In this context, recent literature emphasizes the need to move beyond a paradigm based exclusively on technical infrastructure ("grey infrastructure") and to shift toward integrated water management approaches (Castañeda Rodriguez et al., 2026). Nature-based Solutions (NbS) use ecosystem processes to support water retention, soil stabilization, erosion reduction, and biodiversity conservation (Santos, 2025). However, these solutions should not be viewed as alternatives to technical infrastructure, but rather as complementary elements within an integrated water management system. The concept of hybrid ("grey-green") infrastructure involves combining hydrotechnical structures with natural elements that can perform part of the system's hydrological functions (Bujak et al., 2025). For example, irrigation systems can be complemented by shelterbelts, wetlands, or vegetative anti-erosion measures, which help reduce pressure on water resources and increase the resilience of agricultural systems to climate variability (Pourmohammad & Hajirad, 2025). Against this background, the present study analyzes the challenges of adapting Romania's land reclamation systems to climate change, highlighting the interdependencies between technical, ecological, economic, and institutional dimensions. At the same time, it explores the potential and limitations of integrating Nature-based Solutions into the modernization of existing infrastructure, as well as the role of hybrid infrastructures in increasing the resilience of agricultural systems. To illustrate the practical application of these concepts, the paper also includes a case study analysis of the Comlod Polder project in Bistrița-Năsăud County. This project represents an example of hybrid hydrotechnical infrastructure designed for flood retention and flood risk reduction, integrating both engineering solutions and elements with ecological functions. The case study highlights how such arrangements can simultaneously contribute to hydrological risk management, water retention in the landscape, and the enhancement of water management system resilience in the context of climate change.

## MATERIALS AND METHODS

The preparation of this article was based on an interdisciplinary approach that combined the analysis of scientific literature with the examination of strategic and legislative documents relevant to water resource management and the adaptation of agriculture to climate change. The research methodology aimed to identify the main challenges associated with the adaptation of land reclamation systems in Romania and to evaluate the potential of Nature-based Solutions (NbS) to complement existing technical infrastructure.

The first methodological step consisted of a critical review of the scientific literature, including national and international journal articles addressing the impacts of climate change on agriculture, the functioning of irrigation and drainage systems, and the role of Nature-based Solutions in water management within agricultural landscapes.

In parallel, an analysis of relevant strategic documents and public policies related to land reclamation and climate change adaptation was conducted. Based on the information derived from the literature and policy analysis, the challenges of adapting land reclamation systems were structured into four main dimensions: technical, ecological, economic, and institutional. This approach made it possible to highlight the interdependencies between infrastructure condition, ecosystem functioning, the economic viability of investments, and the institutional capacity to implement adaptation policies. To complement

the theoretical analysis, the study also includes an applied case study represented by the Comlod Polder project, located in Bistrița-Năsăud County. The case study was used to illustrate how hydrotechnical infrastructure can integrate elements of hybrid ("grey-green") infrastructure and contribute to adaptive water management in the context of climate change. The analysis was based on the technical documentation prepared for obtaining the environmental permit for the project, as well as on information regarding the construction solutions, hydrological functioning, and environmental constraints associated with the development of the polder. The principal author of the article participated, as an environmental expert, in the environmental permitting procedure for the Comlod Polder project. This direct involvement provided access to the technical documentation and to the environmental impact assessment process, enabling a detailed understanding of the interaction between the project's technical requirements, environmental constraints, and biodiversity protection measures. It also allowed the author to contribute to the identification of mitigation measures during the project planning phase.

By combining literature review, analysis of public policy documents, and the applied case study, the methodology provides an integrated perspective on the challenges and opportunities associated with the adaptation of land reclamation systems to climate change in Romania.

## RESULTS AND DISCUSSIONS

In Europe, agriculture is one of the sectors most vulnerable to climate change, particularly in southern and eastern regions where droughts are becoming increasingly frequent and severe. European adaptation policies highlight the need to adapt agricultural infrastructure and water management systems, including their integration into the Common Agricultural Policy, in order to maintain productivity and food security (Naumann et al., 2020). At the global level, national adaptation plans frequently identify agriculture as a priority sector, and the integration of ecosystem-based solutions and green infrastructure is increasingly promoted to reduce vulnerability and enhance the resilience of agricultural systems (Terton et al., 2024).

In this context, land reclamation systems - such as irrigation, drainage and dewatering works, and anti-erosion measures - represent essential infrastructures for water management in agriculture and for stabilizing agricultural production. By regulating the soil water regime, these systems reduce risks associated with drought or excess water and contribute to increasing crop productivity while limiting soil and nutrient losses (Pistocchi et al., 2022). Under climate change conditions, the role of these infrastructures becomes even more important. Increasing precipitation variability and prolonged droughts raise dependence on irrigation, while intense rainfall events increase the need for drainage systems and anti-erosion works. At the same time, inefficient water management in irrigation systems can generate hydrological imbalances and additional pressure on water resources (Junquera et al., 2024). From a food security perspective, land reclamation infrastructure contributes to stabilizing agricultural production and reducing the vulnerability of agri-food systems. In many regions, these systems enable agriculture to be practiced in areas with water deficits or erosion-prone soils, thereby supporting agricultural production and rural economies (Polo-Ballinas et al., 2022).

In recent decades, climate change adaptation strategies have been dominated by technical solutions based on grey infrastructure, such as dams, irrigation canals, drainage systems, and river regulation works. Although these measures reduce hydrological risks associated with climate variability, their high maintenance costs and ecological impacts have led to reconsideration of their exclusive use in adaptation policies (Naumann et al., 2020; Pistocchi et al., 2022). As an alternative or complement to grey infrastructure, the concept of Nature-based Solutions (NbS) has gained increasing importance, as it uses natural ecosystem processes to address challenges such as climate change adaptation, water management, and biodiversity conservation. In agriculture, NbS include measures such as artificial wetlands, natural water retention in

the landscape, agroforestry, and the restoration of riparian ecosystems (Pistocchi et al., 2022).
Recent studies show that NbS can generate multiple co-benefits, including flood risk reduction, increased biodiversity, and enhanced ecosystem carbon storage capacity (Santos, 2025). However, their large-scale implementation remains limited by institutional, financial, and planning barriers, which maintains grey infrastructure as the dominant solution in many sectors (Ryfisch et al., 2023). Although the literature on agricultural adaptation to climate change is expanding, significant gaps remain in integrating water management infrastructure with Nature-based Solutions. Most studies analyze technical infrastructures or ecological solutions separately, without addressing their interactions within complex agricultural systems (Polo-Ballinas et al., 2022). In many European countries, including those in Eastern Europe, land reclamation infrastructure was designed for the climatic conditions of the twentieth century and does not reflect current climate realities. This situation highlights the need to integrate Nature-based Solutions into the modernization of existing agricultural infrastructure, using ecosystem processes to provide similar or complementary services such as natural water retention, wetland restoration or conservation, and afforestation or reforestation (Pistocchi et al., 2022).

## 1. Romania's Context in Relation to Climate Change

In Romania, climate change is manifested through the intensification of water deficits, the aridification of southern and eastern regions, and increasing precipitation variability, with direct effects on agriculture. Recurrent droughts have led to the degradation of extensive areas and are associated with the decline of agricultural systems and the abandonment of irrigation infrastructure (Prăvălie et al., 2013). A national-scale analysis based on the Normalized Difference Drought Index (NDDI) for the period 2001-2020 shows that these regions remain consistently the most affected, even in relatively wetter years, indicating a structural vulnerability of agriculture in the Romanian Plain, Dobrogea, and southern Moldova, where water availability becomes critical during the growing season (Dobri et al., 2021). Dobrogea shows a high vulnerability to drought. Analyses for the period 2001-2021, based on the CDI, SPI, and SPEI indices, indicate an increasing frequency of drought episodes associated with high temperatures and reduced precipitation. Severe droughts were recorded particularly in 2011, 2012, and 2020, while between 2018 and 2020 a prolonged drought episode affected more than 70% of the region (Șerban et al., 2025). Climatological analyses for Constanța County also indicate a frequent transition between slightly arid and semiarid conditions, with more pronounced aridity episodes especially after 2000 (Maftei et al., 2024). From an agricultural perspective, this variability reduces soil water reserves and increases uncertainty regarding crop selection and the timing of agricultural operations. At the same time, the precipitation regime is changing, with intense rainfall events occurring more frequently as isolated episodes with large amounts of water. The analysis of pluviometric indices for the period 1961-2013 shows an increase in days with very intense precipitation (R10, R20, R30), with regional differences between northern and southern Romania (Croitoru et al., 2016). For agriculture, this pattern increases both the risk of soil drought between rainfall events and the risk of erosion or waterlogging during intense precipitation. The impact on production is particularly evident in Dobrogea, where maize productivity depends on climatic conditions by approximately 40%, and each additional 1 mm of water deficit can reduce yields by 7.1-11.0 kg/ha, reaching up to about 1.1 t/ha for a deficit of 100 mm (Prăvălie et al., 2014).
In this context, drought monitoring becomes essential for adaptation strategies. Studies conducted in southeastern Romania show an intensification of drought conditions in recent decades, reflected by SPI and SPEI indices, and emphasize the need to expand climate monitoring networks (Venturi et al., 2024).

## 2. Current State of Land Reclamation Infrastructure in Romania

Romania has approximately 15 million hectares of agricultural land, of which about 7 million hectares are potentially irrigable, while around

3.2 million hectares have been equipped for irrigation. However, the area actually irrigated each year is significantly smaller than the equipped area, highlighting a major gap between the existing infrastructure and its real use (Beilicci et al., 2019). A key factor is the poor technical condition of irrigation infrastructure. Before rehabilitation works, pumping stations operated at about 50% efficiency, the degradation level of canals and hydrotechnical structures reached 72%, and water losses along conveyance canals were estimated at 52% (Cojocinescu et al., 2017; Stanciu et al., 2024).

Similar difficulties occur in drainage and dewatering systems, where temporary excess water, sedimentation, and infrastructure wear reduce the operational capacity of existing arrangements, highlighting the need for strategies adapted to new hydrological conditions (Ilca et al., 2024). At the same time, recent literature indicates that a large part of Romania's irrigation infrastructure is technologically outdated and requires modernization, as the lack of investment and maintenance has led to network deterioration in many agricultural areas (Stanciu et al., 2024). These aspects suggest that simple physical rehabilitation of infrastructure is insufficient without technological and managerial reconfiguration adapted to current climatic conditions. Although some studies highlight local examples of modernization - such as the introduction of modern irrigation techniques in western Romania that can increase yields and reduce vulnerability to water deficits - these initiatives remain isolated and are not yet widely implemented at the national level (Șmuleac et al., 2024).

## 3. **The Role of Public Policies and European and National Funding**

Public policies have significantly influenced the modernization of land reclamation systems in Romania, although the results have been uneven. While the National Strategy for Reducing the Effects of Drought represents an important reference framework, recent analyses indicate limited progress and a gap between strategic planning and actual implementation (Stanciu et al., 2024).

From a financing perspective, the National Program for the Rehabilitation of the Main Irrigation Infrastructure has been one of the main public interventions, with investments of approximately €1.015 billion. In parallel, the National Rural Development Programme (NRDP) 2014-2020, through sub-measure 4.3, allocated around €435 million for the modernization of secondary irrigation infrastructure managed by Water Users Organizations (Cojocinescu et al., 2017). The program aimed to increase the share of economically viable functional irrigated areas from about 50% to 70% by 2020 and to 90% by 2030. However, the literature shows that funding policies in Romania have focused mainly on the technical rehabilitation of existing infrastructure, while the integration of Nature-based Solutions remains limited. Although climate change is increasing pressure on agriculture, current infrastructure still faces significant problems related to functionality and incomplete modernization, highlighting the need for an integrated approach that combines technical modernization, efficient water management, and Nature-based Solutions.

## 4. **Challenges of Adaptation in Land Reclamation Systems**

Adapting land reclamation systems to climate change goes beyond the simple rehabilitation of existing infrastructure and requires viewing them as socio-technical-ecological systems, in which infrastructure, ecosystems, and management practices are closely interconnected. In Romania and across the Danube region, increasing climatic pressure highlights the limitations of the traditional model based on grey infrastructure and emphasizes the need for more flexible and integrated solutions grounded in adaptive water management (Dogaru et al., 2019; Chitu et al., 2020).

### 4.1. ***Technical Challenges***

One of the main technical challenges is the outdated irrigation infrastructure and the rigidity of water distribution systems. In many irrigation schemes in Romania, systems still operate according to design principles developed for more stable climatic conditions, which limits their ability to adapt to current variability. Studies show that irrigation

scheduling is often influenced more by infrastructure characteristics than by the actual water needs of crops, while efficiency assessment is complicated by the lack of reliable data and by losses through evaporation, infiltration, or runoff (Dogaru et al., 2019; Chitu et al., 2020). With the intensification of drought conditions, existing infrastructure is increasingly insufficient to meet current agronomic requirements. Simulations using the CROPWAT model for wheat cultivation in southwestern Romania indicate the need for up to four additional irrigation events per year, while insufficient water supply may reduce yields by 17.9-43.3%, highlighting the growing inflexibility of traditional irrigation schemes under new climatic conditions (Constantin et al., 2025). The increasing frequency of droughts, the alternation between very dry periods and intense rainfall events, and rising temperatures exert additional pressure on irrigation systems. Under these conditions, existing infrastructure is often under-dimensioned and operationally rigid, reducing the efficiency of water distribution and increasing the vulnerability of agricultural production. Consequently, adaptation requires not only the technical rehabilitation of infrastructure but also more flexible and integrated water management solutions.

Water losses represent not only a technical problem but also an issue related to monitoring and institutional organization. The lack of efficient measurement and coordination systems makes it difficult to identify losses and optimize water distribution, meaning that even rehabilitated infrastructure may operate below optimal parameters. In addition, many existing drainage systems are rigid and designed primarily for rapid water evacuation, which becomes problematic under the increasing alternation between intense rainfall and drought. This situation requires more flexible water management approaches capable of addressing both water excess and deficit simultaneously (Bogdan et al., 2024; Petruța et al., 2025).

Excess soil moisture also represents a major pedological limitation, often caused by precipitation, high groundwater levels, or insufficient drainage, which negatively affects soil aeration and biological processes (Lațo et al., 2022). Although drainage systems can mitigate these effects, interventions based exclusively on rapid water evacuation may simplify hydrological regimes and reduce the ecological functions of agricultural landscapes.

### 4.2. *Ecological Challenges*

Ecological challenges associated with land reclamation systems arise because grey infrastructure modifies natural water regimes and reduces ecological connectivity, thereby affecting biodiversity. River regulation and declining groundwater levels have contributed to the degradation of floodplain ecosystems and to the reduction of ecosystem services (Constandache et al., 2022). At the same time, environmentally friendly practices such as shelterbelts and small water retention structures have been abandoned or degraded, although they previously played an important role in water and soil conservation (Hălbac-Cotoară-Zamfir et al., 2019). The tension between agricultural productivity and environmental conservation therefore has not only a biogeophysical dimension but also a historical and institutional one, as infrastructure and land-use patterns have been shaped by changing economic priorities. In this context, drainage works may negatively affect wetlands and aquatic biodiversity by reducing floodable areas and simplifying hydrological regimes. Consequently, drainage interventions should be evaluated in a broader perspective that considers the role of wetlands in maintaining biodiversity and supporting the natural regulation of water within agricultural landscapes.

### 4.3. *Economic Challenges*

The economic dimension of adaptation is strongly influenced by the high costs of modernizing irrigation infrastructure, which involve not only physical rehabilitation but also investments in monitoring systems, digitalization, and energy efficiency (Corcheș, 2025). At the same time, the uneven agrarian structure of Romanian agriculture makes such investments more accessible to large farms, while small farms often face difficulties in securing financing and covering operational costs (Burja et al., 2020). Studies on family farms in Central and Eastern Europe show that

production scale and market integration are key factors influencing economic resilience, placing small farms at a structural disadvantage in the adaptation process (Borychowski et al., 2020). In addition, the high dependence on subsidies and the limited impact of eco-schemes in reducing inequalities make the transition difficult without substantial public support (Borychowski et al., 2020; Toma et al., 2023). As a result, the modernization of water infrastructure risks increasing agricultural polarization, as large farms are able to adopt new technologies more rapidly, while smaller farms remain more vulnerable due to constraints related to access to technology, professional training, and the productivity of production factors (Florea et al., 2021).

### 4.4. *Institutional and Governance Challenges*

Institutional and governance challenges represent an important barrier to the adaptation of land reclamation systems, as they involve numerous actors and administrative levels, making the coordination of investments and decisions more difficult. In Romania, climate services are still at an early stage, and the lack of a dedicated platform limits the operational use of climate information in decision-making processes (Falcescu et al., 2024). Although agriculture, water resources, biodiversity, and the forestry sector are recognized as highly vulnerable to climate change, the implementation of adaptation measures remains fragmented, and the transition from strategic planning to integrated territorial interventions is still limited (Dumitrașcu et al., 2025).

At the river basin level, there is a gap between the need for integrated water management and current administrative practice. Studies emphasize the importance of a basin-based approach and the use of forecasting and decision-support tools to optimize water distribution (Dogaru et al., 2019; Chitu et al., 2020). However, their application is constrained by limited institutional capacity for data collection, intersectoral cooperation, and the integration of scientific knowledge into routine management. Overall, the literature indicates that technical, ecological, economic, and institutional challenges are strongly interconnected. Outdated infrastructure generates water losses and high operating costs, hydrological rigidity may negatively affect ecosystems, and structural inequalities within agriculture limit the ability of many farms to participate in modernization processes. Without adaptive governance capable of integrating grey infrastructure with Nature-based Solutions and territorially differentiated policies, the adaptation of land reclamation systems risks remaining incomplete and largely reactive rather than transformative (Hălbac-Cotoară-Zamfir et al., 2019; Burja et al., 2020; Falcescu et al., 2024).

## 5. **The Role and Potential of Nature-based Solutions (NbS)**

The integration of Nature-based Solutions (NbS) into the management of land reclamation systems represents an emerging direction in the adaptation of agriculture to climate change. Unlike approaches based exclusively on engineering solutions, NbS rely on natural ecosystem processes to provide services such as water retention, soil stabilization, and erosion reduction. These solutions do not replace hydrotechnical infrastructure but rather complement it, contributing to improved water management efficiency within agricultural landscapes (Ion et al., 2024).

In Romania, Nature-based Solutions are becoming increasingly relevant because much of the land reclamation infrastructure was designed within a rigid technical model focused on artificial hydrological control. Under current climate change conditions, the integration of NbS can support the natural regulation of hydrological flows, increased soil water retention, and the strengthening of ecosystem functions, thereby contributing to the development of more resilient and sustainable agricultural systems.

### 5.1. *Examples of Nature-based Solutions*

- Shelterbelts (Protective Forest Belts)

Shelterbelts represent effective Nature-based Solutions in agricultural areas vulnerable to drought and wind erosion. By reducing wind speed and evapotranspiration, they protect crops, favor snow accumulation, and limit soil losses. In Romania, the reintroduction of shelterbelts is considered an important measure for reducing land degradation and supporting

agricultural adaptation to climate change (Hălbac-Cotoară-Zamfir et al., 2019).

- Wetland Buffers and Wetland Restoration
Wetlands and riparian buffer zones represent important Nature-based Solutions for water management in agriculture, as they retain and filter water, reduce nutrient runoff, and help stabilize local hydrological regimes. At the same time, they provide valuable habitats for biodiversity and can reduce flood risk by absorbing excess water. In Romania, the degradation of these ecosystems through drainage and river regulation has negatively affected biodiversity, and their restoration is considered an effective solution for restoring ecosystem functions and increasing the resilience of agricultural landscapes (Constandache et al., 2022).

- Green Anti-Erosion Measures
Green anti-erosion measures include practices such as vegetative soil cover, strip cropping, and the use of perennial plants, which reduce surface runoff, limit soil erosion, and enhance water infiltration into the soil (Ion et al., 2024). Soil stabilization can also be optimized through laboratory methods and geotechnical modeling to identify effective solutions for reducing the degradation of agricultural land (Olinic et al., 2023).

- Natural Water Retention in the Landscape
An increasingly discussed concept in the European literature on Nature-based Solutions is that of Natural Water Retention Measures (NWRM). These measures include the restoration of floodplains, the creation of micro-depressions, the restoration of wetlands, and the use of vegetation to increase water infiltration into the soil.

### 5.2. *Benefits of Nature-based Solutions*

A major advantage of Nature-based Solutions lies in their ability to generate multiple benefits for socio-ecological systems. They contribute to climate adaptation by increasing the capacity of agricultural landscapes to manage hydrological variability and by reducing risks associated with drought or extreme precipitation. At the same time, NbS improve soil quality, reduce erosion, and support biodiversity. They also provide essential ecosystem services such as water purification, carbon sequestration, and microclimate regulation, thereby contributing to the development of more resilient agricultural systems (Hălbac-Cotoară-Zamfir et al., 2019; Ion et al., 2024).

## 6. **Case Study: The Comlod Polder - Hybrid Infrastructure for Flood Management and Climate Adaptation**

To illustrate the transition of land reclamation infrastructure toward adaptive water management models, the Comlod Polder project, located in Bistrița-Năsăud County and promoted by the Mureș River Basin Administration, can be analyzed (Figure 1).

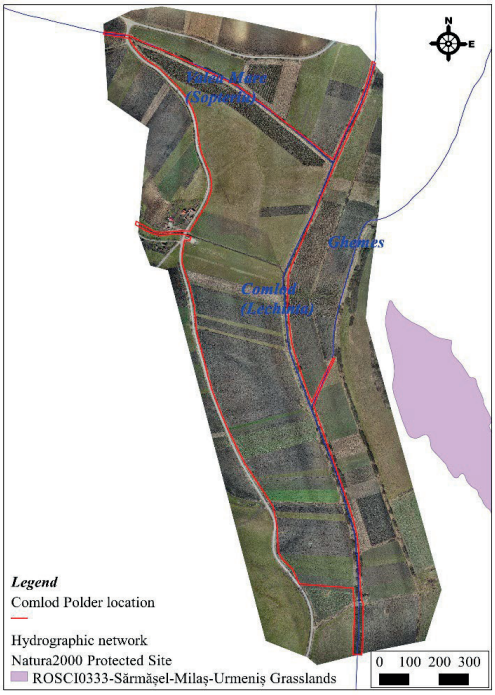

Figure 1. Comlod Polder Location (original)

The project is designed as a hybrid flood-retention infrastructure within the catchment of the Valea Mare and Comlod rivers, integrating the Fânațe tributary. The technical solution involves the construction of a compartmentalized polder with a single water intake threshold, while Fânațe river is channelized and functions as an internal

spillway separating the two compartments of the polder (SC 4C Project Consulting SRL, 2023). The concept of the project is based on the temporary retention of flood waves by storing excess water volumes inside the polder and releasing them in a controlled manner through a spillway and a bottom outlet. Through this mechanism, the polder reduces peak downstream flows and mitigates flood risk, functioning as a local hydrological regulation system. From a technical perspective, the polder covers an area of approximately 43.04 ha and has a total retention capacity of about 1.75 million m³, divided into two functional compartments: 17.93 ha (0.62 million m³) and 25.11 ha (1.13 million m³). The hydrological supply is ensured by Valea Mare and Comlod rivers, while Fânațe river is integrated through a reinforced concrete channelization of 370 m, designed to convey flows with a 1% exceedance probability (Q1%) (SC 4C Project Consulting SRL, 2023). Water intake into the polder is controlled through a system of hydraulic thresholds: a broad-crested intake weir with a length of 24 m and a downstream diversion weir measuring 7.5 m in length and 1 m in height. To maintain hydrological connectivity during non-flood periods, the structure includes a low-flow slot (1.0 m × 0.50 m) that ensures the continuity of the watercourse and the movement of aquatic biodiversity. Downstream works include energy dissipation and riverbed stabilization structures, such as concrete lining, an energy dissipator, and a mobile stilling basin (SC 4C Project Consulting SRL, 2023). The containment and guidance of water volumes are achieved through a system of embankments with a total length of 5,715 m, of which 4,000 m are perimeter embankments and 1,715 m are guiding embankments. The embankments have 1:2 slopes and a crest stabilized with crushed stone to allow maintenance access. Slope stabilization is achieved through grassing, while areas exposed to higher hydraulic stress are protected with concrete lining. Controlled water evacuation is performed through a 24 m spillway and a bottom outlet consisting of two gated openings, with a maximum discharge capacity of approximately 24.6 m³/s.

In the context of current climatic trends characterized by the increasing frequency of extreme hydrological events, including intense rainfall and flash floods alternating with drought periods, the Comlod polder highlights the role of such infrastructure as a climate adaptation measure, capable of temporarily storing significant water volumes and reducing flood peaks. Beyond its flood protection function, the polder also presents characteristics similar to Nature-based Solutions. During non-flood periods, its surface can function as a temporary wetland, promoting water retention in the landscape, infiltration, and groundwater recharge. Vegetation established on the embankment slopes and within the polder also contributes to soil stabilization, erosion reduction, and the enhancement of local biodiversity.

The project also raised several challenges during the environmental permitting process. Near the project site lies the Natura 2000 site ROSCI0333 - Sărmășel - Milaș - Urmeniș Grasslands, covering 1,127.10 ha, designated for the protection of habitats and species of community interest. The environmental assessment analyzed the potential impact on amphibian species such as *Bombina bombina*, *Bombina variegata*, and *Triturus cristatus*. As a result, specific measures were required to maintain the longitudinal connectivity of the watercourse, ensured through the low-flow slot integrated into the diversion weir structure.

The case study analysis shows that the Comlod polder represents an example of hybrid hydrotechnical infrastructure, combining engineering solutions with natural stabilization elements and potential ecological functions. Through temporary water retention, flood peak reduction, and the potential formation of seasonal wetland habitats, the project contributes both to reducing hydrological risks and enhancing local ecosystem services. In the context of climate change, such integrated solutions become increasingly important for strengthening the resilience of water management systems.

## CONCLUSIONS

The analysis highlights that the adaptation of land reclamation systems to climate change represents a complex challenge that goes beyond the strictly technical dimension of

hydrotechnical infrastructure. The increasing frequency of droughts, the growing variability of precipitation, and the occurrence of extreme hydrological events intensify pressures on agriculture, emphasizing the dependence of agricultural systems on efficient water resource management. In the case of Romania, the results show that land reclamation infrastructure continues to play an essential role in stabilizing agricultural production; however, its functioning is limited by technical degradation, high water losses, and the rigidity of operational schemes. These aspects indicate that the adaptation challenge is not related solely to water availability, but also to technical efficiency, institutional capacity, and the organization of water management.

The study also demonstrates that the challenges associated with adaptation should be analyzed from an integrated perspective that simultaneously considers the technical, ecological, economic, and institutional dimensions of land reclamation systems. In this context, the literature and the present analysis suggest that Nature-based Solutions can play an important role in increasing the resilience of agricultural systems by improving water retention in the landscape, reducing erosion, and strengthening ecosystem functions.

The results further indicate that integrating grey infrastructure with Nature-based Solutions may represent a promising direction for adapting water management systems. The concept of hybrid ("grey-green") infrastructure allows the combination of hydrotechnical control of water resources with natural hydrological regulation processes, thereby reducing the vulnerability of agricultural systems to climate variability.

The case study analysis of the Comlod Polder illustrates how hydrotechnical infrastructure can integrate multiple functions, contributing both to flood risk reduction and to water retention and the development of temporary wetland habitats. In this sense, retention structures can be interpreted as hybrid infrastructures capable of combining hydrological protection objectives with ecosystem conservation goals. At the same time, adapting land reclamation systems to climate change requires a paradigm shift, in which the modernization of technical infrastructure is correlated with the integration of Nature-based Solutions, the development of institutional capacity for adaptive management, and public policies focused on the sustainable management of water resources in agriculture. Such an approach can contribute to strengthening the resilience of agricultural systems and enhancing food security in an increasingly uncertain climatic context.

## ACKNOWLEDGEMENTS

The authors would like to thank SC 4C Project Consulting SRL for the support provided in the preparation of this study and for facilitating access to the technical information and documentation related to the analyzed project.

***Abstract***

*Monitoring building vibrations provides important information on structural health and, through on the detection of changes in dynamic characteristics, can serve as an early indicator of potential degradation or damage. However, detection reliability depends substantially on appropriate instrumentation capable of clearly capturing the building response to ambient, natural and anthropogenic vibrations. The paper presents an in-depth study based on data recorded during recent seismic events on a higher-education building in Bucharest, Romania. The building has been continuously monitored for vibrations for more than a decade. Unlike many other urban buildings monitored in Romania, the building's location within a university campus - characterized by large open spaces - enabled the installation of a free-field-type station approximately 30 m away from the building, such that reference ground motion records were also available. Based on multiple types of analyses, the study provides valuable insights into the building's dynamic characteristics, soil-structure interaction phenomena and kinematic effects.*

***Key words****: building vibrations, dynamic characteristics, kinematic effects, soil–structure interaction, structural health monitoring.*

## INTRODUCTION

Monitoring building vibrations is an essential tool for the rapid detection of potentially unsafe changes in structural dynamic characteristics, which may indicate degradation or damage. However, especially in urban environments, complete instrumentation is often challenging, due to the difficulty of identifying open spaces for installing reference free-field stations in the vicinity of the building (COSMOS, 2001; Skolnik, 2010). The National Institute for Research and Development in Constructions, Urbanism and Sustainable Spatial Development, URBAN-INCERC (NIRD URBAN-INCERC) has a long history of activities in the field, with the first seismic stations installed on buildings in the late 1960s and early 1970s (Berg et al., 1977; Bălan et al., 1982). A large campaign of temporary building instrumentation was carried out in the years preceding the catastrophic March 4, 1977, $M$ = 7.2 earthquake. The dynamic characteristics (natural periods of vibration) measured within this campaign on 47 buildings in Bucharest (Bălan et al., 1982) provided essential information for assessing their post-earthquake condition. In the years that followed, several buildings in Bucharest and in other major cities were permanently instrumented. After 1990, despite the reduction of the number of instrumented buildings (mainly due to ownership changes and equipment obsolescence), both temporary and permanent instrumentation for building vibrations monitoring continued. A large-scale, multi-annual campaign - still ongoing within the "Nucleu" Programme PN 23 35 "ECODIGICONS" - has focused on the temporary instrumentation of several public buildings and the determination of their reference dynamic characteristics, particularly

for those hosting national research and development institutes. The campaign is carried on through the National Network for the Seismic Monitoring and Protection of the Building Stock (RNMPSPC), an infrastructure of national interest operating within NIRD URBAN-INCERC (https://incd.ro/reteaua-nationala-de-monitorizare-siprotectie-seismica-a-patrimoniului-construit-iosin/).

The building examined in this study has been subjected to continuous vibration monitoring for over a decade. Unlike many other urban buildings monitored in Romania, the building's location within a university campus – characterized by large open spaces – enabled the installation of a free-field-type station approximately 30 m away from the building, such that reference ground motion records are also available. Based on multiple types of analyses, this study aims to provide valuable insights into the building's dynamic characteristics, soil-structure interaction phenomena, and kinematic effects.

## MATERIALS AND METHODS

### Description of the monitored building

The monitored building is situated on the campus of the University of Agriculture and Veterinary Medicine in Bucharest and serves as the headquarters of the Faculty of Biotechnologies (Figures 1 and 2). The campus, with a surface area of 38 hectares, benefits from large spaces between the buildings, arranged as parks and recreational areas.

The building, completed in 2016, comprises a basement and three above-ground stories. Its structural system consists of reinforced concrete frames combined with shear walls.

