration of 2500 mg $NO_2^-$/kg detected in SP1R (root) is markedly higher than $NO_2^-$ content typically reported in the literature for fresh lettuce, generally below 10-50 mg/kg in leaves and below 100 mg/kg in roots (Chung et al., 2003). This anomaly may indicate either intensive post-harvest $NO_3^-$ reduction or methodological interference at 520 nm from root pigments. This warrants further investigation, including validation against an independent analytical method.

The localization of $NO_2^-$ in the roots of the lettuce samples shows that $NO_2^-$ accumulation is blocked in the lower parts of the plant, possibly due to reduced foliar absorption. This pattern indicates that the agronomic strategies applied in the greenhouse (ventilation, N dose limitation, short time between harvest and analysis) help maintain low $NO_2^-$ content in the edible part of the plant. Regarding $NO_2^-$ accumulation, the data highlight a clear contrast between lettuce samples from supermarkets and those from local

producers. The problem is more pronounced in supermarket samples, with worryingly high values.

***Ammonium content in lettuce samples***

In the supermarket lettuce samples, $NH_4^+$ values varied significantly depending on the plant parts analyzed, as illustrated in Figure 4. The maximum concentration was recorded in the SP1R (root) sample, with a value of 30.93 ± 1.08 mg $NH_4^+$/kg, followed by SP2R with approximately 25.56 ± 0.50 mg $NH_4^+$/kg and SP3R with approximately 20.77 ± 0.77 mg $NH_4^+$/kg. In contrast, the soil samples (SP1S - SP3S) showed lower concentrations, ranging from 3.5 to 5.5 mg $NH_4^+$/kg. These results suggest that $NH_4^+$ ions tend to be present in higher amounts in the roots and absent in the leaves.

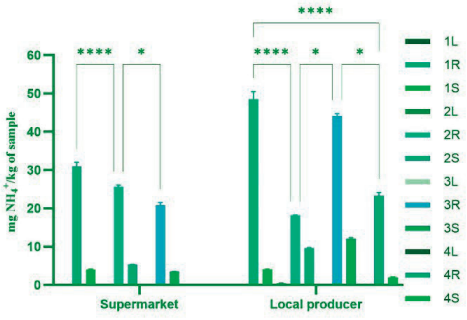

Figure 4. Ammonium content in different lettuce samples collected from supermarkets and local producers. Significant differences were noted at the following levels: * = $p < 0.05$, and **** = $p < 0.0001$

Samples from local producers showed a clear trend toward higher $NH_4^+$ accumulation in both the roots and the soil. The maximum values were recorded in samples LP1R (48.55 ± 2.00 mg $NH_4^+$/kg) and LP3R (44.11 ± 0.66 mg $NH_4^+$/kg). These concentrations are nearly double those observed in the supermarket lettuce samples. Soil samples LP2S and LP3S also recorded significant concentrations (from 9.5 to 12 mg $NH_4^+$/kg), while samples LP1S and LP4S showed values from 2 to 4 mg $NH_4^+$/kg. This pattern suggests progressive $NH_4^+$ accumulation, possibly favored by localized application of N fertilizers, high temperatures, increased humidity, and poor aeration. Additionally, the low $NO_3^-$ content in some of these samples may indicate incomplete conversion of $NH_4^+$ to $NO_3^-$ at physiological levels.

The presence of $NH_4^+$ can have significant implications for the plant's internal ionic balance and the nutritional quality of the product. Although the $NH_4^+$ ion is a natural and metabolically active form of N, its accumulation in tissues indicates physiological stress and can lead to the formation of secondary compounds (such as biogenic amines) that contribute to bitter taste or accelerate post-harvest spoilage. From a consumer health perspective, high concentrations of $NH_4^+$ are not strictly regulated, but when present alongside $NO_3^-$ and $NO_2^-$, they can contribute to metabolic imbalances, digestive discomfort, or cumulative effects with frequent consumption. Thus, concentrations of approximately 50 mg/kg should be viewed with caution, especially in the context of unprocessed consumption (raw plant), which is characteristic of this type of vegetable.

Analysis of $NH_4^+$ concentrations by source and plant part revealed uneven distribution and a high potential for accumulation under protected cultivation conditions (e.g., greenhouses). In all cases, the root was the dominant accumulation compartment, reflecting active translocation of reduced N to metabolically active areas of the plant. Differences between samples from local producers and those from the supermarket suggest that, in commercial crops, there may be stricter control of the dose and form of applied $NH_4^+$, whereas samples from local producers point to a potential N overapplication, likely combined with environmental conditions that suppress nitrification.

***Dietary exposure and chronic health risk***

The EDI of $NO_3^-$ varied considerably among the lettuce samples, ranging from 0.831 to 4.578 mg/kg BW/day, as seen in Table 2. The highest EDI values were obtained for the supermarket samples SP1L (4.578 mg/kg BW/day) and SP3L (3.997 mg/kg BW/day), both exceeding the ADI of 3.7 mg/kg BW/day. Accordingly, their HQ values were above unity (HQ = 1.237 and 1.080, respectively), indicating that the estimated exposure exceeded the selected health-based guidance value. In contrast, SP2L showed an EDI of 3.145 mg/kg BW/day and an HQ of 0.850, while all samples obtained from local

producers had substantially lower EDI (0.831–2.754 mg/kg BW/day) and HQ values (0.225–0.744). Thus, only SP1L and SP3L were identified as samples of potential concern based on the adopted EFSA ADI.

These findings are consistent with previous dietary exposure assessments showing that lettuce can represent an important source of nitrate intake. Luetic et al. (2023) reported that, assuming consumption of a 100 g portion, one lettuce sample contained sufficient $NO_3^-$ to exceed the ADI, demonstrating that individual high-$NO_3^-$ lettuce samples may substantially increase dietary exposure. Similarly, Brkić et al. (2017) estimated that consuming 150 g of lettuce would account for 47.5% of the ADI in spring and as much as 85.4% in autumn, emphasizing that $NO_3^-$ exposure from lettuce strongly depends on its $NO_3^-$ concentration. More recently, Dodocioiu et al. (2025) reported an EDI of 3.65 mg/kg BW/day for adults, whereas the estimated EDI for children reached 8.11 mg/kg BW/day. Lettuce with elevated $NO_3^-$ concentrations may represent a substantial contribution to daily $NO_3^-$ exposure and, under specific exposure scenarios, may exceed health-based guidance values (Brkić et al., 2017; Luetic et al., 2023; Dodocioiu et al., 2025).

Table 2. Estimated Daily Intake and Hazard Quotient of nitrate in supermarket and local producer lettuce samples

| Sample code | $NO_3^-$ (mg/kg) | EDI (mg/kg BW/day) | HQ | Risk |
|---|---|---|---|---|
| **SP1L** | 5340.81 | 4.578 | 1.237 | Risk exceeded |
| **SP2L** | 3669.32 | 3.145 | 0.850 | Acceptable |
| **SP3L** | 4663.58 | 3.997 | 1.080 | Risk exceeded |
| **LP1L** | 3212.92 | 2.754 | 0.744 | Acceptable |
| **LP2L** | 1069.20 | 0.916 | 0.248 | Acceptable |
| **LP3L** | 2593.25 | 2.223 | 0.601 | Acceptable |
| **LP4L** | 969.98 | 0.831 | 0.225 | Acceptable |

### *Pearson Correlation and Heatmap Matrix*

To evaluate potential relationships among the N forms accumulated in lettuce, Pearson correlations were computed for the $NO_3^-$, $NO_2^-$, and $NH_4^+$ contents across all samples examined (Figure 5).

Weak positive correlations were observed between $NO_3^-$ and $NO_2^-$ (r=0.35) and between $NO_2^-$ and $NH_4^+$ (r=0.31), while a very weak negative correlation was found between $NO_3^-$ and $NH_4^+$ (r=-0.06). These low values indicate weak associations among the reactive N forms, suggesting that $NH_4^+$, $NO_2^-$, and $NO_3^-$ behave largely independently in lettuce rather than through direct biochemical coupling. This finding indicates that the accumulation of each N form is driven by multiple physiological and environmental factors, such as sample origin and post-harvest conditions, highlighting the need for integrated monitoring of all N forms to accurately assess product quality.

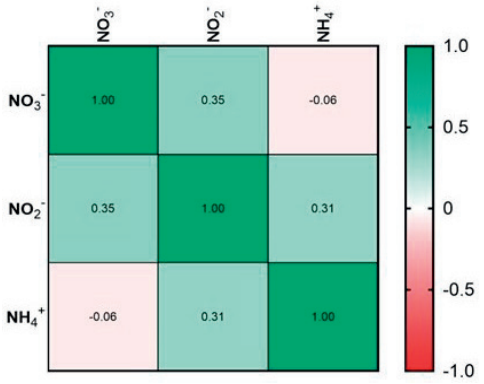

Figure 5. Pearson correlation between nitrate, nitrite, and ammonium contents in lettuce samples

In soil, N circulates through the biogeochemical N cycle, which includes essential processes such as biological N fixation, nitrification, and denitrification, each regulated by specialized microbial communities. These processes are mediated by functional genes that encode enzymes involved in the transformations of N compounds. In biological fixation, molecular nitrogen ($N_2$) is reduced to ammonia ($NH_3$) or other N-containing compounds by enzymes produced by N-fixing bacteria, enabling plants to absorb it. Non-symbiotic N fixation, carried out by free-living diazotrophs, is a major source of N for terrestrial ecosystems (Hao et al., 2022). Nitrification occurs under aerobic conditions and is mediated by nitrifying bacteria, which oxidize reduced inorganic forms of N, such as $NH_4^+$, to $NO_2^-$ and then to $NO_3^-$. $NH_4^+$ and $NO_3^-$ are taken up by plant cells through transport across the plasma membrane (Figure 6).

When $NO_3^-$ absorption greatly exceeds plant assimilation, $NO_3^-$ can accumulate in plant

tissues. The type of fertilizer used plays a key role in the $NO_3^-$ accumulation in the edible parts of vegetables. N can be supplied not only as $NO_3^-$ but also as $NH_3$, urea ($CO(NH_2)_2$), or other organic compounds. Choosing the appropriate fertilizer, depending on the plant part intended for consumption, can help reduce the concentration of $NO_3^-$ in the final product (Popa et al., 2021).

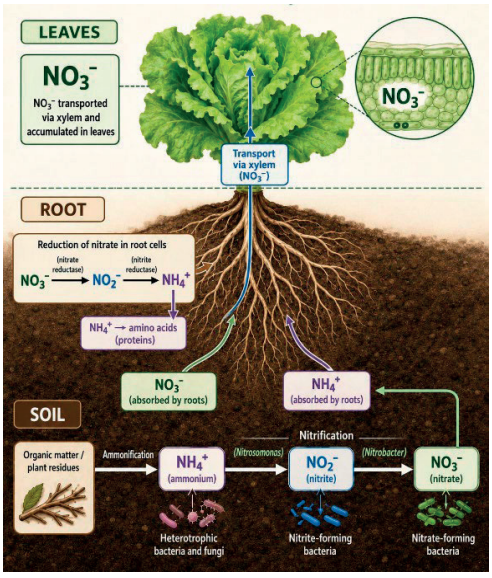

Figure 6. Formation and conversion of N forms in lettuce (Source: Authors-generated using AI)

The $NO_3^-$ accumulation is influenced by multiple factors, including soil composition, cropping system, fertilizer application regime, and climatic and seasonal conditions during the growing season (Martín Leon & Luzardo, 2020). In non-legume crops, higher $NO_3^-$ concentrations tend to accumulate in the leaves, whereas lower concentrations accumulate in the roots. For this reason, leafy vegetables, e.g., arugula, spinach, lettuce, celery, and parsley, are considered prominent species that accumulate $NO_3^-$ (Colonna et al., 2016).

The effect of N forms ($NH_4^+$, $NO_2^-$, and $NO_3^-$) on plant growth depends not only on the cultivated species but also on their concentrations and relationships. Usually, the form in which N is applied influences the anion-to-cation absorption ratio, thereby affecting dry matter production and root nutrient uptake. The quantity and quality of applied fertilizers are determining factors in the growth, production, and quality of leafy vegetables (Cencič et al., 2013).

It is emphasized that N accumulation varies significantly not only between species but also among varieties within the same species, with these differences influenced by environmental factors. Additionally, the N content depends on the specific plant part consumed (Jakabová et al., 2022).

The current results clearly show that the source of the lettuce sample significantly affects $NO_3^-$ buildup. On average, the leaf $NO_3^-$ contents were about 2.3 times higher in the supermarket samples compared to the local producer ones. This suggests that the sample origin, along with related cultivation methods and N management practices, plays a key role in $NO_3^-$ accumulation. This source-dependent variation aligns with previous research indicating that $NO_3^-$ contents in lettuce are strongly influenced by factors such as N availability, fertilization approach, growing system, environmental conditions, and plant physiology. For example, Aires et al. (2013) found higher $NO_3^-$ concentrations in conventionally grown baby-leaf vegetables than in organic ones, highlighting how production systems impact $NO_3^-$ contents. Similarly, Pinto et al. (2014) linked soil inorganic N contents to differences in $NO_3^-$ and $NH_4^+$ contents in lettuce. More recently, Martínez-Moreno et al. (2024) demonstrated that nutrient solution management effectively controls $NO_3^-$ accumulation, while Nguyen et al. (2026) revealed that N assimilation and the resulting $NO_3^-$, $NO_2^-$, and $NH_4^+$ concentrations are also strongly affected by light intensity and plant genotype.

Interestingly, the $NO_3^-$ contents in soil at harvest did not directly match the pattern seen in lettuce leaves. Although the supermarket samples had the highest leaf $NO_3^-$ contents, the soil $NO_3^-$ concentrations were relatively low, except for LP1 soil, which contained 1243.48 mg $NO_3^-$/kg. This discrepancy indicates that lettuce $NO_3^-$ accumulation reflects the plant's entire history of N availability, uptake, transport, and assimilation. Pinto et al. (2014) also showed that soil physicochemical properties affect inorganic N mobility and that differences in $NO_3^-$ leaching and plant availability can significantly influence N transfer from soil to lettuce. Moreover, Zhang

et al. (2025) found that just five days of nutrient deprivation before harvesting reduced $NO_3^-$ contents by 57.49% in leaves and 50.77% in roots, highlighting how short-term pre-harvest N availability strongly impacts tissue nitrate concentrations.

In this study, $NO_3^-$ distribution was tissue-dependent, with higher concentrations in leaves than roots, and much lower in soil. This pattern reflects $NO_3^-$ uptake by roots and transport to shoots, where it may be stored or reduced through assimilation. $NO_3^-$ metabolism occurs in both roots and shoots, with their relative roles influenced by N supply and environmental factors. Schiefloe et al. (2023) demonstrated substantial differences in $NO_3^-$ partitioning between lettuce shoots and roots, depending on the $NH_4^+$:$NO_3^-$ ratio supplied to plants; increasing $NH_4^+$ availability reduced $NO_3^-$ concentrations in both compartments by approximately 7–8 times. Likewise, Zhang et al. (2025) observed coordinated yet tissue-specific changes in $NO_3^-$ concentration and $NO_3^-$ transporter expression in lettuce leaves and roots during nutrient deprivation. These findings support the marked root–leaf compartmentalization observed in the present study.

The distribution of $NH_4^+$ differed markedly from that of $NO_3^-$. $NH_4^+$ was absent or present only at trace levels in leaves, whereas appreciable concentrations occurred in roots. Soil $NH_4^+$ concentrations were intermediate but substantially lower than those measured in roots. This preferential accumulation in roots aligns with their primary role in $NH_4^+$ uptake and assimilation. Schiefloe et al. (2023) reported that lettuce grown under a high-$NH_4^+$ nutrient regime accumulated almost three times more $NH_4^+$ in roots than plants receiving a low-$NH_4^+$ treatment, whereas changes in shoot $NH_4^+$ were comparatively limited. Pinto et al. (2014) also observed a close relationship between $NH_4^+$ concentration and glutamine synthetase activity in lettuce, supporting the rapid incorporation of $NH_4^+$ into organic N compounds. Consequently, the very low $NH_4^+$ concentrations detected in the leaves of the present samples likely indicate efficient assimilation and limited translocation or storage of free $NH_4^+$ in edible tissues.

$NO_2^-$ showed a different distribution pattern. Leaf concentrations were low, while some root and soil samples, especially in the supermarket samples, showed higher values. This pattern suggests root-zone N transformations and tissue-specific $NO_2^-$ reduction may contribute to $NO_2^-$ formation. $NO_2^-$ is an intermediate of $NO_3^-$ assimilation, usually rapidly reduced during N metabolism, so its accumulation is lower than $NO_3^-$. Nguyen et al. (2026) found that the balance among $NO_3^-$, $NO_2^-$, $NH_4^+$, nitrate reductase, and nitrite reductase in lettuce depends on enzyme activity and environmental conditions.

Leaf $NO_2^-$ concentrations also show the large variability reported for commercial lettuce. Aires et al. (2013) reported $NO_2^-$ concentrations ranging from 0.25 to 1.89 mg $NO_2^-$/kg FW in green and red lettuce from conventional and organic production systems. In contrast, Luetic et al. (2023) reported $NO_2^-$ concentrations ranging from 21.1 to 378.1 mg $NO_2^-$/kg FW. The authors noted that cultivation, post-harvest handling, and storage affect nitrite levels. While the leaf $NO_2^-$ concentrations in this study were higher than some reports for freshly harvested baby-leaf lettuce, they stayed within the variability seen in commercial leafy vegetables. From a food-safety perspective, $NO_3^-$ accumulation in the edible leaves is the most relevant finding. Luetic et al. (2023) reported $NO_3^-$ concentrations of 169.7–3184.2 mg $NO_3^-$/kg FW in commercial lettuce. In comparison, LP2 and LP4 in the present study were close to this literature range, whereas the supermarket samples showed considerably higher $NO_3^-$ concentrations. Qureshi et al. (2026) reported approximately 2900 mg $NO_3^-$/kg FW and 2.29 mg $NO_3^-$/kg FW in lettuce and considered $NO_3^-$ control an important criterion of nutritional quality.

## CONCLUSIONS

The present work aimed to compare the N forms ($NO_3^-$, $NO_2^-$, and $NH_4^+$) in lettuce grown in greenhouses and sold in supermarkets and by local producers. Based on experimental data, clear source- and tissue-dependent differences in the distribution of $NO_3^-$, $NO_2^-$, and $NH_4^+$ in greenhouse lettuce were observed between these two sources in the concentrations and internal distributions of these compounds across the leaves, roots, and soil. These variations suggest different N uptake and assimilation patterns

across the production sources rather than isolated parts of the N cycle.

Supermarket samples generally showed higher $NO_3^-$ concentrations in the edible leaves and higher $NO_2^-$ levels in the roots, whereas $NH_4^+$ was predominantly associated with the root compartment. Several supermarket leaf samples exceeded the EU maximum $NO_3^-$ content of 4000 mg $NO_3^-$/kg for greenhouse lettuce harvested between April and September, highlighting a potential food-safety concern.

From an agronomic standpoint, the findings emphasize the importance of N management just before harvest. For food safety, the high $NO_3^-$ contents observed in some edible leaves highlight a need for careful monitoring.

## ACKNOWLEDGEMENTS

This work was supported by a grant of the Ministry of Education and Research, CCCDI-UEFISCDI, project number PN-IV-P6-6.1-CoEx-2024-0120, within PNCDI IV.

Mihaela Dragoi Cudalbeanu expresses her gratitude to the Romanian-American Foundation and the Romanian Fulbright Commission for the opportunity to participate in the Fulbright-RAF Scholar Award.