The instrumentation system, installed ever since the building completion, consists of a Kinemetrics Granite digitizer and recorder, with ES-T triaxial episensors placed in the basement, at the roof of the building and in a special encasement, located about 30 m away from the building, in a neighbouring green space (Figure 3). The digitizer, placed in the central building section, is equipped with 12 channels, of which channels 1-3, 5-7 and 9-11 are assigned, in order, to vibration measurements at the three mentioned locations: free field, basement and roof. Channels are identified as HNZ, HNN and HNE, respectively, with suffixes indicating the location (FF – free field, B1 – basement, 04 – roof).

Map location and orientation of the monitored building (Google Maps screenshot) (https://www.google.com/maps/place/Facultatea+de+Biotehnologii+Bucure%C8%99ti/@44.4699931,26.0620898,132m/data=!3m1!1e3!4m6!3m5!1s0x40b2023b3338d51f:0xa7a705d357d7ce12!8m2!3d44.4696946!4d26.0625279!16s%2Fg%2F1hc0sxqyv?entry=ttu&g_ep=EgoyMDI2MDQwMS4wIKXMDSoASAFQAw%3D%3D)

a) b) c)

Figure 3. Station BTH: a) free-field station encasement, b) free-field episensor, c) installation of permanent online connection with the Data Centre of NIRD URBAN-INCERC

The station, identified by the code BTH, is permanently connected to the Data Centre of NIRD URBAN-INCERC, enabling the continuous acquisition of co-located structural and free-field seismic records. Through a secure communication link provided by the

Romanian Special Telecommunications Service, STS, the station transmits real-time data to the SeisComP (https://www.gempa.de/products/seiscomp/) seismological software running on the main server of the centre.

**Ground motions considered**

Ground motions recorded from two significant earthquakes ($M_L$ = 5.2 and $M_L$ = 4.8) originating in the Vrancea seismic zone of Romania, with epicentres located approximately 200 km from the building site, were used in the study. Their main characteristics, according to the website of the National Institute for Earth Physics (https://www.infp.ro/), are shown in Table 1.

**Processing and analyses**

The processing steps and analyses performed are presented below, with explanations on their meaning and relevance for the current study. The processing was carried out using the ViewWave software (Kashima, 2016; 2024).

***Acceleration, velocity, and displacement waveforms***

The recorded waveforms illustrate the temporal variation of the vibrations measured by sensors placed at different locations in the structure and in its vicinity. They also show the peak values reached during the earthquake, the amplification between the base and the roof of the building, as well as the primary differences between the free field motion and the motion recorded in the building's basement, at the foundation level.

Table 1. Main characteristics of Vrancea earthquakes considered in the study

| Date and time (UTC) | Focal depth (km) | Epicentral coordinates | Local magnitude ($M_L$) |
|---|---|---|---|
| 31.01.2020, 01:37:52 | 118.2 | 45.6937°N 26.6918°E | 5.2 |
| 03.12.2023, 22:05:48 | 133.3 | 45.5939°N 26.4734°E | 4.8 |

***Husid plots***

Husid plots illustrate the evolution of normalized Arias intensity throughout the seismic motion. They can be also used to estimate the significant duration of the earthquake (the duration of strong ground shaking), which is important for assessing its destructive potential by indicating when the largest amount of energy is induced during the event. Arias intensity is defined by the following equation:

$$I_A = \frac{\pi}{2g} \int_0^{T_d} a^2\,(t)\,dt \qquad (1)$$

where $T_d$ is the duration of the ground motion and $a(t)$ is the acceleration.

***Fourier and power spectra***

*Fourier analysis* is the most widely used method for estimating the dynamic characteristics of a structure. This analysis transforms measured structural vibrations from the time domain to the frequency domain, allowing the identification of the natural frequencies of the structure, which generally correspond to the peaks of the Fourier amplitude spectra. Estimating the values of these natural frequencies provides a reference point for identifying future degradation or damage that alters the dynamic parameters of the structure, thus enabling structural health monitoring.

The *power spectrum* highlights the predominant frequencies/periods of the ground or structure vibration, the distribution of earthquake-induced energy over frequency ranges, and the bandwidth characteristic of the motion.

***Response spectra***

The following spectra and diagrams were determined:

- the acceleration spectrum (*Sa*);
- the velocity spectrum (*Sv*);
- the displacement spectrum (*Sd*);
- the pseudovelocity spectrum (*pSv*);
- the input energy spectrum (equivalent velocity) (*Ve*).

The *acceleration, velocity, and displacement spectra* are standard seismic record processing tools used to highlight the frequency content of ground motion, amplification effects, and related phenomena.

The *pseudovelocity spectrum* is computed by multiplying the ordinates of the relative displacement spectrum (Sd) by the corresponding circular frequency ($\omega$):

$$pSv = \omega \cdot Sd \qquad (2)$$

The pseudovelocity spectrum is proportional to the elastic deformation energy of the system and serves as an indicator of the frequencies/periods associated with the maximum destructive potential of seismic motion, with direct applications in structural engineering.

Another important indicator is the *total input energy induced by the earthquake* ($E$). This is often expressed through the equivalent velocity $V_E$, defined by:

$$V_E = \sqrt{\frac{2E}{m}} = \sqrt{-2\int_0^{T_d} \ddot{x}_g(t)\dot{x}(t)dt} \quad (3)$$

where $m$ is the mass, $\ddot{x}_g(t)$ and $\dot{x}_g(t)$ are the ground acceleration and relative velocity of the oscillator, respectively, and $t$ is the time. The equivalent velocity (and thus the energy, $E$) is a significant measure of the destructive potential of seismic motion, with various structural engineering applications as well. It has the advantage of representing a scalar value, rather than a vectorial value.

***Spectral ratios – transfer functions***

The analysis of the *ratios* between the *Fourier amplitude spectra* recorded at the roof and those recorded at the base/foundation is another widely used method for determining the natural frequencies/periods of the structure, revealing the transfer functions. These ratios exhibit pronounced peaks at those frequencies. Such analyses are especially important for Structural Health Monitoring (SHM), because performing them at different time intervals allows detection of changes in the structure's dynamic characteristics. When free-field records are available near the building, comparing the Fourier amplitude spectra of the motions recorded at the foundation with those in free-field reveals the modification of free-field motion by the buildings' presence and the influence of soil–structure interaction.

## RESULTS AND DISCUSSIONS

The obtained results are presented selectively in the following, with focus on the most significant observations and on the larger-magnitude earthquake.

Figure 4 presents the acceleration waveforms recorded during the 31 January 2020 earthquake. The P- and S-wave arrivals, as well as the amplitude and timing differences can be noticed. For each recording channel, the maximum acceleration amplitudes ($a_{max}$) are marked on the plot and summarized in Table 2, together with the corresponding maximum velocities ($v_{max}$), displacements ($d_{max}$), and Arias intensities ($I_A$). The table also includes the values recorded during the second earthquake considered, i.e., the one on 3 December 2023.

Figure 5 displays the Husid plots for the 31 January 2020 earthquake. As it can be noticed, the onset of the most pronounced intensity increase occurs around second 50 of the record, indicating when the maximum amount of energy is induced during this event.

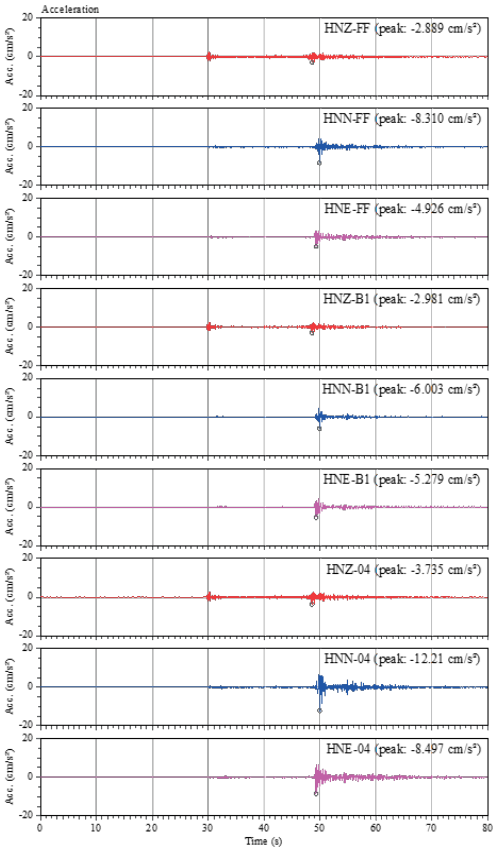

Figure 4. Acceleration waveforms for the 31.01.2020 earthquake

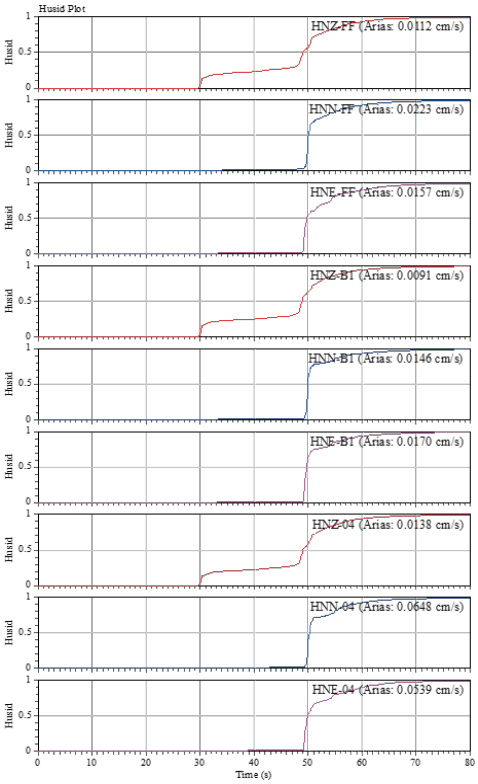

Figure 5. Husid plots for the 31.01.2020 earthquake

Values in Table 2 also show that, as expected, all ground motion parameters recorded for the 3 December 2023 ($M_L$=4.8) event are below those of the 31 January 2020 ($M_L$=5.2) event. They also reflect the differences in the spectral content of the two earthquakes considered.

In what concerns the variation of the parameters between the FF (free field), B1 (basement) and 04 (roof) sensors, an interesting attenuation of the amplitudes of the ground motion by the building, on certain frequency ranges, can be noticed – from FF to B1 – for the HNN components and, as a weaker effect, for the HNZ components. Regarding the B1–04 variation, amplification is observed consistently, on wide frequency ranges, especially for the horizontal channels. The features are also noticeable in Figure 6. These general amplification patterns are observable for both earthquakes.

An analysis of the spectral content of the FF, B1 and 04 components, as reflected by the acceleration spectra in Figure 6 and the values in Table 3, shows that the largest spectral peaks occur at short periods ($T < 0.5$ s) for both earthquakes, with differences regarding the dominant peaks of the spectra, but with similarities in the location of other peaks, which are persistent for both earthquakes.

Table 2. Maximum values of accelerations ($a_{max}$), velocities ($v_{max}$), displacements ($d_{max}$), and Arias intensities ($I_A$) for the earthquakes of 31 January 2020 ($M_L$ = 5.2) and 3 December 2023 ($M_L$ =4.8)

| | 31.01.2020 Earthquake ($M_L$ = 5.2) | | | | 03.12.2023 Earthquake ($M_L$ = 4.8) | | | |
|---|---|---|---|---|---|---|---|---|
| Channel | $a_{max}$ (cm/s$^2$) | $v_{max}$ (cm/s) | $d_{max}$ (cm) | $I_A$ (cm/s) | $a_{max}$ (cm/s$^2$) | $v_{max}$ (cm/s) | $d_{max}$ (cm) | $I_A$ (cm/s) |
| HNN-04 | 12.210 | 0.522 | 0.0456 | 0.0648 | 4.049 | 0.155 | 0.0083 | 0.0053 |

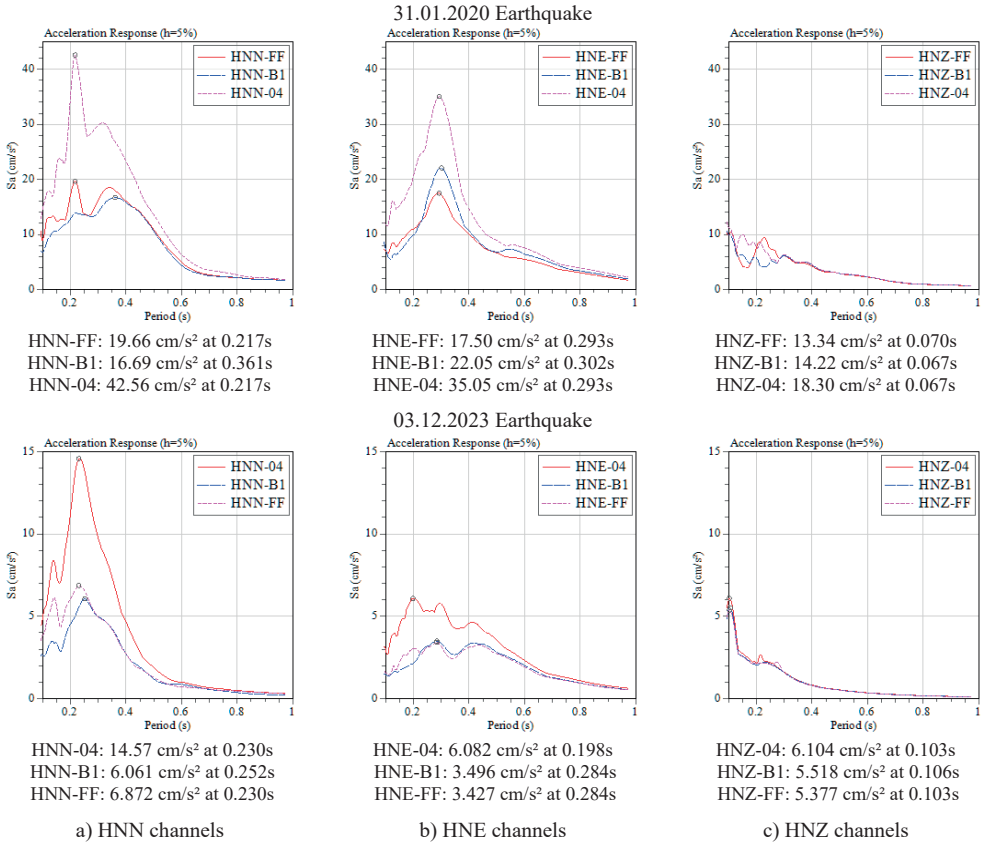

Figure 6. Acceleration spectra (5% damping) for the 31.01.2020 and 03.12.2023 earthquakes

Table 3. Periods corresponding to the maximum peaks if the acceleration spectra for the earthquakes of 31 January 2020 ($M_L = 5.2$) and 3 December 2023 ($M_L = 4.8$)

| Channel | 31.01.2020 Earthquake ($M_L = 5.2$) | 03.12.2023 Earthquake ($M_L = 4.8$) |
|---|---|---|
| HNN-04 | 0.217s | 0.230s |
| HNE-04 | 0.293s | 0.198s |
| HNZ-04 | 0.067s | 0.103s |
| HNN-B1 | 0.361s | 0.252s |
| HNE-B1 | 0.302s | 0.284s |
| HNZ-B1 | 0.067s | 0.106s |
| HNN-FF | 0.217s | 0.230s |
| HNE-FF | 0.293s | 0.284s |
| HNZ-FF | 0.070s | 0.103s |

Power spectra (with values listed in Table 4 and illustrated in Figure 7) show a more differentiated situation, given their multiple peaks, characteristic to a broadband motion. For the 31.01.2020 earthquake, a persisting period of approximately 0.44 seconds can be noticed on the HNN channels, where amplitudes increase progressively from FF to B1 and then, to 04.

Table 4. Periods corresponding to the dominant peaks of the power spectra, 30.01.2020 and 3.12.2023 earthquakes

| Channel | 30.01.2020 | 03.12.2023 |
|---|---|---|
| HNN-04 | 0.235 | 0.225 |
| HNE-04 | 0.306 | 0.181 |
| HNZ-04 | 0.183 | 0.254 |
| HNN-B1 | 0.439 | 0.314 |
| HNE-B1 | 0.328 | 0.311 |
| HNZ-B1 | 0.352 | 0.113 |
| HNN-FF | 0.442 | 0.314 |
| HNE-FF | 0.330 | 0.288 |
| HNZ-FF | 0.235 | 0.113 |

For the HNN-04 channel (roof), the 0.44 seconds peak is not the dominant one, as it is exceeded by the peak at $T = 0.235$ s, which most probably indicates the fundamental period

of vibration of the building on this direction, including the effects of soil-structure interaction (SSI). For the HNE channels, the FF and B1 records exhibit a clear peak at $T \approx 0.33$ s, visible also for the 04 records. The dominant peak for the roof record HNE-04 is slightly shifted to a shorter period, $T = 0.306$ s, which probably identifies the fundamental period of vibration of the building, including SSI effects, for this direction. The vertical (HNZ) channels exhibit the highest peaks at 0.235 s (FF), 0.352 s (B1) and 0.183 s (04). Again, the value $T = 0.183$ s could indicate the natural period of the structure on this direction, including SSI effects.

These assumptions will be however checked in the next section, where the transfer functions will be analysed as well.

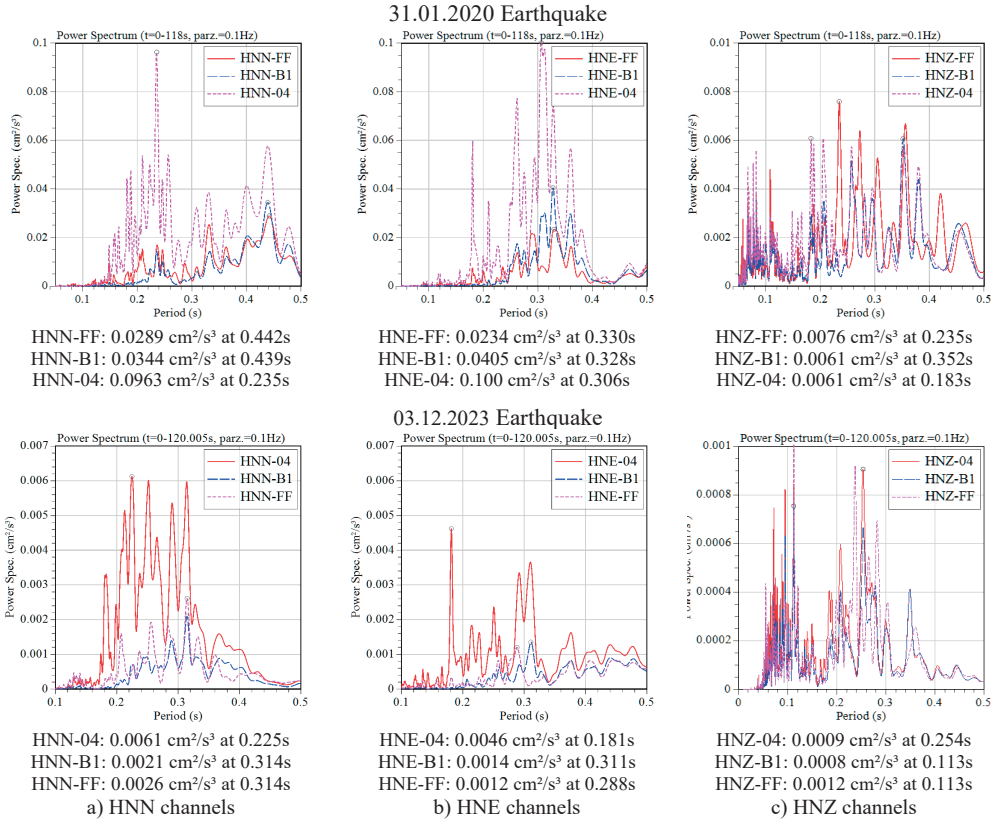

Figure 7. Power spectra for the 31.01.2020 and 03.12.2023 earthquakes

For the 03.12.2023 earthquake, the power spectra exhibit different patterns, as compared to the 31.01.2020 event. However, the two earthquakes share some common or close peaks.

Table 5 synthesizes the maximum Fourier amplitudes and their corresponding periods for the two earthquakes considered. The table shows marked differences between the two seismic events, especially the variation of amplitudes.

The pseudovelocity spectra and the equivalent velocity spectra (normalized input energy) are displayed in Figures 8 and 9, for the seismic event of 31.01.2020, while the periods corresponding to their dominant spectral peaks are synthesized in Table 6.

The spectral shapes are overall quite similar, even though their highest spectral peaks occur at different periods. The most noticeable difference appears in the spectral shapes associated with the HNN-04 channel, but also for HNZ-04.

Table 5. Maximum Fourier amplitudes and corresponding periods for the two earthquakes considered

| Channel | 31.01.2020 Earthquake | | 03.12.2023 Earthquake | |
|---|---|---|---|---|
| | Fourier max. amplitude (cm/s) | T (s) | Fourier max. amplitude (cm/s) | T (s) |
| HNN-04 | 3.973 | 0.235 | 0.654 | 0.314 |
| HNE-04 | 4.047 | 0.306 | 0.444 | 0.288 |
| HNZ-04 | 0.998 | 0.183 | 0.445 | 0.113 |
| HNN-B1 | 2.375 | 0.439 | 0.587 | 0.314 |
| HNE-B1 | 2.577 | 0.328 | 0. 471 | 0.311 |
| HNZ-B1 | 0.997 | 0.352 | 0.352 | 0.113 |
| HNN-FF | 2.175 | 0.442 | 1.002 | 0.225 |
| HNE-FF | 1.958 | 0.330 | 0.870 | 0.181 |
| HNZ-FF | 1.116 | 0.235 | 0.385 | 0.254 |

Table 6. Periods corresponding to the highest spectral peaks of the pseudovelocity spectra and of the equivalent velocity spectra (normalized input energy), 31.01.2020 earthquake

| Channel | From pseudovelocity spectra | From normalized input energy spectra |
|---|---|---|
| HNN-04 | 0.340 | 0.237 |
| HNE-04 | 0.302 | 0.311 |
| HNZ-04 | 0.383 | 0.204 |
| HNN-B1 | 0.432 | 0.432 |
| HNE-B1 | 0.311 | 0.330 |
| HNZ-B1 | 0.383 | 0.361 |
| HNN-FF | 0.372 | 0.432 |
| HNE-FF | 0.302 | 0.330 |
| HNZ-FF | 0.230 | 0.276 |

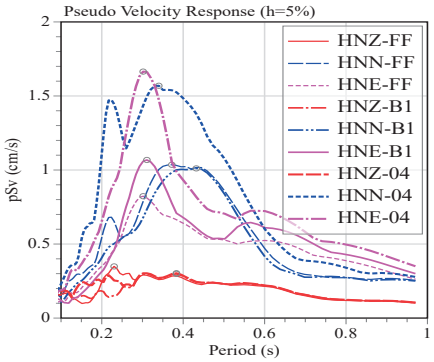

Figure 8. Pseudovelocity spectra for the 31.01.2020 earthquake

However, for HNN-04, both spectra have a peak at $T = 0.22$ - 0.237 s, which is consistent with the values obtained from the power spectrum and which also indicates a maximum of the energy induced by the earthquake.

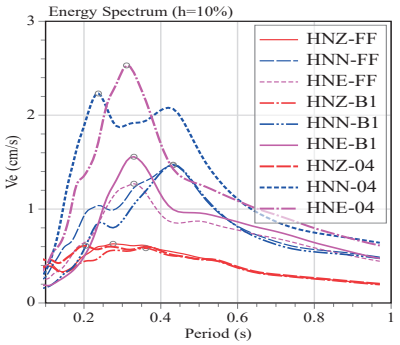

Figure 9. Equivalent velocity spectra (normalized input energy) for the 31.01.2020 earthquake

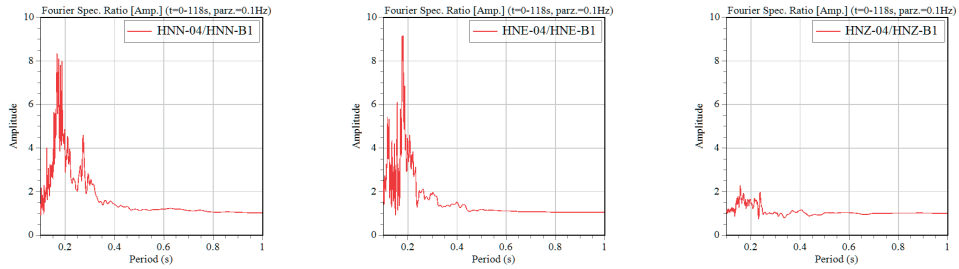
A distinct part of the study focused on transfer functions, both from the basement to the roof of the building and between the free-field motion and the basement motion. The first type of transfer function provides insight into the natural periods of the building, while the second type highlights how the presence of the structure modifies the motion of the surrounding soil.

Figures 10 and 11 show the transfer functions from basement to roof, while Figures 12 and 13 show the transfer functions from free field to basement motion.



Tables 7 and 8 show the periods corresponding to the dominant peaks of the transfer functions between the foundation motion and the roof motion and, respectively, between the ground motion and the foundation motion. The first set of values is generally used to represent the natural vibration periods of the building, while the second set serves for highlighting the influence of the buildings' presence.

Table 7. Periods corresponding to the highest peaks of the transfer functions between the foundation and the roof motions - 31.01.2020 and 03.12.2023

| Channels | 31.01.2020 | 03.12.2023 |
|---|---|---|
| HNN-04/HNN-B1 | 0.167 s | 0.179 s |
| HNE-04/HNE-B1 | 0.180 s | 0.179 s |
| HNZ-04/HNZ-B1 | 0.157 s | 0.180 s |

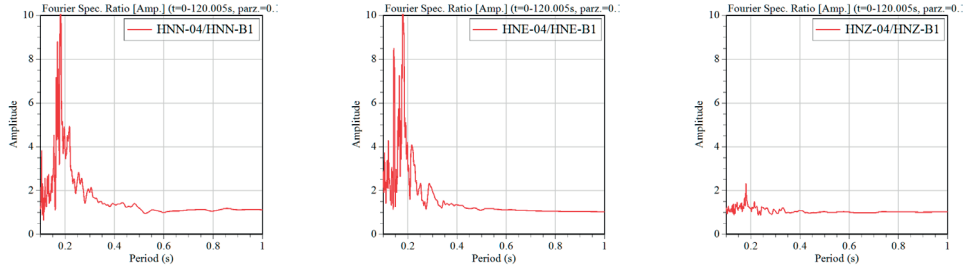


Table 8. Periods corresponding to the highest peaks of the transfer functions between the ground motion and the foundation motion - 31.01.2020 and 03.12.2023

| Channels | 31.01.2020 | 03.12.2023 |
|---|---|---|
| HNN-B1/HNN-FF | 0.256 s | 0.272 s |

Figure 13. Transfer functions (ground - foundation), 03.12.2023

A case study summary, presenting periods corresponding to dominant peaks of Fourier spectra and transfer functions, is given in Table 9.

As it can be noticed from the first row of the table, the natural periods of vibration of the monitored building, without considering SSI (~0.16 - 0.18 s) are characteristic to a rigid structure, which is the case, considering its constructive system. The 0.18 s value results from the analysis of both earthquakes. It is interesting to notice that the 0.16 - 0.18 s value also represents the dominant peak of the transfer function for the vertical components of both earthquakes, which could indicate coupling between the horizontal and the vertical motion, possibly due to rocking or torsion, given the shape of the central section of the building, where sensors are located.

Table 9. Case study summary – BTH station, earthquakes on 31 January 2020 and on 3 December 2023 (in parentheses). Periods corresponding to the highest peaks of spectral and transfer functions

| | Source | HNN channel | HNE channel | HNZ channel | Analysis outcome |
|---|---|---|---|---|---|
| 1. | Transfer functions between the basement and the roof (04/B1) | 0.167 s (0.179 s) | 0.180 s (0.179 s) | 0.157 s (0.180 s) | Natural periods of the structure, assuming a fixed base (no SSI) |
| 2. | Fourier amplitude spectra & power spectra of the roof record (04) | 0.235 s (0.314s) | 0.306 s (0.288 s) | 0.183 s (0.113 s) | Natural periods of the structure, considering soil–structure interaction (SSI) |
| 3. | Fourier amplitude spectra & power spectra of the free field record (FF) | 0.442 s (0.225 s) | 0.330 s (0.181s) | 0.235 s (0.254s) | Information on ground motion spectral content |
| 4. | Fourier amplitude spectra & power spectra of the basement record (B1) | 0.439 s (0.314 s) | 0.328 s (0.311 s) | 0.352 s (0.113 s) | Information on the frequency content of the motion at the building's foundation |
| 5. | Transfer functions between the ground motion and the foundation motion (B1/FF) | 0.256 s (0.272 s) | 0.314 s (0.309 s) | 0.256 s (0.256 s) | Kinematic effects at the buildings' foundation |

Nevertheless, transfer function amplitudes are small in the amplification range. Most probably, 0.18 s is not the actual natural period of the building on the vertical direction, and possibly the 0.113 s value resulting from the analysis of the second earthquake could be a more plausible value.

The influence of the soil-structure interaction, reflected in the increase of the natural periods, can be noticed by comparing the values listed in the first two rows of the table. The exception occurs for the vertical component of the roof record on 03.12.2026, as explained above.

By analysing rows 3 and 4 of the table, it results that, for the horizontal components of the first earthquake, there is practically no influence of the presence of the building on the spectral content of the ground motion, in the case of the first earthquake. For the horizontal components of the second earthquake and for both vertical components, the highest peak values lack relevance due to the presence of multiple comparable peaks on the spectrum, which makes it difficult to discern the dominant periods.

Row 5 of the table illustrates the kinematic effects at the buildings' foundation. The dominant peaks of the transfer function are highly stable and show little variation across the two earthquakes, which suggests that the soil-foundation system moderately amplifies the ground motion over a rather narrow frequency band, i.e., 0.26 - 0.31 s, with higher values generally occurring only up to about 0.4 s.

It is important to note that the values in Table 9 should be interpreted only in correlation with the actual shape of the diagrams which they refer to. For instance, for many of the analysed graphs, multiple secondary peaks can be observed. Although their amplitudes are smaller than that of the dominant peak, they still indicate additional significant motion frequencies.

## CONCLUSIONS

The article presented a detailed analysis of the seismic response of a higher education building that has been instrumented for over a decade and is located on the campus of the University

of Agronomic Sciences and Veterinary Medicine in Bucharest. Unlike many instrumented buildings in densely populated urban areas, the specific location of the building has allowed the installation of vibration sensors not only on the structure itself, but also within a nearby green space, thus enabling the continuous acquisition of co-located structural and free-field seismic records. The data recorded during two recent seismic events (local magnitude 5.2 and 4.8) originating in the seismogenic Vrancea zone of Romania were processed. Response spectra, Fourier amplitude spectra, power spectra, pseudovelocity spectra, normalized input energy spectra and transfer functions were computed, for free field, basement and roof records.

The most significant observations and conclusions are presented below.

- The natural periods of the building have been identified as ~0.17 s (HNN), ~0.18 s (HNE) – without considering soil-structure interaction (SSI), and ~0.24 s (HNN), ~0.31 s (HNE) – with the consideration of SSI. The vertical periods, more difficult to determine due to the broad frequency content of the motion are probably around 0.11 s. The values are in line with previous studies of the authors, based on a different approach (Dobre et al., 2024).
- The frequency content of the two considered earthquakes differs significantly, which also impacts the response of the soil-foundation system.
- The influence of the soil-structure interaction is considerable for the horizontal components of both earthquakes. Coupling between the horizontal and the vertical motion was also identified, indicating possible rocking or torsion effects.
- Kinematic effects at the foundation of the building are moderate and stable, being confined to a rather narrow frequency range.
- Complex resonance phenomena were identified with respect to different frequencies of the site, such that additional investigations are needed, especially concerning soil conditions determined from deeper borehole measurements.
- Pseudovelocity and normalized energy spectra provide important information on the spectral content of the ground motion and serve as indicators of the periods associated with the maximum destructive potential of the seismic motion. According to the results obtained, the most destructive period interval for both earthquakes considered in the study is situated between 0.2 and 0.6 seconds.