***Abstract***

*Steel furnace slags is a strategically important secondary resource for sustainable building materials, but its efficient utilization requires a clear understanding of its highly variable behaviour. Previous studies indicate that slag-derived composites often exhibit reduced workability due to particle size and shape, high water demand, and the slow reactivity of certain silicate phases. Dimensional stability remains a critical issue, as several types of steel slag from furnaces contain phases predisposed to delayed expansion, mainly related to the mineralogical composition of the particles. Furthermore, the presence of heavy metals requires detailed characterization, representing a critical factor in assessing the safety of using steel furnace slag in construction composites. In addition to these generalized mechanisms, an important regional challenge is the utilization of the large quantities of steel furnace slag accumulated in Romania from decades of steel production. These materials remain in landfills without being given a new cycle of use, despite their potential for integration into cement-based composites and civil infrastructure. This article examines the main technical limitations associated with the use of steel furnace slag, while highlighting possible characterization strategies and processing methods that can enable the safe and efficient use of existing steel furnace slag resources in Romania.*

***Key words****: circular economy, secondary raw materials, steel furnace slag valorization.*

## INTRODUCTION

The construction industry faces intensifying pressure to mitigate its environmental impact through optimized utilization of secondary raw materials and systematic reduction of industrial waste (Müller et al., 2014; European Commission, 2015; Ghisellini et al., 2016). Within this framework, steel slag has garnered substantial attention due to its abundance and prospective applications in cementitious composites and civil infrastructure (Shi & Qian, 2000; Motz & Geiseler, 2001; Brand & Fanijo, 2020). As a by-product of steel manufacturing processes, steel slag represents both an environmental challenge and an opportunity for the development of more sustainable building materials (Mousavinejad & GilKalaye, 2024).

Global steel production generates each year very large volumes of steel slag, amounting to hundreds of millions of tons worldwide, and although partial reuse is achieved in certain regions, a significant portion of this material remains landfilled due to technical, environmental, and regulatory constraints (World Steel Association; Motz & Geiseler, 2001).

The literature consistently highlights the need for systematic characterization, controlled processing, and appropriate qualification for specific applications to enable the safe and efficient reuse of steel slag in construction materials (Shi & Qian, 2000; Provis & Van Deventer, 2009; Brand & Fanijo, 2020). However, the main obstacles to large-scale recycling include the pronounced variability between different types of slag (electric arc furnace slag, EAF; basic oxygen furnace slag, BOF; ladle metallurgy furnace slag, LMF; argon oxygen decarburization slag, AOD), the risk of delayed volumetric expansion associated with free CaO and MgO or other mineralogical

mechanisms, reduced workability in fresh composites, and concerns about heavy metal content and mobility (Shi & Qian, 2000; Deja, 2000; Santamaría et al., 2018; Brand & Fanijo, 2020).

In Romania, decades of steel production have resulted in the accumulation of substantial quantities of steel slag, which remain largely underutilized or landfilled in industrial waste dumps (Figure 1) (Baera et al., 2024; 2026). Research and exploitation strategies in the Romanian context, the term steel furnace slag (SFS) is particularly suitable, as most slag deposits come from primary steel production processes, mainly from basic oxygen furnaces (BOF) and electric arc furnaces (EAF) (Figure 1). The term SFS proves particularly apt for Romanian research and exploitation strategies, reflecting the predominance of furnace-derived deposits.

The principal national impediment remains the absence of comprehensive slag inventories and standardized qualification frameworks, severely constraining construction sector integration (Kurecki et al., 2024). Addressing this issue requires coordinated strategies focused on rapid characterization protocols, pilot-scale valorisation projects, and targeted pre-treatment methods, such as aging or carbonation, to mitigate expansion risks and environmental issues, while allowing the use of locally available secondary raw materials in civil infrastructure projects (Santamaría et al., 2018; Shi & Qian, 2000; Deja, 2000; Provis & Van Deventer, 2009; Brand & Fanijo, 2020;).

Despite these prospects, SFS deployment remains circumscribed by pronounced physicochemical and mineralogical variability arising from disparate steelmaking parameters, feedstock compositions, and cooling regimes materials (Shi & Qian, 2000; Motz & Geiseler, 2001; Brand & Fanijo, 2020).

Poor workability consistently manifests when SFS substitutes natural aggregates, attributable to angular morphology, rough surface texture, and elevated water absorption that exacerbate mixture friction and water demand (Yildirim & Prezzi, 2011; Ouda & Abdel-Gawwad, 2017; Loureiro et al., 2022). Parallel fresh-state concerns, dimensional stability constitutes a major technical challenge. Certain furnace slag typologies harbor reactive mineral phases capable of protracted hydration, inducing delayed volumetric expansion that compromises long-term durability (Santamaría et al., 2018; Adegoloye et al., 2016).

Environmental safety further requires consideration: the metallurgical provenance introduces trace metallic elements with exposure-dependent mobility, necessitating rigorous physicochemical characterization and leaching assessment (Alizadeh et al., 2003; Liu et al., 2016).

Regardless of these technical constraints, the substantial volumes of steel slag generated globally over decades of steel production constitute a valuable secondary resource. Extensive research validates its viability across diverse applications: concrete, mortar, asphalt mixtures, and specialized uses (Maslehuddin et al., 2013; Loureiro et al., 2022). Nevertheless, significant underutilization persists, underscoring the critical need for integrated approaches that synergize material characterization, performance validation, and tailored processing methodologies to enable safe, efficient valorisation (Fuente-Alonso et al., 2017; Loureiro et al., 2022). In this context, this article examines the main technical challenges associated with the use of steel slag in construction applications and discusses potential pathways for its safe and efficient use.

This review systematically outlines the principal technical challenges impeding steel slag deployment in construction while elucidating viable mitigation pathways for its effective utilization.

Despite inherent technical complexities necessitating rigorous evaluation, steel furnace slag remains a high-potential waste-by-product. Its recovery offers strategic opportunities to address environmental liabilities while advancing Circular Economy principles within the construction sector.

## MATERIALS AND METHODS

### Review methodology

The present study was developed as a literature-based review focused on the main technical challenges and valorisation opportunities associated with the use of steel furnace slag (SFS) in construction applications. The paper was also supported by the research activities carried out within the research program PN 23 35 04 01 of Nucleu Programme of the National Research Development and Innovation Plan 2022-2027, "ECODIGICONS", supported by the Ministry of Research, Innovation and Digitalization. Baera et al. (2024), focused on the sustainable integration of secondary raw materials into construction materials and infrastructure applications.

The analysis was carried out by examining scientific publications addressing the physical, chemical, mineralogical, and environmental behaviour of steel furnace slag, together with its integration into cement-based materials and civil infrastructure systems. In parallel, selected observations obtained during the preliminary investigations performed within the research program PN 23 35 04 01 were considered as practical examples supporting the discussion regarding the behaviour of SFS-containing cementitious composites.

The literature selection process focused primarily on studies investigating the influence of SFS on fresh-state properties, dimensional stability, long-term durability, and leaching behaviour. Particular attention was also given to research discussing characterization methods, processing approaches, and potential mitigation strategies intended to improve the safe and efficient utilization of SFS in construction materials.

The reviewed information was collected from scientific journal articles, conference papers, technical reports, and relevant research studies published in recent decades. The analysis included studies related to different types of steel furnace slag, particularly electric arc furnace (EAF) slag and basic oxygen furnace (BOF) slag, due to their relevance for construction applications and their significant accumulation in industrial waste deposits.

The collected literature was subsequently organized according to the main technical aspects influencing the practical utilization of SFS, including chemical and mineralogical characteristics, fresh-state behaviour, dimensional stability, environmental assessment, and

potential valorisation pathways in construction and environmental applications.

**Characterization and general properties of steel furnace slag**

Steel furnace slag (SFS) forms during primary steelmaking processes (Figure 2), predominantly via basic oxygen furnaces (BOF) and electric arc furnaces (EAF), through high-temperature interactions among molten steel, fluxing agents, and furnace refractories (Figure 3).

As Brand & Fanijo (2020) emphasize, SFS exhibits pronounced compositional variability stemming from disparate steelmaking methodologies, raw material inputs, operational parameters, and cooling regimes, a characteristic profoundly influencing its performance within cementitious composites and necessitating rigorous consideration.

During steelmaking, fluxes including limestone ($CaCO_3$) and dolomite ($CaMg(CO_3)_2$) facilitate impurity removal from molten steel, yielding slag enriched with calcium oxides (CaO), magnesium oxides (MgO), iron oxides (Fe), and silicates ($SiO_2$) (Yildirim & Prezzi, 2011; Brand & Fanijo, 2020).

BOF slags are generally characterized by high CaO contents and a strongly basic nature, whereas EAF slags tend to exhibit greater compositional diversity due to the heterogeneous nature of scrap feedstock. According to Brand and Fanijo, (2020), these differences in formation conditions result in distinct slag types with varying chemical, mineralogical, and physical characteristics.

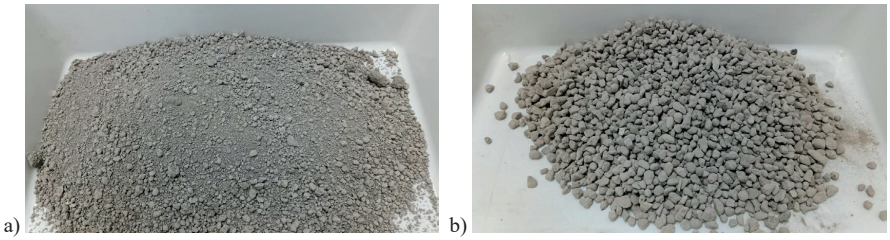

Figure 2. Representative electric arc furnace (EAF) slag: a) 0-4 mm fraction; b) 4-8 mm fraction

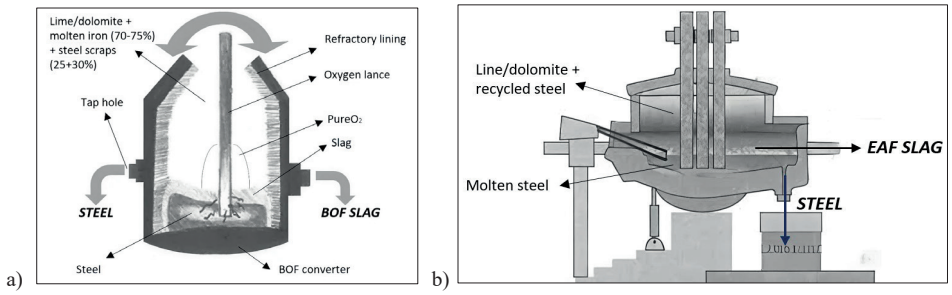

Figure 3. Schematic representation of: a) BOF process (Linz and Donawitz process); b) EAF steelmaking (Yldirim and Prezzi, 2011)

**Chemical composition and mineralogical features**

Steel furnace slag (SFS) typically comprises CaO, $SiO_2$, $FeO/Fe_2O_3$, and MgO as predominant constituents, with $Al_2O_3$ and other oxides present in smaller proportions (Yildirim & Prezzi, 2011; Brand & Fanijo, 2020). However, both Brand & Fanijo, (2020) and Yildirim & Prezzi (2011) report that the relative proportions of these oxides can vary significantly not only between BOF and EAF slags but also between different batches produced within the same steel plant.

From a mineralogical perspective, SFS consists of a complex assemblage of crystalline and amorphous phases, including dicalcium silicate ($C_2S$), wüstite (FeO), periclase (MgO), merwinite ($Ca_3MgSi_2O_8$), and calcium ferrites (e.g., $C_2F$). The presence of free CaO and free MgO is particularly important, as these phases

are associated with delayed hydration reactions and volumetric instability when exposed to moisture (Yildirim & Prezzi, 2011; Brand & Fanijo, 2020).

**Microstructural characteristics and phase heterogenity**

At the microscale, steel furnace slag particles frequently exhibit heterogeneous internal structures, characterized by differences between particle surfaces and cores. This phase heterogeneity originates from non-equilibrium cooling and localized chemical segregation during solidification, leading to the coexistence of phases with different reactivity within the same particle. Such internal heterogeneity has been shown to influence the interaction between slag particles and cementitious matrices, particularly at the interfacial transition zone, thereby affecting mechanical performance and long-term durability (Yildirim & Prezzi, 2011; Brand & Fanijo, 2020).

**Variability and implications for construction applications**

The combined chemical, mineralogical, and microstructural variability of steel furnace slag represents a major challenge for its standardized use in construction materials. As emphasized in the literature, differences in slag characteristics can lead to inconsistent workability, mechanical properties, and dimensional stability of SFS-containing composites if appropriate characterization is not performed. Consequently, the effective valorization of steel furnace slag requires thorough preliminary assessment, including chemical composition, mineralogical phase analysis, and microstructural evaluation, to ensure predictable performance in construction applications (Yildirim & Prezzi, 2011; Brand & Fanijo, 2020). The essential steps involved in the initial characterization of steel furnace slag are outlined below:

- *X-ray Fluorescence (XRF) analysis* used for the chemical evaluation of mineral wastes is a non-destructive analytical technique employed to identify and quantify the chemical elements present in solid materials;
- *X-ray Diffraction (XRD) analysis* is an instrumental analytical technique used for the identification and quantification of crystalline phases in mineral material;
- *Fourier Transform Infrared (FTIR) Spectroscopy* is an instrumental analytical technique used to identify functional groups and chemical bonds in the analysed materials by examining the absorption of infrared radiation by their molecular structure.
- *Thermogravimetric Analysis (TGA) and Differential Thermal Analysis (DTA)* comprise a set of thermoanalytical techniques used to evaluate the thermal behavior, chemical stability, and physicochemical transformations of materials.
- *Visual Analysis and Microscopy* represent a set of morphological and microstructural investigation methods used for the observation, description, and interpretation of the physical, structural, and mineralogical characteristics of the analysed materials. The method includes macroscopic (visual) and microscopic examinations (optical microscopy and scanning electron microscopy - SEM, optionally coupled with energy-dispersive spectroscopy, EDS) and is applied for the characterization of mineral wastes.

Figure 4 summarizes the key steps required to achieve an initial characterization of any steel furnace slag.

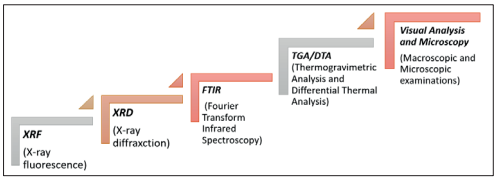

Figure 4. Schematic overview of the initial characterization steps for SFS slag

Following the initial characterization of the steel furnace slag type, the main issues to be addressed include reduced workability, dimensional stability, and concerns related to heavy metal content.

**Experimental Observations Regarding Fresh-State Properties**

Workability is widely regarded as one of the main challenges associated with incorporating steel furnace slag (SFS) into cement-based composites. As summarized by Brand and Fanijo (2020) mixtures containing SFS

generally exhibit reduced workability compared to reference mixtures with natural aggregates, usually manifested by lower slump values and increased mixture stiffness. However, the magnitude of this reduction depends largely on the type of slag, particle size distribution, and specific physical characteristics.

The angular morphology of steel slag particles is a major factor contributing to reduced workability. Unlike natural aggregates, SFS particles are characterized by irregular shapes and sharp edges, which increase internal friction and restrict particle mobility in the fresh state. Steel slag particles typically have rough and porous surfaces, which leads to higher water absorption compared to conventional aggregates (Yildirim & Prezzi, 2011; Brand & Fanijo, 2020). As a result, part of the mixing water is absorbed by the slag particles, leading to an increased water demand to achieve comparable workability.

In order to examine this aspect, two representative examples were considered.

The first example is based on previously published research that examined the incorporation of electric arc furnace (EAF) slag as a partial replacement for natural fine aggregates in cement-based materials (Darwis et al., 2024), while the second example consists of preliminary observations obtained as part of the program PN 23 35 04 01 of Nucleu Programme. The mixtures studied within the program PN 23 35 04 01 included different levels of replacement of natural fine aggregates with EAF slag. The evaluation focused on the behaviour of the cementitious mixtures in the fresh state, particularly on consistency and workability. The experimental determinations were performed in accordance with the applicable testing procedures for fresh mortars, in accordance with EN 1015-3.

**Dimensional Stability and Expansion Mechanisms**

In addition to issues related to fresh workability, the incorporation of steel furnace slag (SFS) into cement-based composites presents significant challenges related to dimensional stability. Unlike conventional natural aggregates, SFS can exhibit delayed volumetric changes when exposed to moisture, which can compromise the long-term performance and durability of cementitious materials (Brand & Fanijo, 2020). These effects are particularly critical in applications where dimensional stability is essential, such as structural concrete and infrastructure elements.

The dimensional instability of EAF is primarily associated with its complex chemical and mineralogical composition, which is significantly influenced by steel manufacturing conditions and cooling patterns (Yildirim & Prezzi, 2011; Brand & Fanijo, 2020). The presence of reactive oxide phases, combined with the heterogeneous distribution of mineral constituents in slag particles, can lead to time-dependent expansion when SFS is incorporated into cementitious systems and exposed to water (Brand & Fanijo, 2020). Unlike fresh workability issues, which are immediately observable, volumetric instability can develop gradually, often after placement, making it more difficult to detect and remediate.

Among the factors contributing to volumetric instability, the presence of free calcium oxide (free CaO) and free magnesium oxide (free MgO) plays a dominant role. Free CaO reacts relatively quickly with water to form calcium hydroxide, accompanied by a significant increase in volume. In contrast, free MgO hydrates much more slowly, leading to delayed expansion that can be observed over long periods of time. The degree of expansion depends not only on the total content of these oxides, but also on the size of the crystals, the degree of encapsulation in other phases, and accessibility to moisture (Yildirim & Prezzi, 2011; Santamaría et al., 2018; Brand & Fanijo, 2020).

The mineralogical heterogeneity of SFS further complicates its dimensional behaviour. As a result, different regions within the same particle may react differently to hydration processes, leading to localized expansion and the development of internal stresses. This heterogeneous behavior can contribute to the formation of microcracks and negatively affect the surrounding cement matrix. When EAF is used as a component in cementitious composites, dimensional instability can lead to internal stresses, microcracks, and, in severe cases, visible cracks or loss of durability (Santamaría et al., 2018; Brand & Fanijo, 2020). These effects are particularly relevant when SFS

is used as a replacement for aggregates, where volumetric changes directly influence the composite matrix.

**Leaching Behaviour of Steel Furnace Slag and SFS Cement-Based Composites**

The environmental evaluation of steel furnace slag (SFS) begins with the assessment of its leaching behavior in the raw materials. For granular materials such as steel slag, the EN 12457 is commonly applied, involving batch extraction under a defined liquid-to-solid ratio and controlled agitation conditions. This procedure enables the quantification of potentially hazardous elements released into an aqueous medium over a fixed period of contact.

Gomes & Pinto (2006) investigated the leaching behaviour of industrial steelmaking slags through laboratory extraction tests aimed at evaluating the mobility of heavy metals. In the experimental approach, slag samples were subjected to controlled leaching conditions, and the concentrations of dissolved elements were subsequently determined through chemical analysis of the leachate. Gomes & Pinto (2006) focused on elements such as Pb, Cd, Cr, and Zn, demonstrating that the release of these metals depends on physicochemical parameters including pH and slag composition. The results indicated that, although certain slags exhibited limited metal mobility under neutral conditions, measurable concentrations could be detected under specific environmental scenarios, emphasizing the importance of systematic leaching testing prior to reuse.

Similarly, investigations conducted under variable acidic and alkaline environments, as reported in the study available through Dhoble & Ahmed (2018), applied controlled leaching protocols over extended exposure periods (up to 50 days). The methodology involved immersing slag samples in aqueous solutions with adjusted pH values, followed by periodic sampling and chemical quantification of elements such as Cr, Fe, Ni, Zn, and As. The findings highlighted that metal release behaviour is strongly influenced by environmental conditions, particularly acidity, and that prolonged exposure may alter the mobility patterns of certain elements.

These experimental approaches confirm that the leaching potential of SFS must be evaluated through standardized or controlled laboratory procedures, rather than inferred solely from bulk chemical composition.

When SFS is incorporated into cement-based composites, the assessment framework shifts from granular waste characterization to evaluation of monolithic construction products. In the European context, the release of dangerous substances from solid construction materials is commonly assessed according to CEN/TS 16637-2, known as the Dynamic Surface Leaching Test (DSLT).

Unlike batch tests applied to granular materials, DSLT evaluates the time-dependent release of substances from the exposed surface of a monolithic specimen. The test involves repeated contact between the concrete sample and deionized water over predefined intervals, with periodic renewal of the leaching solution and subsequent chemical analysis of the eluate. This methodology allows the assessment of cumulative release and diffusion-controlled mechanisms over time.

In cementitious systems containing SFS, the alkaline matrix may contribute to partial immobilization of heavy metals through physical encapsulation and chemical stabilization. However, long-term exposure to water, environmental carbonation, or surface degradation may influence the release dynamics. Therefore, even if preliminary EN 12457 tests on the raw SFS indicate acceptable leaching levels, complementary assessment on the final cement-based composite remains essential to ensure environmental compliance throughout its service life.

The differentiation between leaching behaviour of the raw SFS and that of the final concrete product is therefore critical for a comprehensive environmental evaluation strategy.

**Assessment of Potential Valorisation Opportunities for Steel Furnace Slag**

The identification of potential valorisation opportunities for steel furnace slag (SFS) was conducted through a systematic review of the scientific literature addressing its applications in construction materials and environmental technologies. The analysis focused on studies investigating the use of SFS in cement-based materials, road infrastructure, and environmental remediation systems.

One of the most extensively investigated valorisation pathways for SFS is integration into

cement-based materials. Numerous studies report the successful use of SFS as a partial replacement for natural aggregates in concrete and mortar mixtures, contributing to improved mechanical performance and enhanced durability of cementitious composites (Chatzopoulos et al., 2021; Ren & Li, 2023; Mitwally et al., 2024; Ibrahim et al., 2025; Khan et al., 2025). The angular particle morphology and high density of steel slag aggregates may improve the mechanical interlocking within the cement matrix, leading to increased compressive strength and improved resistance to mechanical loading. Beyond its use as aggregate, SFS has also been investigated as a potential substitute for cement components in mortar and concrete mixtures. In such applications, finely processed SFS may partially replace clinker-based materials, contributing to the reduction of cement consumption and associated $CO_2$ emissions (Cai et al., 2024; Zhou et al., 2025).

Another important opportunity of valorisation pathway involves the use of SFS in road infrastructure applications. Due to its high hardness, abrasion resistance, and favorable mechanical properties, SFS have been widely investigated for use in asphalt mixtures, base layers, and other pavement structures (Hainin et al., 2015; Dayioğlu et al., 2023; Patel et al., 2023). These properties contribute to improved load-bearing capacity, enhanced skid resistance, and increased durability of pavement systems compared to conventional granular aggregates. In addition to asphalt mixtures and road base layers, SFS has also been explored for the production of paving elements such as concrete paving blocks used in urban infrastructure. The high density and mechanical stability of SFS aggregates make them suitable for prefabricated pavement elements where resistance to wear and mechanical stress is required (Pasetto et al., 2023; Sun et al., 2025).

In addition to construction applications, SFS has also been explored for environmental remediation purposes, particularly in water treatment systems. Due to its mineralogical composition and alkaline nature, SFS can act as an effective adsorbent for removing pollutants from aqueous solutions. Experimental studies demonstrate that SFS can adsorb heavy metal ions and other contaminants from water, highlighting their potential application as filtration media in water purification systems (Song et al., 2014; Plaza et al., 2021; Maarup et al., 2023). Overall, the literature indicates that steel furnace slag represents a versatile secondary resource with multiple valorisation opportunities across construction and environmental applications (Figure 5).

Figure 5. Main valorisation pathways of steel furnace slag in construction and environmental applications (AI-generated image)

## RESULTS AND DISCUSSIONS

### Effects of SFS on Fresh-State Properties

The influence of steel furnace slag (SFS) on the fresh-state behaviour of cementitious composites was evaluated through two representative examples.

The first example refers to investigations performed within the framework of the PN 23 35 04 01 research programme and reported by

Baera et al. (2024). The study evaluated the partial replacement of natural fine aggregate with electric arc furnace (EAF) slag originating from western Romania at substitution levels of 25% and 50%. The results demonstrated a consistent reduction in fresh-state workability for mixtures containing EAF slag compared to the reference compositions. Furthermore, the decrease in consistency became more pronounced as the replacement level increased, indicating a direct relationship between slag content and workability loss.

The second example conducted by Darwis et al. (2024), steel slag was used as a substitute for fine aggregate (sand) in concrete mixtures at replacement levels ranging from 0% to 100%. The results indicate a clear reduction in workability with increasing steel slag content. The reference mixture exhibited the highest slump value, while progressively lower slump values were recorded as the proportion of steel slag increased. Overall, the slump decreased from values of approximately 84 mm for the reference composition to around 60-70 mm at high substitution levels (80% and 100%), highlighting the adverse effect of steel slag incorporation on fresh-state workability due to its higher water absorption and irregular particle morphology.

The results indicate that fresh-state performance is strongly influenced by the characteristics of the slag used and the degree of replacement adopted. The consistent behavior observed in cement-based mixtures underscores the importance of specific material evaluation when blast furnace steel slag is considered as an alternative component in cementitious composites.

The patterns observed are consistent with those reported in the literature and support the hypothesis that the physical characteristics of SFS play a significant role in determining the workability of cement-based mixtures.

**Dimensional Stability and Expansion Mechanisms**

Based on studies Baera et al. (2024), Baera et al. (2026) and Darwis et al. (2024), cementitious composites containing steel furnace slag substitutions demand increased monitoring attention, as insufficient assessment may result in adverse long-term performance. Although no immediate dimensional instability was detected during the early stages, the behaviour of the investigated mixtures indicates that the incorporation of SFS requires careful evaluation in relation to potential time-dependent volumetric changes.

The results suggest that the risk of delayed expansion is closely related to the intrinsic characteristics of the SFS rather than to the cementitious compositions itself. In this context, the presence of reactive oxide phases and the heterogeneous internal structure of SFS particles, as described previously, may contribute to localized expansion and internal stress development when favourable conditions are present. These effects are not necessarily evident at early ages, emphasizing the importance of correlating experimental observations with material characterization data. Any volumetric changes occurring within the SFS particles may directly affect the surrounding cement matrix, potentially leading to microcracking and reduced durability over time. The results underline that dimensional stability should not be assessed exclusively based on short-term performance, but rather in relation to the long-term behaviour expected under service conditions.

Overall, the findings confirm that the dimensional stability of SFS-containing composites is strongly dependent on slag-specific properties, reinforcing the need for a material-oriented evaluation approach prior to practical application.

**Mitigation Strategies in Case of Elevated Leaching**

In cases where leaching tests indicate elevated concentrations of hazardous elements, several mitigation strategies may be considered to reduce metal mobility prior to or after incorporation into cement-based compositions. Experimental investigations on SFS have shown that the release of heavy metals is strongly influenced by physicochemical parameters, particularly pH and environmental exposure conditions (Gomes & Pinto, 2006). Adjusting these parameters through controlled aging or conditioning treatments may therefore contribute to lowering metal solubility.

Furthermore, studies performed under variable acidic and alkaline conditions demonstrate that

prolonged exposure and pH variation significantly affect the mobility of elements such as Cr, Fe, Ni, Zn, and As (Dhoble & Ahmed, 2018). These findings suggest that pre-treatment approaches aimed at stabilizing reactive phases, reducing surface reactivity, or promoting the formation of less soluble compounds may enhance environmental compatibility.

In addition, incorporation of SFS into cementitious matrices may contribute to partial immobilization through physical encapsulation and chemical stabilization mechanisms, particularly under highly alkaline conditions (Gomes & Pinto, 2006). Consequently, appropriate material conditioning combined with optimized mix design may represent effective pathways to mitigate excessive leaching where initial tests indicate environmental risk.

## CONCLUSIONS

This study highlights the importance of a comprehensive and specific approach to the material in terms of utilizing steel furnace slag (SFS) in cement-based composites. The conclusions highlight that the successful integration of SFS largely depends on the initial thorough characterization of the raw material, as steel furnace slag cannot be considered a uniform or inherently stable constituent.

The preliminary characterization stage is essential in identifying the key physical, chemical, and mineralogical characteristics of SFS and establishing correlations between these characteristics and the most critical challenges associated with its use. In particular, reduced workability, dimensional instability, and the presence of heavy metals have been identified as the main issues requiring careful evaluation. These challenges are closely related to the specific properties of the SFS, such as particle morphology, mineralogical heterogeneity, reactive oxide phases, and chemical composition.

Among these aspects, dimensional stability is a major concern due to the potential for delayed expansion effects. Therefore, the potential for delayed expansion highlights the need for comprehensive characterization, including mineralogical evaluation and expansion-related testing, prior to the practical application of SFS in construction materials. At the same time, workability effects and environmental considerations further reinforce the need to correlate material characterization results with performance indicators in the short and long term.

The assessment of leaching behaviour represents a critical component in the environmental evaluation of steel furnace slag (SFS) and its cement-based compositions. While preliminary testing on raw materials of SFS provides essential information regarding the intrinsic mobility of potentially hazardous elements, the behaviour of the final cementitious composite may differ substantially due to encapsulation and chemical stabilization mechanisms. A comprehensive evaluation strategy must therefore integrate both stages of assessment, ensuring that material conditioning, mix design, and long-term exposure conditions are collectively considered. Such an approach supports the responsible valorisation of SFS while maintaining environmental safety and regulatory compliance.

The results also demonstrate that short-term observations are not sufficient to fully assess the behaviour of SFS-containing composites. Long-term monitoring and performance evaluation are essential to capture time-dependent processes and to support the development of appropriate mitigation strategies. Addressing these challenges requires not only systematic testing, but also the identification and optimization of potential solutions, such as adjusting the composition design, material processing methods, or conditioning treatments.

Despite the challenges identified, SFS remains a material with significant potential for recovery. When properly characterized and controlled, SFS offers important opportunities for sustainable resource use, contributing to waste reduction, conservation of natural aggregates, and implementation of circular economy principles in the construction sector.

***Abstract***

*Peatlands represent globally significant carbon reservoirs, and the microalgae inhabiting these sensitive ecosystems play an essential role in climate change mitigation. Peatland microalgae occur not only in surface waters but also within peat layers, contributing to carbon fixation through photosynthesis. This study investigates the diversity of cultivable microalgae from peatland waters and provides a preliminary characterisation based on pigment composition. Water samples were collected from two restored Romanian peatland sites, Avrig Peatbog and Mlaca Tătarilor Peatbog, selected due to their similar characteristics. Microalgal strains were isolated and cultivated under laboratory conditions in BG-11 medium. Identification was performed at the genus level using the microphotography method, an approach suitable for baseline diversity assessment studies. Photosynthetic pigments were extracted from the isolates and analysed using UV–Vis spectrophotometry. Ten cultivable microalgal strains were obtained, with higher diversity in Avrig Peatbog compared to Mlaca Tătarilor Peatbog. The combined morphological and pigment-based analysis revealed microalgal genera adapted to acidic, humic-rich peatland waters and differences in pigment profiles among isolates. These findings provide baseline data and support future molecular, ecological, and biotechnological investigations.*

***Key words:*** *cultivable microalgae, peatlands, pigments spectrophotometry.*

## INTRODUCTION

Peatlands are dynamic ecosystems that provide essential ecological services, including biodiversity conservation, carbon storage, and water regulation. Although they cover only a small proportion of the Earth's land surface (about 3%), peatlands store a disproportionately large amount of global soil carbon (about 30%), making them key components of climate regulation and long-term carbon sequestration (Parish et al., 2008; Yu et al., 2010; Leifeld & Menichetti, 2018). The functioning of these ecosystems is strongly controlled by complex interactions between vegetation, hydrology, and microbial communities that regulate the balance between carbon fixation and decomposition.

In peatland environments, microorganisms play a fundamental role in carbon cycling processes. Among them, microalgae represent an important yet relatively understudied component of peatland biodiversity. These unicellular photoautotrophic microorganisms occur not only in surface waters but also within moist peat layers, where they contribute to primary production and carbon fixation through photosynthesis (Rydin & Jeglum, 2013; Yadav & Singh, 2020). Their ability to tolerate acidic conditions, high concentrations of humic substances, and nutrient-poor environments allows them to thrive in peatland habitats and makes them valuable indicators of environmental conditions (Bellinger & Sigee, 2015). In addition, microalgae are increasingly recognised as aquatic bioindicators with multiple ecological and applied research applications (Tsuraya et al., 2023).

The physicochemical characteristics and biodiversity of peatland surface waters are influenced by climatic and geographical factors but also by land management practices and anthropogenic pressures (Kowalik et al., 2014; Serafin et al., 2023). Changes in hydrology, drainage, or vegetation structure may alter water chemistry and light availability, thereby influencing the composition and ecological strategies of phototrophic microorganisms.

Romanian peatlands represent an important component of the national natural heritage and contribute significantly to biodiversity conservation and climate regulation. Among these ecosystems, Mlaca Tătarilor Peatbog was designated as a Site of Community Importance (ROSCI0112) in 2011 under the Natura 2000 network, primarily for the habitat type 7150 "Depressions on peat substrates of the Rhynchosporium" (Natura 2000 Reference Portal; Natura 2000 Viewer). Currently, the site is designated as a Special Area of Conservation (SAC) - ROSAC0112 under Government Decision No. 47/2024. The Avrig Peatbog overlaps with the Natura 2000 site ROSPA0098 Piemontul Făgăraș and was recently proposed as a Special Area of Conservation (SAC) in April 2024 (Ștefănuț et al., 2025) for habitats 7120 "Degraded raised bogs still capable of natural regeneration" and 7110* "Active raised bogs".

Following more than fifteen years of ecological monitoring, Mlaca Tătarilor Peatbog was selected in 2016 within the PeatRO project as a pilot area for demonstrating restoration methods applied to degraded peatland ecosystems. Similarly, the Avrig Peatbog, first described by Pop (1960) and rediscovered during the PeatRO project, was restored in 2023 through the PeatRO2 project. In both sites, the main factor responsible for the deterioration of peatland conservation status was long-term hydrological imbalance caused by drainage channels and the expansion of woody vegetation. Due to their comparable size, hydrological recovery, and restoration history, these two peatbogs provide suitable systems for comparative ecological investigations.

Despite their ecological importance, the diversity and ecological roles of microalgae inhabiting Romanian peatland waters remain poorly documented. Baseline studies based on the isolation and cultivation of microalgal strains are therefore important for understanding the composition of these communities and for exploring their physiological and biochemical characteristics.

In this context, the present study aimed to isolate cultivable microalgae from the surface waters of two restored Romanian peatbogs, Mlaca Tătarilor and Avrig, and to perform a preliminary characterization based on morphological features and pigment composition. Microalgal strains were identified using optical microscopy and the microphotography method, while pigment profiles were analysed using UV–Vis spectrophotometry. By integrating morphological observations with pigment-based characterization, this study provides baseline information on the diversity and physiological traits of microalgae inhabiting restored peatland ecosystems and supports future ecological, molecular, and biotechnological research.

## MATERIALS AND METHODS

### Sites` localisation and description

Both study sites lie in Sibiu County, Romania, within the Făgăraș Depression (northern sector of the Southern Carpathians, subalpine biogeographic region). The Mlaca Tătarilor Peatbog (SB-001; Figure 1) covers an area of 3.7 ha at an altitude of 548 m a.s.l. (45.425486°N, 24.3915012°E) and is administrated by the Arpașu de Sus town hall. The Avrig Peatbog (SB-013; Figure 2) covers 3.6 ha at 405 m a.s.l. (45.716282°N, 24.400133°E) and falls within the administrative boundaries of Avrig town. Their similar size and hydrological recovery after restoration make them ideal for parallel microalgal assessment.

### Water sampling and physicochemical analysis

***Water samples*** for microalgae identification were collected during the March 2025 field trip from zones with relevant water accumulation at both sites.

***Physicochemical parameters*** of the peatland water were measured *in situ* at five points (P1-P5) per site (Figures 1 and 2), using a HI9829 multiparameter probe (Hanna Instruments). Parameters recorded included pH, oxidation-reduction potential (ORP), oxygen saturation (DO%), dissolved oxygen (DO), conductivity, total dissolved solids (TDS), salinity (PSU), turbidity, water temperature and water pressure (PSI).

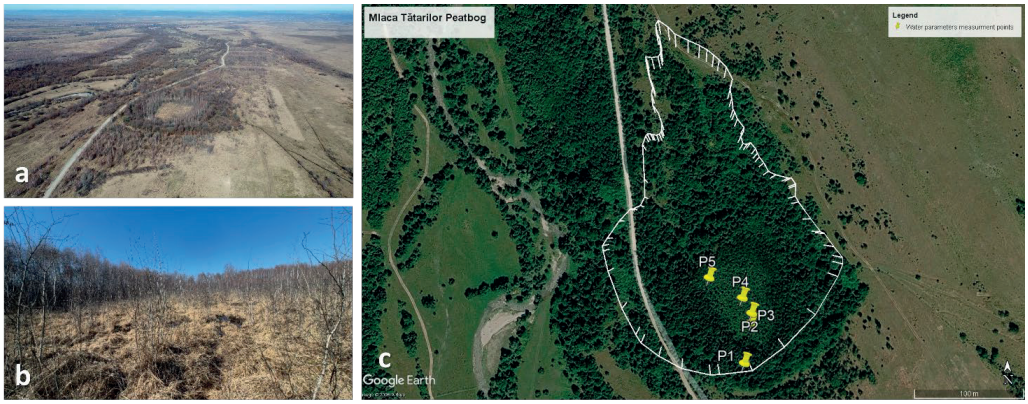

Figure 1. Mlaca Tătarilor Peatbog: (a) Drone view (Photo: Ștefănuț S., 10.03.2026); (b) Ground view (Photo: Moroșanu A.-M., 09.03.2026); (c) Site`s limits; marked points of water parameter measurements (Google Earth)

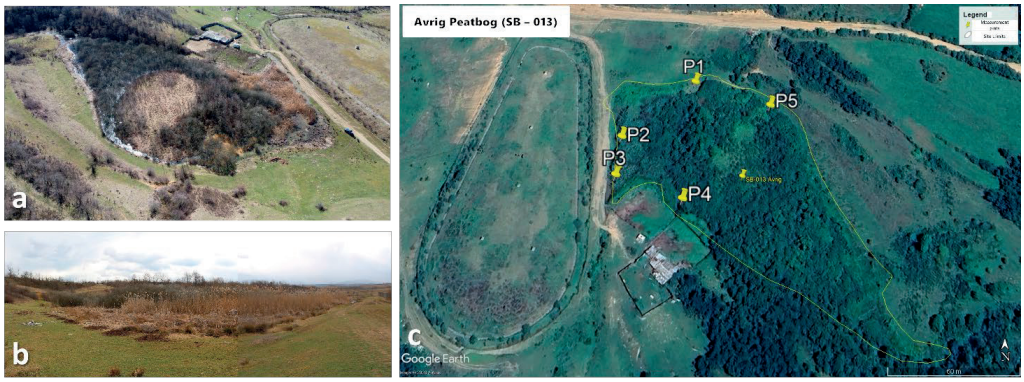

Figure 2. Avrig Peatbog: (a) Drone view (Photo: Ștefănuț S., 11.03.2026); (b) Ground view (Photo: Moroșanu A.M., 13.03.2025); (c) Site`s limits; marked points of water parameter measurements (Google Earth)

**Isolation, identification, and characterization of microalgae**

***Microalgae isolation and cultivation***. Peat water samples were collected at each site from the upper layer of the water column directly into sterile 50 mL plastic bottles. The bottles were labelled and transported to the laboratory for further processing. The collected water samples were enriched in microalgae by mixing the water sample 1:1 with BG-11 medium (Allen & Stanier, 1968). The mixtures were incubated in Erlenmeyer flasks on a shelf under natural illumination at ambient temperature for at least one month, until algal growth became apparent. Well-grown algal cultures were streaked onto BG-11 agar plates, which were then incubated under aerobic conditions at 28 ± 2°C in a thermostatically controlled incubator. Cultures were illuminated with fluorescent lamps at an intensity of 16,500 lux under a 12:12 h light: dark cycle. A single colony was aseptically transferred and streaked onto fresh BG-11 agar plates, and the procedure was repeated until axenic algal cultures were obtained.

***Morphological identification***. Enriched microalgal samples and isolates grown on solid media were examined using a Zeiss AxioScope.A1 optical microscope (Carl Zeiss) equipped with an AxioCam ERc 5s camera. Identification was performed using the microphotography method based on detailed analysis of captured images. Microalgal cells were observed, documented, and morphologically identified to the genus level based on cell size and shape, chloroplast morphology, presence of pyrenoids, and the presence or absence of flagella, using standard microalgal identification keys (Prescott, 1962;

1964; Belcher & Swale, 1976; Serediak & Huynh, 2011; Bellinger & Sigee, 2015; Jeuck & Arndt, 2013).