The results of the study gain additional relevance when considered in the dual context of the recent seismicity in Bucharest and of the need for the identification of the optimal approaches to the structural health monitoring of buildings located in densely populated urban areas.

## ACKNOWLEDGEMENTS

This work was performed in the PNCDI 2022-2027 framework, within the “Nucleu” Programme PN 23 35 “ECODIGICONS”, Project PN 23 35 01 01 “Integrative concept for the digital analysis of data from the large-scale seismic monitoring of the national territory and of the building stock, intended for the rapid identification of the destructive potential of seismic events produced in Romania and in the adjacent regions”, with the support of the National Authority for Research. The maintenance and operation of the infrastructures used were supported by funding provided by UEFISCDI to the National Network for the Seismic Monitoring and Protection of the Building Stock (RNMPSPC–I.O.S.I.N.) at INCD URBAN-INCERC, through PNCDI IV, Programme 5.5 "Research Infrastructures". This financial support is gratefully acknowledged.

***Abstract***

*Wave energy represents an important renewable resource with significant potential for sustainable energy production. As interest in alternative energy sources continues to grow, this paper presents the conceptual design and preliminary laboratory testing of a novel submerged wave energy converter based on differential pressure conversion. The submerged wave energy converter will be evaluated and optimized in the Hydraulics and Environmental Protection Laboratory of the Technical University of Civil Engineering Bucharest, under controlled wave conditions with varying wavelengths and periods. Preparatory measurements of wave characteristics will guide the optimal dimensioning of the device to maximize energy capture efficiency. Preliminary results identify relevant wave parameters and indicate potential power generation efficiency. The advantages of the device are primarily based on the concentration of the large but diffuse hydraulic energy of waves into the high-pressure hydraulic energy of a working fluid, enabling operation of industrial installations with superior efficiency. Additionally, the research investigates the device's effect on reducing wave energy, contributing to coastal protection and the preservation of marine ecosystems.*

***Key words****: costal protection, wave energy, differential pressure conversion, energy capture efficiency, submerged wave energy convertor.*

## INTRODUCTION

Wave energy constitutes a significant renewable resource due to its high-power density, widespread availability in coastal regions, and minimal environmental emissions. Sea waves are generated primarily by wind transferring energy from the atmosphere into the sea surface. Waves effectively concentrate solar energy over vast areas of the world's oceans and seas. As a result, the theoretical global potential of wave energy resources has been estimated to reach tens of thousands of terawatt-hours per year (Wen & Low, 2026). This value exceeds current annual global electricity consumption, in principle indicating a substantial but largely untapped energy reservoir.

For the Romanian coastline along the Black Sea, which stretches approximately 200 km, studies estimate a potential wave energy around 8 TWh/year. The technically exploitable potential is assessed at roughly half of this value, approximately 4 TWh/year (Degeratu & Bandoc, 2007). The wave energy potential of the Black Sea is significantly lower than that of offshore wind energy. This suggests that, although wave energy may contribute to the Romanian national energy mix, it is unlikely to match the scale of offshore wind resources.

However, wave energy remains attractive for coastal regions where land availability is limited, or energy costs are high. This is due to the higher power density of waves compared to many other renewable sources (Guillou et al., 2020). Moreover, wave energy's predictable nature offers potential advantages for grid integration and energy planning relative to more variable sources (Wen & Low, 2026).

Even though the technological maturity and commercial implementation of wave energy converters (WECs) is behind solar and wind technologies, ongoing research highlights the potential of wave energy to contribute significantly to future sustainable energy systems and climate change mitigation strategies (Azam et al., 2024).

There are three main concepts of wave energy converters (WECs): (a) oscillating water column converters; (b) overtopping (reservoir-type) converters; and (c) oscillating body converters. The devices from the last category, oscillating body converters, can be either floating or submerged and includes attenuators and point absorbers. Attenuators are elongated, articulated

structures positioned parallel to the direction of wave propagation, and the captured energy is generated through the flexing of their joints. Point absorbers are relatively small floating bodies that oscillate vertically (heave motion). The energy is extracted from the relative movement between the floating body and a fixed reference point. The WECs with oscillating body category includes, also, differential pressure converters. Those devices are typically installed on the seabed in near-shore coastal areas.

In Romania, a few research efforts have been undertaken in the field of wave energy harvesting. Moreover, regarding differential pressure converters, have not yet resulted in commercially developed products (Tatu, 2014).

This paper introduces the conceptual design and preliminary laboratory evaluation of a novel submerged wave energy converter (WEC) that operates on the principle of differential pressure conversion. The proposed device is intended to harness the energy of sea waves by exploiting pressure variations of the water at the seabed, due to the variation of water level induced by the waves.

The advantages of the device are based, first at all, on the fact that the large, but diffuse, hydraulic energy of the waves is concentrated into the hydraulic energy of a working fluid at high pressures which then can be taken over by a hydraulic Power Take-Off system (PTO). PTO converts hydraulic energy into electrical energy through a generator. Second at all, the proposed device offers potential advantages in terms of stability, reduced visual impact, and resilience in harsh marine conditions.

Experimental investigations are conducted at the Hydraulics and Environmental Protection "Dumitru Cioc" Laboratory of the Technical University of Civil Engineering Bucharest (UTCB), under fully controlled wave conditions (Figure 1).

Figure 1. Wave channel, Hydraulics and Environmental Protection "Dumitru Cioc" Laboratory

The testing program will systematically vary wavelengths, periods, and amplitudes to assess the device's performance, characterize its energy conversion efficiency, and provide data to inform subsequent design optimization and scale-up for nearshore deployment. The results of this study are expected to contribute to the development of efficient, site-adapted submerged WECs suitable for the Romanian Black Sea coast and similar environments worldwide.

The paper also presents preliminary results aimed at identifying relevant wave parameters and estimating the potential power generation efficiency of the proposed device. Furthermore, the research investigates the attenuation effect of the converter on incident wave energy, with implications for coastal erosion protection and the mitigation of extreme wave event impacts.

## CONCEPTUAL DESIGN OF THE DIFFERENTIAL PRESURE CONVERTOR

The wave energy convertor (Figures 2 and 3) consists of a fixed part, the base frame of the device (7), and a movable part, a light plate (2) that rests on two flexible steel springs (3) (Figures 2 and 3). The movable plate together with the springs is enclosed in a waterproof foil (1), fixed to the upper part of the base frame

through a waterproof foil fixing frame (8). Water access is made at the base of the device, through holes (4) provided with valves (5) that allow unidirectional access, in the direction of water flow.

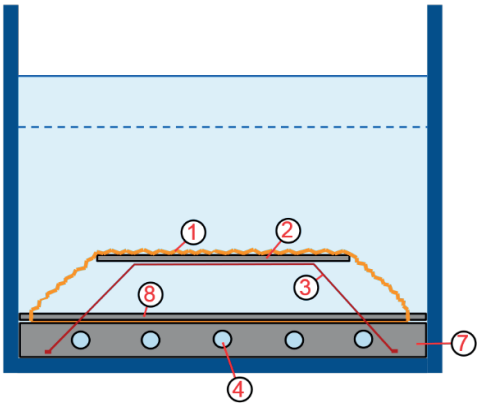

Figure 2. Schematic of the wave energy capture device – front view of the device in the wave channel

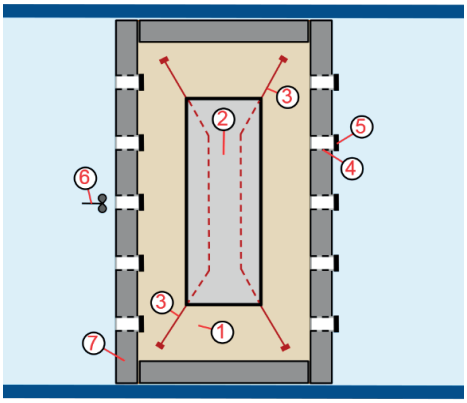

Figure 3. Schematic of the wave energy capture device – top view of the device

The notations in the Figure 2 and Figure 3 represent: 1- waterproof foil, 2- light plate, 3 - steel wire (spring), 4 - holes, 5 - valves, 6 - mill, 7 base frame, 8 waterproof foil fixing frame.

## PRELIMINARY MEASUREMENTS FOR WAVE CHARACTERISTICS DETERMINATION

For the dimensioning of the differential pressure converter, experimental determinations were carried out in the wave channel under fully controlled wave conditions to determine the relevant wave parameters.

The wave channel has a length of 16 m and a width of 1 m. The maximum water depth in the channel is 0.9 m, and the generated waves correspond to water depths ranging from 0.2 m to 0.6 m. The wave channel is equipped with a wave generator at one end. The wave generation system consists of a movable flap, articulated at the bottom of the channel and set in motion at the top by a connecting crank-slider mechanism. At the opposite end of the channel a wave energy attenuator is installed. This is designed to dissipate the wave energy and prevent the occurrence of the wave reflection phenomenon, which can outhouse alter the characteristics of the incident waves (Iancu et al., 2024).

The experimental determinations systematically varied the wavelengths, periods and amplitudes of the waves generated in the wave channel at different water depths. To measure the wave amplitude and height, two level sensors placed at 4 m from each other were used, as shown in Figure 4.

Figure 4. Placement of pressure sensors in the wave channel

The wavelength and period of the wave were determined by measuring the distance and time between two consecutive wave peaks. Based on those measurements, the wave propagation speed (celerity) of the waves was calculated, using the formula:

$$c = \frac{\lambda}{T}$$

The results obtained from the experimental tests are presented in Table 1.

Table 1. Waves characteristics determined from experimental test

| Water depth H (cm) | Wave height h (cm) | Wavelength λ (m) | Period T (s) | Wave celerity c (m/s) |

| | 24 | 1.67 | 1.04 | 1.61 |

The parameters experimentally determined in the wave channel and considered were those corresponding to the waves that characterize, at natural scale, the waves in the Black Sea, in the Romanian coastal area.

Wind-generated waves have periods of approximately 1 to 30 s, with dominant periods for storm surges being between 5 and 15 s (Coveianu, 2016).

Figure 5 presents a schematic of the differential pressure converter's placement in the wave channel, along with the wave parameters that will determine the device dimensions and efficiency.

Based on these experimental determinations, a preliminary estimate of the device's energy generation efficiency was performed using the theoretical framework of differential pressure conversion.

These estimates will be validated upon scaled physical model testing of the converter in the wave channel under the wave conditions established herein.

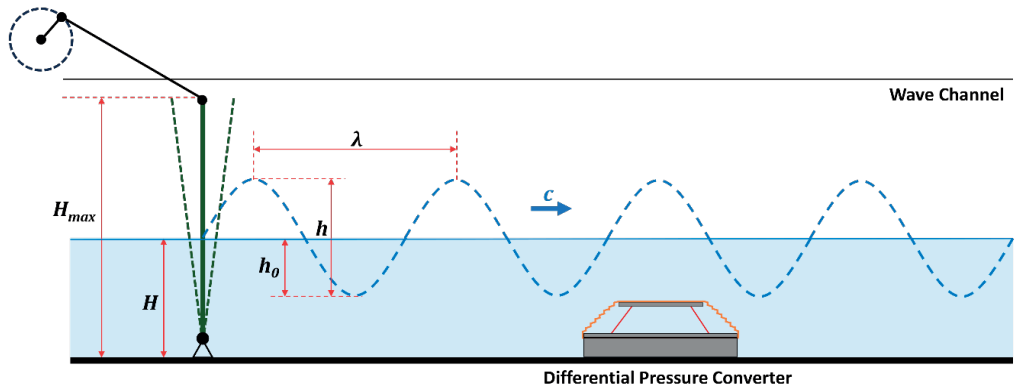

Figure 5. Schematic of the wave energy capture device – front view of the device in the wave channel

## PERFORMANCE ANALYSIS OF THE DIFFERENTIAL PRESSURE CONVERTER

Essentially, the energy converter behaves like a volumetric pump. Volumetric pumps are hydraulic machines that transfer fixed volumes of fluid at equal intervals of time between the suction and discharge sections of the pump, using a piston driven by a crank-rod mechanism.

The power of such a pump is calculated using the formula:

$$P = \Delta p \cdot \Delta Q \text{ (Watt)}$$

where $\Delta p$ is pressure variation created by the piston (Figure 6) (force applied to the piston / piston surface) (N/m$^2$) and $\Delta Q$ is flow variation (piston displacement, i.e. volume swept by the piston / half-period of the reciprocating motion) (m$^3$/s).

In the case of the converter, the piston is represented by the movable cover (light plate).
The pressure variation created by the piston $\Delta p$ is the pressure variation given by the wave and which produces the oscillation of the cover placed on the springs. The suction and discharge are represented by the access and exit slots provided with one-way valves.
Unlike the classic volumetric pump, in the case of the converter, the displacement of the piston (light plate) and, implicitly, $\Delta Q$ are not a fixed value. These and, implicitly, the performances of the converter proposed in the work, depend on several parameters:

- wave characteristics ($H$, $h$, $\lambda$);
- the mass of the device cover (light plate), $m$;
- the elastic constant of the springs, $k$;
- the hydraulic resistance of suction and discharge valves.

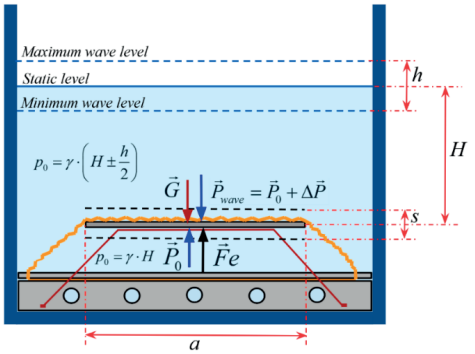

Figure 6. Representation of the forces acting on the energy converter

In addition, the mass of the movable cover together with the elastic constant of the springs is defined as the natural oscillation period of the system, $T = 2 \cdot \pi \cdot \sqrt{\frac{m}{k}}$ which is conjugated to the wave period.
The outer part of the movable cover, the one exposed to the wave action, is subjected to a variable pressure, between the limits:

$$p = \gamma \cdot \left(H \pm \frac{h}{2}\right),$$

which transmits to the water inside the device the pressure variation:

$$\Delta p = \gamma \cdot \frac{h}{2}.$$

and this value can be calculated.

In nature, the pressure variation given by the oscillatory movement of the waves can be calculated with the relationship (Luca & Luca, 2002; Sorensen, 2006; Holthuijsen, 2007):

$$\Delta p_H = \pm\rho \cdot g \cdot \frac{\frac{h}{2}}{ch\left(\frac{2 \cdot \pi \cdot H}{\lambda}\right)}$$

where:

- $\Delta p_H$ (Pa) represents the pressure variation at depth $H$ (m);
- $\lambda$ (m) represents the wavelength of the wave;
- $h$ (m) represents the height of the wave;
- $\rho$ (kg/m$^3$) represents the density of water;
- $H$ (m) represents the depth of water at which the converter is located.

Instead, as shown, $\Delta Q$ and, implicitly, the converter's performance, depend on those parameters mentioned above and the experimental measurements on the reduced-scale model in the wave channel aim to find the influence of these parameters with the final goal of finding that combination that leads to maximum efficiency. During the experiments, it is possible to know, respectively measure, in addition to the wave characteristics (period, wavelength):

- the mass of the cover;
- the elastic constant of the springs;
- the vertical displacement/oscillation of the cover from which $\Delta Q$ results;
- the hydraulic resistance of suction and discharge valves.

The power absorbed by the converter can then be calculated for each combination of the mentioned constructive parameters.
To this end, it is proposed:

- measuring the water velocities through the orifices provided with valves;
- measuring the vertical displacement/ oscillation of the cover.

The advantages of the proposed constructive structure are the following:

- all the previously mentioned parameters can be easily changed; the elastic system supporting the movable cover can be removed from the box, allowing the change of the elastic constant $k$ by replacing the springs;
- the additional masses on the movable cover can be changed, allowing the calculation of the elastic constant with precision;

- since the converter box is equipped with one-way valves (flaps), the Archimedean force is equal to zero, so the converter box can be easily placed on the bottom of the channel; the waterproof foil allows water access to the box only through the valves.

## CONCLUSIONS

The paper introduces a novel submerged wave energy converter operating on the principle of differential pressure conversion, starting with a preliminary experimental program carried out under controlled conditions in the wave channel. The proposed converter, comprising a movable cover supported by calibrated steel springs, enclosed within a waterproof membrane and equipped with unidirectional valves, constitutes a structurally simple yet physically coherent solution for harnessing the oscillatory pressure field generated by surface waves at seabed level. The experimental measurements conducted across a systematic variation of water depths (20-60 cm), wave heights (2-24 cm), wavelengths (0.65-1.74 m), and periods (0.61-1.15 s) provided a comprehensive characterization of the wave parameters reproducible in laboratory conditions. The wave celerity values recorded, ranging from 0.96 to 1.61 m/s, are consistent with theoretical predictions for shallow-water wave propagation and confirm the reliability of the measurement methodology employed. These determinations establish the hydrodynamic baseline required for dimensioning the differential pressure converter, ensuring that the natural oscillation period of the cover-spring system can be tuned to resonate with the incident wave period, a condition essential for maximizing energy capture efficiency.

From an analytical standpoint, the converter behaves as a volumetric pump in which the pressure variation, governed by the wave height and water depth, drives a variable volumetric flow through the system. The theoretical framework presented demonstrates that the output power is a function of both wave characteristics and constructive parameters – specifically the mass of the movable cover, the elastic constant of the spring system, and the hydraulic resistance of the valves – all of which are independently adjustable in the proposed experimental setup.

Beyond its energy harvesting function, the proposed device presents a secondary benefit of considerable practical relevance: through the attenuation of incident wave energy, the converter contributes to the reduction of coastal erosion. This dual functionality, energy generation and wave energy dissipation, positions the proposed device as a potentially valuable component of integrated coastal management strategies, particularly in environments such as the Romanian Black Sea coast where wave energy resources, although modest in comparison to offshore wind potential, remain largely unexploited.

Based on preliminary wave characterization measurements, the estimates of the potential energy generation efficiency will be subject to confirmation through direct experimental testing of the converter at reduced scale in the wave channel.

The results are expected to provide the empirical basis for the design of a nearshore prototype suitable for deployment in the specific marine conditions of the Romanian coastal zone.

***Abstract***

*Data obtained from seismic instrumentation campaigns enable the identification of buildings' dynamic characteristics, the objective evaluation of structural performance, and the investigation of damage and degradation mechanisms induced by earthquake loading. For each monitored building, detailed information is compiled, including location (city or municipality), year of construction, applicable seismic design code, structural system characteristics, type of functionality (research institutes, administrative, education, healthcare, residential, commercial), site and soil conditions (where available), and the seismic events recorded during its service life. Using simplified dynamic models with natural periods of vibration matching those of instrumented buildings, this paper analyses their structural response to the 1977, 1986, and 1990 Vrancea earthquakes through time-history, linear, and elasto-plastic comparative approaches, and evaluates their seismic performance. Relevant regulatory provisions and findings from previous studies are considered to establish correlations between the exceedance of admissible inter-storey drift limits and observed damage levels. The results demonstrate that long-term seismic instrumentation campaigns are integral to structural health monitoring, providing a robust basis for post-earthquake assessment and risk-informed decision-making.*

***Key words****: measured response, performance evaluation, structural behaviour.*

## INTRODUCTION

Traditional methods for assessing structural performance provide a physical understanding of structural behavior, but they rely on idealized assumptions and uncertain parameters. The development of structural monitoring systems and seismic instrumentation networks, together with advances in computational power and machine learning techniques, has enabled the emergence of data-driven approaches. These approaches use large volumes of empirical data derived from seismic recordings and structural response to identify relationships between excitation and response, detect changes in structural properties, and improve predictive models. At present, data-driven approaches do not replace physics-based models, but rather complement and calibrate them, contributing to the development of modern hybrid frameworks for the analysis and monitoring of structural behavior under seismic actions. Also, data-driven methodologies are particularly useful for analysing soil-structure interaction (SSI) because they rely on measured structural responses rather than assumed soil and foundation parameters. By comparing recordings from the free-field, basement, and upper structural levels, amplification factors can be derived that implicitly capture SSI effects (Dobre & Dragomir, 2018; Dobre et al., 2024). This empirical approach also provides direct insight into how seismic waves are modified by the soil–foundation–structure system and transmitted through the building.

On the other hand, there is a direct connection between the data-driven approach, Building Information Modeling, and Structural Health Monitoring in the management and monitoring of built infrastructure. Consequently, the integration of BIM and SHM within a data-driven framework enables more efficient

structural monitoring, supports predictive maintenance, and contributes to the development of digital twins for infrastructure systems (Dobre et al., 2025).

The importance of pre-earthquake SHM data was proved after the 1977 earthquake (Balan et al., 1982), when INCERC published measured vibration periods for 47 buildings, before and after the earthquake, with obvious increases due to damage, thus a comparison was possible for both that situation and for the one after strengthening, if done. The unique INCERC accelerogram of the March 4, 1977, Vrancea earthquake (Mw 7.4) revealed a pronounced long-period spectral content, which contributed to damage in tall and slender structures. However, relying on a single seismic record limits the generalization of structural response characteristics. In contrast, the available database includes multiple Vrancea earthquakes with different spectral features, complemented by ambient vibration recordings obtained from structural health monitoring. This expanded dataset enables a data-driven analysis framework, where structural behavior is inferred from a larger set of measured responses, allowing for more robust identification of dynamic properties and a better understanding of variability in soil–structure interaction effects (Pavel et al., 2018; 2020; Del Gaudio et al., 2019; Morandi & Albanesi, 2026). Conceptual differences between the two approaches are presented in Table 1.

Table 1. Fundamental differences between physics-based and data-driven frameworks

| Traditional Approach | Data-Driven Approach |
|---|---|
| Physics-based (constitutive material models, structural dynamics equations, idealized boundary conditions) | Data-based (acceleration time histories, drift measurements, frequency shifts, damping evolution) |
| Assumed parameters (elastic modulus, damping ratio (often 5%), boundary fixity, soil-structure interaction, hinge properties) | Measured parameters (actual natural frequencies, actual damping ratios, real stiffness degradation, residual displacements) |
| Pre-event prediction (predicts performance before earthquake occurs, uses design spectra, checks demand vs capacity) | Real-time/post-event learning (seismic response recordings evaluated immediately after each event, models recalibrated accordingly) |
| Static model (analytical model created at the design stage, remains unchanged, assumes constant structural properties) | Continuously updated model (modal properties tracked over time, damage detected via frequency drift, stiffness degradation quantified) |
| Physics-informed models: integration of physical model data with instrumentation data | |

The workflow illustrated in Figure 1 represents the internal process of the data-driven analysis stage.

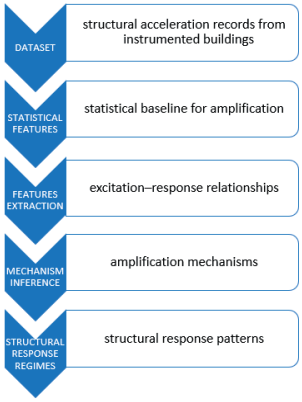

Figure 1. Data-driven workflow

Starting from structural acceleration records obtained from instrumented buildings, statistical characterization and feature extraction are used to identify excitation–response relationships, infer amplification mechanisms, and classify structural response regimes. These insights contribute to the development and calibration of hybrid physics-based and data-driven models used in structural health monitoring and digital twin frameworks.

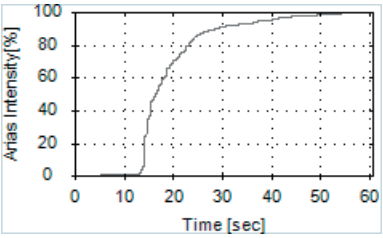
## MATERIALS AND METHODS

The methodological framework adopted in this study combines physics-based structural modeling with empirical evidence derived from seismic monitoring data.

In the first direction, a set of buildings is idealized as simplified dynamic systems represented by single-degree-of-freedom models with identical fundamental vibration periods (Saiidi & Sozen, 1979; 1981), while differing in key structural characteristics such as height, number of stories, and construction period. The seismic input consists of recorded accelerograms corresponding to the Vrancea earthquakes of 1977, 1986, and 1990, which are used as input motions in time-history analyses. Both elastic and inelastic responses are evaluated, accounting for stiffness degradation; however, the fundamental vibration period is assumed to remain approximately constant, as

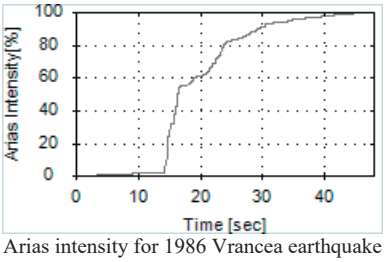
the expected stiffness reduction is relatively small. Structural response is characterized through parameters such as inter-storey drift ratios, which are compared with code-based thresholds associated with different damage states (P100-1/2013; Luca et al., 2015; Zaker Esteghamati at al., 2018; Ibrahim & Makhloof, 2023; Habibi & Asadi, 2017; Sen et al., 2023; Mohsenian et al., 2024; Genikomsou et al., 2025).

The second direction, shown in Figure 1, supports the numerical investigation by analysing recorded data from a case-study of a building equipped with seismic instrumentation. This approach enables the evaluation of seismic motion transfer and amplification throughout the structural system. The amplification factor at the basement level, AF_basement, is defined as the ratio between the acceleration recorded at the basement and the free-field acceleration, expressing how much the seismic motion is amplified from the ground unaffected by the structure to the foundation level. Similarly, the amplification factor at the terrace level, AF_terrace, describes the amplification of motion from the free field to the top of the building. Finally, the structural amplification factor, T, represents the ratio between the terrace and basement amplification, indicating how much the motion increases vertically from the foundation to the top of the structure.



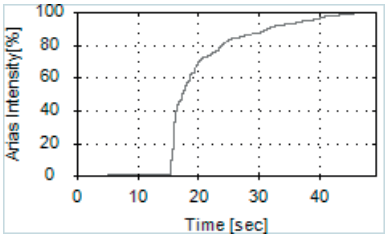
Together, these two directions provide complementary perspectives on structural behavior under seismic excitation: numerical simulations allow the systematic investigation of structural performance across different building configurations, while the instrumentation-based analysis provides empirical evidence of amplification mechanisms and response patterns observed in real structures.

Seismic monitoring systems provide acceleration data from instrumented buildings under ambient vibrations and earthquake events, forming the empirical basis for data-driven analysis. The recorded signals are pre-processed to remove trends and noise and are subsequently analysed using system identification techniques to extract modal parameters such as natural frequencies, damping ratios, and mode shapes. Additional statistical and spectral features are computed and organized into a structured feature matrix describing the dynamic characteristics of the monitored structure.



## RESULTS AND DISCUSSIONS

The first approach focuses on the seismic response of the structural models. The results obtained for the different structural models constitute a dataset that will subsequently allow for additional comparative analyses aimed at identifying trends and correlations between the structural parameters of buildings (height, number of storeys, fundamental vibration period, year of construction) and seismic response indicators (inter-storey displacements – angular drifts, stiffness degradation). By applying statistical analysis methods to these basic results, the objective is to highlight the distribution of the structural response and to estimate the probability of exceeding certain performance thresholds associated with different damage levels, as defined in current codes or existing studies. Thus,



– The maximum spectral seismic response, linear and bilinear, associated with different dynamic characteristics, is estimated.
– Based on the determined dynamic characteristics, the structural behavior under the three types of seismic actions (Vrancea 1977, 1986, 1990, with the total energy of the seismic ground motion over time, represented by the Arias intensity) is highlighted, as shown in Figure 2a and Figure 2b.

Arias intensity for 1977 Vrancea earthquake

Arias intensity for 1986 Vrancea earthquake

Arias intensity for 1990 Vrancea earthquake

Figure 2a. Arias Intensity and Cumulative Severity

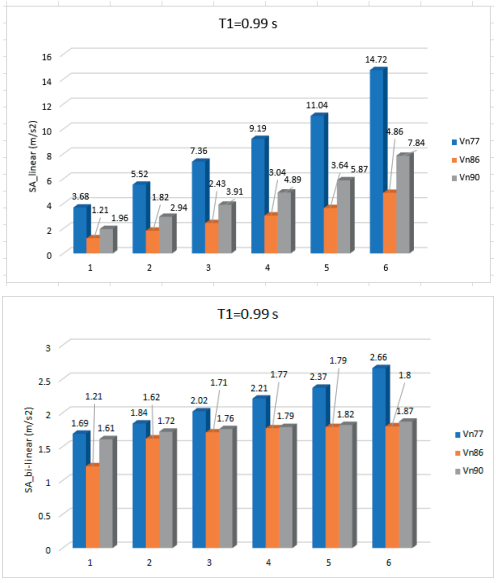


Figure 2b. Spectral acceleration in the linear and bilinear domain

– Two correlations are identified between the period and height (Figure 3a), and between the period and the spectral displacement (Figure 3b).

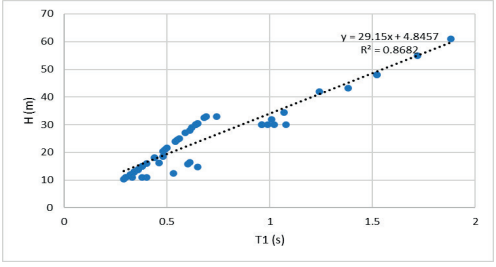

Figure 3a. Period and Height relationship

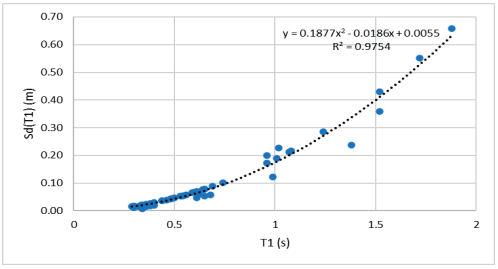

Figure 3b. Period and Spectral displacement relationship

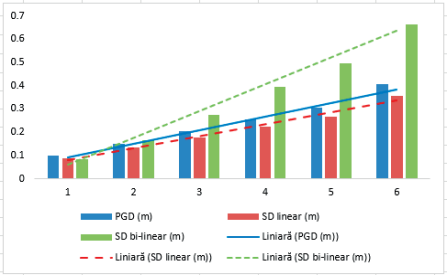
– For structural systems with different dynamic characteristics, the results of a time-history analysis, both linear and nonlinear (comparative), are presented, considering the inter-storey displacement response under the Vrancea 1977, 1986, and 1990 seismic actions (Figure 4).



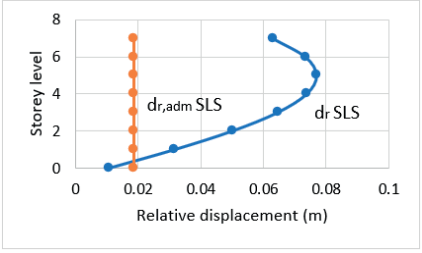


Figure 4. Structural displacement response ($T_1$ = 0.99 s)

– For several of the absolute storey displacements mentioned above, determined by considering a linear variation along the height of the model and multiplied by a shape function, the relative displacements are calculated for the Serviceability Limit State (SLS) and the Ultimate Limit State (ULS), as well as the inter-storey drifts (angular drifts) and their allowable limits (Figure 5).