***Pigment extraction and characterization***. For pigment extraction, 50 mL of each enriched culture (14–20 days old) was harvested by centrifugation at 7,500 rpm for 10 min to remove the water content. The resulting algal biomass was homogenized in 10 mL of 99% acetone and kept overnight in the dark at 4°C to ensure complete pigment extraction. The samples were then centrifuged at 13,000 rpm for 5 min, and the supernatant was collected. The pellet was re-extracted by repeated washing with 5 mL of 99% acetone until it became colorless. All extracts were pooled and evaporated under reduced pressure at 30°C, then stored at −20°C until pigment quantification.

***UV-Vis characterization*** of the extracted pigments was recorded using a Specord 210 Plus spectrophotometer (Analytik Jena) over the wavelength range of 350-750 nm at room temperature.

The pigment concentrations were calculated using the equations of Lichtenthaler (1987) for 100% acetone at 470 nm, 661.6 nm and 644.8 nm. Pigment data were primarily interpreted using pigment ratios, namely chlorophyll a to chlorophyll b (Chl a/Chl b) and total carotenoids to total chlorophyll (Car/(Chl a+b)).

## RESULTS AND DISCUSSIONS

### The physico-chemical parameters

#### Mlaca Tătarilor Peatbog (SB-001; ROSCI0112)

Water parameters were measured at five points (P1-P5): four within the *Sphagnum*-dominated zone and one point at the entrance, all characterized by a high water table (Figure 2; Table 1). Measurements revealed pH values of 6.62-7.13 (slightly acidic to neutral), likely due to mineral influence or degradation, potentially favoring microalgae tolerant to slightly acidic to neutral conditions. ORP values were near-neutral to slightly reducing, indicating predominantly anoxic conditions that favor anaerobic processes typical to waterlogged peat bogs. Moderate-to-good DO% values reflected variable oxygenation, with hypoxic microsites (anaerobic processes) alongside oxygenated zones (aerobic decomposition); this variability reflects hydrological heterogeneity. Also, DO values confirm moderate oxygenation in the surface water of Mlaca Tătarilor, yet hypoxic conditions in some areas. Low conductivity values and TDS values confirmed oligotrophic conditions with minimal mineral input. Invariable PSU values indicated extremely pure freshwater, while turbidity values reflected extremely clear water, typical of oligotrophic peat bogs, favoring light penetration for microalgae and *Sphagnum* photosynthesis. Early spring water temperatures minimized organic matter decomposition, favoring carbon sequestration in waterlogged *Sphagnum* zones. A stable hydrology and an elevated water table were reflected by PSI values.

Overall, there is a high consistency between the physicochemical parameters at the five points (P1-P5), indicating typical oligotrophic conditions in a hydrologically stable ecosystem that favors microalgae and *Sphagnum* species development as well as active carbon sequestration.

#### Avrig Peatbog (SB-013)

Measurements were taken in water pools and drainage channels (Figure 2; Table 2). The water pH ranged between 6.61 and 7.47 (slightly acidic to neutral). The water pool showed the highest ORP and DO concentration, while the drainage channels exhibited had the highest TDS, salinity, conductivity, and turbidity values due to sediment accumulation. Water temperature and pressure were nearly similar across both location types, correlating with seasonal biochemical processes. ORP varied from positive (oxidation of organic matter) to negative (reducing reactions).

Overall, parameters indicated a gradient from well-oxygenated, low-mineralised reed-fringed pools (P2) to mineralised, drainage-influenced points (P3-P4) and highly reductive, hypoxic channels (P5), reflecting combined peatland hydrology and anthropogenic drainage influences.

Table 1. Water parameter values - Mlaca Tătarilor Peatbog

Our slightly acidic-neutral pH (6.6-7.5), low conductivity/TDS, and variable ORP/DO values in both studied restored peatbogs align with post-restoration recovery trends in European minerotrophic peatlands (Andrews et al., 2025). Mlaca Tătarilor Peatbog`s stable anoxia resembles typical waterlogged peatbog conditions, while Avrig`s hydrological gradient reflects anthropogenic disturbance, creating microalgae niches. These patterns indicate incipient hydrological recovery post-restoration.

The physicochemical characteristics of peatland waters provide the environmental context in which phototrophic microorganisms develop. In order to further investigate the physiological traits of the cultivable microalgae associated with these environments, pigment extracts obtained from enriched cultures were analysed using UV–Vis spectrophotometry.

## Pigment profiles of enriched microalgal cultures

Pigment extracts obtained from enriched microalgal cultures originating from the two studied peatland sites were analysed using UV-Vis spectrophotometry in order to investigate the physiological characteristics of the cultivable phototrophic microorganisms.

The recorded spectra (Figure 3) showed the characteristic absorption bands of photosynthetic pigments. Strong absorption maxima were observed in the blue region of the spectrum (Soret bands) and in the red region (Qy bands), corresponding to electronic transitions of chlorophyll molecules, while the spectral region between 400 and 500 nm corresponded to the main absorption domain of carotenoids. These pigments play essential roles in light harvesting and photoprotection and are widely used as indicators of physiological status and environmental adaptation in microalgae (Lichtenthaler, 1987; Falkowski & Raven, 2007).

Pigment ratios calculated from the spectra revealed variability among enriched cultures obtained from both peatlands (Table 3), suggesting differences in physiological acclimation of the cultivated microalgae.

In the cultures originating from Avrig Peatbog, the Chl a/Chl b ratio varied widely between 0.64 and 3.16. Higher ratios observed in several cultures (e.g., Avrig-2 and Avrig-3) indicate a relative predominance of chlorophyll a and may

reflect acclimation to environments with higher or more variable irradiance. Reduced antenna size associated with increased Chl a/Chl b ratios is commonly interpreted as an adaptive strategy in microalgae exposed to elevated light conditions or fluctuating illumination regimes (Falkowski & Raven, 2007; Bellinger & Sigee, 2015).

Conversely, lower Chl a/Chl b ratios, such as those observed in Avrig-1, suggest a relatively higher contribution of chlorophyll b and may indicate adaptation to shaded or optically filtered environments. Such conditions are typical for peatland waters where high concentrations of dissolved humic substances significantly modify the spectral composition and penetration of light in the water column (Rydin & Jeglum, 2013).

The Car/(Chl a+b) ratio also varied among the analysed cultures. Elevated carotenoid proportions recorded in some Avrig samples (e.g., Avrig-4 and Avrig-5) may reflect increased photoprotective investment. Carotenoids are known to play a key role in protecting the photosynthetic apparatus against oxidative stress and excessive irradiance, particularly in shallow or dynamic aquatic habitats (Falkowski & Raven, 2007).

Enriched cultures originating from Mlaca Tătarilor Peatbog displayed somewhat narrower Chl a/Chl b variation (0.85-1.79), suggesting a more balanced contribution of chlorophyll a and b compared with some of the Avrig cultures. These intermediate values may reflect adaptation to relatively stable light conditions within *Sphagnum*-dominated peatland microhabitats, where vegetation structure and water colour create diffuse light environments typical for bog ecosystems (Rydin & Jeglum, 2013).

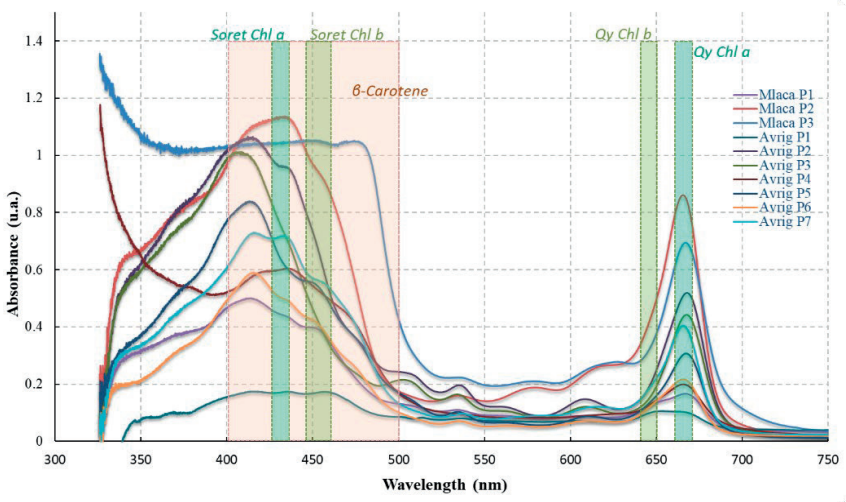

Figure 3. UV-Vis absorption spectra (300-750 nm) of pigment extracts from the analyzed microalgal cultures. The Soret bands (blue region) and Qy bands (red region) correspond to characteristic electronic transitions of chlorophylls. The 400-500 nm region represents the main carotenoid absorption range, overlapping with the chlorophyll Soret bands

Table 3. Pigment ratios of the analyzed microalgal enriched cultures

| Sample | Mlaca-1 | Mlaca-2 | Mlaca-3 | Avrig-1 | Avrig-2 | Avrig-3 | Avrig-4 | Avrig-5 | Avrig-6 | Avrig-7 |
|---|---|---|---|---|---|---|---|---|---|---|
| Chl a/Chl b | 0.85 | 1.79 | 1.78 | 0.64 | 2.74 | 3.16 | 1.13 | 1.91 | 1.46 | 1.92 |
| Car/(Chl a+b) | 0.20 | 0.13 | 0.37 | 0.09 | 0.20 | 0.15 | 0.44 | 0.33 | 0.26 | 0.26 |

The Car/(Chl a+b) ratio also showed variability among Mlaca samples, with the highest value observed in Mlaca-3. Increased carotenoid proportions are frequently associated with microalgal responses to environmental stress factors such as fluctuating irradiance or oxidative stress (Falkowski & Raven, 2007). Conversely, lower carotenoid values recorded in

Mlaca-1 and Mlaca-2 may indicate more stable microhabitat conditions where photoprotective requirements are reduced.

Although the physicochemical parameters were measured at representative monitoring points rather than at the exact locations of each enrichment culture, they provide a useful characterization of the environmental conditions prevailing within the studied peatland waters.

When interpreted together, the pigment patterns observed in the enriched cultures suggest that the cultivated microalgae exhibit considerable physiological plasticity, enabling them to cope with the heterogeneous environmental conditions typical of peatland ecosystems.

**Microalgae identification and ecological interpretation**

In addition to pigment analysis, microscopic examination of enriched cultures revealed several dominant microalgal morphotypes corresponding to common freshwater green algal and cyanobacterial genera (Figure 4). The observed taxa included representatives of *Chlorella*, *Chlorococcum*, *Scenedesmus*, *Closterium*, *Stichococcus*, *Chlamydocapsa*, *Gonium*, *Palmellopsis*, *Aphanocapsa*, and *Nostoc*.

The observed morphotypes correspond well with the pigment signatures detected in the UV–Vis spectra, which suggested the presence of chlorophyll-containing green algae and cyanobacteria in the enriched cultures.

It should be noted that enrichment cultivation may selectively favor fast-growing taxa. Consequently, the microalgal assemblages described in this study represent the cultivable fraction of the natural community rather than the complete *in situ* diversity.

During the isolation procedure, several strains were also transferred to solid BG-11 medium in order to obtain axenic cultures. Although these pure cultures were not the primary focus of the present study, their establishment ensures the availability of well-defined strains for future physiological, molecular, and biotechnological investigations. In the present work, however, pigment analysis was performed on enriched cultures in order to better reflect the dominant phototrophic components of the original peatland microbial assemblages.

**Morphological characterization of the observed morphotypes**

Figure 4 (a-c) shows solitary spherical cells measuring approximately 11-12 µm in diameter, which may tentatively be assigned to the genus *Chlorella* based on their morphological characteristics.

Figure 4 (d) shows solitary cylindrical cells with rounded ends, measuring approximately 11-12 µm in length and 5-6 µm in width. Considering the observed morphology and the habitat of origin, the isolate can be provisionally assigned to the genus *Stichococcus*.

In Figure 4 (e), a solitary elongated cell slightly curved with gradually tapered ends can be observed, measuring approximately 25 µm in length and 2.85 µm in width.

The high length-to-width ratio gives the cell a filiform appearance typical of small desmids. The observed morphology is consistent with the genus *Closterium*, a taxon frequently encountered in acidic oligotrophic ecosystems such as peatlands.

Figure 4 (f) illustrates cells with an ovoid morphology forming grape-like colonies composed of approximately eight cells embedded within a gelatinous sheath. The cells measure approximately 8-9.5 µm in length and 5.5-6.5 µm in width, and a pyrenoid is visible. Based on these characteristics, the colony may tentatively be assigned to the genus *Chlamydocapsa*, which is commonly reported from freshwater environments.

In Figure 4 (g), filamentous structures composed of spherical cells measuring approximately 3-6 µm in diameter are observed. Based on their morphology, these filaments most likely belong to the genus *Nostoc*.

Figure 4 (h) shows a flat plate of spherical cells embedded in a mucilaginous matrix. The colony consists of approximately 16 well-spaced cells and measures around 15 µm in length. The observed morphology is consistent with the genus *Gonium*.

In Figure 4 (i), cells embedded within a mucilaginous matrix forming a compact irregular colony can be observed. The cells are ovoid to ellipsoidal, measuring approximately 2-3.5 µm in width and 5-8 µm in length, and contain a distinct chloroplast with a visible pyrenoid. This palmelloid organization suggests affiliation with the genus *Palmellopsis*.

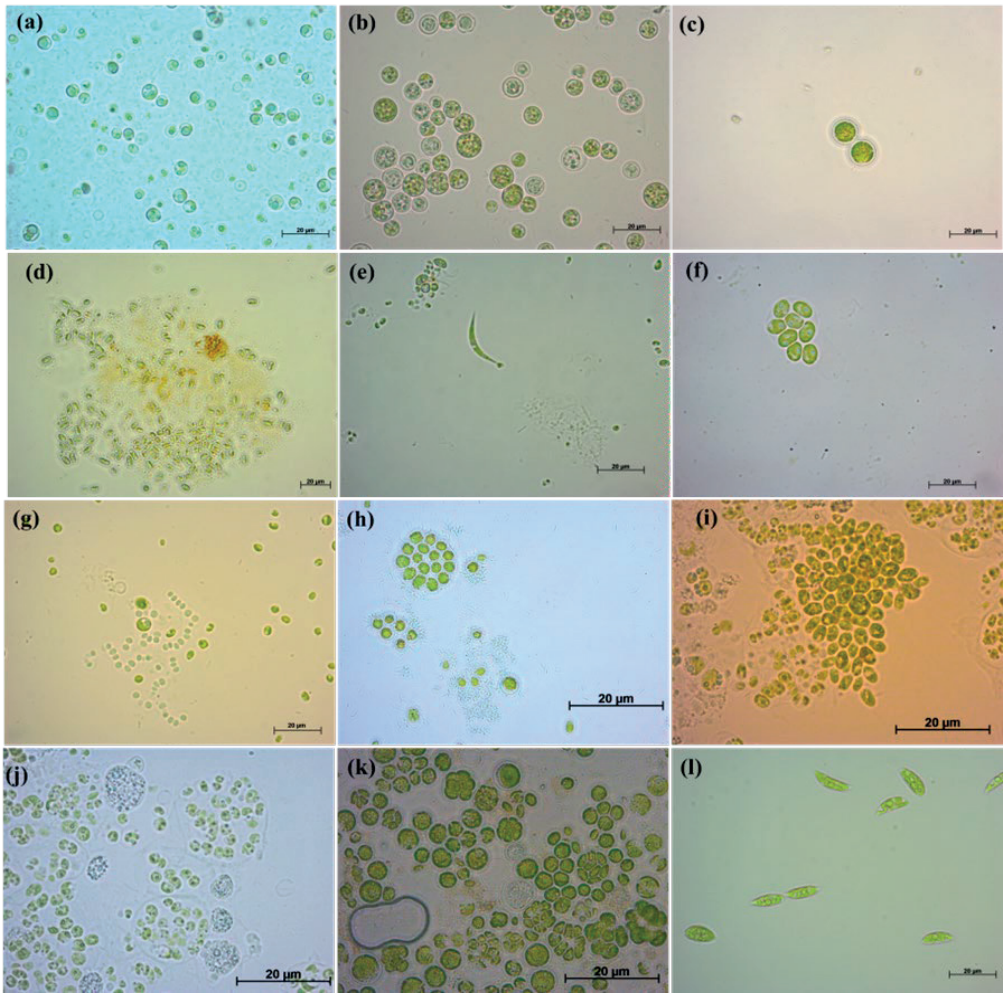

Figure 4. Representative microalgal morphotypes observed in enriched cultures derived from peatland water samples. (a-c) *Chlorella*-like cells; (d) *Stichococcus* sp.; (e) *Closterium* sp.; (f) *Chlamydocapsa* sp.; (g) *Nostoc* sp.; (h) *Gonium* sp.; (i) *Palmellopsis* sp.; (j) *Aphanocapsa* sp.; (k) *Chlorococcum* sp.; (l) *Scenedesmus* sp. Images were captured using bright-field microscopy. Scale bar = 20 µm

Figure 4 (j) shows a group of small cells embedded within a wide mucilaginous sheath resembling colonies of *Aphanocapsa*. Cells appear spherical and reach up to 4 µm in diameter. Species of *Aphanocapsa* typically form gelatinous colonies composed of spherical cells measuring approximately 1-5.5 µm depending on the species.

In Figure 4 (k), unicellular spherical cells with smooth cell walls are observed, occurring both as solitary individuals and in small colonies. These characteristics are consistent with the genus *Chlorococcum*.

Figure 4 (l) shows solitary unicellular organisms with elongated fusiform to ellipsoidal shapes measuring approximately 13-18 µm in length and 5.2-7 µm in width. Cells contain a parietal chloroplast with a visible central pyrenoid, a morphology consistent with the genus *Scenedesmus*, a taxon commonly reported from nutrient-rich freshwater environments.

The observed morphotypes reflect the taxonomic diversity of cultivable phototrophic microorganisms present in the studied peatland waters.

**Distribution of microalgal genera across sampling sites**

The distribution of the identified genera across sampling sites provides additional insight into the ecological characteristics of the studied peatland habitats and is summarized in Table 4. Overall, the results indicate the presence of a diverse assemblage of green algae and cyanobacteria in both peatland systems.

In Mlaca Tătarilor Peatbog, several colonial and mucilage-producing taxa were detected, including *Chlamydocapsa, Palmellopsis* and *Aphanocapsa*. These genera are commonly associated with freshwater environments rich in dissolved organic matter and are frequently reported from peatland pools where extracellular mucilage provides protection against environmental stress and facilitates colony formation (Bellinger & Sigee, 2015).

The presence of *Gonium*, a colonial volvocalean alga, suggests the existence of shallow water microhabitats with sufficient illumination for colonial flagellate algae. Volvocalean taxa are commonly observed in nutrient-poor freshwater environments where they contribute to planktonic primary production (Bellinger & Sigee, 2015).

Table 4. Dominant microalgal morphotypes observed in enriched cultures obtained from peatland water samples.

| Sampling site | Observed microalgal and cyanobacterial genera | Dominant morphotype | Cell morphology | Approx. cell size (µm) |
|---|---|---|---|---|
| Mlaca P1 | *Chlorella* sp.<br>*Chlamydocapsa* sp. | *Chlamydocapsa* sp. | ovoid morphology forming grape-like colonies | 8-9.5 µm in length 5.5–6.5 µm in width |
| Mlaca P2 | *Aphanocapsa* sp.<br>*Palmellopsis s*p. | *Aphanocapsa* sp. | spherical<br>ovoid to ellipsoidal | 3-4 µm in length<br>2-3.5 µm in width |
| Mlaca P3 | *Chlorella* sp.<br>*Gonium* sp. | *Gonium* sp. | mucilaginous matrix with spherical cells | 15 µm |
| Avrig-P1 | *Chlorella* sp. | *Chlorella* sp. | solitary spherical cells | 11-12 µm |
| Avrig-P2 | *Chlorella* sp.<br>*Scenedesmus sp.*<br>*Chlorococcum* sp. | *Scenedesmus sp.* | fusiform to ellipsoidal | 13-18 µm |
| Avrig-P3 | *Chlorella* sp. | *Chlorella* sp. | solitary spherical cells | 11-12 µm |
| Avrig-P4 | *Chlorella* sp.<br>*Nostoc* sp. | *Chlorella* sp. | solitary spherical cells | 11-12 µm |
| Avrig-P5 | *Chlorococcum* sp.<br>*Chlorella* sp.<br>*Closterium* sp. | *Closterium* sp. | solitary elongated cell, slightly curved | 25 µm in length 2.85 µm in width |
| Avrig-P6 | *Stichococcus* sp. | *Stichococcus* sp. | solitary cylindrical cells with rounded ends | 11-12 µm length<br>5-6 µm in width |
| Avrig-P7 | *Chlorella* sp.<br>*Chlorococcum* sp. | *Chlorococcum* sp. | spherical | 5-8 µm |

The frequent occurrence of *Chlorella*-like cells in Mlaca samples further indicates the presence of ecologically versatile microalgae capable of colonizing a wide range of aquatic habitats. Species of *Chlorella* are widely distributed in freshwater ecosystems and are known for their high physiological tolerance to variations in nutrient availability, light conditions and mineralization (Bellinger & Sigee, 2015).

In Avrig Peatbog, a broader morphological diversity was observed, including *Chlorococcum, Scenedesmus, Closterium, Stichococcus* and the cyanobacterium *Nostoc*. Several of these taxa are commonly reported from freshwater environments characterized by fluctuating nutrient concentrations and dynamic hydrological conditions.

The occurrence of *Scenedesmus* sp. and *Chlorococcum* sp. suggest the presence of microhabitats influenced by increased nutrient availability or environmental disturbance, as these genera are well known for their ability to rapidly colonize nutrient-enriched aquatic environments (Bellinger & Sigee, 2015).

In contrast, the presence of *Closterium* sp., a representative of desmid algae, indicates the occurrence of microhabitats typical of peatland ecosystems. Desmids are frequently associated with oligotrophic, slightly acidic waters rich in dissolved organic matter and are considered characteristic components of bog and fen algal communities (Coesel & Meesters, 2007).

The detection of *Nostoc* sp., a filamentous cyanobacterium capable of atmospheric

nitrogen fixation, may further indicate localized nitrogen limitation in certain peatland microhabitats. Nitrogen-fixing cyanobacteria are known to play an important ecological role in nutrient-poor aquatic systems by contributing biologically available nitrogen (Falkowski & Raven, 2007).

When interpreted together, the pigment data and the morphological identification provide complementary information regarding the ecological strategies of the cultivable microalgae inhabiting the studied peatland waters.

**Ecological significance of cultivable microalgal assemblages**

The ecological characteristics and indicator value of the most frequently identified genera are summarized in Table 5. Several of these taxa are widely used as indicators of water quality and trophic conditions in freshwater ecosystems (Bellinger & Sigee, 2015).

Table 5. Ecological characteristics and indicator value of the main microalgal genera

| Genus | Typical habitat | Indicator value |
|---|---|---|
| *Chlorella* | freshwater, planktonic | mesotrophic–eutrophic waters |
| *Scenedesmus* | planktonic green algae | eutrophic conditions |
| *Closterium* | oligotrophic acidic waters | peatland/desmid flora |
| *Nostoc* | benthic or colonial cyanobacteria | nitrogen-limited environments |
| *Stichococcus* | aerophytic / oligotrophic | tolerant to stress |

Ecologically versatile genera such as *Chlorella, Chlorococcum* and *Scenedesmus* are commonly reported as early colonizers of newly formed or disturbed aquatic habitats. Their presence in several enriched cultures suggests the ability of these taxa to rapidly establish populations in peatland pools and shallow water accumulations, contributing to primary production and the initial development of microbial food webs.

At the same time, the occurrence of taxa typically associated with oligotrophic peatland habitats, such as *Closterium* and *Stichococcus*, indicates the persistence of microhabitats characterized by low nutrient concentrations and high levels of dissolved organic matter.

Colonial and mucilage-producing forms such as *Palmellopsis, Chlamydocapsa* and *Aphanocapsa* may represent adaptive strategies to humic-rich waters where extracellular mucilage provides mechanical protection and facilitates colony stability.

Together, these observations suggest that the cultivable microalgal assemblages reflect the environmental heterogeneity of restored peatland ecosystems, where variations in hydrology, light availability and nutrient concentrations generate a mosaic of ecological niches for phototrophic microorganisms.

Similar patterns of microalgal colonization have been described in other peatland systems, where phototrophic microorganisms play an important role in primary production and in the re-establishment of microbial communities following ecological disturbance or restoration (Yadav & Singh, 2020).

These findings contribute to the baseline knowledge of peatland microbial phototroph diversity in Romanian wetlands and provide a starting point for future ecological and molecular investigations.

Future studies integrating molecular identification techniques and seasonal monitoring would further improve our understanding of the ecological dynamics of microalgal communities in restored peatlands.

## CONCLUSIONS

The present study provides a first overview of the cultivable microalgal diversity inhabiting the surface waters of two restored Romanian peatlands (Avrig Peatbog and Mlaca Tătarilor Peatbog).

The physicochemical measurements revealed a clear environmental gradient across sampling points in Avrig Peatbog, ranging from well-oxygenated pools to mineralized drainage channels and reductive, hypoxic microhabitats. In contrast, Mlaca Tătarilor Peatbog exhibited more uniform, stable oligotrophic conditions with predominant anoxia. Both sites shared slightly acidic-neutral pH and low mineralization favoring non-acidophilic microalgae and carbon sequestration, with incipient hydrological recovery post-restoration.

Pigment analysis of enriched cultures indicated variations in photosynthetic pigment composition, suggesting physiological acclimation of microalgal strains to local environmental conditions such as light availability, mineralization, and redox status.

Microscopic observations revealed several representative freshwater microalgal genera, including *Chlorella*, *Chlorococcum*, *Scenedesmus*, *Closterium*, and *Stichococcus*, whose ecological preferences are consistent with the physicochemical characteristics of peatland waters.

These findings provide baseline information on the cultivable fraction of peatland microalgal communities and contribute to a better understanding of the microbial diversity associated with restored peatland ecosystems.

## ACKNOWLEDGEMENTS

This research work was carried out with the support of the Institute of Biology Bucharest, Romanian Academy, through the Projects Project RO1567-IBB05/2026, and also was financed from PeatRO2 Project (RO-ENVIRONMENT-0004), and PDD project, SMIS 336936,"Enhancing knowledge of biodiversity through the implementation of the monitoring system for the conservation status of species and habitats of community interest in Romania and reporting under Article 17 of the Habitats Directive 92/43/EEC".

# INTEGRATED GEOTECHNICAL AND STRUCTURAL APPROACHES FOR REDUCING SEISMIC VULNERABILITY OF HERITAGE BUILDINGS

**Stefan Florin BALAN, Bogdan Felix APOSTOL**

National Institute of C-D for Earth Physics, 12 Calugareni Str., Magurele, Romania

***Abstract***

*The paper outlines key characteristics of heritage buildings and explains why they require protection against strong seismic motions generated by the Vrancea source. One of the most common challenges these structures face is differential settlement during earthquakes; to mitigate this, several supplementary measures can be implemented. Resonant column or dynamic triaxial tests, used alongside standard geotechnical investigations, provide additional insight into soil behaviour. These methods focus on evaluating the variation of the shear modulus with strain, enabling a more accurate assessment of soil properties. The resulting data support the selection of appropriate interventions to improve site conditions and reduce the risk of structural damage during future major seismic events. Structural protection can also be enhanced through base-isolation techniques, applied according to site conditions and the specific characteristics of each building. This approach reduces seismic forces and modifies critical response parameters to safer levels. The paper highlights the advantages of these optional measures for safeguarding historical monuments and older administrative buildings, emphasizing both their technical effectiveness and their broader economic and social benefits.*

***Key words****: heritage buildings, seismic vulnerability, settlements, seismic isolation, resonant column.*

## INTRODUCTION

The protection and rehabilitation of heritage buildings include consideration of the impact of seismic movements affecting the soil deposit on which their foundation rest and the structure. The paper considers heritage buildings situated in Bucharest - capital of Romania - a city under the influence of Vrancea seismic region. This seismic source, the most important in Romania, in terms of magnitude, human and economic losses in the country, only in the last century has triggered 2 major earthquakes: November 10, 1940 with moment magnitude Mw = 7.7, approximately 600 victims, and March 4, 1977 with moment magnitude Mw = 7.4, approximately 1500 victims (Mărmureanu, 2020). The latter seismic event damaged and destroyed approximately 32900 buildings in Bucharest and in other parts of S-E of the country (Balan et al., 1982).

The paper focuses on some optional measures considered by structural designers during rehabilitation, necessary to mitigate the seismic vulnerability of these structures, beyond those imposed by the norms in force. First of them is an optional evaluation to be performed, after standard geotechnical studies were accomplished, and involves tests on resonant columns or dynamic triaxial. They allow to calculate geotechnical and rocks specific parameters, as they varying inside the soil deposit during strong seismic shakings. The reason of this evaluation is linked to the settlement phenomenon that may appear in the aftermath of a strong earthquake, for foundation of structures, especially if located on soft, sedimentary soils.

Situated in the central sector of the Vlăsia Plain - a sub-division of the broader Romanian Plain - Bucharest is located approximately 165 km from the Vrancea seismic zone. The region is geologically characterized by thick, unconsolidated sedimentary deposits. The local topography is heavily influenced by the Dâmbovița and Colentina rivers, which created distinct zones prone to natural erosion and alluvial sedimentation. Consequently, evaluating the geological, geotechnical, and hydrological properties of the local aquifer systems is essential for assessing the overall environmental and structural stability of the urban area.

These soil conditions can favour the development of ground settlements, either due to naturally soft soil layers or anthropogenic factors such as artificial fills. Identifying these zones and understanding the processes that

cause such soil behaviour is essential. Equally important is knowing what types of buildings occupy these areas, their structural systems, and whether they have undergone previous repairs or experienced past seismic events.

Settlements can introduce additional stresses into building structures, and during an earthquake these stresses may amplify damage, leading to cracks in structural elements, displacement of interior walls, or deterioration of floors and installations. Building vulnerability increases when settlement-induced stress is compounded by seismic stress from strong earthquakes.

Earthquakes generate seismic waves that propagate from the source through the geological environment and reach sediment layers. The soil material of the subsurface layers is subjected to seismic stresses equivalent to dynamic loads with variable levels of strain. The level of soil deformation depends on many parameters, such as: the event duration, maximum ground acceleration, number of wave cycles, type of waves, soil type, and depth.

When soils are subjected to time-dependent dynamic loading (e.g. earthquakes or vibrations), their deformation directly depends on the amplitude and repetition of the cyclic shear deformation (Ishihara, 1996; Braja & Ramana, 2011). The soil exhibits a transition to nonlinear behaviour at deformation ranges above $10^{-4}$-$10^{-2}$%, associated with the accumulation of permanent deformations. This leads to progressive crack widening and significant differential settlements. For deformation levels greater than $10^{-2}$ %, the soil configuration undergoes strong nonlinearity and elastoplastic deformation; structural bonds break, severely reducing soil cohesion. This reduction in internal strength results in soil sliding (shear failure), excessive compaction/consolidation, and increase in pore water pressure. This behaviour leads to soil instability, foundation settlement, and liquefaction during seismic loading (Bratosin, 2002; Yoshida, 2015). The degradation of soil stiffness and cyclic settlements induced by strong earthquakes can be significant in urban areas formed by granular soil types, and Bucharest is one of the cases (Vucetic & Dobri, 1991).

Earthquake-induced settlements should be considered separately for two cases, the one with structures and the other without structures on the surface of the ground. For the former: total incremental settlement $\Delta S_t = \Delta S_{is} + \Delta S_{cy\,s}$, where immediate settlement – immediately after earthquake is $\Delta S_{is}$, and due to dissipation of cyclic-induced excess pore pressures $\Delta S_{cy\,s}$.

Another optional measure to protect the construction from powerful forces inside it during a strong seismic event is to isolate the structure from the foundation through different methods (Apostol et al., 2017; Liu et al., 2014; Taniguchi et al., 2008). The paper points out the results of seismic-base isolation intervention, highlighting the monitoring buildings activity and data processing performance (Balan et al., 2020).

The benefits of these optional measures to protect heritage buildings from strong earthquakes are discussed.

## MATERIALS AND METHODS

An essential step at the start of any rehabilitation project is evaluating whether the existing soil deposit can safely support the additional loads introduced by the planned construction activities. To do this, it is advisable to repeat the standard geotechnical investigations. (Common tests to re-evaluate the site include the Standard Penetration Test (SPT) for relative density and soil strength, Cone Penetration Test (CPT) for detailed soil profiles, Pressure meter tests (PMT) and Cross-hole/Down-hole Seismic Tests).

In regions where strong earthquakes ($M_W > 7$) may occur, designers are particularly concerned about potential seismic-induced settlements. If the standard tests indicate that the soil is susceptible to settlement under dynamic loading, additional specialized tests may be carried out to better understand and control these effects (Wong et al., 2022; Jurček et al., 2024).

Authors recommend in this situation to perform resonant column or dynamic triaxial tests. Both are showing the variation of the shear modulus (G) and damping (D) with strain (γ) induced in the soil deposit by strong earthquakes ($M_W > 7$). Resonant columns and dynamic triaxial are electro-mechanical devices which could simulate seismic stress/strain to a soil sample from the site of interest, gathered from different depths.

The resonant columns are devices functioning in a dynamical regime to determine soils-specific

parameters and characteristics. They can perform engineering seismology-devoted activities and highlight the non-linear effects of the behaviour of degraded rocks under strong seismic movement and experimental studies on dynamical devices. For example, the non-linear behavior of the soil as observed in laboratory tests on Hardin-Drnevich resonant columns, for strain level exceeding $10^{-5}$ - $10^{-4}$ % is a result of reference in geotechnical research (Bratosin, 2002). The devices use a procedure that analyses the non-linear soil behaviour of shear modulus G = G(γ) and damping function D = D(γ), function of strain level (γ).

Principle of functioning as based on standard configurations, employs a typically cylindrical soil sample fixed at the base and free to vibrate at the top. A torque device attached to the top generates a torsional moment, $M = M_0 \sin\omega t$, and another device generates a longitudinal force $F = F_0 \sin\omega t$ to vibrate the sample, in turn. The Drnevich-type resonant column as in Figure 1 (left), (Bratosin, 2002) typically utilizes only torsional vibration, including refinements to the driving system to better measure damping and accommodate higher strains. Hardin-type device applies $M = M_0 \sin\omega t$ and an axial force (F) to simulate in-situ confining pressure (for example a construction).

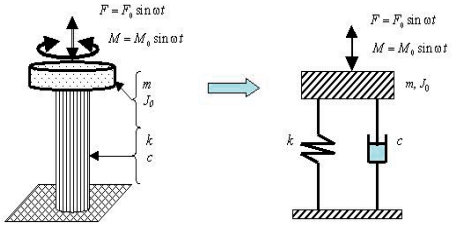

Figure 1. Scheme of resonant column (left) and nonlinear Kelvin-Voigt model (right)

In the Figure 1 (right) (Bratosin et al., 2009) the harmonic excitation for a single degree of freedom model is represented either as external time-varying force $F$ with amplitude $F_0$, or external moment $M$ with excitation amplitude $M_0$. The employed parameters are: moment of inertia of vibration $J_0$, stiffness $k$, damping $c$, pulsation of the external input $\omega$ and mass of the soil sample $m$. The constitutive stress-strain relationships imply the need for viscoelastic laws, and the appropriate model used in this situation is the nonlinear Kelvin-Voigt type (Bratosin et al., 2009).

For higher values of strain (> $10^{-3}$ %), characteristic of strong earthquakes, stress tests are recommended to be performed on a classic/ dynamic triaxial device, (Kumar et al., 2021) which imply a specialized laboratory method used in geotechnical engineering to measure soils behaviour under cyclic or rapidly changing loads, such as those caused by earthquakes.

It is necessary, therefore, the adaptation to the specific situations occurring in the territory, aiming at obtaining the parameters of foundation soil behaviour (Mărmureanu et al., 2004).

The second optional measure employed herein to mitigate the seismic vulnerability of heritage buildings is seismic base-isolation.

Heritage buildings are in general fragile structures, of old materials and in no case designed under seismic codes (also Bucharest situation). During a strong earthquake (for example, above $M_W > 7$) in any construction appear strong shear and axial forces therefore vibrations with higher amplitudes than usual from daily traffic or sporadic construction works. The magnitude of these seismic solicitations that a structure could withstand, and their effects, depend on the characteristics of the construction and the orientation of its main axes with respect to the action of the incoming seismic waves. The purpose of rehabilitation design is to reduce the level of these seismic solicitations and one method to make this happen is to isolate the structure from its foundation through different methods.

The method of seismic base-isolation was already implemented in many parts of the world with very good results in mitigation of seismic vulnerability of important and old buildings (Pietra et al., 2015; Yenidogan & Erdik, 2016; Ghafar et al., 2025). It allows for large horizontal movements while maintaining vertical stiffness, thus minimizing the damage to both structural and non-structural components. Base isolation consists in inserting flexible layer (isolator devices) at the base of the building, separating the structure from its foundations. In the paper is shown that this technique is particularly effective for historic buildings (it reduces the amplitudes in the supra structure), also ensuring operational continuity of the building functioning.

The method was applied also in Bucharest on rehabilitation of four historic buildings. The particularities of these structures are shortly described as follows:

- The Bucharest Town Hall was constructed between 1906 and 1908, using brick masonry combined with reinforced concrete floors supported by turned caissons. A major consolidation project began in 2010, during which a seismic isolation system was installed. The building includes a basement, a ground floor, three upper levels, and an attic.
- The Bucharest University of Economic Studies building on "Calea Griviței" street, constructed between 1905 and 1908, features brick masonry and a truss roof. It includes a basement, a ground floor, two upper levels, and an attic. After consolidation works carried out post 2011, a seismic isolation system was added with two sensors one above and one under it.
- The Triumphal Arch is a distinctive historic monument dating back to the 1930s. Since 2016, when it was rehabilitated, it was monitored using two seismic sensors installed on the isolated structure - one positioned at ground level above the isolator devices and the other at the top of the monument.
- "Foisorul de Foc" constructed between 1890 – 1892, initial a water tank tower, then fire watching from the finish of XIX-th century, then used for other purposes, 42m height.

All four buildings are heritage ones, the first two are still in operation for the initial purpose, administrative and educational, the third is a monument in connection with World War One and the fourth is now the "Museum of Firefighters".

An example of a seismic isolator with rubber and a viscous damper used in retrofitting Bucharest University of Economic Studies building is shown in Figure 2 (Balan et al., 2020).

Figure 2. Example of seismic isolator (left) and viscous damper (right) used for retrofitting

## RESULTS AND DISCUSSIONS

Soil strain thresholds define the transition from linear-elastic behaviour (negligible degradation) to non-linear behaviour (significant degradation). Stiffness degradation typically begins at shear strain levels of 0.0001 % ($10^{-4}$ %) with significant degradation occurring above 0.01 % - 0.1 %. Thresholds are lower for clay (1-2 x $10^{-4}$ %) compared to sand (3-4 x $10^{-4}$ %). For geotechnical applications, understanding these thresholds is critical because strains in the soil, often called the "active compression zone", can lead to permanent settlement or deformation if the threshold is exceeded.

The "active compression zone" refers to the depth within the soil profile where the applied stress (e.g., from a building, embankment, or tunnel) exceeds the soil's strength, causing significant, non-recoverable compression and rearrangement of soil particles.

In engineering, this zone defines the depth over which changes in loading or moisture content will cause substantial settlement or heaving. If foundations are placed above this zone without addressing the compression, long-term settlement will occur.

Exceeding these thresholds leads to different types of settlement: consolidation, consisting in gradual, long-term squeezing of water from saturated soil voids, and creep, which is a long-term, time-dependent settlement that occurs even after excess pore water pressure has dissipated, driven by the distortion of the soil skeleton. Creep in soft clays is a long-term geotechnical phenomenon characterized by time-dependent settlement that persists even after excess pore water pressure from primary consolidation have completely dissipated. This process is driven by the viscous deformation, rearrangement, and inter-particle sliding of the soil skeleton under constant effective stress. In soft, highly compressible soils (e.g., soils like organic clays or soft mud, characterized by high water content, low shear strength, and often a high degree of saturation, including several types of soft, cohesive soils), creep can produce substantial deformation over decades, often leading to settlement that exceeds the magnitude of initial consolidation settlement. The magnitude of creep is heavily influenced by the soil's stress history (over consolidation ratio),

the stress level applied, and the soil's inherent anisotropy.