Inter-storey drifts - allowable limits (linear)

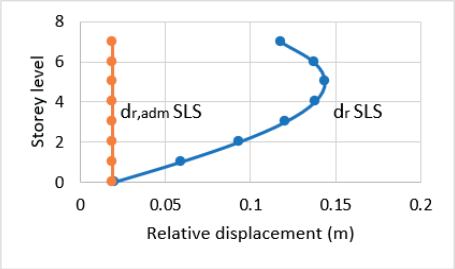

Figure 5. Seismic performance of the structural system with $T_1$ = 0.99 s (linear and bilinear analysis at SLS)

– Identification of situations in which, both in the linear and nonlinear domains, residual displacements occur - an indicator of structural performance.
– Estimation of the possible damage level through the relationship between the accelerogram scaling factor and the drift/drift indicator.

The variation of inter-storey drift along the height of the building is illustrated in Figure 6a for linear analysis and in Figure 6b for bilinear analysis.

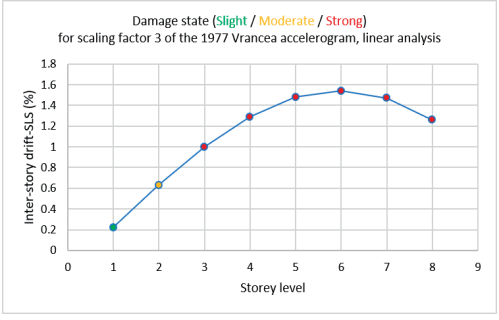

Figure 6a. Distribution of inter-storey drift along the building height and corresponding damage state for Scaling Factor = 3 (Vrancea 1977), linear analysis

For the linear analysis, drift values increase with the increase of the accelerogram scaling factor. For scaling factor 3, the SLS drift ranges between 0.22% and 1.54%, while the SLU drift varies between 0.84% and 5.95%, with predominantly serious damage at the upper floors. In the bilinear analysis, drift values are significantly higher. For scaling factor 3, the maximum values reach 2.87% (SLS) and 11.08% (SLU), indicating severe damage at the upper floors.

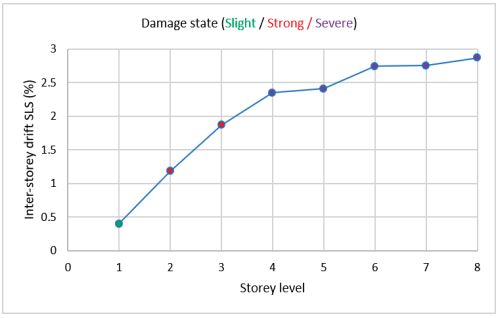

Figure 6b. Distribution of inter-storey drift along the building height and corresponding damage state for Scaling Factor = 3 (Vrancea 1977), bilinear analysis

The second approach uses the obtained results to perform a statistical characterization of the amplification indicators, highlighting their distribution and variability. Descriptive statistics were calculated for the indicators AF_basement ($A_{basement}/A_{free-field}$), AF_teracce ($A_{terrace}/A_{free-field}$), and T ($A_{terrace}/A_{basement}$) to characterize the baselines for 2024 and 2025 in both NS and EV categories. The statistical analysis included the computation of minimum and maximum values, medians, and quartiles (Q1–Q3, corresponding to the 25th, 50th, and 75th percentiles) in order to describe the distribution of the data and assess their variability. Based on these indicators, characteristic ratios were derived, allowing the identification of the amplification patterns expressed through the relationships between the considered variables. The obtained values provide an overview of the variability of the ratios and enable a comparative assessment of the two baselines.

To enhance the visual comparison of indicator distributions, the statistical results were illustrated graphically, enabling a direct comparison between the baselines corresponding to 2024 and 2025, for the NS and EW categories. Figure 7 illustrates the quartile distribution of the amplification factors for the 2024 and 2025 baselines, showing a progressive increase in amplification from Q1 to P95-including the 95th percentile. The results indicate slightly higher basement amplification for the 2025 baseline compared to 2024, Figure 7a, while the terrace amplification exhibits a stronger increase toward the upper quartiles, Figure 7b.

The ratio T highlights the vertical amplification between the basement and terrace levels, with higher values observed for the upper quartiles, Figure 7c. These observations reveal a consistent and repeatable response pattern, characterized by a monotonic increase in amplification across quartiles and a clear amplification gradient from the basement to the terrace level.

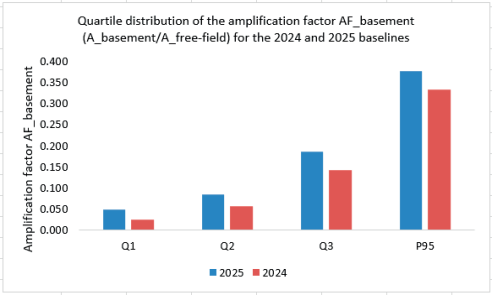

Figure 7a. Amplification trends between the 2024 and 2025 baselines for AF_basement

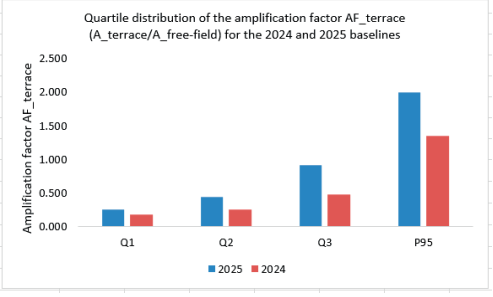

Figure 7b. Amplification trends between the 2024 and 2025 baselines for AF_terrace

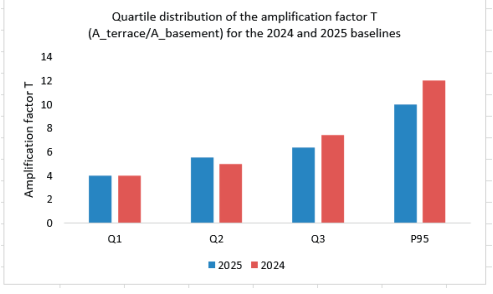

Figure 7c. Amplification trends between the 2024 and 2025 baselines for T

While the basement amplification remains relatively similar for both components, the terrace amplification shows significantly higher values in the EW direction, particularly toward the upper percentile range. This behavior suggests a stronger structural response along the EW axis. The median values indicate a consistent increase in amplification with height, reflecting the typical structural response, while the higher mean values suggest the presence of occasional higher-amplitude events. Tracking the temporal evolution of median values and interquartile ranges enables the identification of changes in both the central tendency and variability of the structural response. Stable quartile distributions over time indicate consistent behavior, whereas systematic shifts in median or dispersion may reflect changes in structural properties or soil–structure interaction conditions. Together, the two approaches provide complementary perspectives, combining the evaluation of structural response with the statistical interpretation of the resulting indicators.

## CONCLUSIONS

Data-driven approaches offer several important advantages in structural monitoring and seismic performance assessment. Unlike traditional analytical models, which rely on assumed parameters such as damping ratios, stiffness degradation, or boundary conditions, data-driven methods use measured structural responses. Dynamic characteristics - including natural frequencies, damping ratios, and modal shapes - are extracted directly from recorded time histories, reflecting the actual behavior of the structure.

Another key advantage is the possibility of post-event evaluation and model calibration. Structural properties may change over time due to cracking, ageing, damage, or retrofitting. Monitoring data enables the detection of frequency shifts, changes in damping, or residual displacements, providing insight into the current structural condition and improving reliability assessment throughout the life-cycle of the building.

Data-driven approaches also support probabilistic performance evaluation by leveraging large sets of recorded structural responses. By processing multiple seismic and ambient vibration records, response parameters

such as peak floor acceleration or inter-storey drift are extracted and statistically analysed. Empirical distributions are then constructed using descriptive statistics (e.g., median, quartiles) or fitted probability models, allowing the variability and uncertainty of the structural response to be quantified. This approach reduces reliance on purely theoretical assumptions and provides a more realistic representation of structural behavior based on measured data.

Additionally, aggregated monitoring databases enable comparative analysis of reinforced concrete and steel structures from various perspectives (Stoian et al., 2022; Köber et al., 2024a,b), enabling the identification of performance trends under similar demands. Such comparisons can support improvements in design provisions and retrofit strategies.

Despite these advantages, several limitations must be considered. The availability of high-quality monitoring data remains limited, particularly for extreme seismic events, which are rarely recorded in real structures. Data quality may also be affected by noise, sensor drift, or incomplete records, requiring careful validation and pre-processing. Machine learning techniques can approximate nonlinear seismic response much faster than conventional dynamic analyses, making them useful for evaluating a large number of structures. However, the performance of the models depends on the quality of the data, the choice of input parameters, and the ability of the model to generalize to new seismic motions or structural typologies (Noor, 2025).

Another challenge is generalization. Structural response depends on building geometry, material properties, and soil conditions, meaning that observations from one structure cannot always be transferred to others. Moreover, data-driven approaches primarily identify statistical correlations rather than physical mechanisms, which limits their ability to explain processes such as stiffness degradation or damage localization.

For these reasons, data-driven methodologies are best used in combination with physics-based models. Analytical approaches provide the mechanical framework governing structural behavior, while empirical data improve calibration, validation, and uncertainty assessment.

Integrating data-driven methods with consistent analytical models creates a strong framework for understanding and enhancing structural resilience.

## ACKNOWLEDGEMENTS

This work was carried out within the framework of the NUCLEU Programme PN 23 35 - "ECODIGICONS", under PNCDI 2022-2027, with the support of the National Authority for Research through Project PN 23 35 01 01, entitled "Integrative concept for the digital analysis of data from large-scale seismic monitoring of the national territory and the building stock, aimed at the rapid identification of the destructive potential of seismic events occurring in Romania and adjacent regions. The maintenance and operation of the infrastructures used in this research were supported by funding provided by UEFISCDI to the National Network for the Seismic Monitoring and Protection of the Building Stock (R.N.M.P.S.P.C. – I.O.S.I.N.) within INCD URBAN-INCERC, through PNCDI IV, Programme 5.5 – Research Infrastructures.

The authors gratefully acknowledge this financial support.

***Abstract***

*The long-term durability and structural integrity of stabilised layers are essential for sustainable infrastructure. Eco-friendly materials that utilise environmentally friendly binders and additives have the potential to improve mechanical performance while minimising environmental impact. Assessing the effectiveness of these materials requires a thorough framework that considers various parameters impacting mechanical stability, thermal resistance, and load-bearing capacity. A performance index (PI) approach is used to assess the structural performance of stabilised layers, incorporating a catalyst to enhance the bitumen-aggregate interface within the bitumen matrix and modifying physicochemical reactions during operation. Key mechanical and physical parameters - including compressive strength, degree of compaction, load-bearing capacity, dynamic modulus, and resistance to mechanical and thermal stresses - were measured or estimated for the stabilised layers. Compared to baseline or minimally compliant layers, the calculated PI showed a significant improvement in overall structural integrity. This reflects enhanced load transfer, stiffness, and durability. These findings support the adoption of environmentally sustainable stabilisation techniques as reliable alternatives for infrastructure applications, providing long-term performance.*

***Key words****: eco-friendly materials, performance, stabilisation, sustainable.*

## INTRODUCTION

In recent years, growing concerns about environmental impact have prompted the development of alternative solutions for stabilizing road infrastructure. Ecologically stabilized road layers aim to reduce the carbon footprint by utilizing biological binders, recycled materials, low-carbon additives, and innovative physicochemical modification processes. These solutions seek to achieve mechanical performance that is comparable to that of conventional cement or lime-treated materials, all while simultaneously lowering energy consumption and greenhouse gas emissions (Consoli et al., 2009; Puppala, 2016; Behnood, 2018). Organosilane additives can enhance the performance of unbound layers by increasing moisture resistance (Barbieri et al., 2019; 2021). They also emphasize the benefits of lignin in stabilizing clayey soils, which can improve stiffness (Vaiana et al., 2021). The use of biopolymers for stabilization has been shown to increase strength and enhance compaction (Cabalar et al., 2023). Additionally, polymer additives have been found to reduce the deformation potential of expansive soils (Liu et al., 2025). Ecological additives used as cement substitutes designed in the process of stabilizing cohesive, non-cohesive materials and aggregates are not directly comparable in terms of their composition or mechanisms of action. Other studies (Radu et al., 2015; Saca et al., 2024; Ionescu & Dobre, 2025) indicate that the mechanical properties of materials are closely related to the composition of the mixture and the ratios between the components, which in turn influence the material's mechanical strength and structural behaviour.

While various methodologies for incorporating alternative materials into stabilization projects have been suggested over the years, there remains a critical need for a systematic evaluation of structural performance (Dobrescu,

2017). Additionally, the analysis of parametric correlations between California Bearing Ratio (CBR) and other geotechnical parameters underscores the significance of a multi-parameter evaluation (Dobrescu, 2017). Therefore, a meaningful comparison can only be made using functional and structural performance indicators, such as stiffness, load-bearing capacity, resistance to deformation, and long-term durability under various traffic and environmental conditions. These indicators can be integrated into a Performance Index (PI), which reflects the overall efficiency of the pavement system, rather than the individual properties of the materials. In this context, the comparison between a hydraulic binder and a organic binder should be interpreted as a comparison between two technological solutions that enhance the performance of the road structure, rather than as a comparison between two materials with identical functions. However, without an integrated evaluation framework, it becomes challenging to make an objective comparison between conventional and eco-friendly solutions. Thus, the study proposes a weighted aggregation method that integrates the mechanical characteristics of stabilized road layers into a synthetic parameter, called performance index. The calculated performance index allows a comparative evaluation of conventional (hydraulic binder)/ecological (organic binder) solutions used for stabilizing road layers.

## MATERIALS AND METHODS

In this study, for the stabilization of the road layer, a hydraulic road binder based on Portland cement (HB) and an organic binder (OB) with a lignosulfonate structure (calcium – CLS, respectively sodium – SLS) were used. CLS is an anionic polymer, extracted from sulfite liquors resulting from cellulose production, water-soluble, with a molecular weight ranging between 2000-100000 and a three-dimensional structure. SLS is an anionic polymer obtained from the semicellulose production stream from wood through the NSSC process (neutral sulfite semichemical process).
The functional group in lignosulfonates are represented in Figure 1.

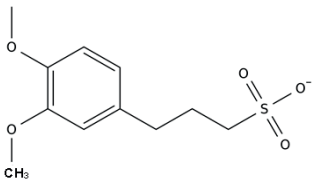

Figure 1. Representative structure of a lignosulfonate molecule showing polar functional groups (–$SO_3^-$, –OH) and the nonpolar hydrocarbon chain (Moldovan, 1978)

Their molecule is composed of polar groups such as –$SO_3^-$ and –OH, and a group of atoms linked by covalent bonds forming the hydrocarbon chain with a nonpolar character, such as $C_6H_4$– and $CH_3$–.
The following figure (Figure 2), illustrates the primary application principles of two approaches: the stabilization of soil and granular materials using lignosulfonates.

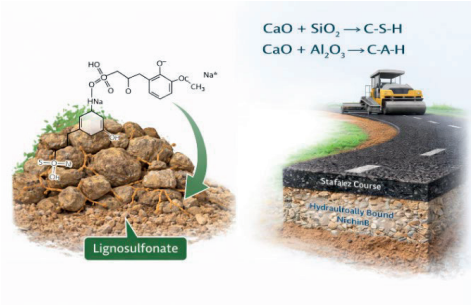

Figure 2. Ecologically stabilised road layers (adapted from Mostafa et al., 2024; Jiang et al., 2021; Yang et al., 2025)

The stabilization of road layers with organic binders consists in their fixation by adsorption onto the surface of solid particles (clay, sand, ballast), forming a layer between particles that reduces the repulsive forces between them and results in their agglomeration.
On the other hand, the polar groups act as molecular bridges, leading to the formation of a three-dimensional structure that enhances cohesion, while the hydrophobic hydrocarbon chain creates a barrier against water penetration. In addition, $Ca^{2+}$ ions contribute to compressing the diffuse double layer and reduce the repulsion between particles through ion-exchange reactions with $Na^+$ ions on the surface of clay particles (Shiyuan et al., 2025).

The stabilization with hydraulic road binders involves mineral reactions between calcium oxide (CaO), silicon dioxide ($SiO_2$), and aluminum oxide ($Al_2O_3$), resulting in the formation of cementitious compounds such as calcium silicate hydrate (C–S–H) and calcium aluminate hydrate (C–A–H).

The differences between the stabilisation mechanisms and their associated structural effects are summarised (Table 1).

A performance index (PI) is established based on four key parameters that reflect the behaviour of the treated or stabilized layer: the degree of compaction (D), the California Bearing Ratio (CBR), the static linear deformation modulus, determined in situ using the static plate (Lucas) test and calculated from the second loading (Ev2), respectively, the 28-day compressive strength ($Rc_{(28)}$) (equation1).

These indicators describe complementary aspects of structural performance, namely the degree of compaction, load-bearing capacity, stiffness, and mechanical strength of the stabilized material. The methodological framework used to evaluate these parameters and to determine the performance index is presented (Figure 3).

Table 1. Comparative analysis of the mechanisms and structural effects of hydraulic road binders and ecological additives used in the pavement system

| Stage | Hydraulic binder | Organic binder |
|---|---|---|
| Product incorporation | Hydraulic road binder incorporated into soil/aggregate mixtures with water | Additive incorporated into soil structure |
| Primary mechanism | Hydration reactions of hydraulic compounds | Modification of the aggregate interface |
| Microstructural process | Formation of cementitious hydration products (C–S–H, C–A–H) | Reduction of interfacial tension and enhancement of binder–aggregate adhesion |
| Structural modification | Particle cementation and development of a rigid structural matrix | Improved and more uniform distribution of aggregate surfaces |
| Mechanical effects | Increase in stiffness of the stabilized layer | Increase in stability of the soil mixture |
| Affected technical parameters | Ev2 ↑, CBR ↑, Rc ↑ | Mechanical properties ↑ |
| Level of action within the pavement structure | Subgrade or stabilised base layer | Soil layers |
| Structural impact | Increase in structural bearing capacity | Improvement in soil durability and stability |
| Overall outcome | Contributes to an increase in the PI | |

$$PI = w_D \cdot S_D + w_{CBR} \cdot S_{CBR} + w_{Ev2} \cdot S_{Ev2} + w_{Rc} \cdot S_{Rc}$$

where:

- $PI$ – global performance index;
- $w_D$, $w_{CBR}$, $w_{Ev2}$, $w_{Rc28}$ – weights associated with each indicator;
- $w_i D_j + w_i CBR_j + w_i Ev2_j + w_i Rc_j = 1$
- $S_D$, $S_{CBR}$, $S_{Ev2}$, $S_{Rc28}$ – normalized values of the indicators.

The weights are assigned based on the significance of each indicator in assessing pavement layer performance. While the PI provides a comprehensive assessment, its interpretation must be linked with the specific values of the parameters being analysed.

This correlation helps identify the technical advantages of each solution. The data were normalised by using the maximum value, resulting in a range between 0 and 1.

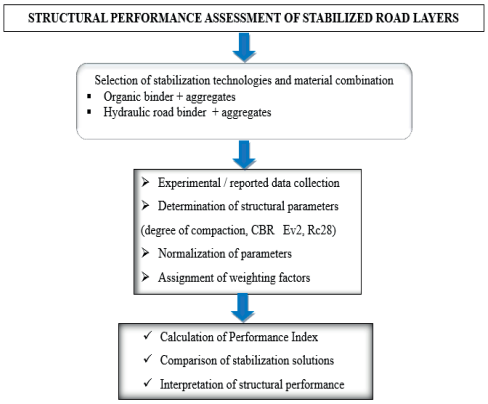

Figure 3. Road Layer Performance Framework (developed by the authors)

## RESULTS AND DISCUSSIONS

To evaluate the mechanical behavior of stabilized materials used in pavement structures, geotechnical parameters were analyzed to assess the performance of the stabilized material. The results are presented in Table 2. Overall, they indicate a general correlation between CBR, $Ev_2$, and $Rc_{28}$, demonstrating a simultaneous increase in bearing capacity, stiffness, and mechanical strength. This relationship suggests that improvements in the stabilization process contribute not only to enhanced load distribution and reduced deformation under traffic loading but also to a more durable pavement foundation. Furthermore, the observed correlation indicates that CBR and $Ev_2$ may serve as practical

indicators of the long-term strength development of the stabilized material, facilitating quality control during construction.

Table 2. Mechanical parameters

| Mixture | D (%) | CBR (%) | Ev2 (MPa) | Rc28 (MPa) |
|---|---|---|---|---|
| Aggregate layer+ SLS | 98.0 | 166.21 | 93.22 | 0.79 |
| Aggregate layer +CLS | 98 | 178.79 | 104.27 | 0.85 |
| Clayey soil + 5% HB | 99.0 | 80 | 160 | 1.24 |
| Sandy soil + HB | 99.0 | 150 | 195 | 2.25 |
| Ballast + 3 % HB | 99.0 | 180 | 300 | 2.49 |
| *Reference values* | *100* | *170* | *350* | *4.0* |

A sensitivity analysis of the performance index was performed by varying the weights associated with the mechanical parameters (Table 3), and the corresponding results are presented in Tables 4a and 4b.

Table 3. Weighting scenarios for the parameters used in the Performance Index calculation

| Scenario | w(D) | w(CBR) | w(Ev2) | w(Rc28) |
|---|---|---|---|---|
| S0 – Current weighting | 0.20 | 0.10 | 0.40 | 0.30 |
| S1 – Balanced weighting | 0.25 | 0.25 | 0.25 | 0.25 |
| S2 – CBR emphasis | 0.15 | 0.40 | 0.25 | 0.20 |
| S3 – $Ev_2$ emphasis | 0.15 | 0.10 | 0.55 | 0.20 |

| S9 – CBR and compaction emphasis | 0.35 | 0.35 | 0.15 | 0.15 |
| S10 – $Ev_2$ dominant | 0.10 | 0.05 | 0.65 | 0.20 |

Table 4a. Multicriteria evaluation scenarios based on the mechanical parameters of the analysed materials

| Solution | S0 | S1 | S2 | S3 | S4 | S5 |
|---|---|---|---|---|---|---|
| Aggregate layer+ SLS | 0.460 | 0.605 | 0.628 | 0.479 | 0.375 | 0.670 |
| Aggregate layer +CLS | 0.484 | 0.636 | 0.665 | 0.507 | 0.396 | 0.683 |
| Clayey soil + 5% HB | 0.521 | 0.557 | 0.567 | 0.527 | 0.460 | 0.653 |
| Sandy soil + HB | 0.678 | 0.748 | 0.761 | 0.717 | 0.674 | 0.827 |
| Ballast + 3% HB | 0.834 | 0.882 | 0.917 | 0.857 | 0.838 | 0.905 |

The scenarios presented in Table 4b highlight the relative influence of the mechanical parameters on the overall performance ranking of the analyzed materials.

Table 4b. Multicriteria evaluation scenarios based on the mechanical parameters of the analyzed materials

| Solution | S6 | S7 | S8 | S9 | S10 |
|---|---|---|---|---|---|
| Aggregate layer+ SLS | 0.439 | 0.680 | 0.384 | 0.755 | 0.360 |
| Aggregate layer +CLS | 0.466 | 0.718 | 0.404 | 0.788 | 0.387 |
| Clayey soil + 5% HB | 0.414 | 0.678 | 0.436 | 0.626 | 0.482 |
| Sandy soil + HB | 0.655 | 0.861 | 0.704 | 0.823 | 0.618 |
| Ballast + 3% HB | 0.802 | 0.972 | 0.831 | 0.939 | 0.834 |

The Performance Index values indicate that all the stabilization solutions examined enhance the structural performance of the subgrade layer compared to the reference level (Figure 4). The graphical representation of the Performance Index highlights a consistent ranking of the stabilization solutions across different weighting scenarios.

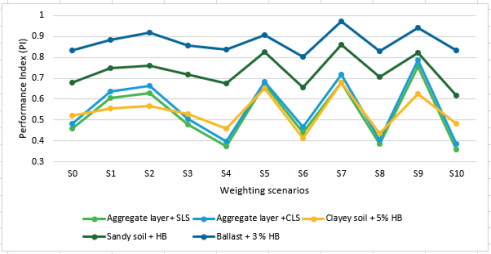

Figure 4. Sensitivity analysis of the PI for the investigated stabilization solutions under different weighting scenarios

The ballast stabilized with hydraulic binder exhibits the highest performance in all cases, followed by sandy soil stabilization. In contrast, clayey soil shows the lowest performance values, reflecting its weaker mechanical behaviour even after stabilization (realistic for cohesive soils). It is important to note that the values presented in the table are not absolute; they stem from a specific normalisation and weighting methodology. If the reference values, normalisation method, representative interval values, or criteria weights are adjusted, the scores and the PI may change. Nevertheless, the general trend in the performance of the analysed solutions is likely to remain consistent.

## CONCLUSIONS

The current study aimed to identify the key mechanical and physical parameters that influence the structural behaviour of stabilised formation layers and to evaluate the impact of various stabilisation methods. Additionally, a

normalized performance index was developed to facilitate consistent comparisons between different stabilization solutions.

The sensitivity analysis conducted with varying weighting scenarios revealed that the combination of ballast + HB consistently achieved the highest performance index (PI) values. This indicates a robust structural performance, irrespective of the relative importance assigned to individual parameters. In contrast, the sandy soil combined with HB exhibited intermediate performance with relatively stable results. Meanwhile, the clayey soil stabilized with 5% HB and lignosulfonate compounds + aggregates showed greater variability depending on the weighting configuration.

This approach serves as a valuable tool for the comparative assessment of stabilization strategies, supporting decision-making in the design and optimization of pavement foundation layers. Future work may refine the weighting methodology and extend the proposed framework to include additional materials, different environmental conditions, and long-term performance indicators.

Also, integrating experimental results and monitoring data into a digital environment based on Building Information Modeling (BIM) and Structural Health Monitoring (SHM) enables the upgrading of traditional infrastructure databases into more advanced and dynamic information systems (Dobre et al., 2025). Through this approach, data related to mechanical behavior, degradation processes, and long-term performance of road layers can be continuously collected, managed, and analyzed. The BIM model acts as a central platform for integrating SHM data and supports the development of a digital twin of the road structure. This synergy improves long-term performance evaluation, facilitates predictive maintenance strategies, and supports the implementation of more sustainable road engineering solutions.

Integrating multicriteria performance assessment with digital monitoring and modelling technologies offers a promising approach to creating more efficient, resilient, and sustainable road infrastructure systems.

The implementation of these products addresses several critical challenges, including the inadequate technical condition of existing road infrastructure, the environmental impact associated with infrastructure development, and the high costs of operation and maintenance of transport systems. In this context, the development of sustainable pavement solutions is further constrained by the poor mechanical behavior of locally available or problematic soils, such as expansive soils, which limits their direct use in structural road layers. Therefore, it is essential to evaluate the effectiveness of ecological stabilization techniques in improving the structural performance, load-bearing capacity, and long-term durability of these materials, enabling their integration as functional components in sustainable pavement systems (Barmade et al., 2023). Another important research direction related to the structural performance assessment of ecologically stabilized road layers involves the characterization of their time-dependent mechanical behaviour under traffic loading. Since such materials-particularly those incorporating stabilized soils or biocomposites based on agro-industrial by-products (Popa et al., 2023; 2025) often exhibit viscoelastic properties, their response cannot be fully described using purely elastic models. In this context, the application of rheological models, such as the Zener viscoelastic model (Bratu, 2020), becomes essential for evaluating their dynamic response under harmonic excitation, enabling a more realistic prediction of their in-service performance.

## ACKNOWLEDGEMENTS

This work was carried out within the framework of the NUCLEU Programme PN 23 35 – "ECODIGICONS", under PNCDI 2022-2027, with the support of the National Authority for Research through Project PN 23 35 01 01, entitled "Integrative concept for the digital analysis of data from large-scale seismic monitoring of the national territory and the building stock, aimed at the rapid identification of the destructive potential of seismic events occurring in Romania and adjacent regions.

The maintenance and operation of the infrastructures used in this research were supported by funding provided by UEFISCDI to the National Network for the Seismic Monitoring and Protection of the Building Stock (R.N.M.P.S.P.C. – I.O.S.I.N.) within INCD

URBAN-INCERC, through PNCDI IV, Programme 5.5 – Research Infrastructures.

***Abstract***

*This paper presents an experimental investigation on the interrelationship between physically measured density, ultrasonic pulse velocity (UPV), and drying shrinkage of Eco-Clay poured-earth materials. Five representative mixtures, covering optimized mineral compositions and biopolymer-modified formulations, were selected from a larger experimental program. Density was determined by direct physical measurements and estimated using UPV as a non-destructive method. Drying shrinkage was monitored throughout the natural curing period. The results indicate that optimized Eco-Clay mixtures exhibit high and narrowly distributed dry densities, increased UPV responses, and reduced shrinkage, confirming the formation of a dense and homogeneous internal structure. In contrast, biopolymer-modified compositions show higher variability, increased sensitivity to curing conditions, and amplified shrinkage. A strong correlation between density, ultrasonic response, and shrinkage is demonstrated, validating the use of UPV as a reliable early-stage quality control indicator for poured-earth materials, with notable limitations for biopolymer-modified systems.*

***Key words****: biopolymer stabilization, drying shrinkage, Eco-Clay, poured earth, ultrasonic pulse velocity.*

## INTRODUCTION

Earthen construction materials have regained significant international interest in recent decades due to their low environmental impact, reduced embodied energy, local availability, and compatibility with sustainable development principles. Stabilized earth products, including compressed earth blocks (CEB), rammed earth, and poured-earth systems are increasingly investigated as viable alternatives for modern ecological construction (Walter et al., 2024). Nevertheless, the large-scale structural application of such materials remains constrained by the variability of their physical properties, particularly density, drying shrinkage, and internal structural homogeneity.
Bulk density is one of the most influential parameters governing the mechanical behavior, durability, and dimensional stability of earthen materials (Turco et al., 2021). It is strongly affected by particle size distribution, moisture content at casting, degree of compaction, and the presence of stabilizing additives (Bogas et al., 2023; Turco et al., 2024). Drying shrinkage represents a critical vulnerability of earth-based materials, as it can generate tensile stresses, surface cracking, and long-term dimensional instability if not properly controlled (Bogas et al., 2023). Consequently, the coupled evaluation of density and shrinkage is essential for assessing the technological reliability of stabilized earth products (Keita & Perrot, 2024).
In parallel with conventional destructive testing, nondestructive testing (NDT) methods have gained increasing attention for the assessment of earthen materials. Among these, Ultrasonic Pulse Velocity (UPV) testing offers a rapid and non-invasive means of evaluating internal compactness, homogeneity, and defect distribution. Numerous studies have

demonstrated strong correlations between UPV, density, moisture content, and mechanical performance for stabilized soils and compressed earth products (Bolborea et al., 2021; Sathiparan et al., 2024; Chajec et al., 2025). Studies have also confirmed the effectiveness of ultrasonic methods for assessing stabilized soils over long curing periods, with UPV shown to be sensitive to compaction level and binder type (Kasinikota & Tripura, 2022; Kozubal et al., 2023).

The integration of biopolymers as sustainable stabilizers for soils and clay-based materials represents a rapidly expanding research area in sustainable geotechnical and construction engineering. Natural polymers such as xanthan gum and lignin have been shown to enhance interparticle bonding, stiffness, and water retention capacity (Armistead et al., 2020; Abbasi et al., 2025). However, biopolymer modification also introduces microstructural heterogeneities and moisture-sensitive behavior, which can significantly affect ultrasonic wave propagation and shrinkage response (Xu et al., 2010; Zhang et al., 2020; Vieira et al., 2026). Recent ultrasonic investigations on biopolymer-stabilized soils confirmed that ultrasonic pulse velocity remains sensitive to both curing evolution and internal heterogeneity induced by bio-based binders (Armistead et al., 2020; Abbasi et al., 2025).