Clays typically exhibit higher, time-dependent strain (consolidation), while sand strains are more immediate. Rapid loading (dynamic, seismic) can lead to higher strains and liquefaction, whereas slow, drained loading causes smaller, manageable strains. Therefore, in geotechnical engineering, seismic design assumes high-risk conditions requiring soil improvement, while static design often deals with smaller deformation levels.

To mitigate these risks, geotechnical engineers use soil strengthening, preloading, or deep foundation systems to bypass this zone, ensuring that strains remain within the allowable elastic limit (Chang et al., 2016; Dammala & Krishna, 2019).

When a soil deposit experiences a medium range of strain, its behaviour transitions to elasto-plastic, and the shear modulus begins to decrease as the shear strain increases. Based on the resonant column tests developed for this study, this behaviour initiates at a shear strain level of approximately $10^{-5}$ % (see Figure 3). In this regime, the damping ratio serves to quantify the energy absorption capacity of the soil.

Resonant column tests provide a quantitative assessment of these dynamic soil properties across their entire range of definition, making the resulting data highly valuable for calibrating and evaluating nonlinear viscoelastic models under dynamic loading. Ultimately, because the behaviour of soils and rocks is fundamentally dependent on the loading level, this characteristic non-linear response directly influences the dynamic performance of the entire site-structure system.

Data gathered from geological, geotechnical, and hydrogeological boreholes across the city have successfully mapped the sequence of subsoil deposits. By utilizing seismic measurements and geotechnical laboratory analysis on the core samples from these drillings, representative dynamic parameters of the local soils and rocks can be determined (Stokoe et al., 1999).

Structures founded on these superficial layers are highly susceptible to the effects of ground shaking. For instance, loose soils and unconsolidated sediments can significantly amplify ground motion, while water-saturated sediments are prone to soil liquefaction. During an earthquake, these phenomena can lead to a complete loss of ground bearing capacity, ultimately resulting in the catastrophic collapse of overlying buildings.

Results obtained using these optional soil tests are illustrated in Figure 3 (NATO Project, 2005) for several soil samples tested with the Drnevich resonant column device from one site (“Tineretului Park”) in Bucharest. The samples include: sandy clay (4-4.5 m depth), coarse sand (7-8.5 m), fine sand (21-24 m), and gravel (35-37 m). As shown in the graph, the shear modulus G decreases - by as much as 50 % for some materials - while the damping ratio D increases with shear strain ($\gamma$).

Tests performed on dynamic triaxial device, Figure 4, (NATO project, 2005) show that equivalent shear modulus, $G_{eq} = G = E/2(1+ \nu)$ for gravel samples is decreasing while hysteretic damping ratio h (%) is increasing with single amplitude shear strain $\gamma_{sa}$, The equivalent shear modulus is defined as secant shear modulus used to represent the nonlinear stress-strain behaviour of soils under cyclic or dynamic loading (e.g. earthquakes, machine vibrations), and $\gamma_{sa}= (\gamma_{max} - \gamma_{min})/2$ is maximum shear strain reached in one direction (where $\gamma_{max}$, $\gamma_{min}$ are maximum, respectively minimum shear strain). The soil specimens were drilled from the same site located in Bucharest (“Tineretului Park’’) at 35 - 37 m depth.

The results are of relevance for various sectors in geotechnics and with implications in evaluating factors of seismic hazard, the path of propagating the seismic waves, as well as for advancing the fundamental knowledge in understanding the phenomena in soil-structure interaction.

The test devices show the behaviour of soils, the reduction of shear modulus (G) and increase in damping ratio (D) with increasing strain $\gamma$ (as caused by strong earthquakes, with moment magnitude $M_w > 7$, and strain above $10^{-4}$ %). Previous studies concluded that a strain of 3.5 x $10^{-5}$ % may roughly corresponds to a Gutenberg-Richter magnitude of $M_{GR} = 6.1$, while higher level of strain of 1.4 x $10^{-3}$ % corresponds to a magnitude of $M_{GR} = 7.2$ (earthquake of March 4, 1977) (Mărmureanu, 2020). This behavior depends on the soil or rock type (soft degraded, cohesive, coarse-grained or noncohesive,

soft/degraded or hard/stable, etc.), sample depth and other stratigraphy and geological conditions.

Higher magnitude events may induce cyclic shear strains ranging between 0.01 % ($10^{-4}$) and 0.5 % (5 x $10^{-3}$). This would lead to significant pore pressure generation, large deformations, and potential liquefaction.

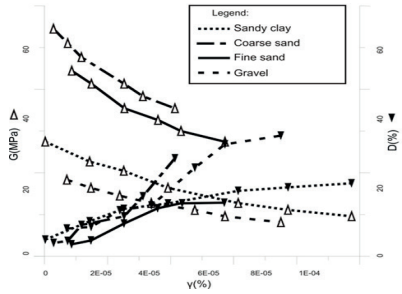

Figure 3. Resonant column tests for core samples (from site "Parcul Tineretului")

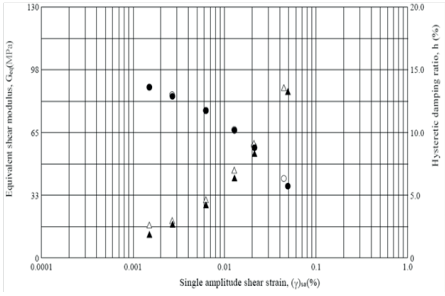

Figure 4: Triaxial tests results for gravel samples (from site "Parcul Tineretului")

High-intensity seismic events triggered by Vrancea intermediate-depth seismic source can produce severe damages and create significant amplification in saturated soils, often leading to large strain, non-linear deformation. The extreme strains values higher than > 1%–10%, may indicate that the soil structure has essentially lost its capacity to bear loads, leading to progressive failure, where the failure zone spreads and induces large, often uncontrollable, deformations in overlying structures.

Based on the provided results, the dynamic model (often in the context of soil-structure interaction or seismic response) assumes a strong dependence of the soil on several, often interlinked factors. For saturated soils, the response is strongly dependent on whether the loading occurs under drained or undrained conditions, which affects pore water pressure and, subsequently, soil stiffness.

In the second part of the study, the goal was to compute the efficiency of seismic isolation for Bucharest University of Economic Studies (ASE, Victor Slavescu) building in Bucharest.

The sensors are placed under and immediately above the seismic isolator, allowing both ground and structure coupling, respectively. They are part of a system consisting of a sensor network and the Data Centre (NDC) capable of acquiring, exchanging and processing data in real time. The computation in terms of maximum recorded accelerations (Amax) and maximum spectral accelerations (SAmax), performed by the Antelope automated system (BRTT, 2018), installed at the National Institute for Earth Physics provides information on the behaviour of the building and the performance of the insulation. The results of monitoring activity and recording of accelerations for 5.5 $M_W$ earthquake of October 28, 2018 (148 km focal depth), (ROMPLUS Catalog, 2025) in this seismic isolated building were analyzed, from the perspective of the earthquake protection system performance. This earthquake was the strongest that hit Bucharest in the last 10 years and originates in the Vrancea intermediate-depth focal area (see Table 1, Balan et al., 2020). All the data above the isolator are consistently less than those under the isolator for both (horizontal) directions N-S and E-W (see Table 1). The maximum values, $A_{max}$, obtained from the recordings above isolator is 3.8 less on N-S direction and 2.12 less on E-W than those under isolator; in the case of spectral response, the maximum spectral acceleration, $SA_{max}$, above the isolator is 3.21 less on N-S direction and 2.1 less on E-W directions than those under isolator.

Table 1. Engineering parameters (maximum recorded acceleration, maximum spectral acceleration) for the 5.5 $M_W$, October 28, 2018 earthquake

| Earthquake ($M_W$ = 5.5) | Acceleration and spectral acceleration ($cm/s^2$) | Position of sensor | |
|---|---|---|---|
| | | Above isolator | Under isolator |
| Component N-S | $A_{max}$ | 33.4 | 129.4 |
| | $SA_{max}$ | 105.0 | 337.2 |
| Component E-W | $A_{max}$ | 46.5 | 98.6 |
| | $SA_{max}$ | 187.6 | 349.9 |

Based on this type of analysis of structural performance during seismic events, the findings confirm that base isolation systems offer a non-invasive, reliable solution for retrofitting older, vulnerable structures, enabling them to withstand earthquakes with minimal damage**.** Base isolation systems decouple the building from the ground, resulting in lower acceleration at upper floor levels compared to fixed-base, non-isolated models. These results support the use of this (modern) technology to rehabilitate infrastructure that was built before modern seismic codes.

For in-depths investigations in this paper were used: resonant column and dynamic triaxial. The two dynamic nonlinear functions modeling the material strength in resonant column experime nts, G = G(γ) and damping D = D(γ) are determined for the soil layers. As a matter a fact almost all site materials exhibit degradable material behavior. However, some of them more and others less, see type of soils in Figure 3.

In soil laboratory testing and geotechnical earthquake engineering, soil cyclic shear strain levels are generally correlated to earthquake magnitude through the intensity of ground shaking (Peak Ground Acceleration, PGA) and the number of loading cycles, which increase with magnitude.

The decrease in the shear modulus (G), could be even 50%, leads to a proportional increase in soil settlements, which can compromise the serviceability and structural integrity of a building.

In geotechnical design, the settlement of a foundation is inversely proportional to the stiffness of the soil. Since G is related to the Young's modulus (E) by the relationship $G = \frac{E}{2(1+\nu)}$, where $\nu$ is Poisson's ratio, a reduction in G directly impacts the elastic modulus used to calculate settlement.

This situation could result in damage in the structure and interior walls. G is a stiffness parameter and its degradation often correlates with a loss in shear strength, potentially reducing the ultimate bearing capacity of the foundation.

In experiments such as cyclic triaxial or resonant column tests, the induced strain levels correspond to varying seismic intensities. often classified by magnitude and proximity to the source. Soil strains generally scale with earthquake magnitude ($M_W$), with significant, non-linear, and permanent deformations (liquefaction or failure) occurring at higher strain levels, typically associated with stronger earthquakes. For moderate to large earthquakes $6 < M_W < 7$ cyclic triaxial or cyclic simple shear tests employed throughout this work show the pore water pressure generation, especially in loose, saturated sands. For large to major magnitudes, $M_W > 7$ high nonlinear behaviour, significant pore pressure generation, and potential for soil liquefaction appear. In many studies, a shear strain of 0.1 % - 0.5 % is considered the threshold for structural damage or significant liquefaction (Díaz-Rodríguez & López-Molina, 2008; Hazirbaba & Omarow, 2019).

Strains exceeding the 0.1 % threshold in soft, saturated soil samples often trigger cyclic softening (degradation, in clays) or liquefaction (in sands), causing a rapid reduction in shear strength and stiffness. The large number of cycles causes a significant pore water pressure level, which reduces the effective stress of the soil, leading to significant post-earthquake cyclic settlement. In soft, saturated alluvial deposits, this mechanism can cause massive ground deformation and substantial settlement.

The paper highlights the significance of knowing the potential of dynamic behaviour of the soil strata under heritage/important buildings during strong seismic events, for taking all measures in the design process to limit such deformations. This way structural damage may be avoided. To have as comprehensive as possible and reliable site information, the necessity is highlighted for considering this method at site evaluation for a safer environment and mitigation of the seismic risk.

By this method, laboratory data are integrated with the parameters available at the site. This approach makes it possible to estimate the site-specific properties by assessing their variability under different loading conditions for the soil components.

Assessing the dynamic parameters for seismic response in Bucharest requires specialized consideration of its unique geological setting, characterized by deep, unconsolidated sedimentary layers and significant intermediate-depth Vrancea earthquakes. A proper estimation of the seismic response involves these

parameters, especially for buildings that are particularly vulnerable to the characteristic long-period, high-intensity shaking experienced in Bucharest. (Bratu & Dobrescu, 2019).
The data processed from recordings on the studied building show an effective earthquake protection system, with a reduction of signal with a factor in the range from 2.0 to 3.8. The output consists in engineering parameters that are maximum acceleration $A_{max}$ recorded on two horizontal directions (N-S, E-W), and the maximum spectral acceleration ($SA_{max}$). The retrofitting technique referenced herein is efficient in urban areas in relation with local and regional seismicity and local site effects parameters (De Domenico et al., 2019).

## CONCLUSIONS

The paper aim is to put forward two optional solutions in the case of rehabilitation of heritage buildings. These buildings are old ones (more than 80-90 years, or even much more) and at their construction there were no building codes with seismic specifications. One of the weak points for these kinds of structures is the foundation soil not studied enough in the design process. The seismic waves are coming from the soil deposit to foundations and structure. In case of rehabilitating such a structure, we should check that the soil would not permit settlements in case of a strong earthquake and this is presented in first case, because a settlement could result in structure damage due to new forces developed in it. If the designers find out that settlements could occur it must be found solutions for consolidating the soil deposit where the construction is situated.
Larger magnitude earthquakes ($M_W$ = 7.2−7.4) create higher PGA and are characterized by longer duration, which generate a higher equivalent number of uniform cycles leading to larger shear strains, with values often exceeding 0.1 % in saturated, soft alluvial soil samples, causing significant cyclic settlement. These conditions lead to strong geotechnical impacts. For example, strains exceeding the 0.1 % threshold in soft, saturated soil samples often trigger "cyclic softening" (in clays) or liquefaction (in sands), causing a rapid reduction in shear strength and stiffness. The large number of cycles causes a significant pore water pressure level, which reduces the effective stress of the soil, leading to significant post-earthquake cyclic settlement. In soft, saturated alluvial deposits, this mechanism can cause massive ground deformation and substantial settlement.
The dynamic tests are used to develop nonlinear constitutive models that define the stress-strain relationship. These models are essential for predicting how soil layers amplify or attenuate ground motion, and how they interact with structures (e.g., in terms of pore-water pressure development and stiffness degradation).
Many old buildings do not have structures to withstand shear and axial forces from strong earthquakes. Therefore, the option of seismic isolation proved highly effective, because separating structure from foundation were achieved ~ 2-3 times smaller accelerations above the isolating system. By diminishing the acceleration recorded, it reduced also the forces applied on the building during a strong seismic movement. Using seismic sensors, vibration data, or similar analysis to continuously monitor structural health, allows for real-time assessment of building stability. Base isolation effectively reduces floor accelerations providing superior protection compared to conventional stiffening and strengthening action. This methodology helps in drawing attention to the seismic benefits for similar, retrofitted buildings.
The implications of these results regarding collapse prevention and enhancing structural resilience are focused on reducing vulnerability through specific, actionable strategies in the seismic risk management for this highly populated zone.
Utilizing quantitative data can target investments where they will generate the highest return in terms of energy savings, operational efficiency, and structural resilience.
Quantifying the efficacy of seismic isolation on historical, or vulnerable buildings in Romania demonstrates a significant reduction in seismic response (acceleration and spectral acceleration) right above the isolation layer, serving as a key indicator for seismic risk and vulnerability mitigation. This technique can be employed as a strategy for seismic risk mitigation, particularly for buildings in Bucharest exposed to Vrancea intermediate-depth earthquake motions.

Seismic isolation, despite high initial financial costs and technical complexities, is a highly effective and beneficial strategy for protecting heritage constructions. This approach is increasingly considered superior to traditional, more invasive strengthening methods (such as adding concrete walls) because it preserves the original materials and architectural integrity. Initial costs for seismic isolation are generally higher than conventional strengthening due to the cost of isolator devices and complex installation. Despite the upfront investment, seismic isolation can offer a better life-cycle cost by minimizing post-earthquake repair expenses, reducing business interruption.

***Abstract***

*The paper aims to study and analyze the succession process of arboreal and shrub vegetation on a series of agricultural lands, which have not been administered and exploited in accordance with their use category, in a non-collectivized hill area, in the Vîrfurile locality, Arad county. The study was carried out for the period 1990-2025, with observations, inventories, comparisons, simulations, and magnetic recordings of relevant images related to the studied lands. Also, the records from the agricultural register and the parcel plan that was drawn up by the Cadastre and Real Estate Advertising Office of Arad county were analyzed, on the occasion of the systematic registration works of the real estates in the rural areas, for this location. The results obtained confirm that on the studied lands, a succession of arborescent and shrub vegetation was triggered, with a relatively active dynamic. Consequently, a series of pioneer, invasive tree species were highlighted, as well as forest tree species of the genus Quercus, which settled on areas ranging between 10-100% of the mentioned location.*

***Key words****: agricultural lands, improper exploitation, non-collectivized areas, shrub species, tree species use category, vegetation succession.*

## INTRODUCTION

The Earth's vegetation cover is characterized by continuous changes in the composition and distribution of its component species, which unfold with differentiated dynamics and particularities, determined by a series of conditions and factors that trigger, influence, and sustain them.

These processes may consist of local or seasonal changes, known as symphenological processes, characterized by a recurrent rhythm influenced by climate, up to secular or millennial developments on a large spatial and very long temporal scale - namely synchronological processes, which are in fact determined by major climate changes and, implicitly, by changes in vegetation conditions, such as the development of vegetation in the post-glacial period (Fickert & Richter, 2025).

Consequently, regeneration processes, which are considered cyclical, and succession processes, which have a strongly directional character, represent indicators of temporal changes in species populations, communities, and even entire ecosystems (Fickert & Richter, 2025).

Vegetation succession represents the modification or replacement, over a period of time, of the phytocoenosis composition on a given land surface, as a direct consequence of changes in vegetation conditions and, implicitly, in interspecific relationships. As a result, species and species associations are eliminated and replaced by others (Florescu & Nicolescu, 1996). According to the theory proposed by Clements (Florescu & Nicolescu, 1996; Fickert & Richter, 2025), the vegetation succession process goes through a series of successive stages: denudation of the territory, species

migration, colonization, competition, reaction, stabilization, and regression.

Denudation, or exposure of the substrate through disturbance, may result from natural phenomena such as landslides, avalanches, vegetation fires (De Giuli et al., 2024), active erosion, the formation of river islands, volcanic eruptions (Moreno-Gonzalez et al., 2025), or climate changes. This stage may also be significantly influenced by anthropogenic activities such as pollution, excessive exploitation or abandonment of agricultural lands (Cioflan, 2025), irrational forest exploitation, improper conservation or abandonment of mining sites (Garate-Quispe et al., 2023; 2024), construction works, hydrotechnical developments, etc.

Migration (immigration) of herbaceous and woody species and the occupation of vacant ecological niches or newly denuded habitats generally occur through seed dispersal, depending on their morphological and physiological characteristics. Thus, this stage unfolds differently depending on the dispersal mechanism, with vector agents including wind, water, animals, and humans (Fickert & Richter, 2025).

Colonization, or establishment of species in the new habitat, involves the installation and development of immigrant species, directly influenced by their ecological requirements and vegetation conditions. In some cases, this stage results in the emergence and spread of valuable natural species (Szirmai et al., 2022). Consequently, this stage includes successive processes: seed germination, seedling emergence, growth, development, maturation, and finally sexual reproduction of mature individuals.

Competition in the newly colonized location occurs both interspecifically and intraspecifically, through competition among new species and between immigrant species and the former inhabitants of the territory, for both underground and aboveground space. As a result, species or groups of species that regenerate easily under the new conditions and do not have high trophic requirements-namely pioneer and invasive species-become dominant, with biodiversity playing an important role in this stage (Pérez-Hernández & Gavilán, 2021).

Reaction represents the habitat's response to the impact of the new phytocoenosis. Consequently, a new ecological niche is shaped, with specific characteristics that may significantly influence all bioecological processes of the emerging ecosystem, as well as its stability and persistence. The new landscape that forms will reflect the interaction between the habitat and the new phytocoenosis (Fickert & Richter, 2025).

Stabilization represents the stage of consolidation of the new phytocoenosis. A dynamic equilibrium is established, characterized by consolidated ecosystem stability, also known as the climax stage. Reaching an advanced climax stage marks the completion of succession.

Regression represents the initial stage of degradation of the advanced climax state, resulting from reduced resistance of the phytocoenosis to competitive pressure from potential immigrant species, which may trigger a new succession (Florescu & Nicolescu, 1996).

In some situations, depending on vegetation conditions and land-use practices, certain stages of vegetation succession may be absent, with migration, competition, reaction, stabilization, and regression being the most commonly observed.