Ultrasonic characterization of poured-earth systems has been previously explored mainly in relation to thermal, hygrothermal, and mineral fiber stabilization behavior (Walter et al., 2024; Canivell et al., 2025). However, direct experimental correlations between physically measured density, drying shrinkage, and UPV response in eco-modified poured-earth clay systems remain insufficiently documented in the scientific literature.

Despite the growing body of research on stabilized earth, ultrasonic testing, and biopolymer-based stabilization, the coupled influence of density, ultrasonic response, and drying shrinkage on poured-earth materials incorporating eco-modified clay systems has not yet been comprehensively quantified.

The present study addresses this gap by experimentally investigating the interrelationship between physically measured density, ultrasonic pulse velocity (UPV), and drying shrinkage for representative Eco-Clay poured-earth compositions, including both optimized mineral mixtures and biopolymer-modified formulations. By combining direct physical measurements with nondestructive ultrasonic testing, the study aims to assess the reliability of UPV as a quality-control indicator and to define the technological boundaries governing the dimensional stability of Eco-Clay materials.

## MATERIALS AND METHODS

### Experimental design and investigated compositions

The experimental program was designed to ensure reproducibility, comparability, and scientific validity of the results. A total of 36 Eco-Clay specimens were prepared and tested, grouped into the following composition families:

- D family (C2-D, C3-D, C4-D): optimized mixtures without additional biopolymers;
- DL family (C2-DL, C3-DL, C4-DL): mixtures with controlled lignin addition;
- DLN family (C2-DLN, C3-DLN, C4-DLN): mixtures with lignin and granulometric corrections;
- NM family: experimental limit compositions;
- R-CAM: reference mixtures used for calibration and comparison; invalid specimens (e.g., zero recorded mass) were excluded prior to statistical processing.

For the present article, five representative formulations were selected: C3-D, C4-D, C2-D, C3-DL, and C3-DLN. These formulations cover optimal, intermediate, and unfavorable behaviors.

### *Specimen preparation and casting procedure*

All specimens were produced using the Eco-Clay poured-earth technology, employing two standardized mold geometries: 150 × 150 × 150 mm and 141 × 141 × 141 mm.

The technological process involved the following steps:

- Mechanical homogenization of the Eco-Clay mixture;
- Single-stage casting without stratification;

- Mechanical vibration for 30–90 s to eliminate internal voids;
- Controlled demolding at 24–48 h, depending on early stability;
- Natural drying for 7–50 days, depending on specimen size, initial moisture, and composition.

**Measurement methods and instrumentation**

Geometrical and mass measurements

Specimen dimensions were measured using a digital caliper (±0.1 mm), and mass was determined using a precision electronic balance (±0.1 g). Initial dimensions at casting ($a_0$, $b_0$, and $c_0$) and final dimensions after drying (a, b, and c) were recorded.

**Density determination**

Density was determined by two independent methods:

Direct physical method based on mass and final volume.

Ultrasonic Pulse Velocity (UPV) measurements were performed using a PUNDIT PL-200 ultrasonic testing device equipped with two 54 kHz transducers. The testing procedure was based on the principles of ultrasonic evaluation commonly applied for non-destructive estimation of material compactness and mechanical performance, using a Salman-type correlation between wave velocity and density. The acquisition methodology followed an approach conceptually similar to the combined non-destructive assessment procedure described in the Romanian code NP 137-2014 for concrete investigations.

Measurements were performed in direct transmission configuration on opposite specimen faces in order to evaluate internal compactness and structural homogeneity. The following parameters were recorded:

- ultrasonic path length (mm);
- propagation time (μs);
- UPV1 and UPV2 velocities (km/s);
- mean UPV (km/s).

**Drying shrinkage evaluation**

Drying monitoring was performed through successive mass measurements during the natural curing period. Moisture loss evolution was evaluated based on the stabilization (flattening) of the weight–time curve, which was considered indicative of the completion of the drying process. The specimens were stored under natural laboratory environmental conditions with uncontrolled temperature fluctuations, maintained within the range of approximately 19-23°C throughout the drying period.

Drying shrinkage was determined by comparing the initial specimen dimensions measured immediately after casting with the final dimensions measured after complete drying. Linear and volumetric shrinkage were evaluated using a digital calliper with an accuracy of ±0.1 mm.

The evaluation procedure followed the general principles commonly applied for dimensional stability assessment of earthen and cementitious materials, adapted to the specific characteristics of Eco-Clay poured-earth compositions.

Visual observations were systematically recorded throughout the drying process, focusing on:

- superficial cracking;
- surface texture and homogeneity;
- localized defects and edge curling.

**RESULTS AND DISCUSSIONS**

**Density of Eco-Clay specimens**

The bulk density of the selected representative Eco-Clay formulations (C2-D, C3-D, C4-D, C3-DL, and C3-DLN) was determined after the completion of the natural drying process. Density values were calculated using the physical method based on the ratio between the final dry mass and the measured specimen volume.

Across the representative series, the measured dry density ranged between 1892 and 2108 kg/m³, while the majority of values were concentrated in the interval 1950-2080 kg/m³, confirming a generally good material compactness and technological repeatability. The highest average densities were recorded for the C3-D and C4-D formulations, reflecting improved particle packing and optimal moisture content at casting.

Mixtures from the DL and DLN families exhibited slightly increased density dispersion, which can be attributed to the influence of lignin addition and granulometric corrections

on the internal structure and water retention during curing. In particular, some C3-DLN specimens showed lower density values, correlated with increased shrinkage and localized drying defects, indicating structural sensitivity to binder dosage.

From a technological perspective, density proved to be a key indicator of:

- mixture homogeneity;
- degree of compaction;
- sensitivity to segregation and void formation.

Lower density values were systematically associated with unfavourable UPV responses and higher drying shrinkage, outlining a clear physical interdependence between these parameters. Table 1 synthesizes the representative density values corresponding to the five selected Eco-Clay formulations determined by the physical method.

Table 1. The representative density values corresponding to the selected Eco-Clay formulations determined by the physical method

| Family | Density mean ($kg/m^3$) | Number of specimens |
|---|---|---|
| C2-D | ~2070 | 3 |
| C3-D | ~2095 | 3 |
| C4-D | ~2084 | 3 |
| C2-DL | ~1995 | 3 |
| C3-DL | ~2072 | 3 |
| C4-DL | ~2027 | 3 |
| DLN | ~1967 | 9 |
| NM | ~2037 | 9 |
| R-CAM | 1937 - 2018 | multiple |

**Density estimation based on Ultrasonic Pulse Velocity (UPV)**

In parallel with the direct physical measurements, density was also estimated non-destructively using Ultrasonic Pulse Velocity (UPV). The method is based on the correlation between wave propagation velocity and material compactness, as expressed by established empirical relationships (e.g., Salman-type) (Bolborea et al., 2021).

The measured UPV values for the representative mixtures covered the interval between 0.965 km/s and 2.315 km/s, which corresponds to a broad spectrum of internal structural conditions, from highly compact to porous or poorly consolidated zones. The low UPV value of 0.965 km/s is attributed to local porosity, air entrapment, and heterogeneous internal structure in some experimental mixtures. This behaviour was mainly observed in non-optimized or biopolymer-modified compositions, where ultrasonic wave propagation is more sensitive to internal discontinuities and moisture gradients. Based on these values, the estimated ultrasonic densities showed a good overall agreement with the physically measured densities, particularly for the C3-D and C4-D formulations.

For mixtures belonging to the DL and DLN families, larger deviations between physical and UPV-based densities were observed. These deviations are attributed to:

- heterogeneous pore distribution induced by lignin addition;
- increased moisture sensitivity during curing;
- localized microstructural discontinuities affecting wave propagation.

Specimens exhibiting UPV values below 1.2 km/s systematically displayed lower estimated densities and were associated with unfavourable technological behaviour, such as high shrinkage and surface cracking. Figure 1 illustrates the density values associated with the various composition families analyzed in this study.

**UPV–density correlation (method validation)**

Comparing the physically measured density with the density estimated using UPV (Salman correlation) reveals a strong linear relationship characterized by:

- coefficient of determination $R^2 \approx 0.98$
- estimation accuracy of 96-107%
- the majority of samples falling within 97-100% agreement.

This relationship is illustrated in Figure 2, where the regression line closely follows the ideal reference line.

**UPV-density correlation for the complete specimen dataset**

The UPV method accurately reflects density variations for the D and DL composition families.

Larger deviations are associated with DLN and NM compositions, where the microstructure is more heterogeneous.

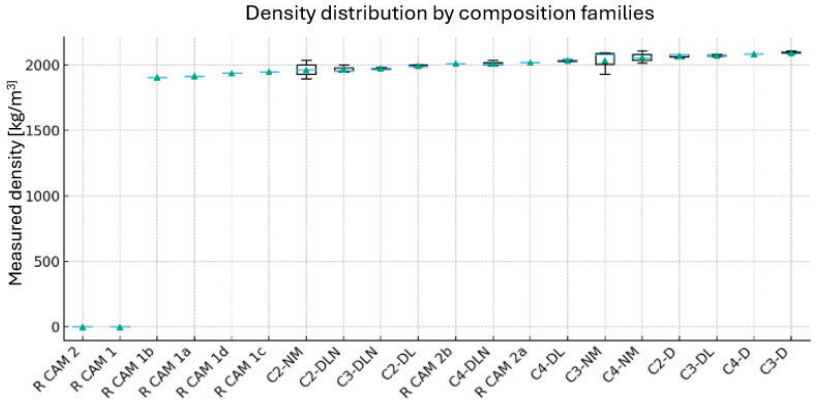

Figure 1. Density distribution by composition families

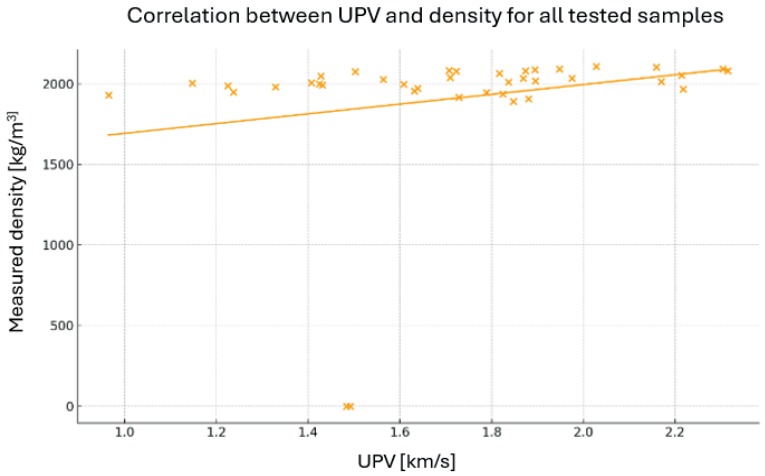

Figure 2. UPV-density correlation by composition families

UPV can, therefore, be used operationally to monitor compaction quality during production stages.

***Comparative analysis between physical and UPV-based densities*** (Figure 2 and Table 2)

The comparative evaluation between physically measured density and UPV-estimated density provides essential insight into the reliability of ultrasonic testing for Eco-Clay materials.

For the optimal mixtures (C3-D and C4-D), the deviation between the two methods remained within a narrow range, confirming that UPV can be reliably used as a non-destructive quality control indicator for compacted poured-earth materials. In contrast, for mixtures with lignin addition (DL and DLN series), the deviation increased, reflecting the sensitivity of ultrasonic wave propagation to microcracking, moisture gradients, and local heterogeneities.

Table 2. Comparison of physical and UPV-estimated density values

| Family | Density mean (kg/m$^3$) | UPV mean (km/s) |
|---|---|---|
| C2-D | ~2070 | ~1.65 |
| C3-D | ~2095 | ~2.00 |
| C4-D | ~2084 | ~1.80 |
| C2-DL | ~1995 | ~1.25 |
| C3-DL | ~2072 | ~1.80 |
| C4-DL | ~2027 | ~1.55 |
| DLN | ~1967 | ~1.30 |
| NM | ~2037 | ~1.95 |
| R-CAM | 1937 - 2018 | 1.45 - 1.90 |

These results emphasize that UPV-based density estimation must be interpreted in conjunction with physical measurements when dealing with biopolymer-modified earth materials.

**Drying and shrinkage behavior of Eco-Clay mixtures**

Drying and shrinkage were monitored throughout the natural curing period for all representative Eco-Clay compositions by comparing the initial specimen dimensions at the casting stage with the final dimensions after complete drying. Both linear and volumetric shrinkage were evaluated.

The C3-D and C4-D formulations displayed the most stable drying behavior, characterized by uniform dimensional reduction and minimal superficial cracking. The average linear shrinkage for these mixtures remained within a controlled range, indicating a balanced moisture diffusion and internal stress redistribution during drying.

In contrast, mixtures modified with lignin (DL and DLN series) exhibited increased shrinkage variability and a higher sensitivity to curing conditions. Several C3-DLN specimens developed localized surface cracking and edge curling, which correlated well with the following:

- lower physical density;
- reduced UPV values;
- increased internal porosity.

The most unfavorable shrinkage behavior was observed for selected limit compositions (NM family), where rapid moisture loss generated significant tensile stresses and early-age microcracking.

Although these mixtures are not part of the five representative formulations, their behavior is mentioned here to outline the technological boundaries of Eco-Clay materials.

The analysis of volumetric shrinkage across the composition families highlights the following general trend (average values):

- C2 family: higher shrinkage values associated with a solid-liquid ratio more sensitive to drying processes.
- C3 family: moderate shrinkage with relatively low variability between specimens.
- C4 family: intermediate behavior between C2 and C3, with some specimens exhibiting shrinkage values below 1%.
- R family (reference specimens): low shrinkage values consistent with their calibration role.

These results indicate that, within the analyzed dataset, the C3 family exhibits the lowest average volumetric shrinkage with reduced dispersion, suggesting improved dimensional stability compared with C2 and, to some extent, with C4 compositions.

To evaluate the relationship between compaction and dimensional stability, volumetric shrinkage was compared with the physically measured density.

The analysis indicates that:

- specimens with densities above approximately 2050 kg/m³ generally exhibit lower volumetric shrinkage, with average values around 3.5-4%;
- specimens with densities below approximately 1980 kg/m³ show higher shrinkage, with average values around 6-7%;
- the intermediate interval 1980-2050 kg/m³ corresponds to average shrinkage values of approximately 4.9%.

This behavior confirms the general trend in which higher density (i.e., a more compact microstructure) is associated with lower volumetric shrinkage, while lower density corresponds to increased shrinkage and a higher risk of cracking (Zhang et al., 2016; Daneti et al., 2024).

To integrate non-destructive results into the drying behavior analysis, volumetric shrinkage was correlated with ultrasonic pulse velocity values. Figure 3 presents the distribution of specimens in the UPV-volumetric shrinkage plane.

**UPV-volumetric shrinkage correlation for Eco-Clay specimens**

The results indicate that:

- specimens with high UPV values (> 1.7 km/s) tend to exhibit moderate volumetric shrinkage, with average values around 4-4.5%;
- the interval 1.4-1.7 km/s is associated with slightly higher shrinkage values, averaging approximately 6%;

- specimens with UPV < 1.4 km/s generally show shrinkage between ≈2-5%, but correspond to more sensitive compositions with increased variability.

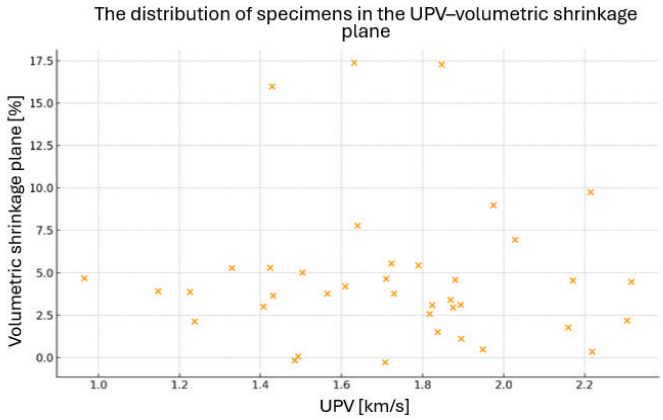

Figure 3. The distribution of specimens in the UPV-volumetric shrinkage plane

Although the UPV-shrinkage relationship is not strictly linear, the results indicate that stable and relatively high UPV values are compatible with reduced to moderate shrinkage levels.

Therefore, UPV can be used as an early indicator for identifying specimens with a more compact microstructure and, consequently, more predictable dimensional behavior during drying (Lim et al., 2018; Chajec et al., 2025).

Overall, the experimental results demonstrate a clear interdependence between density, UPV response, and drying shrinkage, confirming shrinkage as a critical indicator of internal structural integrity and long-term dimensional stability.

**Integrated interpretation of density, UPV, and shrinkage**

The combined analysis of physically measured density, UPV response, and drying shrinkage highlight a consistent and coherent physical behavior of the Eco-Clay material when optimal granulometry and moisture control are ensured.

For the reference and optimized mixtures (C3-D and C4-D), high dry density values were systematically associated with increased UPV and reduced shrinkage. This triad confirms a dense internal structure, reduced pore connectivity, and improved resistance to drying-induced tensile stresses.

By contrast, the lignin-modified compositions (DL and DLN series) exhibited a more complex behavior. Although certain formulations showed comparable density levels, the presence of biopolymer introduced microstructural heterogeneities that affected ultrasonic wave propagation and amplified shrinkage sensitivity. These effects were particularly visible in the C3-DLN formulation, where lower UPV values coincided with increased dimensional instability.

The limit compositions (NM family), although not central to this article, defined the technological boundaries of Eco-Clay materials. The NM specimens exhibited a more heterogeneous ultrasonic response and increased variability in drying behavior compared with the optimized formulations. Although the mean UPV value of the NM family remained relatively high (approximately 1.95-1.98 km/s), certain individual specimens displayed significantly lower ultrasonic velocities, indicating local heterogeneity, incomplete consolidation, or drying-induced discontinuities. These results suggest that the unfavorable behavior of the NM family is primarily associated with variability and local structural instability rather than with uniformly low UPV values.

From an engineering perspective, the strong interdependence between density, ultrasonic response, and shrinkage validates the use of UPV as a reliable non-destructive indicator for early-stage quality control of poured-earth materials, provided that it is calibrated against

physical density measurements (Kasinikota & Tripura, 2022).

## LIMITATIONS OF THE STUDY

The present study has several limitations that should be considered when interpreting the experimental results.

Although the investigated formulations were tested using replicated specimens, the number of samples remained limited for certain composition families, particularly for the experimental and boundary mixtures.

In addition, the drying process was performed under natural laboratory environmental conditions and was not fully climate-controlled. Although the temperature during drying was maintained within an approximate interval of 19-23°C, natural variations in ambient humidity and drying kinetics may have influenced moisture loss evolution and shrinkage variability.

Furthermore, the UPV method presents intrinsic limitations when applied to heterogeneous biopolymer-modified materials. Local discontinuities, pore distribution, moisture gradients, and microstructural heterogeneity may affect ultrasonic wave propagation and generate localized deviations between UPV-estimated and physically measured properties.

Future research should therefore include larger experimental datasets, climate-controlled curing conditions, and extended ultrasonic calibration for highly heterogeneous Eco-Clay systems.

## CONCLUSIONS

This study investigated the interrelationship between physically measured density, ultrasonic pulse velocity (UPV), and drying shrinkage for representative Eco-Clay poured-earth compositions, with the objective of supporting early-stage quality control and technological optimization.

The optimal formulations (C3-D and C4-D) exhibited the most stable and consistent behavior, characterized by high and narrowly distributed dry density values ranging approximately between 2070 kg/m$^3$ and 2095 kg/m$^3$, increased UPV responses, and reduced linear and volumetric shrinkage. These results confirm the formation of a dense internal structure with limited pore connectivity and improved resistance to drying-induced tensile stresses.

Lignin-modified mixtures (DL and DLN series) displayed a more complex response. Although competitive density levels were achieved in certain cases, the presence of biopolymer introduced microstructural heterogeneities, leading to increased dispersion of UPV values, higher sensitivity to curing conditions, and amplified shrinkage and localized cracking.

The comparative analysis between physically measured and UPV-estimated densities demonstrated that UPV can be reliably employed as a nondestructive indicator for Eco-Clay quality assessment, provided that it is calibrated against direct density measurements and interpreted with caution for biopolymer-modified compositions.

Therefore, for biopolymer-modified materials, it is recommended to combine UPV evaluation with direct physical measurements of density and shrinkage in order to improve the reliability of quality assessment.

From an engineering standpoint, the combined use of density, UPV, and shrinkage offers an efficient and complementary diagnostic framework for optimizing poured-earth Eco-Clay materials. Future research will focus on extending the ultrasonic calibration range for densities below approximately 1800 kg/m$^3$ and for highly heterogeneous biopolymer-modified systems, refining biopolymer dosage, and correlating nondestructive parameters with mechanical strength for full structural validation.

***Abstract***

*During winter operation, passive solar greenhouses with limited auxiliary heating are frequently affected by nocturnal thermal stratification and elevated humidity, promoting condensation on structural surfaces and increasing fungal disease risk at canopy level. This study evaluates an internal air recirculation strategy for condensation prevention, implemented in a double-layer Chinese solar greenhouse at the University of Agronomic Sciences and Veterinary Medicine of Bucharest. Twenty axial fans were installed at 3.5 m height along both longitudinal sides, controlled by adaptive dew margin thresholds derived from a distributed canopy sensor network. Two experimental phases were compared: Phase I used synchronized control of both ventilation units driven by the worst-case canopy dew margin; Phase II introduced asynchronous zonal control, with each unit independently responding to its local canopy sensor. Results indicate that canopy-based recirculation control successfully maintained positive dew margins at plant level throughout the monitoring period, with no leaf wetness events detected at canopy level in either phase, while structural condensation on the inner polyethylene cover persisted. The dew margin indicator proved more operationally discriminating than relative humidity alone under the conditions observed.*

***Key words:*** *condensation risk, dew point, internal recirculation, passive greenhouse, zonal microclimate control.*

## INTRODUCTION

Winter greenhouse operation in passive or semi-closed structures is frequently constrained by limited external ventilation, either due to energy penalties or the risk of cold stress for sensitive crops. Under such conditions, relative humidity often remains high, and localized stagnant air zones may develop, promoting condensation on cold structural surfaces and, in some cases, within the crop canopy. Condensation is not only an undesirable physical phenomenon but also a major biological risk factor, strongly associated with fungal disease development and reduced crop quality during the cold season (Piscia et al., 2012; Amani et al., 2020). This challenge becomes particularly acute in greenhouses with modest auxiliary heating, where nocturnal thermal stratification leads to the accumulation of warm, humid air in the upper volume while the crop zone remains prone to saturated boundary layers.

From a physical perspective, condensation is governed by the proximity of air temperature to the dew point and the presence of sufficiently cold surfaces acting as sinks for water vapor. In greenhouse environments, nocturnal radiative cooling of the envelope is often the dominant driver, making the roof or inner cover the coldest surface where condensation is initiated (Piscia et al., 2012). Consequently, dew point-based indicators provide a more robust framework for condensation risk assessment than relative humidity alone, since they quantify the thermodynamic margin to saturation. Moreover, condensation typically develops locally in the coldest or most humid zones, meaning that bulk-average climate variables may fail to capture critical risk conditions (Boulard & Draoui, 1995; Gao et al., 2024).

Natural ventilation remains the classical tool for controlling temperature and humidity, yet its effectiveness depends strongly on wind conditions, buoyancy forces, vent geometry, and

the effective opening area. Experimental studies and models have shown that ventilation rates generally increase with wind speed and vent aperture, but the relationship is highly variable and sensitive to airflow regimes and structural design (Boulard & Draoui, 1995; Baptista et al., 1999; Teitel & Tanny, 1999). Because ventilation rate fluctuates continuously with weather conditions, its reliable characterization requires real-time measurement rather than static assumptions (Tusi & Shimazu, 2020). Importantly, seemingly secondary parameters such as pressure and discharge coefficients can substantially affect ventilation predictions; wind tunnel measurements have demonstrated clear dependencies on wind direction and vent configuration (Sase et al., 1980). Therefore, during winter, when vent opening is deliberately restricted, external ventilation becomes both difficult and energetically costly as a dehumidification strategy. In addition to energy limitations, modern greenhouses frequently employ insect-proof screens, which can significantly reduce effective ventilation due to increased aerodynamic resistance, thereby enhancing humidity accumulation and microclimate heterogeneity (Katsoulas et al., 2006). Under cold-season conditions, this creates a critical trade-off: ventilation sufficient to remove moisture may induce excessive heat losses and compromise energy efficiency. Studies quantifying the thermal cost of dehumidification have shown that a substantial fraction of heating energy may be indirectly expended through moisture removal via ventilation, motivating alternative or complementary approaches with reduced losses (Maslak & Nimmermark, 2017; Amani et al., 2020). Mechanical humidity-control options have been proposed for winter operation, yet their effectiveness must be evaluated in relation to thermal impacts and crop-zone relevance (Lee et al., 2020).

A key point emphasized in recent literature is that "ventilation" does not simply refer to air exchange rates, but rather to internal airflow patterns and climate uniformity at canopy level. Spatial heterogeneity in temperature and humidity may persist even in ventilated greenhouses, and stagnant zones can remain critical hotspots for condensation risk (Gao et al., 2024). This is consistent with experimental and CFD-based studies showing that ventilation design strongly determines distributed microclimate rather than only mean conditions (Bournet & Boulard, 2010; Zhang et al., 2025). Seasonal differences are also important: while summer ventilation is dominated by cooling requirements, winter ventilation must address humidity control under strong energy constraints (Kittas et al., 2005; He et al., 2015). Classical work has highlighted that air movement and climate uniformity are central objectives in greenhouse operation, not merely side-effects of vent opening (Sase, 2006).

Biologically, the relevant humidity is not necessarily the greenhouse-average value but the microclimate in the immediate vicinity of leaves, where boundary-layer effects may produce conditions substantially different from bulk air. Experimental evidence confirms that ventilation influences not only greenhouse humidity but also leaf boundary-layer humidity, with direct implications for condensation and disease risk (Boulard et al., 2004). Similarly, research on leaf wetness duration indicates that simple empirical thresholds (e.g., RH > 90%) may be insufficient in greenhouse environments, where spatial variability is high and locally calibrated models are required (Wang et al., 2019). These findings support approaches that explicitly separate structural condensation zones from agronomically relevant canopy zones and rely on physically grounded indicators such as dew point or dew margin combined with distributed sensing.

Alongside external air exchange strategies, increasing attention has been directed toward internal air recirculation and mixing as means to reduce stratification and limit the persistence of humid stagnant pockets without major ventilation heat losses. Horizontal airflow fan systems have been discussed as practical tools for reducing vertical gradients, improving canopy drying, and lowering the probability of reaching dew point at leaf level (Blanchard, 2008). Recent studies further indicate that non-uniform ventilation and airflow distribution can affect both energy consumption and plant growth, reinforcing the need for canopy-oriented microclimate control rather than reliance on bulk averages (Wang et al., 2025). CFD simulations of greenhouse airflow similarly emphasize the sensitivity of internal climate to geometry and vent configuration, making uniformity a design target rather than an automatic outcome (Zhang et al., 2025).

Based on these converging gaps in the literature, a clear applied problem emerges in passive winter greenhouses where external ventilation is restricted, there is a need for condensation-risk mitigation strategies that do not depend primarily on-air exchange with the outdoor environment. The present study therefore evaluates an internal air recirculation approach implemented in a double-layer passive greenhouse, using multi-point monitoring and dew point-based control indicators. Rather than treating the greenhouse climate as a single average value, the approach emphasizes (i) spatial characterization of microclimate variability, (ii) conservative worst-case risk definition, and (iii) canopy-oriented zonal control to limit stratification and condensation-prone stagnation zones. We hypothesized that independent control of lateral compartments, driven by local canopy dew margin measurements, would enhance protection against canopy-level condensation - thereby reducing the risk of fungal disease development - compared to a synchronized worst-case control strategy.

## MATERIALS AND METHODS

### *Greenhouse structure and winter experimental context*

The experiment was conducted during the cold season (December 2025 - February 2026) in a passive double-layer Chinese solar greenhouse located at the University of Agronomic Sciences and Veterinary Medicine of Bucharest, Romania. The structure analyzed in this study is referred to as the Solar Double Chinese greenhouse (SDC) and is used for overwintering exotic and subtropical crops under minimal conventional heating input (Figure 1).

Figure 1. Overview of the passive double-layer Chinese solar greenhouse used in the experiment (December 2025 – February 2026). Left: eastern compartment showing blueberry crops. Right: western compartment with tropical species, illustrating the spatial heterogeneity of the experimental environment.

The greenhouse has an external length of approximately 45 m and an internal length of 42 m, due to the presence of two independent polyethylene layers (outer and inner envelope). The usable internal width is approximately 18 m (20 m external), while the maximum internal height reaches about 6 m, a geometry that strongly promotes nocturnal thermal stratification during winter conditions.

Such stratification is a well-known feature of passive greenhouses operating under limited ventilation, where warm humid air accumulates in the upper volume while the crop zone remains prone to saturation (Sase, 2006; Piscia et al., 2012). The structure is oriented along the South-North axis and is longitudinally divided by a central corridor approximately 2 m wide, separating two main compartments referred to in this study as the eastern zone and the western zone.

### *Heating system and nocturnal stratification*

Auxiliary heating is provided by 18 radiant electric panels installed above the central corridor at a height of approximately 2.5 m. Each panel has a nominal power of 500 W, resulting in a total installed capacity of approximately 9 kW. Under typical winter

operation, this radiant system generates a warm and humid air reservoir accumulating in the upper greenhouse volume. In the absence of sufficient circulation, the crop zone remains prone to stagnant moisture-laden boundary layers. Relative humidity frequently exceeds 90%, and condensation develops preferentially on cold structural surfaces (polyethylene foil and metallic elements), increasing the risk of fungal diseases and latent heat losses. Nocturnal radiative cooling of the envelope has been identified as a dominant driver of condensation initiation in greenhouse environments (Piscia et al., 2012). Natural ventilation through lateral openings is strongly restricted during winter, since external air is often too cold for subtropical crops and would induce significant energy penalties. Therefore, this study focuses on condensation-risk mitigation without relying on external air exchange, using only internal air recirculation, consistent with the need for low-energy humidity control strategies in winter greenhouses (Maslak & Nimmermark, 2017; Amani et al., 2020).

***Internal air recirculation system***

To reduce thermal stratification and limit condensation-prone microclimates, an internal air recirculation system was installed, consisting of 20 axial fans, each rated at approximately 40 W with a nominal airflow of about 400 $m^3\ h^{-1}$. Fans were mounted longitudinally at approximately 3.5 m height, distributed symmetrically: 10 fans on the eastern side and 10 fans on the western side. Airflows are directed downward toward the crop zone, aiming to create a turbulent mixing loop: warm humid air accumulated above the radiant heaters is pushed downward, while cooler air near the polyethylene envelope is mixed upward along the structural surface. This strategy is intended to weaken stratification and reduce the persistence of saturated boundary layers, without the energy losses associated with external ventilation (Blanchard, 2008; Bournet & Boulard, 2010). Fans were physically installed in early December 2025, while automated operation was implemented beginning in January 2026 after full integration into the Home Assistant control platform.

Distributed microclimate monitoring network (Figure 2 and Figure 3).

***Distributed microclimate monitoring network***

Microclimate monitoring was performed through a distributed sensor network measuring air temperature and relative humidity at multiple vertical and lateral positions, designed to capture spatial gradients associated with condensation development. Spatial heterogeneity is frequently observed even in ventilated greenhouses, and local stagnant zones may remain critical hotspots for condensation risk (Gao et al., 2024). The initial monitoring configuration included sensors positioned in peripheral regions influenced by envelope cooling: S4 (Eastern zone, 100 cm above ground), S6 (Western zone, 100 cm above ground), S5 (Central upper volume, 400 cm height), and S8 (Southern upper zone, 400 cm height).

These sensors enabled computation of spatial dew point distributions and identification of structural zones with elevated condensation risk. Although S4 and S6 are defined by their mounting height (100 cm), their relatively marginal placement means they primarily reflect structural condensation conditions rather than direct canopy microclimate. The upper central sensor (S5) was used to characterize the general moisture reservoir in the greenhouse air mass, whereas fan control was always driven by the minimum (worst-case) dew margin measured in the canopy zone (Figure 4).

Figure 4. Canopy-level sensor deployment. Left: Sensor S1 (East compartment, 170 cm height) labelled with identification tag. Right: Sensor S2 (West compartment, 170 cm height). Both sensors measure air temperature and relative humidity for dew point and dew margin computation

***Leaf wetness sensor and foil-adjacent measurements***

A leaf wetness sensor (LWS) was deployed as a qualitative indicator of liquid water film formation. The sensor was validated prior to deployment by direct application of a water film (spray and moist tissue contact), confirming that it responds exclusively to liquid water film formation and remains at zero output in the absence of free water. When positioned within the crop canopy, the sensor recorded zero output throughout the entire monitoring period. When attached directly to the inner polyethylene foil surface - where condensation was visually confirmed on multiple nights - the sensor consistently detected condensation events. Repositioning the sensor 5 cm away from the foil surface was sufficient to return output to zero, confirming that condensation was confined to the immediate foil surface and did not extend into the adjacent air volume or the crop zone. This distinction between structural condensation and biologically relevant canopy wetness is consistent with studies showing that leaf boundary-layer humidity may differ substantially from bulk greenhouse air conditions (Boulard et al., 2004). The absence of liquid water detection within the canopy should be interpreted as evidence that the recirculation strategy successfully prevented leaf-level condensation, while structural condensation remained confined to the inner envelope. Leaf wetness duration models often require calibration beyond simple RH thresholds, highlighting the complexity of canopy-level moisture processes (Wang et al., 2019).

Three auxiliary temperature probes (Temperature 1–Temperature 3) were installed near the inner foil surface at different heights (30 cm, 150 cm, and 300 cm). Initially fixed directly on the foil, these probes primarily reflected surface cooling. Beginning on 1 February 2026, they were repositioned approximately 5 cm away from the foil, in order to better capture air temperature variations influenced by recirculation rather than direct conductive coupling to the cold surface (Figure 5).

Figure 5. Foil-adjacent temperature probe installation (Mobile Sensor 10). Left: Temperature 1 probe positioned at foil surface level. Right: Temperature 2 probe mounted inside the foil layer. Both probes monitor the thermal regime near the inner cladding surface to detect condensation-prone zones

***Dew point computation and dew margin indicator***

To evaluate condensation risk physically, dew point temperature was calculated using the Magnus–Tetens approximation, based on measured air temperature and relative humidity:

$$T_{te}^{W} = b \cdot \gamma(T,RH) / [a - \gamma(T,RH)]$$
$$\gamma(T,RH) = ln(RH/100) + aT / (b + T)$$

where T is the air temperature (°C), RH is the relative humidity (%), and γ(T, RH) is an intermediate dimensionless variable used in the Magnus-Tetens formulation. The constants were set to a = 17.27 and b = 237.7°C, which are commonly applied for temperature ranges relevant to greenhouse environments.

Condensation proximity was expressed through the thermodynamic indicator dew margin, defined as:

$$\Delta T = T_a^{IR} - T_{te}^{W}$$

Large values indicate air far from saturation, whereas small values indicate proximity to condensation. Dew point–based indicators provide a more robust condensation-risk framework than relative humidity alone, particularly under heterogeneous greenhouse conditions (Piscia et al., 2012). In this study, the primary operational threshold was set at 2°C, while values below 1°C were considered indicative of imminent condensation risk within the crop zone.

***Definition of the critical scenario: Worst-Case Dew Margin***

In large greenhouse volumes, condensation develops locally in the coldest or most humid regions rather than uniformly. For preventive control, a conservative indicator termed Worst-Case Dew Margin was defined as the minimum dew margin value across monitored points:

$$\Delta T_m^{In} = min(\Delta T_1, \Delta T_2, \ldots, \Delta T_n)$$

This parameter continuously represents the point closest to condensation and serves as the main control variable for fan automation, consistent with the need for worst-case microclimate assessment rather than bulk averages (Gao et al., 2024).

***Transition to canopy-based control (1 February 2026)***

During the initial phase (December 2025-January 2026), worst-case control was dominated by marginal sensors (S4/S6) influenced by envelope cooling. While this configuration reflected structural condensation risk on the foil, it did not directly demonstrate agronomically relevant improvement in the leaf-level microclimate. To ensure biological relevance, two additional sensors were installed in the canopy zone on 1 February 2026: S1 (East canopy, 170 cm) and S2 (West canopy, 170 cm). These sensors are positioned within the vegetative zone, approximately 3.5 m from the fans, providing representative measurements of leaf-level temperature and humidity. From this date onward, fan automation was based exclusively on the canopy worst-case dew margin, while marginal sensors remained monitored as structural reference. The importance of canopy-oriented microclimate monitoring has been emphasized in studies addressing boundary-layer humidity and crop-level risk processes (Boulard et al., 2004; Sase, 2006).

***Experimental Phase I - Synchronized canopy-based control***

Between 1 February 2026 and 11 February 2026 (09:59), the system operated under a synchronized canopy-based control configuration, hereafter referred to as Phase I. During this interval, both ventilation units (Vent1 - East and Vent2 - West) were driven simultaneously by the canopy worst-case dew margin (S1), defined as the minimum ΔT among canopy sensors. This configuration ensured a conservative, homogeneous response across the greenhouse volume, treating the structure as a single thermodynamic control domain. Phase I thus represents the baseline experimental configuration against which subsequent zonal refinements are evaluated.

Beginning on 1 February 2026, internal air recirculation was controlled through an adaptive three-regime strategy:

- Critical regime (ΔT < 1.0°C) - fans operate continuously, indicating maximum agronomic condensation risk in the canopy.
- Intermediate regime (1.0-2.0°C) - fans operate in pulse mode (10 min ON / 20 min OFF), maintaining mixing while reducing energy consumption.
- Safe regime (ΔT > 2.5°C) - fans are fully switched off after stabilization, introducing hysteresis and preventing excessive cycling.

A hysteresis margin was introduced to prevent rapid fan cycling: recirculation was activated when ΔT fell below 2.0°C but switched off only after recovery above 2.5°C. Adaptive strategies with hysteresis are consistent with recommendations to avoid excessive switching while maintaining canopy-level uniformity (Bournet & Boulard, 2010; Zhang et al., 2025).

***Transition to Phase II – Asynchronous canopy-based zonal control***

Beginning on 12 February 2026, the control strategy was experimentally modified in order to evaluate the effect of spatially differentiated canopy-based recirculation. While Phase I relied on a synchronised worst-case control approach, both ventilation units being driven by the minimum canopy dew margin (S1), Phase II introduces an asynchronous zonal configuration. In this second phase, Vent1 (East compartment) continues to be controlled by the canopy worst-case dew margin (S1), whereas Vent2 (West compartment) is independently driven by the local canopy dew margin measured at S2 (170 cm height).

This modification was motivated by the persistent lateral asymmetry observed during Phase I, where S1 systematically exhibited lower dew margin values than S2. In addition, the eastern compartment is subjected to slightly higher irrigation frequency due to crop distribution, which may locally increase air humidity and influence dew point dynamics. Consequently, treating both compartments as a single homogeneous control volume may mask relevant microclimatic variability. The asynchronous configuration maintains identical thermodynamic thresholds (continuous operation for $\Delta T < 1°C$, pulse regime for 1-2°C, and shutdown above 2.5°C), ensuring comparability between phases while allowing independent zonal response.

***Air velocity measurements***

To quantify airflow intensity, air velocity was measured using a vane anemometer (TROTEC BA06) over 30-minute intervals at two locations: at 1.5 m from the fan (maximum velocity $\approx 1.0$ m $s^{-1}$) and at canopy level near S1, at 2.5 m distance (maximum velocity $\approx 0.4$ m $s^{-1}$). Although measured canopy air velocities were moderate (~0.4 m $s^{-1}$), the primary objective was not intensive convective drying but the reduction of stratification and the homogenization of humidity distribution within the crop zone, consistent with the role of airflow uniformity emphasized by Sase (2006).

***Operational condensation risk definition and intervention quantification***

For automation and quantitative evaluation, a binary condensation risk sensor was defined as active when the canopy worst-case dew margin fell below the critical threshold of 2°C, indicating conditions favorable for condensation. To validate the system experimentally, not only fan triggering but also the duration of exposure and intervention were quantified through two cumulative history statistics sensors implemented in Home Assistant: Condensation Risk Time Today (total daily hours during which condensation risk was active) and Recirculation Runtime Today (total daily operating time of the internal recirculation system). These metrics provide a reproducible framework for comparing climatic pressure against the effective response of the control strategy.

***Data acquisition and storage***

All temperature, relative humidity, dew point, dew margin, and fan-state data were collected automatically through the Home Assistant platform and continuously stored in an InfluxDB time-series database. This infrastructure enables full reconstruction of temporal series and subsequent statistical analysis of microclimate evolution and system response under winter operating conditions (Figure 6).

## RESULTS AND DISCUSSIONS

### *Performance of the synchronised dew-margin-based recirculation control (Phase I)*

During Phase I (1 February 2026 - 11 February 2026, 09:59), both recirculation fans (Vent1 - East compartment; Vent2 - West compartment) operated under a strictly synchronised control strategy, driven by the conservative canopy worst-case dew margin parameter (S1). Over the analysed interval of approximately 240 hours, both ventilation units exhibited nearly identical operational behaviour, with a cumulative runtime of 50.22 hours for Vent1 and 50.03 hours for Vent2, corresponding to an average daily operation of approximately 5 hours per ventilator. This confirms the deterministic and fully synchronised implementation of the initial control logic.

The distribution of canopy dew margin values during this phase indicates that the system maintained effective control over condensation risk. For the worst-case canopy parameter (S1), the cumulative duration during which the dew margin fell below 2°C was 164.56 hours, while the time spent below the more critical threshold of 1°C was limited to only 0.089 hours (approximately 5.3 minutes) over the entire observation period. The absolute minimum recorded value for S1 was 0.55°C, and the 5th percentile was 1.29°C, indicating that severe proximity to condensation conditions was rare and short-lived.

In contrast, the west-local canopy sensor (S2) exhibited less severe conditions. The cumulative time below 2°C was 139.11 hours, while no instances of dew margin below 1°C were recorded. The minimum observed value for S2 was 1.41°C, and the 5th percentile was 1.77°C. These results reveal a persistent lateral asymmetry between the two compartments, with the worst-case zone (S1) consistently exhibiting lower dew margin values and longer exposure to moderate condensation risk conditions compared to the western compartment.

Despite this spatial variability, both ventilation units operated with virtually identical runtimes due to the synchronised control strategy. Consequently, while the implemented logic proved effective in preventing severe condensation risk ($\Delta T < 1°C$) and maintained overall system stability, it did not account for lateral differences in microclimatic behaviour within the greenhouse. This observation provides the experimental justification for the subsequent implementation of an asynchronous, zone-based control strategy in Phase II.

***Leaf wetness validation***

The leaf wetness sensor, validated prior to deployment to confirm exclusive response to liquid water film, recorded zero output throughout the monitoring period when positioned within the canopy. This result is not attributable to sensor insensitivity: the same sensor consistently detected condensation events when in direct contact with the inner polyethylene foil surface, confirming both instrument functionality and the spatial confinement of condensation to structural surfaces. No leaf wetness events were recorded at canopy level during Phase I, despite multiple nocturnal intervals in which the dew margin approached critical thresholds. This indicates that the canopy-based control strategy successfully prevented actual condensation at plant level. Condensation was, however, visually observed on the greenhouse plastic cover during several nights, consistent with expected radiative cooling of structural surfaces. These observations confirm that dew margin values at canopy level remained above the condensation point even when structural surfaces experienced local cooling (Figure 7).

Figure 7. Home Assistant History record of canopy dew margin for S1 (East, blue) and S2 (West, yellow) during Phase I (1-11 February 2026), with ventilator activation states shown in the upper panel. Nocturnal peaks correspond to critical condensation risk events triggering continuous fan operation

***Performance of the asynchronous zonal recirculation control (Phase II)***

Phase II was initiated on 12 February 2026 and extended through 26 February 2026, covering a total monitoring interval of 15 days (360 hours). During this period, Vent1 (East compartment) continued to be driven by the canopy worst-case dew margin (S1), while Vent2 (West compartment) was independently controlled by the local canopy sensor S2, implementing the asynchronous zonal strategy described in the Materials and Methods section.

Over the 15-day interval, the recirculation system accumulated a total runtime of 63.1 hours, corresponding to a mean daily operation of 4.21 ± 2.30 h day$^{-1}$. The day-to-day variability in runtime was substantially higher than in Phase I (coefficient of variation: 55% vs. approximately 5% in the synchronized phase), reflecting the adaptive nature of the control logic responding to variable nocturnal conditions. On nights with more severe external conditions, daily runtimes reached up to 10.2 hours (21 February), while on milder nights the system operated as little as 2.3 hours, demonstrating the energy-modulating effect of the threshold-based hysteresis strategy.

The daily mean canopy dew margin for the eastern compartment (S1) ranged from 1.25°C to 10.45°C, with an overall mean of 5.24 ± 3.29°C. The western compartment (S2) exhibited slightly higher values, with a mean of 5.86 ± 3.49°C and a daily range of 1.34°C to 11.14°C. The persistent lateral asymmetry first identified during Phase I was maintained throughout Phase II, with S1 consistently recording lower daily mean dew margins than S2. This asymmetry is visually apparent in the

continuous monitoring record (Figure 3) and is consistent with the higher irrigation frequency in the eastern compartment noted in the Methods section.

The daily minimum dew margin - representing the closest approach to condensation within each 24-hour period - was maintained above 0.8°C for S1 (mean minimum: 1.10 ± 0.17°C, absolute minimum: 0.81°C on 25 February) and above 0.87°C for S2 (mean minimum: 1.24 ± 0.24°C). Critically, the cumulative condensation risk counter for the canopy zone recorded zero hours of active risk across all monitored days in Phase II, indicating that the dew margin remained above the 2°C intervention threshold for the dominant part of each day and that brief excursions below this threshold were successfully intercepted by recirculation activation.

A Spearman rank correlation analysis between daily recirculation runtime and daily minimum dew margin in the western compartment yielded a statistically significant negative association ($r_s = -0.582$, $p = 0.010$, $n = 15$), confirming that the control system responded appropriately to microclimatic pressure: higher recirculation effort was consistently associated with days of greater condensation proximity. A similar trend was observed for the eastern compartment ($r_s = -0.396$), though this did not reach statistical significance ($p = 0.12$), likely reflecting the more frequent activation of continuous-mode recirculation in S1 which partially saturated the runtime response.

The inter-phase comparison of daily mean dew margin values (Phase I: S1 mean 3.39 ± 1.80°C; Phase II: S1 mean 5.24 ± 3.29°C) indicates numerically higher margins in Phase II, consistent with generally milder external conditions during the later observation period (mean inter-layer temperature 3.60 ± 2.61°C in Phase II vs. 0.96 ± 3.50°C in Phase I). A Mann-Whitney U test did not identify a statistically significant difference between phases for either compartment (S1: $U = 58.0$, $z = -1.27$, $p = 0.20$; S2: $U = 65.0$, $z = -0.91$, $p = 0.36$), and the Spearman correlation between external temperature and daily dew margin did not reach significance in either phase (Phase II S1: $r_s = 0.34$, $p = 0.19$; Phase II S2: $r_s = 0.38$, $p = 0.14$). These results indicate that inter-phase differences in dew margin are not attributable to a single confounding thermal driver, though the relatively small sample sizes preclude definitive causal attribution.

Analysis of individual fan activation events confirmed the high degree of operational synchrony between the two ventilation units throughout Phase II, with Vent1 recording 90 total activations and Vent2 recording 83 activations over the 15-day period ($r = 0.856$, daily activation counts). Meaningful divergence between units was observed on only two days (17 and 18 February), when Vent1 activated three times more than Vent2, corresponding to the nights with the most pronounced S1-S2 dew margin asymmetry. These results indicate that, under the observed winter conditions, the microclimatic difference between the eastern and western compartments was insufficient to produce systematic operational decoupling of the two ventilation zones. The asynchronous zonal strategy nevertheless provided the control infrastructure for independent response, which may become more relevant under more contrasted lateral humidity conditions.

No leaf wetness events were detected at canopy level during Phase II, consistent with the results of Phase I and confirming the biological effectiveness of the control approach across both experimental configurations (Table 1, Table 2).

***Late-phase lateral asymmetry (24 February - 3 March 2026)***

Towards the end of Phase II, a progressive and sustained lateral asymmetry became evident between the eastern (S1) and western (S2) compartments (Figure 8). During the period 24 February - 3 March 2026, sensor S2 consistently recorded higher dew margin values than S1, with peak nocturnal differences exceeding 6°C. Both zones retained the characteristic diurnal pattern of low nocturnal margins and elevated daytime values driven by solar gain, yet the intensity of nocturnal condensation risk diverged substantially between compartments.

A probable contributing factor is differential irrigation between the two zones: higher water application in the eastern compartment would elevate local vapour pressure and reduce the dew margin independently of fan state, while the western zone - receiving less irrigation - maintained a consistently higher safety margin. This observation directly demonstrates the

agronomic value of asynchronous zonal control: Vent1, driven by S1, operated at higher activation frequency during this period, while Vent2, driven by S2, ran at reduced duty - delivering localised energy efficiency without compromising condensation prevention in the higher-risk eastern zone. This dynamic would be unachievable under the synchronised strategy of Phase I.

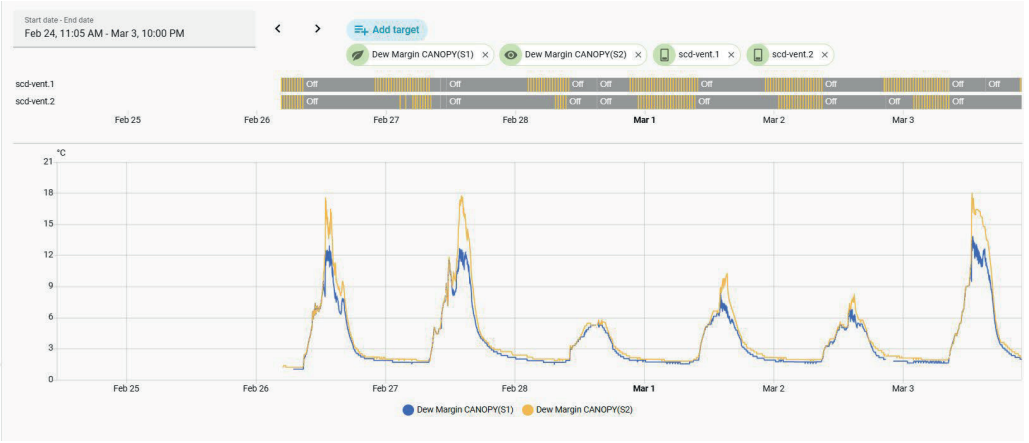

Figure 8. Canopy dew margin for S1 (East, blue) and S2 (West, yellow) during the final period of Phase II (24 February - 3 March 2026), with asynchronous ventilator activation states shown in the upper panel. A progressive lateral asymmetry is visible from 26 February onward, with S2 consistently exceeding S1 during nocturnal risk periods. The divergence is consistent with differential irrigation practices between compartments and illustrates the operational relevance of independent zonal control

Table 1. Summary statistics of canopy dew margin (ΔT, °C) for Sensor S1 (East, 170 cm) and Sensor S2 (West, 170 cm) during Phase I and Phase II

| Parameter | Phase I S1 (East) | Phase I S2 (West) | Phase II S1 (East) | Phase II S2 (West) |

[2] Near-zero standard deviation confirms fully deterministic synchronized operation in Phase I. [3] Synchronised operation in Phase I makes individual correlation analysis redundant — both units operated identically by design.

The results demonstrate that internal air recirculation, driven by canopy-level dew margin indicators, effectively prevented plant-level condensation throughout the monitoring period. The complete absence of leaf wetness events at canopy level - despite multiple nocturnal intervals of critical proximity - supports the central hypothesis that canopy-oriented control provides biologically relevant protection even when envelope condensation remains unavoidable. This distinction between structural and canopy condensation is consistent with Piscia et al. (2012) and Boulard et al. (2004), who showed that leaf boundary-layer humidity can differ substantially from bulk greenhouse air. The use of dew margin as a control variable proved essential in this context: RH values consistently exceeded 85–90% throughout the monitoring period, yet canopy condensation did not occur, illustrating the well-documented limitation of RH thresholds for site-specific condensation risk assessment (Wang et al., 2019).

The persistent lateral S1-S2 asymmetry, observed in both phases, is consistent with the broader literature emphasising that spatial heterogeneity may persist even in actively mixed greenhouses, and that stagnant zones can remain localised condensation hotspots independent of bulk conditions (Bournet and Boulard, 2010; Gao et al., 2024). Although Phase II produced high operational synchrony between ventilation units (r = 0.856), this reflects the relatively moderate lateral contrast observed during the specific monitoring period rather than a failure of the zonal architecture. The asynchronous configuration provides the control infrastructure for independent zonal response, which may become operationally decisive under more contrasted humidity conditions - for instance, following differential irrigation events or under asymmetric solar radiation patterns.

From an energy perspective, the recirculation system operated at duty cycles of 19.0% (Phase I) and 17.5% (Phase II), corresponding to a mean daily energy consumption of approximately 3.6-3.7 kWh for recirculation alone - a modest fraction of the thermal energy that would have been required for equivalent dehumidification through external ventilation under the same conditions (Maslak & Nimmermark, 2017; Amani et al., 2020). The adaptive three-regime control strategy ensured that fan operation was restricted to periods of genuine microclimatic need, contributing to the relatively low overall duty cycle.

Several limitations must be acknowledged. The absence of a concurrent unventilated control treatment prevents direct causal attribution of condensation prevention to the recirculation system, and the inter-phase comparison was confounded by differences in external thermal conditions between the two monitoring periods. The Mann-Whitney comparison between phases did not reach statistical significance ($p > 0.20$), meaning that the observed numerical differences in dew margin cannot be unambiguously attributed to the change in control strategy rather than to more favourable meteorological conditions. Air velocity measurements were also limited to two positions and a single session, precluding full characterisation of the three-dimensional airflow field. Despite these limitations, the study contributes a reproducible, low-cost methodology for preventive condensation-risk management based on distributed dew point monitoring and threshold-driven recirculation, integrated within a unified Home Assistant and InfluxDB infrastructure replicable without specialised instrumentation.

## CONCLUSIONS

Internal air recirculation driven by canopy dew margin indicators successfully prevented plant-level condensation in a passive double-layer solar greenhouse throughout the winter monitoring period, with zero leaf wetness events recorded at canopy level despite persistent nocturnal condensation on structural surfaces.

The dew margin indicator proved more operationally discriminating than relative humidity alone for condensation risk control, enabling the system to maintain biologically safe canopy conditions even when bulk RH consistently exceeded 85-90%.

A persistent lateral microclimate asymmetry between the eastern and western compartments was identified in both experimental phases, providing experimental justification for the asynchronous zonal control architecture, even though operational decoupling between ventilation units remained limited under the observed meteorological conditions.

The recirculation system operated at duty cycles of 17-19% of total monitoring time, with mean daily runtimes of 4.2-4.6 h day$^{-1}$, confirming that the energy cost of internal mixing is modest compared to equivalent dehumidification through external ventilation.

The integrated monitoring and control framework - combining distributed dew point sensing, adaptive threshold-based automation, and continuous time-series archiving - represents a reproducible methodology applicable to other passive greenhouse contexts without specialised instrumentation.

***Abstract***

*Accurate prediction of soil–structure interaction is essential for the safe design of deep excavations in urban environments. This paper presents a three-dimensional numerical investigation assessing the influence of different soil constitutive models on the predicted behavior of a deep excavation. Finite element analyses were carried out using the Mohr–Coulomb (MC), Hardening Soil (HS), and Hardening Soil with Small-Strain Stiffness (HSS) models, applied to a real excavation case supported by retaining walls. The comparative study focuses on excavation-induced stress redistribution and horizontal wall deformations. The results indicate that the MC and HS models overestimate wall deformations, whereas the HSS model offers a significantly improved prediction due to its ability to capture soil stiffness at small strain levels. The study confirms that incorporating small-strain stiffness is critical for realistic deformation assessment and reliable design of deep excavations.*

***Key words****: constitutive model, deep excavation, MEF.*

## INTRODUCTION

Due to the continuous development of urban areas, it is necessary to choose modern solutions for carrying out new buildings. At present, vertical development of civil buildings is preferred, including a significant number of underground levels that require deep excavations in the vicinity of existing structures, without affecting their functionality. Thus, to analyse the behaviour of the retaining structure, the finite element method (FEM) is often used. In order to obtain the best results, consistent with reality, it is necessary to have a good understanding of the calculation method, the constitutive models used to model different soil types or structural elements, the mesh distribution, the calculation phases, and to consider the effects of the assumptions made.

The choice of constitutive model has a decisive influence on the predicted response of deep excavations, and this has been the subject of numerous comparative studies. Although the linear elastic–perfectly plastic Mohr-Coulomb model remains widely used in practice for its simplicity, it is generally recognised as inadequate for serviceability predictions, since it cannot reproduce the stress-dependent stiffness of soils or their markedly higher stiffness at small strains (Obrzud, 2010). The Hardening Soil model (Schanz et al., 1999) introduced a stress-dependent stiffness and a clear distinction between primary loading and unloading/reloading, while its extension to small strains (Benz, 2007) additionally captures the non-linear decay of stiffness from the very small-strain shear modulus. Comparative analyses of braced and anchored excavations have repeatedly shown that the Mohr-Coulomb model tends to overestimate wall deflections and to predict an unrealistic ground heave behind the wall, whereas the Hardening Soil model and, in particular, the Hardening Soil with small-strain stiffness model reproduce field-measured wall displacements far more closely (Lim et al., 2010; Teo & Wong, 2012; Dahal et al., 2024). Similar conclusions were reached by Herold & von Wolffersdorff (2009), who back-calculated two instrumented large-scale geosynthetic-reinforced earth structures and found that the HSsmall model almost exactly matched the measured horizontal displacements, while the Mohr-Coulomb model deviated clearly, over-predicting displacements at low surcharge and under-predicting them at high surcharge. The HSsmall model has likewise been applied

successfully to the probabilistic assessment of diaphragm walls (Kawa et al., 2021). These findings motivate the present comparative study, in which the three constitutive models are applied to the same real deep excavation supported by a diaphragm wall.

The Mohr-Coulomb (MC) constitutive model is a linear elastic perfectly - plastic model often used due to the small number of the required parameters and the ease with which they can be determined.

In the elastic domain, the model shows linear behavior based on Hooke's Law, defined by two parameters: Young's modulus (E), and Poisson's ratio (ν). In the plastic domain, the failure criterion is defined by two parameters: the internal friction angle (ϕ), and cohesion (c), also known as the shear resistance parameters. Additionally, the dilatancy angle (ψ) is used to describe the plastic volumetric strain variation.

According to the Mohr-Coulomb constitutive model, the soil will reach failure in shear, along an arbitrary plane when, due to the applied loads, the tangential stress is in a linear relationship with the normal stress, which is unique for each type of soil. Also, it is based on the use of the stress state at a point (Figure 1), that is, from a graphical point of view, the use of the Mohr circle. This circle represents all possible stress states (σ, τ) at a point when any plane with any orientation passing through that point is considered (Șerbulea, 2013).

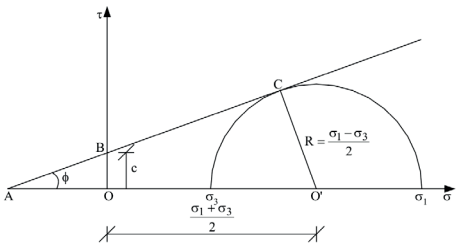

Figure 1. Stress state tangent to the intrinsic line (Șerbulea, 2013)

The equation that describes the Mohr-Coulomb failure criterion is given by:

$$\tau = \sigma \tan(\phi) + c$$

where τ is the tangential stress and σ is the normal stress.

If the pore water pressure is known, the effective shear strength parameters can be calculated:

$$\tau = \sigma' \tan(\phi') + c'$$

In the three-dimensional space of principal stresses, $\sigma_1 - \sigma_2 - \sigma_3$, the Mohr-Coulomb failure criterion is represented as a pyramid with a hexagonal base (Figure 2), whose axis lies along the trisectors $\sigma_1 = \sigma_2 = \sigma_3$.

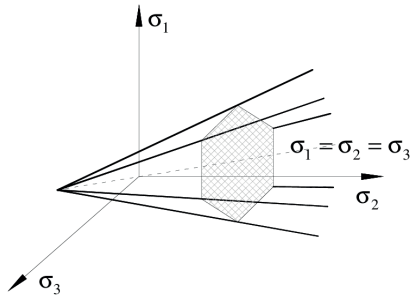

Figure 2. Mohr-Coulomb representation in the space of principal stresses (Popa & Batali, 2010)

In the space of principal stresses, a stress state will not result in failure as long as it remains inside the surface (Șerbulea, 2013).

The Hardening Soil (HS) model is an advanced constitutive model for representing the nonlinear-elastic-plastic behavior of soils, suitable for both soft and stiff soil types (Schanz et al., 1999).

When subjected to a deviatoric stress, soil exhibits a decrease in stiffness and simultaneously undergoes plastic deformations. The relationship between deviatoric stress and axial strain is most readily observed in a triaxial compression test and can be approximated by a hyperbolic curve (Figure 3) (Brinkgreve et al., 2023).

The principal characteristics of the nonlinear Hardening Soil constitutive model are:

- Stiffness depends on the stress, as defined by the parameter $m$;
- Plastic straining due to primary deviatoric loading, represented by the parameter $E_{50}^{ref}$ (secant stiffness in a standard drained triaxial test);
- Plastic straining due to primary compression, represented by the parameter $E_{oed}^{ref}$ (tangent stiffness for primary oedometer loading);
- Elastic unloading/reloading, represented by the parameters $E_{ur}^{ref}$ (unloading/reloading stiffness) and $\nu_{ur}$ (Poisson's ratio for unloading/reloading);
- The failure criterion used is Mohr-Coulomb,

characterized by the parameters ϕ, c, and ψ (Brinkgreve et al., 2023).

A basic concept of the model is the hyperbolic relationship between the vertical strain, $\varepsilon_1$, and the deviatoric stress, $q$.

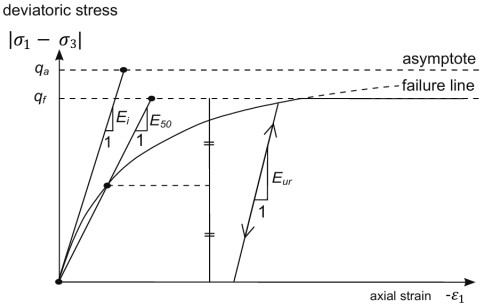

Figure 3. The hyperbolic stress-strain relationship resulting from the drained triaxial test (Brinkgreve et al., 2023)

The advantage of the Hardening Soil model lies not only in the use of a hyperbolic stress-strain curve instead of a bilinear curve, as in the Mohr-Coulomb model, but also in the stress-dependent stiffness of the soil. In the Mohr-Coulomb model, a fixed value of the Young's modulus is used, whereas in reality this value depends on the magnitude of the stress (Brinkgreve et al., 2023).