The rate at which successions occur may be rapid or slow. If species replacement occurs within a relatively short time-years or decades-the succession is considered rapid. When species replacement occurs over more than a century, the succession is considered slow and can be analyzed using the chronosequence method (Nasibullina et al., 2024) and pollen analyses (O'Connell & Wolters, 2025), based on the study and analysis of vegetation maps (Fickert & Richter, 2025) prepared over time for the respective region.

Improper exploitation and abandonment of agricultural lands in non-collectivized areas, gradually after 1989, in the medium and high hill regions of western Romania, created the premises for the initiation of vegetation succession processes. The abandonment of agricultural lands resulted directly from depopulation of these areas, lack of modern equipment, absence of adequate agricultural strategies and policies for local farmers, excessive land fragmentation in non-

collectivized areas, and the effects of climate change.

Considering the aspects presented, vegetation succession represents a fundamental concept of great importance for agro-forestry activities, as it indicates how species populations, communities, and ecosystems change over time in a new habitat or after a disturbance (Poorter et al., 2023) that affects their previous ecosystem stability.

The objectives of this study are to analyze the climatic conditions that favored and sustained the succession of arboreal and shrub vegetation, as well as the dynamics and particularities of this process, on a series of agricultural lands in a non-collectivized area that were abandoned or not exploited according to their land-use category.

## MATERIALS AND METHODS

The case study was conducted in the locality of Vârfurile, which is the seat of the Vârfurile commune in Arad county, which was a non-collectivized area. It is located in the east of Arad county, in the Hălmagiu Depression in the Apuseni Mountains. The depression is crossed by the Crișul Alb River and is located on its upper course. Vârfurile village is located in the northwest of the Hălmagiu Depression and is bordered by the Bihor Mountains to the northeast, the Codru-Moma Mountains to the northwest and the Zarandului Mountains to the south and southwest (by the Gorgana Massif, more precisely). Vârfurile Commune consists of 8 localities and has an average altitude of 231 m (Pop, 2005; https://primariavirfurile.ro/despre-noi/prezentare/).

Vârfurile Commune has a temperate-continental, moderate climate, with slight Mediterranean influences, the summers not being excessively warm, and the winters being generally mild. The depression area in which the locality is situated communicates to the west with the Zarandului Depression, which has a wide opening to the west, towards the Crișurilor Plain. That favors the easy penetration of western air masses (of Atlantic or Mediterranean origin), rich in moisture, which makes precipitation abundant. During certain periods of the year, hot and dry continental-tropical air masses from northern Africa can also penetrate, generating heatwaves and drought. The thermal inversions are frequent in the cold season, specific to the intermontane depression areas, generating dense fogs. The shelter provided by the surrounding mountains reduces wind speed and protects the village from strong winds. The moderate thermal climate with abundant rainfall makes the region well forested (Pop, 2005; https://primariahalmagiu.ro/download/urvqbaO3Rf0Eh7w9f690f8ugJ6lAzB8W4JBO4a7g.pdf).

The studies and research fall within the scope of doctoral studies regarding the category of agricultural land use in the mentioned location. To achieve the established objectives, appropriate bibliographic documentation was created (Duduman, 2023).

Data from the Gurahonț meteorological station were used for the climatic characterization of the studied area, being the closest to the Vârfurile locality. The station is located at an altitude of 177 m, has the code 15182 and the geographical coordinates 46°27' N latitude, 22°33' E longitude (www.meteomanz.com).

Meteorological data regarding the monthly and annual average air temperature and the monthly and annual precipitation amount were used in the paper. The analyzed period was 1990-2025 (36 years). The temporal variability, frequency and linear trend of the average annual values of temperature and precipitation, as well as the polynomial trend of annual precipitation amounts, were analyzed. The average annual values of air temperature and precipitation were compared with the multiannual average of the period 1966-2025 (60 years), to better highlight the climate trends of recent years. The variation during the year of the multiannual monthly average values of air temperature and precipitation (1990-2025) was also analyzed.

The meteorological data used in the paper came from the database of the National Meteorological Administration (N.M.A.) of Romania and from the Meteomanz.com (www.meteomanz.com) and rp5.ru (https://rp5.ru/) websites.

For the purpose of conducting the study and analyzing the dynamics and particularities of the vegetation succession process in the established location, route-based and stationary observations were carried out, along with inventories on experimental surfaces, simulations, comparisons, and analyses.

As a result, the study and analysis of the dynamics of the vegetation succession process were performed on 100 agricultural parcels that had been improperly exploited or abandoned.

The parcels were identified on the parcel plan corresponding to cadastral sector no. 15 (provided by OCPI Arad), which was superimposed on the orthophotomap using the mapSys 10.1 software. Also, the category and subcategory of use were identified from the agricultural register of the Vârfurile locality, with the agreement and collaboration of the owners.

Field identification of the studied parcels and delimitation of the areas where vegetation succession had been triggered and was ongoing were performed using GNSS technology, with TRIMBLE R10I receivers, through the real-time kinematic (RTK) method, using the permanent GNSS station Gurahonț, Arad County.

In this context, the parcels were physically surveyed, allowing direct observation of the stages of succession, identification of the arboreal and shrub species that had established, and the manner in which these areas were being exploited. The field data were recorded in tabular field sheets, prepared to streamline the data collection and processing procedure. These sheets included the following fields: Nrp - number of the analyzed parcel, Sp - surface area of the analyzed parcel, Sc - surface colonized by the identified species, Pc - percentage of colonization of the studied lands where vegetation succession is occurring, land-use category and subcategory, and installed arboreal and shrub species.

Additionally, for the study and analysis of the structural characteristics defining the arboreal and shrub vegetation that had established, inventories were carried out in five representative and relatively accessible parcels. On the surfaces where arboreal vegetation had established, complete inventories were performed, recording all individuals within the identified biogroups. A biogroup of trees represents a cluster of 7-10 trees, either of the same species or of different species, which mutually influence each other and exhibit evident intra- or interspecific competition, both underground and aboveground. These can occupy different areas, depending on a series of factors and vegetation conditions, and if the area occupied exceeds 0.5 hectares, the height of the component trees is greater than 5 m, and the consistency index k > 0.4, they can be considered as a forest (Law no. 331/2024).

Tree diameter was measured with a forest caliper at a height of 1.30 m above ground (diameter at breast height - d1.30), at 2 cm intervals, starting from a minimum diameter of 4 cm. Tree height up to 8.0 m was measured with a special rod graduated in millimeters, while heights above 8.0 m were determined using the VERTEX 5 device. On surfaces covered with shrubs, inventories were carried out on rectangular experimental plots, with areas ranging between 1 m² and 5 m², depending on their distribution and accessibility. Shrub diameter was measured with a caliper or measuring tape (with millimeter divisions), depending on accessibility and biogroup density. Their height was measured with a special rod graduated in millimeters.

For the analysis of the structural characteristics of the inventoried tree biogroups, a series of structural indices representative for forest stands were used by similarity. Consequently, the following were determined: the number of trees ($N_{exp}$), diameter at breast height (d1.30), cumulative basal area ($G_{exp}$), composition by number of trees and by basal area, the density index ($I_N$) and the density coefficient ($I_G$); the slenderness coefficient (Z%) and the Hart-Beking spacing factor in the square ($S_{4\%}$) and hexagonal ($S_{6\%}$) The indicators were calculated using the formulas established by Florescu & Nicolescu (1996) and Crainic et al. (2024). The values obtained are presented below:

$$I_N = \frac{N_{exp}}{N_{th}} \quad (1)$$

$$I_G = \frac{G_{exp}}{G_{th}} \quad (2)$$

$$Z_{(\%)} = \frac{h}{d} \quad (3)$$

$$S_{(\%)} = \frac{a}{h_{dom}} \times 100 \quad (4)$$

$$S_{4(\%)} = \frac{a_4}{h_{dom}} \times 100 \quad (5)$$

$$S_{6(\%)} = \frac{a_6}{h_{dom}} \times 100 \quad (6)$$

$$h_{dom} = h + 0.15\,h = 1.15\,h \quad (7)$$

$$a_4 = \sqrt{\frac{10000}{N}} \quad (8)$$

$$a_6 = \sqrt{\frac{10000}{N\sqrt{\frac{3}{2}}}} \quad (9)$$

The elements of formulas (1) - (8) have the following meaning:
**$I_N$** - density index determined according to the number of trees;
**$I_G$** - density index determined according to the cumulative basal area;
**$N_{exp}$** - number of trees per hectare, determined experimentally through inventories;
**$N_{th}$** - theoretical values of the number of trees from general yield tables, for the same species, yield class, and age;
**$G_{exp}$** - cumulative basal area per hectare, determined experimentally through inventories;
**$G_{th}$** - theoretical values of the cumulative basal area from general yield tables, for the same species, yield class, and age;
**$Z_{(\%)}$** - slenderness coefficient of the stand;
**h** - mean height of the stand;
**d** - mean diameter of the stand;
**$S_{(\%)}$** - Hart-Beking spacing index;
**$h_{dom}$** - dominant height of the stand;
**a** - theoretical spacing between trees
**$S_4$** - spacing index for the square arrangement;
**$a_4$** - theoretical spacing between trees in a square layout;
**$S_6$** - spacing index for the hexagonal arrangement;
**$a_6$** - theoretical spacing between trees in a hexagonal layout.

Additionally, for comparing the experimental values with the theoretical ones corresponding to forest arboreal vegetation, it was necessary to extrapolate the experimental values to one hectare. The theoretical values of the structural characteristics used were those provided by Biometrics of trees and stands in Romania (Giurgiu et al., 1972).

## RESULTS AND DISCUSSIONS

The multiannual average air temperature was 10.9°C for the period 1990-2025, at the Gurahonț meteorological station. It was 0.4°C higher than the multiannual average of the period 1966-2025 (10.5°C) and 1.0°C higher than that of the period 1966-1990 (9.9°C).
The average annual air temperature ranged between 9.5°C (in the years 1991 and 1997) and 12.8°C (in 2024), during the period 1990-2025 (Figure 1). The coldest years were 1991, 1997, 2005, 1996, 1993, 1998 and the warmest years were 2024, 2019, 2023, 2014, 2018, 2025. So, the coldest years were recorded at the beginning of the analyzed period, and the warmest towards its end. Five years had an annual average value above 9°C, 11 years above 10°C, 16 years above 11°C, and 4 years above 12°C, during the analyzed period. 24 years out of the 36 analyzed (2/3 of the years) had an annual average value above the multiannual average of the period 1966-2025 (of 10.5°C).
Since 1994, an increase in air temperature has been observed in Gurahonț. Moreover, the linear trend of the average annual values of air temperature is strongly upward. It is due to the very high values of recent years, which have been exceptionally warm. The 2007-2025 interval was the warmest, being characterized by annual average values above the multiannual average of the 1966-2025 period (Figure 1).

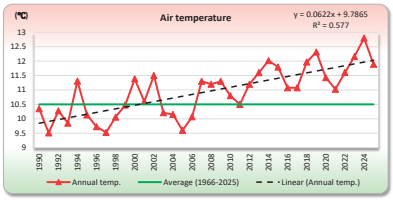

Figure 1. Average annual air temperature, its linear trend (1990-2025) and multiannual average (1966-2025), at the Gurahonț meteorological station

The multiannual average amount of precipitation was 747.5 mm for the period 1990-2025, at the Gurahonț weather station. It was only 4.5 mm lower than the multiannual average of the period 1966-2025 (752.0 mm) and only 3.2 mm lower than that of the period 1966-1990 (750.7 mm).
The annual amount of precipitation varied between 438.4 mm (in 2025) and 996.2 mm (in 2005), during the period 1990-2025 (Figure 2). The rainiest years were 2005, 2001, 2004, 2016, 1999, 2023 (with a rainfall surplus between 125 and 245 mm), and the driest were 2025, 2024, 2000, 2011, 1990, 1992, 1993 (with a rainfall deficit between 130 and 314 mm). There were 15 years with over 800 mm of precipitation and 14 years with under 700 mm of precipitation, during the mentioned period.

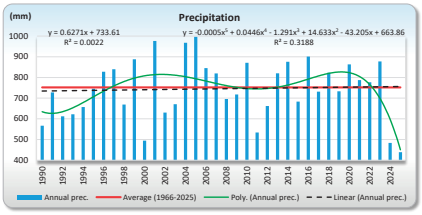

Figure 2. Annual precipitation amounts and their linear and polynomial trend, at the Gurahonț meteorological station (1990-2025)

The linear trend of the annual precipitation amounts is slightly upward.
The polynomial trend, rendered based on the 5th order polynomial, shows that after the dry period 1990-1994, there is a rainy period 1995-2007 (of 13 years), followed by a short dry period 2008-2012, then by a rainy one 2013-2023 (of 11 years) and two extremely dry years 2024-2025. It is noted that the drought of 2024-2025 exceeded the great drought of 2000. Also, these years followed the very rainy year 2023 and a longer period of precipitation excess.
During the year, the air temperature increases from January (the multiannual monthly average: 0.0°C) to July (21.3°C), when it reaches a maximum, after which it decreases until December (1.4°C) (Figure 3).

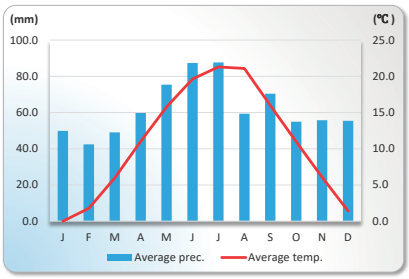

Figure 3. Multiannual monthly average values of air temperature and atmospheric precipitation, at the Gurahonț meteorological station (1990-2025)

Precipitation follows a somewhat similar pattern, being higher in summer (except August) and lower in winter and early spring. The most rain falls between May and July (75.4-87.7 mm), and the least between January and March (42.4-49.9 mm). It is noted that the rainfall maximum was not recorded in June (87.3 mm), but in July (87.7 mm), in the period 1990-2025. This is due to the large amounts of precipitation that fell in July, amid the severe heatwaves of recent years, in this month, when the land surface strongly heats up and generates intense thermal convection. August is a very hot and dry month, because the anticyclonic baric formations prevail, which generate clear and warm, even scorching weather.
Comparing the multiannual monthly average of the months of the period 1990-2025 with the multiannual average of the period 1966-2025, it can be said that the months of June, August, May and January recorded lower amounts of precipitation during the period 1990-2025, compared to the period 1966-2025. So, they were drier. All months of the year were warmer during the period 1990-2025 than during the period 1966-2025. The warmest months were August, June, July, January and November.
From the analysis of the results obtained after processing the data recorded during the study of the particularities of the vegetation succession process on the 100 parcels, presented in Table 1, it is observed that the process of colonization and establishment of arboreal and shrub vegetation on a series of agricultural lands occurred with differentiated dynamics, depending on the land-use categories and subcategories, as well as on the manner in which these lands had been exploited.
Consequently, the land-use subcategory most affected by the succession process was wooded pasture, with 76% of its analyzed surface undergoing succession, followed by wooded hayfield with 53%, hayfield with trees with 46%, arable land with shrubs and isolated trees with 38%, traditional orchard with 27%, pasture with trees with 25%, and finally clean hayfield and hayfield with shrub patches, each with 19%.
Overall, it is found that 55% of the total surface of the 100 analyzed parcels was colonized by arboreal and shrub vegetation (Table 1), as a result of the vegetation succession process, which occurred due to improper exploitation and the abandonment of agricultural land.
The initiation and development of the vegetation succession process on the 100 studied parcels took place without a specific denudation stage of the habitat, the premises for triggering this process being represented by improper land use and the abandonment of considerable areas of agricultural land.
The arboreal species that have established in the studied location are represented by forest species that form the fundamental natural forest types of the surrounding areas, in relatively high proportions - *Quercus cerris*, *Quercus robur*, *Fagus sylvatica*, *Carpinus betulus*, *Prunus avium*, *Tilia tomentosa* - followed by pioneer species such as *Betula pendula*, *Populus tremula*, *Salix caprea*, *Salix alba*, and a single invasive species, *Robinia pseudacacia*.

Table 1. Synthetic record of the surface areas of agricultural land-use categories and subcategories on which arboreal and shrub vegetation has established, following the onset of the vegetation succession process

| Nr. crt. | Nrp | Sp (ha) | Land use Category | Land use Subcategory | Sc (ha) | Pc (%) | Inatalled species Forest trees | Inatalled species Shrubs |

| Total | 100 | 55.94 | / | / | 30.74 | 55 | / | / |

Nrp - number of analyzed parcels, Sp - surface area of the analyzed parcels, Sc - surface area colonized by the identified species, Pc - percentage of colonization of the studied lands on which vegetation succession occurred, *Qr-Quercus robur* L., *Qc-Quercus cerris* L., *Pt-Populus tremula* L., *Rp-Robinia pseudacaccia* L., *Bp-Betula pendula* Roth, *Tt-Tilia tomentosa* Monech., *Sc-Salix caprea* L., *Sa-Salix alba* L., *Fs-Fagus sylvatica* L., *Cb-Carpinus betulus* L., *Ms-Malus sylvestris* (L.) Mill., *Pp-Pyrus pyraster* (L.) Burgsd., *Ps-Prunus spinosa* L., *Jc-Juniperus communis* L., *Rh-Rubus hirtus* W. et. K., *Ca-Corylus avellana* L., *Crataegus momogyna* Jacq., *Rosa canina* L. (Stănescu, et al., 1997).

Consequently, the migration of oak species, which have relatively large seeds, occurred exclusively through zoochorous dispersal, with vector agents represented by birds and certain rodents (Yang & Yi, 2022). Moreover, the zoochorous dispersal of acorns immediately after abundant fructification events led to their germination under optimal conditions, a phenomenon identified especially in several traditional orchards and agro-silvopastoral systems (Crainic et al., 2023a), located at distances of over 1500-2000 m from mature oak trees.

These processes result from the dispersal of acorns, which do not enter dormancy, thus ensuring a high efficiency of germination and seedling emergence (Yang & Yi, 2022). Fruit trees and certain shrub biogroups or pioneer species also play an important role in supporting and enhancing these bioecological processes, as they partially fulfill the role of nurse species (Fodor et al., 2018), by providing protection for young oak individuals.

Recent studies have highlighted a clear trend of expansion of some native oak species in western Romania, as a result of abundant fruiting (Crainic et al., 2023b), on a series of lands with forestry and agricultural use, as a direct consequence of climate change and easy vegetation conditions.

A similar pattern is characteristic of the establishment of *Fagus sylvatica*, but only on small areas and at shorter distances from an existing forest (a stand) or from larger biogroups of trees. This is due to the species' shade-tolerant temperament and its difficulty in regenerating in open terrain without protection.

Mixed species and pioneer species establish relatively more easily due to their more efficient dispersal mechanisms, determined by seed size and the greater diversity of vector agents. Their germination characteristics also positively influence their ability to germinate and emerge under favorable conditions.

The *Robinia pseudacaia* species, which is considered invasive, was identified in a location bordering an area from which nine years ago all the biogroups formed by mature trees of this species were extracted and exploited. These trees had produced abundant seed crops in the year prior to harvesting, and the seeds were easily dispersed onto the neighbouring land (which had not been exploited during that period), where they germinated and emerged under optimal conditions. They now show a tendency to form a closed forest stand within 9-10 years, without any anthropogenic intervention.

Recent research has highlighted that excessive fragmentation of agricultural landscapes causes changes in the composition of plant associations and implicitly reduces the size of plant populations and genetic diversity, with direct implications for biodiversity (Hurajová et al., 2024).

Consequently, conservation and restoration efforts for grasslands, pastures, and other agricultural lands must take into account the information provided by fine-scale monitoring of vegetation matrix organization (Bartha et al., 2025), as part of the sustainable use of plant resources, considering the trend of climate change and society's need for high-quality agricultural products and integrated ecosystem services.

The values of the structural characteristics of the arboreal and shrub forest biogroups, determined after processing the field data, are presented synthetically in Table 2 for each parcela.