The Hardening Soil constitutive model assumes elastic behavior during unloading and reloading. However, the strain range within which soil can be considered elastic is very small. With increasing strain, the shear stiffness of the soil decreases in a nonlinear manner.

Figure 4 shows the variation of the soil stiffness with shear strain.

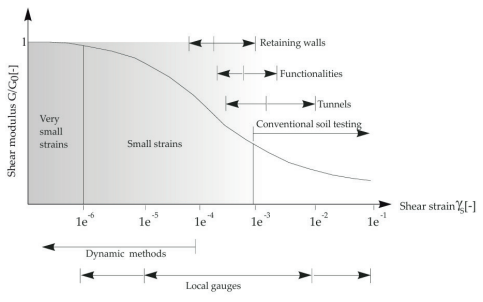

Figure 4. Hardening Soil with small strain model stiffness - strain behavior of soil (Brinkgreve et al., 2023)

The characteristics shear strains that can be measured near geotechnical structures, as well as the strain range applicable in laboratory tests, are also represented. It can be observed that, for the minimum strains that can be measured in laboratory tests, the soil stiffness decreases to about half of its initial value (Brinkgreve et al., 2023).

Compared to the Hardening Soil model, the Hardening Soil with small strain (HSSS) model assumes the use of additional parameters (Benz, 2007):

- The reference shear modulus at very small strains ($\varepsilon < 10^{-6}$), $G_0^{ref}$;
- The shear strain corresponding to 70% of the value of $G_0^{ref}$, $\gamma_{0.7}$.

## MATERIALS AND METHODS

For this study, in order to compare the three constitutive models descried above, the 3D finite element method was used. Thus, the same case study was modelled using the Mohr-Coulomb, Hardening Soil and the Hardening Soil with small strain models. The numerical modelling was carried out using Plaxis 3D software.

The case study project is located in the city of Timișoara, Romania. It is a building with two basements and three stories above the ground. Therefore, an excavation depth of 6.80 m is required to construct the two basements' levels. The retaining structure solution consists of a diaphragm wall with a thickness of 0.45 m and a depth of 11.00 m (Figure 5). At the top of the diaphragm wall, a capping beam with a height of 0.45 m and a width of 0.60 m is provided.

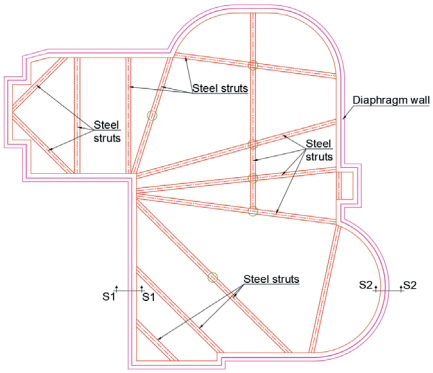

Figure 5. Layout of the excavation site

To limit the lateral displacements of the diaphragm wall, one level of bracing struts was used. The bracing strut system consists of circular steel hollow sections with a diameter of 610 mm and a thickness of 10 mm, spaced at approximately 6 m intervals, installed at a depth of 2.00 m.

In the three - dimensional finite element software, the diaphragm wall was modelled as plate elements, the capping beam as beam elements, and the steel struts as node-to-node anchors. The linear elastic constitutive model was used for both diaphragm wall and capping beam. Thus, the concrete modulus of elasticity is $3.1 \cdot 10^7$kPa, the Poisson's ratio is 0.2 and the unit weight is 25kN/m$^3$.

The site investigations consist of four geotechnical boreholes with a maximum depth of 22.00m and four light dynamic penetration tests (DPM) with a maximum depth of 15.00m. Based on these in situ investigations and the results of the laboratory tests, the soil stratigraphy and parameters are presented in Figure 6, Table 1 and Table 2.

Table 1. Soil stratigraphy

| Soil layer | Depth [m] | Soil layer description |
|---|---|---|
| 1 | 0.00÷ -0.70/2.10 | Fill composed of construction debris mixed with clay, sand and gravel |
| 2 | -0.70/-2.10÷ -2.30/2.70 | Clay to sandy silty clay, grey, with reddish intercalation, stiff. |
| 3 | -2.30/2.70÷ -7.00/10.10 | Fine sand to silty sand, grey, loose to medium dense toward the base of the layer. |
| 4 | -7.00/10.10÷ -11.10/12.30 | Clay to silty clay, greyish-green, with yellowish intercalations, stiff. |
| 5 | -11.10/12.30÷ -22.00 | Sand to silty sand, grey, dense. |

Table 2. Soil parameters used in the numerical analysis

| Soil type | $\Gamma$ | $\gamma_{sat}$ | $E_{50}^{ref}$ | $E_{oed}^{ref}$ | $E_{ur}^{ref}$ | $\nu_{ur}$ | c' | $\phi$' | $G_0$ | $\gamma_{0.7}$ | $R_{inter}$ |

$\gamma$ - Unit weight; $\gamma_{sat}$ - Saturated unit weight; $E_{50}^{ref}$ - Secant stiffness in standard drained triaxial test; $E_{oed}^{ref}$ - Tangent stiffness for primary oedometer loading; $E_{ur}^{ref}$ - Unloading/reloading stiffness; $\nu_{ur}$ - Poisson's ratio for unloading-reloading; c' - Effective cohesion; $\phi$' - Effective angle of internal friction; $G_0$ - Shear modulus at very small strains; $\gamma_{0.7}$ - Shear strain corresponding to 70% of the value of $G_0$; $R_{inter}$ - Strength reduction factor.

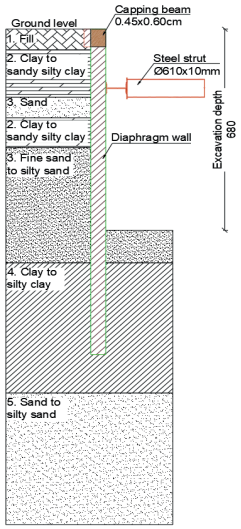

Figure 6. Construction phases and soil stratigraphy

The soil parameters required for the HSSS model were determined based on field investigations.

The finite element calculation phases, which correspond to the in-situ execution stages, are:

- Generation of the initial stress state;
- Installation of the diaphragm wall and the capping beam;
- Lowering of the groundwater level;
- Excavate to 3.00 m below the ground level;
- Installation of the bracing strut level;
- Excavation to the final depth of 6.80 m;
- Execution of the raft foundation and the slab over the second basement.

In order to perform finite element calculations, the numerical model was discretized into finite elements using a fine mesh.

## RESULTS AND DISCUSSIONS

### The lateral displacements of the retaining structure

Figure 7 shows the lateral displacement diagrams of the diaphragm wall for Section 1 (S1-S1), for the three constitutive models considered: Mohr-Coulomb, Hardening Soil and Hardening Soil with Small Strain. Figure 8 shows the lateral displacement diagrams for Section 2 (S2-S2), which is located in the circular area of the diaphragm wall. The two sections were selected based on the maximum stress values, lateral displacements, and the in-plan configuration of the diaphragm wall.

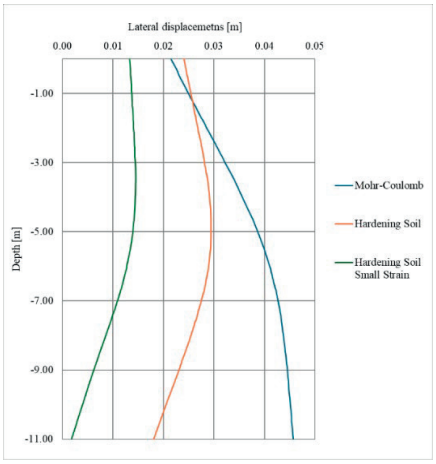

Figure 7. Lateral displacements of the retaining structure, Section 1

For both sections, the lateral displacement diagrams show that the Mohr-Coulomb constitutive model leads to the maximum lateral displacements of the retaining structure, while the minimum values are obtained when using the Hardening Soil with Small Strain constitutive model. In the case of the Mohr-Coulomb constitutive model, the maximum lateral displacement occurs in the lower part of the retaining structure, whereas for the other two constitutive models, it occurs in the upper part of the diaphragm wall. When comparing the Hardening Soil and Hardening Soil with Small Strain models, the latter results in a maximum lateral displacement that is approximately half of that obtained using the former model.

The differences between the two analysed sections are due to the in-plan shape of the retaining structure. Thus, for Section 2 (S2-S2), the lateral displacements are smaller than those in Section 1 (S1-S1), due to the circular shape of the diaphragm in this area and the resulting arching effect.

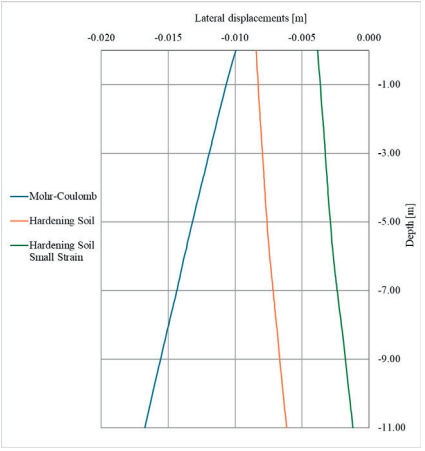

Figure 8. Lateral displacements of the retaining structure, Section 2

### The bending moment of the retaining structure

Figure 9 and Figure10 shows the bending moment diagrams of the retaining structure for the three analysed constitutive models and the two section, S1-S1 and S2-S2.

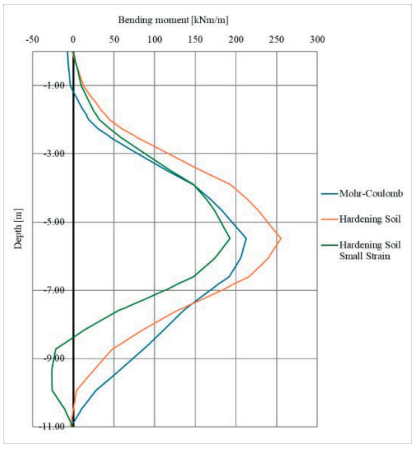

Figure 9. Bending moment diagrams - Section 1

In the case of Section 1 (S1-S1), where the diaphragm wall has a linear in-plan shape, the maximum bending moment occurs for the Hardening Soil constitutive model, while the

minimum value is obtained when the Hardening Soil with Small Strain model is used. For all constitutive models, the bending moment diagrams have a similar shape, and the maximum values occur at approximately the same depth, close to the final excavation depth.

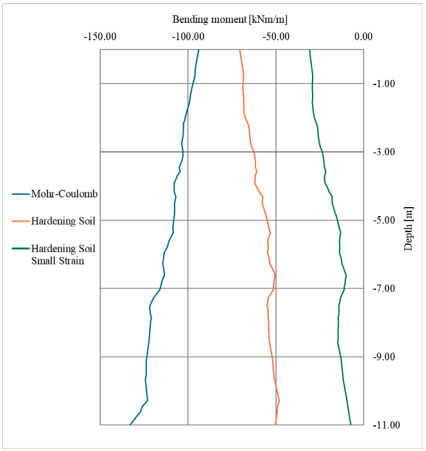

Figure 10. Bending moment diagrams - Section 2

In the case of Section 2 (S2-S2), where the diaphragm wall has a circular in-plan shape, the maximum bending moment occurs for the Mohr-Coulomb constitutive model, while the minimum value is obtained for the Hardening Soil with Small Strain model, similar to Section 1. Unlike Section 1, the maximum bending moment in Section 2 occurs in the upper part of the diaphragm wall for both the Hardening Soil and Hardening Soil with Small Strain models, and in the lower part of the retaining structure when the Mohr-Coulomb model is used.

In general, regardless of the constitutive model used, the maximum bending moments are smaller for Section 2 than for Section 1 due to the arching effect.

## CONCLUSIONS

This paper presents a comparative study on the influence of the constitutive models used to simulate soil behavior. Three-dimensional finite element numerical models were developed for the same project using the Mohr-Coulomb, Hardening Soil and Hardening Soil with Small Strain constitutive models.

While the soil parameters required for the Mohr-Coulomb constitutive model can generally be determined from conventional geotechnical investigations and standard laboratory tests, the Hardening Soil model, and especially the Hardening Soil with small strain model, require more advanced in-situ and laboratory testing. The findings of this study demonstrate that the enhanced complexity of the Hardening Soil with small strain model leads to a more realistic representation of the retaining structure behavior compared to simpler constitutive models, regardless of the structure's in-plan configuration.

***Abstract***

*Grouting materials used in geothermal boreholes represent a key component in the efficient operation of ground source heat pump (GSHP) systems, as they simultaneously control heat transfer between the borehole heat exchanger and the surrounding geological formation while ensuring hydraulic sealing of the annular space between the pipes and the borehole wall. The thermo-hydraulic and mechanical performance of these materials directly influences the long-term energy efficiency of geothermal systems and contributes to groundwater protection by limiting vertical fluid migration between permeable geological layers intersected by the borehole. In this context, the present study presents a laboratory-based experimental program aimed at evaluating the thermal and mechanical performance of water-based grout mixtures composed of mineral binders and clay additives (bentonite), with controlled variation of the granular fraction (sand) and bentonite content. The research investigates the relationships between material composition, microstructural characteristics and the physical-mechanical properties relevant for geothermal applications. The experimental methodology includes the determination of thermal conductivity, saturated hydraulic permeability, uniaxial compressive strength and shrinkage or segregation behaviour, complemented by the analysis of rheological characteristics such as injectability and mixture stability under installation conditions. The results highlight the inherent trade-off between enhancing thermal conductivity through the introduction of granular materials and maintaining effective hydraulic sealing by reducing permeability and controlling pore structure. The findings contribute to the development of technical recommendations for optimizing grout formulations used in geothermal boreholes, with the aim of improving heat transfer efficiency, ensuring mechanical integrity and protecting groundwater resources in geothermal systems designed for nearly zero-energy buildings (NZEB).*

***Key words****: environmental sustainability, grouting materials, nearly zero-energy buildings (nzeb), thermal conductivity.*

## INTRODUCTION

The transition towards low-carbon and energy-efficient buildings has increased interest in shallow geothermal energy systems as reliable renewable technologies for heating and cooling applications. Ground source heat pump (GSHP) systems are recognised as effective solutions for reducing primary energy consumption and greenhouse gas emissions while supporting building decarbonisation strategies (Lund & Toth, 2020; Mahmoud et al., 2021).

Vertical borehole heat exchangers (BHEs) are widely used in densely urbanised areas where available land is limited. The thermal performance of these systems depends on the combined properties of the geological formation, the heat exchanger pipes and the material filling the annular space between the pipes and the borehole wall (Spitler & Gehlin, 2015; Albers et al., 2024).

The annular backfill material, commonly referred to as grout, performs multiple functions within a geothermal borehole. In addition to providing mechanical stability and hydraulic sealing, grout establishes thermal contact between the heat exchanger and the surrounding ground, thereby influencing borehole thermal resistance and overall system efficiency (IEEE Standards Association, 2017; Albers et al., 2024). Consequently, geothermal grout design requires balancing thermal conductivity, hydraulic performance and mechanical strength.

Commercial geothermal grouts are typically composed of cement, bentonite and mineral aggregates. Previous studies have shown that increasing the proportion of thermally

conductive granular materials, particularly quartz sand, can improve heat transfer efficiency, whereas higher bentonite contents generally enhance sealing performance but may reduce thermal conductivity (Borinaga-Treviño et al., 2013; Mahmoud et al., 2021; Mascarin et al., 2022; Nakládal et al., 2024).

In this context, the experimental evaluation of geothermal grout formulations remains essential for identifying compositions capable of simultaneously providing efficient heat transfer, low permeability and adequate mechanical strength. The present study investigates fourteen grout formulations containing different proportions of cement, bentonite and quartz sand in order to evaluate the relationships between composition, thermal conductivity, hydraulic permeability and uniaxial compressive strength. The results contribute to the identification of compositional trends governing the trade-off between thermal performance, sealing capacity and mechanical resistance in geothermal grouting materials.

## GEOTHERMAL DRILLING TECHNOLOGY

Closed-loop shallow geothermal systems provide an efficient solution for harnessing thermal energy from the subsurface and are widely used in residential, commercial, and industrial applications. Heat transfer is achieved through a closed hydraulic circuit in which the heat transfer fluid circulates in buried pipes without direct interaction with groundwater, thereby reducing hydrogeological risks and ensuring stable long-term operation (Borinaga-Treviño et al., 2013).

The most common configuration is represented by vertical borehole heat exchangers (BHEs), which are constructed through boreholes typically 50 to 200 m deep, with high-density polyethylene (HDPE) pipes installed in a double U-tube configuration. The circulating heat transfer fluid exchanges heat with the surrounding ground, taking advantage of the thermal stability of the subsurface (Spitler & Gehlin, 2015).

A key component of the system is the material used to fill the annular space between the borehole wall and the pipes, known as the grout. This material directly influences the thermal resistance of the borehole and plays a dual role in providing mechanical stability and hydraulic sealing, as well as providing effective thermal coupling between the heat exchanger and the surrounding ground. Consequently, the thermal and structural properties of the grout are critical to the overall efficiency of the system (Albers et al., 2024).

From a design perspective, the thermal performance of a geothermal borehole is determined by the total thermal resistance of the system, which includes contributions from the surrounding ground, pipes, and grout. Reducing the thermal resistance of the grout layer is therefore a key objective in improving system efficiency.

At the same time, the grout must have low permeability to prevent vertical migration of groundwater, which requires careful optimization of the material composition (Spitler & Gehlin, 2015; IEEE, 2017).

The design and construction of geothermal wells must take into account the local geological and hydrogeological conditions, including the thermal conductivity of the ground, the stratigraphic structure, the presence of groundwater, and the stability of the borehole walls. These factors affect both the technical feasibility and the long-term performance of the system.

The design and construction of geothermal wells must take into account the local geological and hydrogeological conditions, including the thermal conductivity of the ground, the stratigraphic structure, the presence of groundwater, and the stability of the borehole walls. These factors affect both the technical feasibility and the long-term performance of the system.

## MATERIALS AND METHODS

Standardized sand was used for sample preparation in accordance with EN 196-1:2016, which specifies the particle size distribution for cement mortars. The particle size distribution corresponds to that defined in Table 1 of the standard, without using alternative gradations, in order to ensure the repeatability of the test and to isolate the influence of the active components in the presence of water.

The hydraulic binder used consisted of high early strength Portland cement (CEM II/A 42.5R) and sodium bentonite. The mixing water was potable water used under controlled laboratory conditions.

Unlike conventional grout studies based on a constant aggregate-to-binder ratio, the present experimental program intentionally varied the proportions of quartz sand, cement and bentonite in order to evaluate their influence on thermal conductivity, hydraulic permeability and mechanical strength across a broad compositional domain representative of geothermal grouting materials.

Sand acts as an inert component and does not participate in hydration processes. Its primary function is to provide structural stability to the material and to facilitate heat transfer through solid-solid contact. By maintaining a constant sand content, the influence of the interaction between cement and bentonite on the material behaviour can be clearly evaluated.

Table 1. Composition of the grout formulations analyzed

| Grout mix | w/s [-] | Sand [%] | Cement [%] | Bentonite [%] |
|---|---|---|---|---|
| R1 | 1.82 | 40 | 45 | 15 |
| R2 | 1.23 | 9 | 55 | 36 |
| R3 | 0.91 | 18 | 50 | 32 |
| R4 | 0.82 | 27 | 45 | 27 |
| R5 | 0.68 | 36 | 41 | 23 |
| R6 | 0.59 | 45 | 36 | 18 |
| R7 | 1.64 | 80 | 10 | 10 |
| R8 | 0.50 | 70 | 20 | 10 |
| R9 | 0.50 | 70 | 15 | 15 |
| R10 | 0.65 | 70 | 10 | 20 |
| R11 | 0.35 | 70 | 25 | 5 |
| R12 | 0.56 | 65 | 20 | 15 |
| R13 | 0.60 | 65 | 15 | 20 |
| R14 | 0.60 | 65 | 25 | 10 |

The investigated formulations were designed to cover a broad compositional domain representative of geothermal grouting materials used in borehole heat exchanger applications. The experimental matrix was intentionally developed to explore the interactions between three functional constituents: cement, responsible for mechanical integrity; bentonite, responsible for hydraulic sealing and mixture stability; and quartz sand, acting as a thermally conductive granular skeleton. The selected formulations do not represent optimized commercial products but experimental compositions covering low, intermediate and high contents of each component in order to identify the relationships between composition, thermal conductivity, permeability and compressive strength.

Formulation R7, characterized by an unusually high sand content (80%), was intentionally included as a boundary composition to investigate the maximum thermal conductivity that could be achieved within the tested material system. Although such compositions may present practical limitations regarding injectability and field applicability, they provide valuable information regarding the upper thermal performance limit associated with granular enrichment.

**Mix preparation**

The mixes were prepared under laboratory conditions using a methodology closely related to field practice. In contrast to procedures involving prehydration of bentonite, all dry components (sand, cement and bentonite) were mixed first and then water was added.

This approach makes it possible to reproduce real-life conditions and reduce preparation time, while maintaining an adequate level of mix homogeneity.

The fresh mix was poured into cylindrical plastic molds with a diameter of 50 mm and a height of 100 mm. The specimens were saturated and tested after 28 days to ensure full development of mechanical properties.

**Thermal test procedure**

The thermal properties of grout materials were determined using the transient line source (TLS) thermal needle method, which is widely used to measure the thermal resistivity and thermal conductivity of soils and geothermal well pack materials. This technique is standardized by IEEE Std 442™-2017 and ASTM D5334 (IEEE, 2017; ASTM D5334, 2022).

The method is based on the application of a controlled thermal pulse generated by a linear probe that functions simultaneously as a heat source and a temperature sensor. The temperature rise recorded over time is used to determine thermal properties through analytical modeling based on the theory of transient heat diffusion.

Thermal resistivity (ρ) is calculated using the following relationship:

$$\rho = \frac{4\pi(T_2 - T_1)}{q \cdot \ln\left(\frac{t_2}{t_1}\right)}$$

where $T_1$ and $T_2$ are the temperatures measured at times $t_1$ and $t_2$, respectively, and $q$ represents the heat input per unit length.

To ensure the accuracy of the results, the data were filtered to exclude time intervals characterized by non-linear behaviour, associated with transient and boundary effects. The analysis was performed by plotting the temperature as a function of the logarithm of time, taking into account only the linear part of the curve.

The following relationship was used to determine the thermal conductivity:

$$\lambda = \frac{1}{\rho}$$

For each sample, a controlled pre-drilling was performed to allow the insertion of the thermal probe, ensuring uniform contact between the probe and the material.

**Mechanical and hydraulic testing**

The permeability coefficient was determined using the constant head permeameter method, which is suitable for low permeability materials.

The uniaxial compressive strength was determined according to EN ISO 17892-7:2018 using standard cylindrical specimens.

For each grout formulation, three independent determinations were made for each type of test and the values reported represent the arithmetic mean of the results, ensuring the reproductibility and statistical reliability of the data.

## RESULTS AND DISCUSSIONS

The ternary plots were constructed considering only the solid constituents (sand–cement–bentonite), normalized to 100%. The water-to-solid ratio was treated as an independent parameter and therefore not included in the ternary representation.

**Presentation of experimental data**

The experimental results obtained for the 14 grout formulations are summarized in Table 2 in relation to the compositions presented in Table 1. The parameters determined include the permeability coefficient (k), the uniaxial compressive strength (Cu), the thermal conductivity (λ) and the thermal resistivity (ρ).

Table 2. Hydromechanical and Thermal Properties of the Formulations Analyzed

| Grout mix | k [cm/s] | Cu [kPa] | λ [W/mK] | ρ [mK/W] |
|---|---|---|---|---|
| R1 | 1.44E-09 | 3248 | 1.292 | 0.774 |
| R2 | 6.30E-08 | 1126 | 0.914 | 1.095 |
| R3 | 4.82E-08 | 1505 | 0.966 | 1.036 |
| R4 | 2.97E-08 | 1884 | 1.012 | 0.988 |
| R5 | 2.70E-08 | 1974 | 1.105 | 0.905 |
| R6 | 1.47E-08 | 2047 | 1.201 | 0.833 |
| R7 | 1.22E-08 | 1955 | 1.901 | 0.526 |
| R8 | 3.52E-08 | 626 | 1.468 | 0.681 |
| R9 | 4.49E-08 | 786 | 1.509 | 0.663 |
| R10 | 6.51E-08 | 317 | 1.413 | 0.708 |
| R11 | 3.54E-08 | 1719 | 1.744 | 0.573 |
| R12 | 8.42E-08 | 893 | 1.442 | 0.694 |
| R13 | 1.23E-08 | 744 | 1.482 | 0.675 |
| R14 | 2.97E-08 | 2000 | 1.624 | 0.616 |

The data show significant variation between formulations, reflecting the influence of composition on material properties. The thermal conductivity ranges from 0.9135 to 1.9005 W/mK, the permeability coefficient from 1.44×10-⁹ to 8.42×10-⁸ cm/s, and the mechanical strength from 316.9 to 3248.2 kPa.

**Thermal conductivity**

The thermal conductivity values show a wide variation among the mixes analyzed (Figure 1). Higher values are observed for mixes characterized by a higher sand content (e.g. Mix 7), while lower values are associated with mixes containing higher proportions of bentonite (e.g. Mix 2).

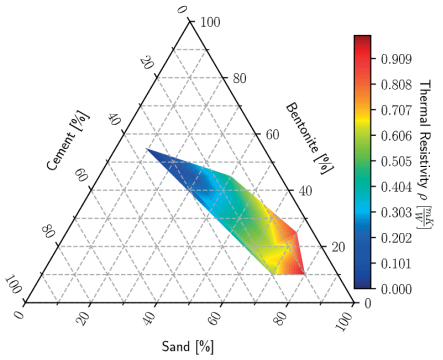

Figure 1. Variation of thermal conductivity for the analysed grout mixes

**Permeability**

The permeability coefficient varies by about one order of magnitude (Figure 2). The lowest values are associated with mixes containing a higher proportion of fines (cement and bentonite), while higher values are observed in mixes with a predominantly granular structure.

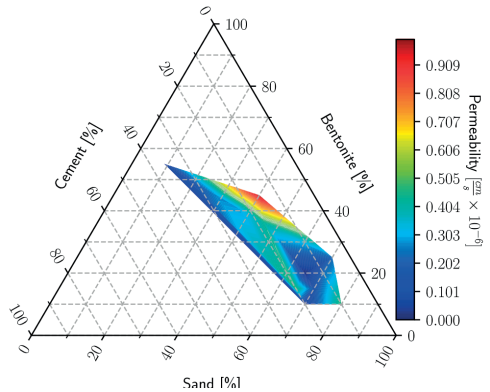

Figure 2. Variation of the coefficient of permeability (logarithmic scale)

**Mechanical strength**

The uniaxial compressive strength shows significant variation among the mixes analyzed (Figure 3). The highest values are recorded for mixes with higher cement content (e.g. Mix 1), while the lowest values correspond to mixes with reduced binder content.

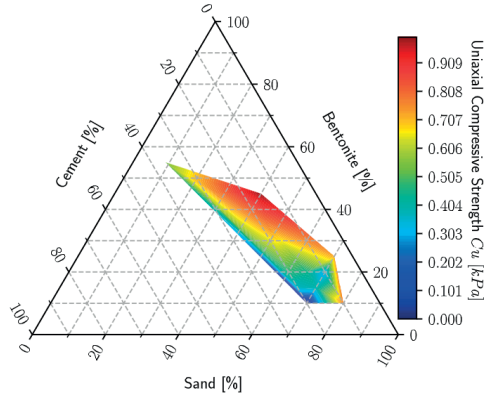

Figure 3. Variation of uniaxial compressive strength

Thermal conductivity–permeability relationship is presented in Figure 4.

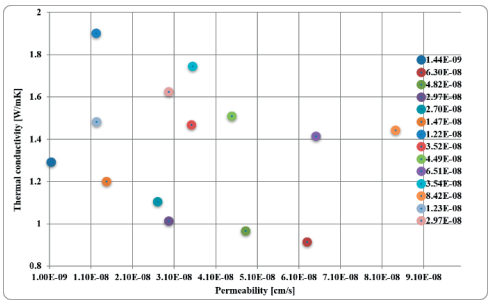

Figure 4. Relationship between thermal conductivity and permeability

The comparative analysis shows simultaneous variations in thermal conductivity and permeability among the analyzed mixes, suggesting that composition has a direct influence on both parameters.

## CONCLUSIONS

The experimental investigation of fourteen geothermal grout formulations demonstrated that the thermal, hydraulic and mechanical behaviour of grouting materials is strongly influenced by the relative proportions of quartz sand, cement and bentonite.

Thermal conductivity increased with increasing sand content, reaching a maximum value of 1.901 W/mK for formulation R7, while higher bentonite contents generally reduced thermal performance. Conversely, increasing the proportions of cement and bentonite improved hydraulic sealing by reducing permeability and contributed to the development of a more mechanically stable matrix.

The results confirm that thermal conductivity, permeability and compressive strength are governed by different physical mechanisms and cannot be simultaneously maximised. Consequently, geothermal grout design requires balancing thermal performance, hydraulic sealing capacity and mechanical resistance.

The ternary analysis provided a useful representation of the investigated compositional domain and enabled the identification of performance trends across the sand–cement–bentonite system. Higher sand contents were associated with improved thermal conductivity, whereas higher cement

and bentonite contents promoted lower permeability and greater mechanical stability.

Overall, the investigated formulations should be regarded as a compositional framework for evaluating performance trade-offs rather than as isolated mixtures. In particular, formulation R7 represents a boundary composition defining the upper thermal conductivity limit of the investigated system.

Future research should focus on the incorporation of thermally conductive additives and industrial by-products, long-term durability under thermal cycling, and the coupled thermo-hydro-mechanical behaviour of geothermal grouts under representative operating conditions.

## ACKNOWLEDGEMENTS

This work was supported by the research grant "Evaluation of the Thermal Conductivity of Soil and Grouting Material in Geothermal Wells" (GeoThermo), awarded to the authors by the Technical University of Civil Engineering of Bucharest, within the ARUST2024 research program.

***Abstract***

*The current context requires the networking of planning decisions on increasing the energy performance of the built environment for sustainability purposes and decisions on reconfiguring urban areas to obtain a resilient environment. The paper aims to highlight ways of multicriterial evaluation on energy performance, environmental performance and resilience in urban areas renovation projects in complementarity with applicable solutions in order to improve the characteristics of the area microclimate. Beyond the aspect of the high energy performance associated with nZEB buildings (Nearly Zero Energy Buildings), we must understand the conditions deriving from the quality of anthropogenic factor that the building has in relation to the urban microclimate, contributing to the amplification of the effect of Urban Thermal Island, a phenomenon with significant impact on the health and quality of life of the inhabitants.*

***Key words****: climate resilience, local climate zones, nearly Zero Energy Buildings (nZEB), Urban Heat Island (UHI), urban retrofitting.*

## INTRODUCTION

The impact of urbanization on the local climate can be analysed through the extent of the urban heat island (UHI) effect. A significant concern is the heightened risk to the population, particularly vulnerable individuals, associated with extreme weather events such as heat waves. The frequency and intensity of these events are increasing in the context of climate change (IPCC, 2022). Cities under the influence of the UHI are experiencing more acute effects with consequences for energy consumption, health and quality of life of residents (Heaviside et al., 2017).