Table 2. Synthetic values of structural indices related to biogroups of inventoried trees from the studied plots

Wav-Weighted average value, Cps ($N_{exp}$)-composition according to the number of trees determined experimentally, Cps ($G_{exp}$)-composition based on experimentally determined base area, $dg_M$-median diameter of the base surface determined experimentally, $H_{dgM}$-the corresponding height $dg_M$, T-average age, CLP-production class

In parcel 1771, over an area of 1350 m², a total of 185 trees were inventoried, belonging to seven species: 33 trees of *Quercus cerris*, 23 trees of *Quercus robur*, 24 trees of *Populus tremula*, 14 trees of *Betula pendula*, 15 trees of *Salix caprea*, 13 trees of *Salix alba*, 43 trees of *Malus sylvestris*, and 21 trees of *Pyrus pyraster* (Figure 4).

Figure 4. Biogroups with trees from plot 1771, Cadastral Sector 15, Vârfurile ATU, Arad County

Additionally, 8 specimens of *Corylus avellana* were identified, along with a cumulative area of 200 m² occupied by shrub biogroups of *Prunus spinosa* L., which exhibit an average density of 12 individuals/m² and an average height of 2.25 m (Figure 5).

Figure 5. Biogroups with shrubs of the *Prunus spinosa* species in plot 1771, Cadastral Sector 15, Vârfurile ATU, Arad County

The total number of inventoried trees extrapolated per hectare is $N_{exp}$ = 1368 trees/ha, with a mean diameter $dg_M$ = 16 cm, a total basal area $G_{exp}$ = 18.636 m²/ha, a mean height $H_{dgM}$ = 14.800 m, a mean age T = 30 years, and a relative yield class of III.
The composition of the inventoried forest vegetation is:
Cps($N_{exp}$):2Qc2Ms1Qr1Pt1Bp1Sc1Sa1Pp, and
Cps($G_{exp}$):2Qc2Qr2Pt1Bp1Sc1Sa1Ms dis.Pp.
From the analysis of the diagrams presented in Figure 6, it is observed that the distribution of the number of trees by diameter classes is plurimodal, due to the particularities of establishment, growth, and development of the species that have colonized this location, as well as the manner in which the land has been exploited.

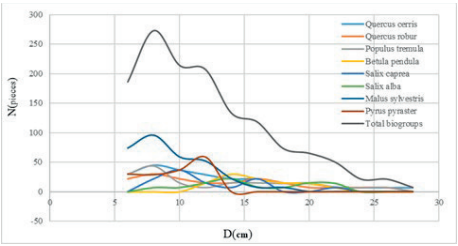

Figure 6. Distribution of the number of trees by diameter classes, extrapolated per hectare, in the fully inventoried biogroup from parcel 1771

The theoretical values for the weighted number of trees are $N_{th}$ = 1830, and the weighted total basal area is $G_{th}$ = 21.040 m²/ha. Consequently, the density index is $I_N$ = 0.7, the density coefficient $I_G$ = 0.9, the slenderness coefficient Z = 93%, and the spacing indices are $s_{4\%}$ = 16% and $s_{6\%}$ = 17% (Table 2).
The biogroups of installed trees present a varied composition, bringing together seven tree species with different ecological behavior, their density is moderate to normal, satisfactory stability to the action of the dominant wind, and they are also moderately spaced. Consequently, a state outlined by climax is highlighted.
In parcel 1774, the inventory of tree biogroups was carried out over an area of 1214 m². As a result, a total of 72 trees were inventoried, of which 37 belonged to *Quercus cerris* and 35 to *Quercus robur* - Figure 7. The total number of inventoried trees extrapolated per hectare is $N_{exp}$ = 593 trees/ha, with a mean diameter $dg_M$ = 29 cm, a total basal area $G_{exp}$ = 26.694 m²/ha, a mean height $H_{dgM}$ = 21.40 m, a mean age T = 60 years, and a relative yield class of III.
The composition of the inventoried forest vegetation, based on both characteristics, is: 5Qr5Qc.
From the analysis of the diagrams presented in Figure 8, it is observed that the distribution of the number of trees by diameter classes is plurimodal, due to the particularities of establishment, growth, and development of the species that have colonized this location.

Figure 7. Biogroups with trees from plot 1774, Cadastral Sector 15, Vârfurile ATU, Arad County

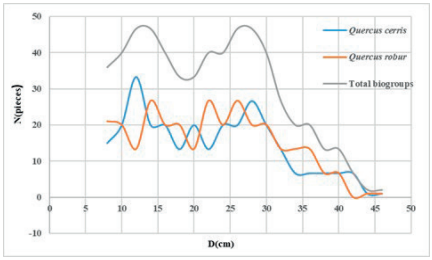

Figure 8. Distribution of the number of trees by diameter classes, extrapolated per hectare, in the fully inventoried biogroup from parcel 1774

The theoretical values for the weighted number of trees are $N_{th}$ = 711 trees/ha, and the weighted total basal area is $G_{th}$ = 26.250 m²/ha. Consequently, the density index is $I_N$ = 0.8, the density coefficient $I_G$ = 0.9, the slenderness coefficient Z = 74%, and the spacing indices are $s_{4\%}$ = 17% and $s_{6\%}$ = 18% (Table 2).
The tree biogroups are characterized by a moderate to normal density and thickness, a high stability to the dominant wind action and a moderate spacing, respectively. These aspects thus confirm a stable climax state, the succession process being completed on the analyzed surface.

In parcel 1776, over an area of 2529 m², a total of 176 trees were inventoried. The arboreal species recorded include *Carpinus betulus* with 48 individuals, *Quercus cerris* with 61 individuals, and *Quercus robur* with 68 individuals, totaling 176 individuals (Figure 9).

Figure 9. Biogroups with trees from plot 1776, Cadastral Sector 15, Vârfurile ATU, Arad County

Additionally, 6 *Quercus robur* trees with diameters between 52-68 cm were affected by extreme meteorological events on 17 September 2017 (Sicoe et al., 2023), and were subsequently removed and utilized by the landowners. The total number of inventoried trees extrapolated per hectare is $N_{exp}$ = 696 trees/ha, with a mean diameter $d_{gM}$ = 27 cm, a total basal area $G_{exp}$ = 17.290 m²/ha, a mean height $H_{dgM}$ = 18.55 m, a mean age T = 60 years, and a relative yield class of III.

The composition of the inventoried forest vegetation is: Cps($N_{exp}$): 4Qr3Qc3Cb, and respectively Cps($G_{exp}$): 5Qr3Qc2Cb.

From the analysis of the distribution of the number of trees extrapolated per hectare, by diameter classes and species, in the inventoried biogroups from parcel 1776, presented in Figure 10, it is observed that the distribution has a plurimodal pattern.

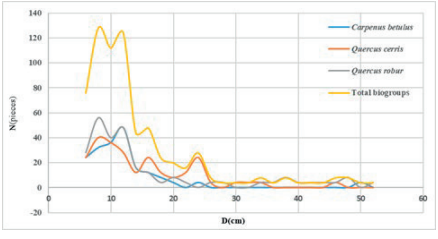

Figure 10. Distribution of the number of trees extrapolated per hectare, by diameter classes and species, in the inventoried biogroups from parcel 1776

This pattern is the consequence of the differentiated ages of the trees, the number of trees within each diameter class, the particularities of the natural regeneration process, and the manner in which the land has been exploited.

The theoretical values for the number of trees are $N_{th}$ = 1418 trees/ha, and the total basal area is $G_{th}$ = 24.240 m²/ha. Consequently, the density index is IN = 0.5, the density coefficient IG = 0.7, the slenderness coefficient Z = 70%, and the spacing indices are $s_{4\%}$ = 18% and $s_{6\%}$ = 19% (Table 2).

As a result, the tree biogroups present a low to moderate density, a high stability to the dominant wind action and a moderate spacing respectively. In this context, a stable climax state is reached, and the process of forest vegetation succession on the studied area can be considered completed.

In parcel 1853, over an area of 600 m², the inventoried arboreal species are represented by *Quercus robur* with 7 individuals, *Tilia tomentosa* with 58 individuals, and *Prunus avium* with 5 individuals, totaling 70 individuals. Also, a number of 5 specimens of pedunculated oak were identified, which were felled by the storm of 17 September 2017 (Figure 11).

The total number of inventoried trees extrapolated per hectare is $N_{exp}$ = 1191 trees/ha, with a mean diameter $d_{gM}$ = 17 cm, a total basal area $G_{exp}$ = 24.976 m²/ha, a mean height $H_{dgM}$ = 15.21 m, a mean age T = 41 years, and a relative yield class of III.

The composition of the inventoried forest vegetation is: Cps($N_{exp}$): 8Tt1Qr1Pa, and respectively Cps($G_{exp}$): 7Tt3Qr dis.Pa.

Figure 11. Biogroups with trees from plot 1853, Cadastral Sector 15, Vârfurile ATU, Arad County

From the analysis of the diagrams in Figure 12, it can be seen that the distribution of the number of trees by diameter categories is multimodal, due to the particularities of vegetation conditions, the ecological demands of the installed woody species and extreme weather phenomena (Sicoe et al., 2023).

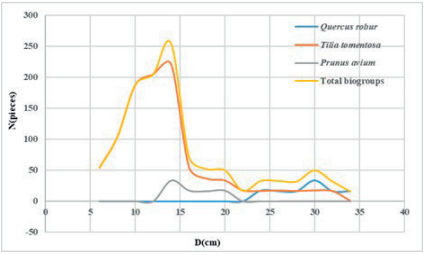

Figure 12. Distribution of the number of trees by diameter classes and species, extrapolated per hectare, for the tree biogroups in parcel 1853

The theoretical values for the number of trees are $N_{th}$ = 1288 trees/ha, and the total basal area is $G_{th}$ = 26.250 m²/ha. Consequently, the density index is IN = 0.9, the density coefficient IG = 0.9, the slenderness coefficient Z = 90%, and the spacing indices are $s_{4\%}$ = 17% and $s_{6\%}$ = 18% (Table 2).

In this case, the analyzed biogroups are characterized by a relatively normal density and thickness, a satisfactory stability to the action of the dominant wind and a moderate spacing. Although the process of succession of forest vegetation on the studied surface was affected by extreme weather phenomena (Sicoe et al., 2023), the tree biogroups are in a relative state of equilibrium, and on the surfaces where the trees were affected, the process of natural regeneration from seed, is carried out with a relatively active dynamic. As a result, the climax state can be identified for this location as well.

In parcel 1930, over an area of 437 m², a total of 80 individuals of *Robinia pseudacacia* and 10 individuals of *Prunus avium* were identified and inventoried (Figure 13). The total number of inventoried trees extrapolated per hectare is $N_{exp}$ = 1945 trees/ha, with a mean diameter d1.30 = 10 cm, a total basal area $G_{exp}$ = 10.280 m²/ha, a mean height H = 8.63 m, a mean age T = 10 years, and a relative yield class of III. The composition of the inventoried biogroups, based on both structural characteristics, is 9Rp + 1Pa.

Figure 13. Biogroups with trees from plot 1930, Cadastral Sector 15, Vârfurile ATU, Arad County

The distribution of the number of trees by diameter classes for the biogroups of *Robinia pseudacacia* and *Prunus avium* appears as a normal distribution with a slight right-side asymmetry (Figure 14), because vegetation establishment on the analyzed surface occurred over a relatively short period of time, without disturbances. The successional process unfolded with active dynamics and high efficiency.

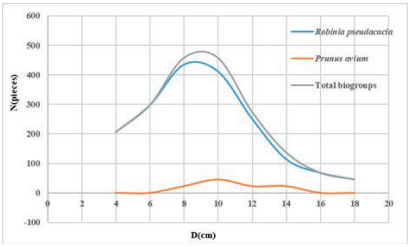

Figure 14. Distribution of the number of trees by diameter classes in the tree biogroups from parcel 1930

The theoretical value for the weighted number of trees is $N_{th}$ = 2369 trees/ha, and the weighted total basal area is $G_{th}$ =11.440 m²/ha. Consequently, the density index is $I_N$ = 0.8, the density coefficient $I_G$ = 0.9, the slenderness coefficient Z = 86%, and the spacing indices are $s_{4\%}$ = 23% and $s_{6\%}$ = 25% (Table 2).

The biogroups of trees installed in a proportion of 90% belong to the species Robinia pseudacacia, which is an allochthonous species, and is considered invasive, successfully colonizing agricultural lands that are improperly exploited or abandoned. They are characterized by a moderate to normal density and thickness, presenting a satisfactory stability to the action of the dominant wind and a very good spacing. Consequently, the biogroups in this plot are in an obvious state of climax.

Although the development of successional processes on various agricultural lands results in excessive fragmentation of the agricultural landscape, with a series of negative effects, the abundance of certain species can be increased and consequently the resistance of the phytocenosis to the effects of climate change can be optimized (Hurajová et al., 2024).

The climatological analysis carried out in the paper shows that the period 1990-2025 was very warm, the linear trend of the average annual values of air temperature being strongly upward. Annual rainy periods were longer than dry periods between 1990 and 2025, but the rainfall extremes were very clearly highlighted. There have been very rainy years, with large amounts of precipitation falling in a short time, interspersed with exceptionally dry years, in which droughts were long and intense. The recent years have been exceptionally hot and dry. The rainfall extremes facilitated the establishment of shrub and arboreal vegetation, both successively and in parallel. As a result, we showed that the climatic conditions favoured and supported the succession of arboreal and shrub vegetation, the first objective of the study being achieved.

The improper exploitation or abandonment of some agricultural use land in non-collectivized areas created the premises for the initiation and development of some succession processes between the grass species afferent to them and the shrub and arboreal species, native and exotic, in the areas bordering the case study location. As a result, the analyzed successions present an active dynamic and a series of specific particularities, due to the categories and subcategories of land use, the vegetation conditions and the size and excessive division of the plots, respectively. Also, anthropogenic impact conditions and influences the dynamics, specificity and particularities of these processes in the studied and analyzed plots.

From the analysis of the obtained results related to the structural particularities of the biogroups with arboreal vegetation, which were inventoried, it is highlighted that the areas on which they were installed meet the conditions to be introduced into the forest fund, according to the forestry code. As a result, the use category can be modified, these areas being considered as forestry use, at the proposal and with the agreement of the owners, obviously. Consequently, the second objective of the study was also achieved.

The results obtained in our study contributed to the advancement of scientific knowledge in the addressed field, by particularizing the succession process of the arboreal and shrub vegetation on agricultural use lands, highlighting the fact that successions of pioneer species and respectively successions between the pioneer species and fundamental ones related to the forest fundamental natural type, in the neighbouring areas, were simultaneously identified in the same plots, under similar climatic and pedo-stationary conditions.

The emergence of some successions between the shrub species and some oak species (*Quercus ceris* and *Quercus robur*) was also highlighted, that being a particularly important aspect for the development of some seed regeneration technologies, under shelter, of some oak species, in the context of climate change and the effect of extreme weather phenomena.

The extension of research to all agricultural use land that have been abandoned or improperly managed, in non-collectivized areas, is limited due to the fact that the exploitation of some areas was carried out with some intermittency (periodicity), an aspect that prevents a coherent analysis of successional aspects. Also, the access to some information from the agricultural register related to the lands that could be the subject of the study could be limited, due to the refusal or lack of a response from the owners.

Studies could be expanded in the future to plots in the mentioned location that are available or in locations with similar conditions, in the Vârfurile commune and/or in neighbouring communes that were not collectivized prior to 1989.

The continuation and expansion of this study in the future, in the presented location, can be achieved in two scenarios: a) if the improper exploitation of agricultural lands will continue or they will be abandoned; b) if the use category will be modified by assigning some lands to forestry use, where the conditions are met, in accordance with the Forestry Code (Low no. 331/2024).

Consequently, if the lands from the present case study will be exploited in the future in accordance with the current use categories and

subcategories, then further studies and research will be irrelevant.

## CONCLUSIONS

The period 1990-2025 was relatively rich in precipitation, with many rainy years, even very rainy, interspersed with exceptionally dry years. Thus, the rainfall extremes in the studied area were highlighted. The period was also very warm. Of course, the amounts of precipitation were not distributed uniformly throughout the year, with frequent cases of very large amounts falling in a short time, but also very long droughts.

Consequently, the extremes of rainfall have favoured the establishment in optimal conditions of arboreal vegetation from the species of the fundamental natural type of forest bordering the study location, respectively of pioneer, invasive and shrub species in dry years.

The process of succession of arboreal and shrub vegetation on agricultural lands in non-collectivized areas presents a series of particularities, and has a specific dynamic, depending on the way these lands are exploited.

Consequently, the denudation stage of the habitat is practically substituted by their abandonment or improper exploitation.

The native oak species, represented by *Quercus cerris* and *Quercus robur*, present a high colonization rate of agricultural lands, which are abandoned, due to the vegetation conditions and respectively their ecological demands, the dissemination of seeds being carried out exclusively zoochorically, by birds and rodent mammals.

The pioneer species that settled in simultaneously colonized the same habitats with the other arboreal species, thus indicating a simultaneous succession of them.

The invasive species *Robinia pseudacaia* colonized 90% of the new habitat, thus forming practically pure biogroups.

The shrub species that colonized some areas, forming compact biogroups with variable extents, facilitate their installation and colonization by the native oak species.

The results obtained confirm that on agricultural areas that were improperly exploited or abandoned, the succession process of arboreal and shrub vegetation took place with a differentiated dynamic, with a series of biogroups identified with the climax stage achieved.

## ACKNOWLEDGEMENTS

We would like to express our gratitude for their collaboration to the representatives of the management of the Arad Office of Cadastre and Real Estate Publicity, the Local Council of the Vârfurile Municipality, Arad County, as well as to the landowners from the location where the studies and research were carried out.

***Abstract***

*Climate change is placing increasing pressure on Romania's agricultural sector through intensified drought, greater precipitation variability, and more frequent hydrometeorological extremes. In this context, land reclamation systems, including irrigation, drainage and dewatering works, and anti-erosion measures, are becoming essential for reducing vulnerability and strengthening agroecosystem resilience. This article analyzes the main challenges in adapting these systems to climate change from an integrated technical, ecological, economic, and institutional perspective. It highlights outdated infrastructure, limited modernization, high water and energy demands, and environmental impacts, especially on hydrological regimes and biodiversity. At the same time, it examines economic and institutional barriers, and the gap between stated policies and practical implementation. The paper also explores the potential of Nature-based Solutions, and integrated green infrastructure, as viable complements or alternatives to traditional grey infrastructure. The findings emphasize the need for adaptive management, combining technological modernization, effîcient water use, and green solutions, to support climate resilience, food security, and territorial sustainability. In addition, the paper includes a case study of the Comlod polder project (Bistrița-Năsăud County, Romania), illustrating how flood retention infrastructure can function as a hybrid grey-green system contributing to climate adaptation and integrated water management.*

***Key words****: adaptation, climate change, environmental impacts, nature-based solutions.*

## INTRODUCTION

Climate change represents one of the most significant challenges for agricultural systems worldwide, affecting crop productivity, water resource availability, and the stability of agroecosystems (Yuan et al., 2024). The intensification of extreme events such as droughts, floods, and heatwaves leads to significant changes in hydrological regimes and plant growth cycles. Recent studies indicate that these processes directly influence land suitability for agriculture and may lead to the degradation of productive potential in many regions of the world (Shevchenko et al., 2023). In this context, European agriculture is considered one of the sectors most vulnerable to climate change, particularly in southern and eastern regions where water deficits and precipitation variability are intensifying (Florea et al., 2025). Consequently, the adaptation of agricultural infrastructure and water management systems becomes essential for maintaining productivity and food security. Land reclamation systems -including irrigation, drainage and dewatering works, and anti-erosion measures - represent fundamental components of this adaptation, as they enable the regulation of soil water regimes and reduce the risks associated with drought or excess water (OECD, 2025). In Romania, the effects of climate change are manifested through the intensification of water deficits, the aridification of certain agricultural regions, and increased precipitation variability (Nițu et al., 2023). Climatic and agronomic analyses highlight the high vulnerability of Romanian agriculture to hydrological imbalances, particularly in the Romanian Plain, Dobrogea, and southern Moldova (Frone et al., 2021).

These findings underline the sensitivity of the agricultural sector to climate variability and water scarcity, with direct effects on agricultural production and the stability of agri-food systems. At the same time, Romania's land reclamation infrastructure faces structural problems related to technical degradation, low efficiency, and the incomplete use of existing capacities. Although large areas have been equipped for irrigation, the actual functioning of these systems remains limited, and water losses are significant (Corcheș, 2025). These conditions indicate that the main issue is not only the availability of water resources, but also the low efficiency of the systems designed to manage water deficits.