The overheating of urban areas is the cumulative result of several factors that influence the energy balance. These include the high proportion of impervious concrete surfaces, reduced vegetation in densely built-up areas, and anthropogenic heat emissions. It is evident that there is an interaction occurring between the radiative properties of anthropogenic surfaces, reduced evapotranspiration, and changes in ventilation that are attributable to urban morphology (Arnfield, 2003; Grimmond, 2007). This phenomenon is further compounded by anthropogenic heat accumulation resulting from traffic, human activities, and air conditioning, which has the potential to significantly exacerbate local warming (Taha, 1997; Santamouris, 2015b).

Strategies for integrated urban planning have the potential to address climate resilience in densely built-up areas by combining solutions for adapting to extreme heat with those designed to increase energy efficiency and, consequently, environmental sustainability (Constantinescu, 2020). The findings presented support the understanding of the need for convergence between efforts to mitigate the effects of urban heat islands and to increase the adaptive capacity of buildings and urban systems, including green infrastructure and urban morphology, to meet the need for transformative adaptation of cities (European Environment Agency, 2016).

The extant literature highlights mitigation solutions based on the efficiency of cool roof technologies and green roofs (Santamouris, 2014; 2015a), and a comparative quantification of their performance (Li et al., 2014). In addition, the benefits of strategies based on green-blue infrastructure are encompassed, as are the utilization of reflective permeable pavements and quantitative references regarding surface temperature reduction (Li et al., 2022). Furthermore, measures to reduce anthropogenic

heat are also addressed. The classification framework for local climate zones also serves as the morphological basis for urban climate analysis (Stewart & Oke, 2012). However, most studies focus on urban-scale indicators or isolated technical measures rather than an integrated methodological approach.

Although recent studies have paved the way for the simultaneous integration and analysis of the urban microclimate and the energy performance of buildings to area scale assessments (Pisello et al., 2017; Turhan et al., 2023; Skandalos & Karamanis, 2025), these are based on complex simulations or case studies specific to a particular context, with less exploration of assessments aimed at providing framework solutions for the planning of urban area renovations by quantifying the co-benefits of renovation measures with nearly Zero Energy Buildings (nZEB) targets and the reconfiguration of urban surfaces in order to reduce the UHI effect. Furthermore, current local design practice often appears to offer fragmented measures to meet energy and environmental performance requirements, which do not always ensure conditions for resilience at the urban area level (Constantinescu, 2020).

At the level of Bucharest Municipality, studies highlight the high thermal risk associated with heat waves and extreme temperatures faced by a large part of the city's area (Zamfirescu et al., 2025). Despite the demonstrable applicability of UHI analysis based on the assessment of land surface temperature (LST) at the local climate zone level for certain Romanian cities, including Iași (Sfică et al., 2023), integrated scenarios combining nZEB objectives with measures to mitigate the UHI effect remain insufficiently analysed.

The assertion that "*every city will have a heat island*" serves to emphasize the significance of these approaches, as the modelling of the reduction of urban heat island intensity constitutes one of the key objectives in sustainable urban planning projects (Chow & Chugh, 2022). Based on the understanding that quality of life and climate action are complementary goals (Montgomery, 2017) we can expect an improvement in the comfort and health of the population associated with major urban renewal projects that adopt a multi-criteria approach aimed at enhancing energy and environmental performance as well as improving the local climate. It should not be overlooked that the attractiveness of outdoor spaces is closely linked to the improvement of the microclimate; thus, mitigating the UHI effect leads to a lifestyle more in harmony with nature during a period of climate change (Sim, 2022).

Flexibility and adaptability appear to be the key attributes of a soft urban environment that, by integrating density and diversity, can offer residents a more pleasant daily life while also responding, in the long term, to the need for transformative adaptation in a global context (European Environment Agency, 2016).

The present study addresses the issue under discussion by means of an analysis of adaptation solutions. This analysis is based on a comprehensive renovation of multi-family residential buildings exposed to UHI intensity, in accordance with nZEB standards, within a Test Urban Zone that is representative of the city of Bucharest. The purpose of this study is to evaluate the potential of the proposed integrated solution packages to enhance microclimate quality and simultaneously increase energy and environmental performance.

The objective of this research is threefold: firstly, to quantify the current proportion of impervious mineral surfaces characterized by low albedo within the analysed urban area; secondly, to highlight the anthropogenic impact of multi-family residential buildings in their current energy state and the proposed nZEB scenario based on estimates of residual heat emissions into the atmosphere (Marin Lazăr, 2021); and thirdly, to compare integrated intervention scenarios that combine building energy retrofits, the implementation of high-reflectance surfaces, and the expansion of green infrastructure, from the perspective of their potential to reduce the UHI effect and improve climate resilience at the neighbourhood scale. The study's contribution stems from the creation of a unified methodological framework through the simultaneous application of energy and environmental performance modelling, the analysis of intervention possibilities at the level of urban surfaces within identified local climatic zones, and the quantification of anthropogenic heat. The aim of this is to obtain quantitative

indicators that can be used in the development of local climate adaptation strategies.

## MATERIALS AND METHODS

The present study proposes expanding the analysis of applicable measures aimed at improving the performance of multi-family residential buildings to meet the nZEB (nearly Zero Energy Buildings) standard. This will be achieved by examining proposals for interventions regarding the proportion and quality of mineral and natural surfaces that can help reduce the UHI effect.
The analysis focuses on a representative test urban area located in Bucharest.

### 1. Heat Island Intensity in Bucharest _Test Urban Area

The specific exposure indicator for Bucharest regarding UHI intensity is approximately 2.22°C, according to thermal maps generated by processing the climate model available through the Destination Earth (DestinE) project.
The Urban Heat Island Explorer application provides a clear visualisation of the increase in average annual surface temperature under the influence of the UHI effect for European cities.
For the designated Test Urban Area, the UHI effect has been found to cause an increase in this parameter ranging from 0°C to +3°C, with some hotspot areas where the temperature exceeds this threshold (Figure 1).
The area under analysis is located in proximity to the city centre, where temperatures in the air and on the surface tend to be higher. Near the area under study, two major natural features (Lake Fundeni and the National Arena Park) help mitigate the urban heat island effect.

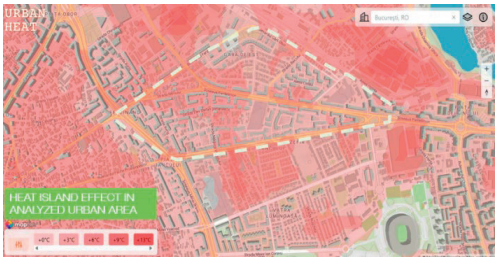

Figure 1. Increase of land surface temperature caused by UHI within the Urban Test Area (https://urbanheat.app/bucuresti)

In order to comprehend the substantial impact of natural spaces in mitigating the UHI effect, it is imperative to acknowledge that surface temperatures in green and aquatic areas remain at 25-28°C, whilst the average surface temperature during the summer months in Bucharest exceeds 35°C and average values for July are above 40°C (Zamfirescu et al., 2025).
The summary Table 1 illustrates climate trends in Bucharest by modelling the increase in average temperatures and the number of tropical nights and days under the RCP 4.5, RCP 8.5 (medium and high impact) scenarios, based on an analysis of measurements taken at the Filaret and Băneasa stations during the reference period 1901-2023 (Zamfirescu et al., 2025).

Table 1. Trends for the projected period 1971-2100, for the RCP 4.5 and RCP 8.5 scenarios, compared with values measured during the period 1901-2023 (Zamfirescu et al., 2025)

| Time frame | Scenario | Incrase avg.max. temp. July (°C) | Tropical nights | Tropical days |
|---|---|---|---|---|
| 2041-2060 | RCP 4.5 | +1.6 | 10 | 23 |
| 2081-2100 | RCP 4.5 | +2.2 | 13 | 30 |
| 2041-2060 | RCP 8.5 | +1.9 | 15 | 29 |
| 2081-2100 | RCP 8.5 | +4.3 | 46 | 54 |

The medium- and long-term projections indicate an increase in vulnerability in the absence of mitigation measures, given the already unfavourable current situation in which over 50% of the capital's population faces a "high or very high risk of extreme temperatures and heat waves" during the summer (Zamfirescu et al., 2025).

### 2. Analysis of Land Use Types within the Test Urban Area

From a structural, functional and urban planning perspective, the analysed area consists primarily of high-rise apartment buildings (P+8E and P+10E) and is located in Sector 2 of Bucharest, between Iancului Road, Pantelimon Road, Mihai Bravu Road, Obor Station, and Baicului Street. It is also noteworthy that there are several areas with single-family homes located in a secondary position relative to the main traffic arteries (Marin Lazăr, 2021).
From a morphological perspective, the layout of multi-unit residential buildings in the study area can be divided into two subzones, as illustrated

in Figure 2. The first of these is the area near Obor Station, built prior to 1970. This area features a distribution of large-scale residential buildings surrounded by extensive green spaces. The second subzone is developed after 1975/1980 and is characterised by more pronounced densification and a fragmentation of small green spaces situated between the blocks. As demonstrated in the relevant literature, Land Surface Temperature (LST) measurements indicate that this parameter is lower for the first type of building layout and higher for the second situation (Sfică et al., 2023). The analysis of urban areas was conducted, as shown in Table 2, in relation to the two defined subzones, Local Climate Zones LCZ 1 and LCZ 2, based on this observation.

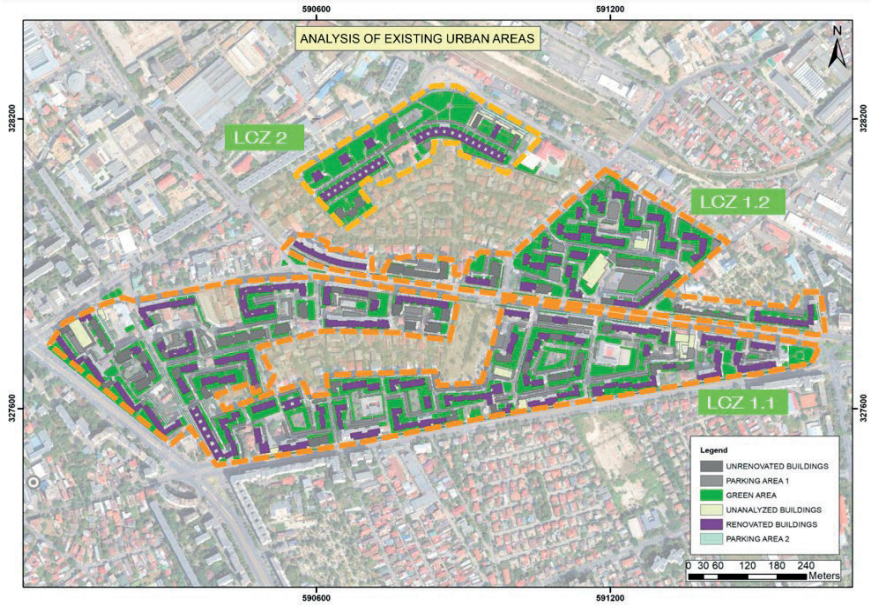

Figure 2. Zonal analysis - indicators of urban composition: built-up/natural areas - existing

Table 2. Zonal analysis - indicators of urban composition: built-up/natural areas - existing

| | **Total analysed area** [m$^2$] | **Built-up area** [m$^2$] | **Green space** [m$^2$] | **Parking area** [m$^2$] | **Sidewalks, streets, alleys** [m$^2$] |
|---|---|---|---|---|---|
| **LCZ 1.1** | 272,600 | 77,689 | 35,626 | 29,800 | 129,485 |
| **LCZ 1.2** | 108,036 | 28,939 | 16,258 | 15,955 | 46,884 |
| **TOTAL LCZ 1** | **380,650** | **106,630** | **51,884** | **45,755** | **176,369** |
| **LCZ 2** | **64,231** | **12,349** | **13,001** | **4,391** | **34,490** |

An analysis of urban areas highlights the low proportion of natural spaces, approximately 14.5%, compared to man-made areas, which account for approximately 85.41% of the total analysed.

For subzone LCZ 1, it is noteworthy that green spaces account for only about 50% of the built-up area, or 13.6% of the total subzone, while for subzone LCZ 2, the ratio of built-up area to green space is slightly more favourable to the latter, reaching approximately 20% of the subzone (Figure 3).

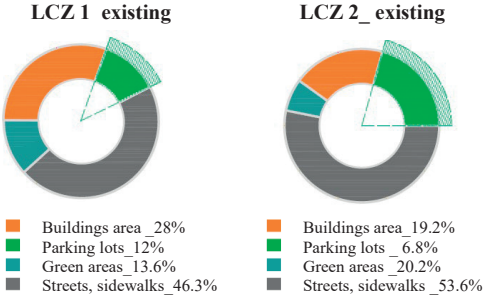

Figure 3. Proportion of anthropogenic existing areas versus natural areas

This mix influences the local energy balance, given that existing man-made surfaces (rooftops of apartment buildings covered with bituminous membranes, courtyards, parking lots, streets, alleys, and sidewalks) are characterised by low albedo and high thermal storage capacity and thus absorb a greater amount of solar radiation during the day, which they gradually release at night, amplifying thermal discomfort (Oke, 1982; Taha, 1997). The high degree of imperviousness of the area as illustrated in Figure 4, and the low percentage of vegetation amplify this effect by limiting evaporative cooling (Arnfield, 2003; Gago et al., 2013).

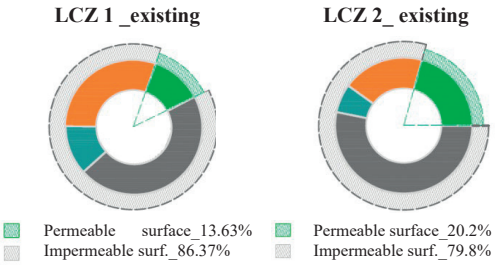

Figure 4. Ratio of permeable/impermeable surfaces (high solar radiation absorption)

## 3. Energy Performance Analysis - Multi-family Residential Buildings in the Test Urban Area

The present energy status of the Test Urban Area, as determined by the energy and environmental performance of multi-family housing, demonstrates elevated levels of specific primary energy consumption (kWh/m²·year) and associated $CO_2$ emissions (kg/m²·year), particularly for buildings that have not undergone previous energy renovation programs, accounting for approximately 31% of the total. The numerical results were supported by dynamic modelling of the building envelope response, as presented in detail in the relevant literature (Constantinescu, 2008; 2020).

The mean zonal values of these indicators (across all buildings belonging to both energy typologies, designated CRA and CRR) are 183.74 kWh/m²·year of specific primary energy and 41.98 kg/m²·year of $CO_2$ emissions (Table 3). These are well above the threshold for classification in the nZEB (nearly zero-energy building) performance category and thus place the area in a lower energy and environmental class (Marin Lazăr, 2021).

Table 3. Assessment of energy consumption in the test urban area - existing (Marin Lazăr, 2021)

| Energy TYPE CRA/ CRR | Specific net energy consump. (kWh/m²/ year) | Specific net $CO_2$ emissions (kg/m²/ year) | Enviro. energy class | Heat emissions (kWh/m²/ year)/ (MWh/year) |
|---|---|---|---|---|
| Regional Enviro. LCZ1+LCZ2 | **183.74** | **41.98** | 4 /4 | 2.42 / **802** |
| | | | | |
| nZEB 2030 | 43-74 | 9-19 | 2/2 | |
| nZEB 2050 | < 43 | < 9 | 1/1 | |

## 4. Assessment of the anthropogenic impact of multi-unit residential buildings

To assess the anthropogenic impact of multi-unit residential buildings on the amplification of urban heat islands, the heat emissions released into the atmosphere by the operation of split-type air conditioning units were determined, in correlation with the cooling demand and the performance of the equipment. The quantity of heat emissions into the atmosphere, as shown in Table 4, was calculated on the basis of the usable floor area of the air-conditioned apartments, which was determined to be 330,097 m², thus accounting for approximately 50% of the total area analysed, which was 690,562.6 m² (Marin Lazăr, 2021).

Table 4. Significant results for several representative building types in the analysed area (Marin Lazăr, 2021)

| Energy TYPE CRA/ CRR | Usable area (m²)/ Heated usable area | Primary en. building (MWh/ year) | Specific net energy (kWh/ m²/year) | Heat emissions (MWh/year) / (kWh/m²/ year) |
|---|---|---|---|---|
| CRA P+8E | 3066/ 1356 | **696** | **223.74** | **5.16** /3.8 |
| CRR P+8E | 3093 / 1308 | **482** | **155.83** | **2.25** /1.72 |
| CRA P+10E | 2450 / 946 | **554** | **226.12** | **3.73** / 3.94 |
| CRR P+10E | 2459/ 782 | **389** | **158.19** | **1.3** / 1.66 |

It is important to emphasize the reciprocal relationship between buildings - viewed as an anthropogenic factor - and the urban micro-climate, since the waste heat released into the atmosphere raises outdoor temperatures in the immediate vicinity of the building, thereby contributing to a further increase in the energy required for cooling. Given the projected rise in temperatures over the medium and long term - which in urban areas is associated with the Urban Heat Island effect - it can be concluded that, in the absence of energy-efficiency improvements and reconfiguration, the energy demand for cooling will increase.

The adaptability of buildings is supported by passive architectural solutions that help minimise the need for sensible cooling and by connections to technical systems that must ensure the operation of HVAC equipment under severe weather conditions (Constantinescu, 2020).

## 5. Indicators of the current situation

The specific exposure indicator for the extent of the urban heat island (UHI) in the analysed area falls within the range of 0-3°C. However, higher intensities of 5-6°C may occur under weather conditions conducive to heat waves.

**Key findings:**

- Analysis of urban surfaces highlights conditions favourable to the amplification of the urban heat island effect at the local level due to the high proportion of impermeable mineral surfaces characterized by low albedo.
- Analysis of heat emissions associated with the operation of buildings in their current energy state illustrates their role as an anthropogenic factor contributing to the amplification of the urban heat island effect.

The European Environment Agency proposes a tool for monitoring climate change adaptation policies organised around the risk, response, and outcome framework (Climate-ADAPT, n.d.). From this standpoint, the text presents several aspects relevant to the analysed case study. These include the current risk level, the proposed intervention scenarios in response to climate challenges, and the relevant outcomes for the analysed area. The assessment of the urban test area highlights an increased risk level regarding extreme temperatures and heat waves, exacerbated by the urban heat island effect (Zamfirescu et al., 2025; UAUIM, 2017). The present analysis of the current situation reveals the thermal vulnerability of buildings during heat waves. This phenomenon can be attributed to the inability to guarantee passive survival conditions in the absence of functional technical systems in dwellings characterised by elevated thermal discomfort (Marin Lazăr, 2021).

## 6. Measures for climate resilience and UHI reduction

In response to the previously delineated risk scenario, a multi-criteria analysis is required of the possibilities for reducing the UHI effect in the Urban Test Area. This analysis should involve a comparison of the existing situation with integrated intervention scenarios at the level of buildings and urban surfaces. The purpose of this comparison is to ensure improved energy and environmental performance and resilience. The proposed specific objectives are twofold: firstly, to mitigate the adverse effects of the high proportion of impermeable mineral surfaces with low albedo, and secondly, to limit heat emissions into the atmosphere by reducing the anthropogenic impact of buildings (Figure 5, Figure 6 and Table 5).

The proposed intervention plan for urban areas includes:

- Converting impermeable parking lots into permeable surfaces with high reflectivity.
- Using cool roof materials for the flat roofs of multi-unit residential buildings, with the integration of photovoltaic panels.
- Targeted interventions to expand green spaces through green roofs and green urban paving. Areas targeted include the flat roofs of schools and kindergartens within the test urban zone, local heating plant buildings, and ground-floor public spaces. Green roof solutions will be analysed with caution, given the difficulty of maintaining them in light of the current summer rainfall deficit specific to the Bucharest area and long-term climate forecasts.
- The installation of green urban paving can bring social benefits by creating community gathering places, so that solutions to improve the microclimate also facilitate resident's "reconnection" with nature.

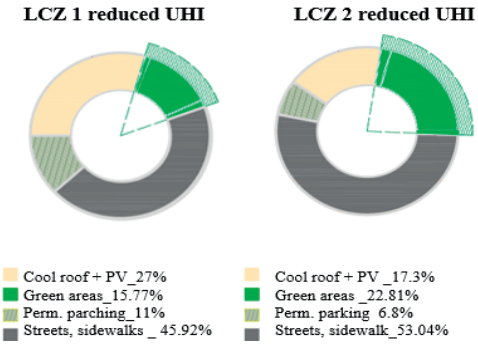

Figure 5. Proposed ratio of anthropogenic versus natural areas

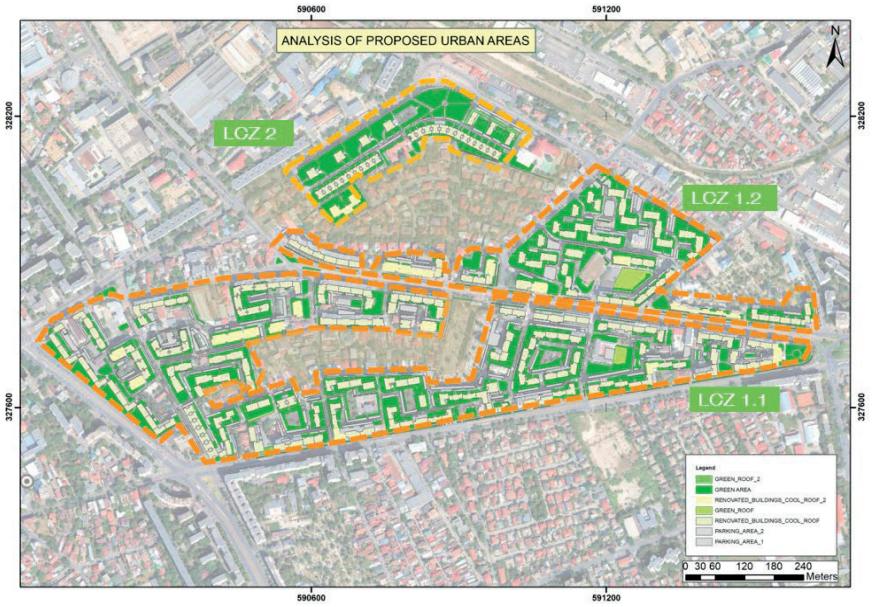

Figure 6. Zonal analysis - indicators of urban composition: built-up/natural areas - proposal

Table 5. Zonal analysis - indicators of urban composition: built-up/natural areas - proposal

| | Total analysed area [m$^2$] | Built-up area [m$^2$] | Green space [m$^2$] | Parking area [m$^2$] | Sidewalks, streets, alleys [m$^2$] |
|---|---|---|---|---|---|
| **LCZ 1.1** | 272,600 | 77,689 | 40,045 | 29,800 | 127,914 |

The maximum scenario applicable to buildings and the modernization of technical systems includes (Marin Lazăr, 2021).

- Passive solutions for the building envelope are to be implemented in order to ensure an appropriate level of thermal insulation and airtightness, as well as the installation of shading systems. The following solutions are to be put into effect: reflective folding thermal insulation shutters and the use of high-albedo façade finishes and cool roof systems with solar radiation absorption coefficients α abs. Wall = 0.3 / α abs. Terrace= 0.1.
- The technical systems to be implemented in the analysed buildings - heat recovery ventilation systems.
- Modernisation of the district-level heating and electricity supply system – high-efficiency cogeneration/trigeneration, and connection of all buildings within the test urban area.
- Installation of photovoltaic panels to harness the area's potential for renewable energy production. The sizing of the panels will account for the building's calculated sensible cooling demand determined under summer design conditions. We should mention that PV have a theoretical efficiency of 22% in laboratory conditions (low net temperature to the outside). In urban conditions, in hot summer days, the efficiency of solar radiation transformation into electricity is about 12%-15% associated with the high temperature of the PV capture surface, 60-70°C. PV produces electric energy, but also thermal pollution. Prosumers are effective for remote areas or in rural areas.
- To ensure conditions for climate resilience, additional nighttime ventilation systems for the spaces via a perforated false ceiling may be selected. This requires that the outdoor temperature drop below 24°C.

Based on indicators of vulnerability, exposure, and adaptive capacity, key measures have been identified that focus on technological adaptation solutions applicable to buildings and built-up areas, as well as green options.

## RESULTS AND DISCUSSIONS

### 1. Estimated outcome of intervention scenarios for urban areas aimed at reducing the urban heat island effect

The proposed intervention scenario ensures an increase in areas conducive to lower temperatures within the test urban area compared to the current situation. In subzone LCZ 1, the proportion of permeable surfaces will increase, from 13.63% to approximately 27%, and from 20% to 29.6% in subzone LCZ 2 (Figure 7).

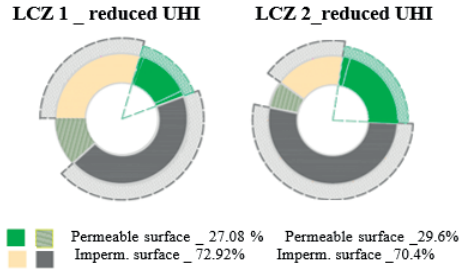

Figure 7. Ratio of permeable / impermeable surfaces

These changes result from the conversion of parking lots from impermeable mineral surfaces to permeable surfaces with high solar reflectance and the cumulative effects of increasing green spaces integrated into the balance of surface categories relative to the analysed area.

Concurrently, the proportion of surfaces with low solar radiation absorption (including cool roofs and the conversion of parking lots) will increase significantly in LCZ 1 from 13.63% to approximately 54.08% and in LCZ 2 from 20.2% to 46.9%. At the same time, the proportion of surfaces with high absorption decreases - 45.92% in LCZ 1 and 53.04% in LCZ 2 - which leads to a reduction in the solar radiation load on the analysed area (Figure 8).

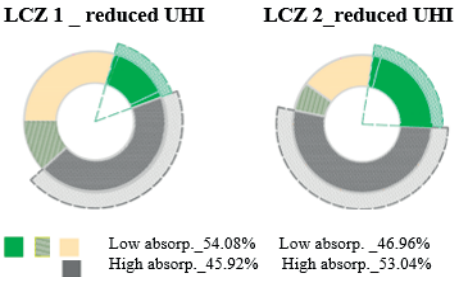

Figure 8. Ratio of high solar radiation absorption

### 2. Estimated results of building-level intervention scenarios

The energy and environmental impact of the technological adaptation measures was estimated by comparing the existing and proposed scenarios regarding net primary energy (kWh/m² per year) and $CO_2$ emissions (kg/m² per year) for buildings in their current state and after implementing the renovation solution packages.

Compared to the permissible thresholds for compliance with the nZEB standard by 2050, it is necessary to combine passive architectural solutions applicable to the building envelope with systems for recovering energy from exhaust air, utilizing the regional potential for renewable energy production, as well as connecting to high-efficiency district heating systems of the cogeneration/ trigeneration type. The solutions analysed implicitly lead to a reduction in the amount of waste heat released into the atmosphere, which results in the emission levels shown in the following Table 6.

Table 6. Assessment of energy consumption in the test urban area - proposed (Marin Lazăr, 2021)

| Energy TYPE CRA/ CRR | Specific net energy consump. (kWh/m²/ year) | Specific net $CO_2$ emissions (kg/m²/ year) | Enviro. energy class | Heat emissions (kWh/m²/ year)/ (MWh/year) |
|---|---|---|---|---|
| Regional Enviro. LCZ1+LCZ2 | **22.16** | **4.64** | 1/1 | 0.85 / **283.31** |
| | | | | |
| nZEB 2030 | 43-74 | 9-19 | 2/2 | |
| nZEB 2050 | < 43 | < 9 | 1/1 | |

### 3. Significance of the Results

In relation to the configuration of urban surfaces, the results of the analysis confirm that, at present, the proportion of impervious surfaces - 86.37% in subzone LCZ1 and 79.8% in subzone LCZ2 - contributes to the amplification of the UHI effect within the test urban area. The reported values are higher than the critical imperviousness threshold of 70%, which leads to a marked decrease in the soil's evaporation and cooling capacity, resulting in an increase in the UHI effect by more than 2°C compared to peri-urban areas (Oke et al., 2017). This highlights the area's high thermal vulnerability, correlated with a specific UHI exposure indicator of 0°C to +3°C according to Urban Heat Island Explorer data.

The contribution of the existing built environment, as an anthropogenic factor that further exacerbates UHI intensity, is highlighted by the quantification of residual heat emissions released into the atmosphere by air conditioning units. The total annual average of these emissions across the area is approximately 802 MWh/year (Table 3), reflecting the current energy status of multi-unit residential buildings. Given the medium- and long-term climate projections (Zamfirescu et al., 2025), it can be estimated that in Bucharest we will see an increase in energy consumption associated with space cooling, which could adversely exacerbate the building-urban microclimate feedback loop in the absence of mitigation solutions.

The mean values for specific primary energy were found to be approximately 183.74 kWh/m²·year, and the mean $CO_2$ emissions were 41.98 kg/m²·year, based on the current level of energy and environmental performance of the analysed buildings. These values illustrate the inadequacy of the solutions generated by previous renovation procedures, based on isolated interventions, as buildings in their current energy state cannot ensure conditions for passive survival at the residential unit level during heat waves and do not meet nZEB objectives (Marin Lazăr, 2021; Constantinescu, 2020).

## 4. The inner validation of results against study objectives

In terms of the objective of reconfiguring urban surfaces, the proposed intervention scenario results in a significant increase in permeable surfaces, from 13.63% to approximately 27% for subzone LCZ1, and from 20% to 29.6% for subzone LCZ2. At the same time, there is a significant increase in areas with reduced solar absorption, from 13.63% to approximately 54.08% in LCZ 1 and from 20.2% to 46.9% in LCZ 2. The proposed interventions lead to a reduction in solar radiation absorbed within the area.

The proposed solutions to achieve the nZEB target have been shown to result in a decrease in specific primary energy consumption from 183.74 kWh/m²·year to 22.16 kWh/m²·year and in associated $CO_2$ emissions from 41.98 kg/m²·year to 4.64 kg/m²·year (Marin Lazăr, 2021). The significantly reduced cooling demand of energy-renovated buildings leads to a substantial reduction in heat emissions into the atmosphere, approximately 65% lower than current levels. This implicitly reduces the anthropogenic impact of buildings, which is a relevant aspect regarding the co-benefits of increasing energy efficiency and mitigating the UHI effect.

The objective of comparatively evaluating integrated scenarios is achieved by simultaneously analysing the impact of interventions on urban land characteristics and measures to improve the energy and environmental performance of buildings. This highlights the cumulative positive effect at the urban area level that justifies the integrated, multi-criteria approach to renovation projects compared to isolated, single-focus interventions.

## 5. External validation of results compared to similar studies

The potential for reducing surface temperature in the analysed test area through the proposed intervention scenarios is qualitatively confirmed by the existing literature. The available reports indicate a potential reduction in surface temperature of up to 34.3°C by replacing dark roofs with reflective roofs equipped with PV, and approximately 8.3°C by converting parking areas from dark impervious to light/permeable surfaces (Li et al., 2022).

The effectiveness of UHI mitigation measures based on green roof and cool roof technologies is increased when implemented at the neighbourhood scale rather than through isolated interventions at the building level (Li et al., 2014), which confirms the need for the urban-scale approach described in this study.

Reference can also be made to the added value of the proposal to partially implement green roofs and permeable pavements, given that multifunctional green infrastructure contributes both to mitigating the urban heat island effect and to stormwater retention and increased biodiversity (Demuzere et al., 2014), which, particularly in Bucharest, given the lack of rainfall during the summer season, requires careful selection of species and minimization of irrigation needs.

The study's findings align with the conclusions summarized in the reports of the European Environment Agency (2016), which show that

integrated interventions combining measures related to green infrastructure, smart surfaces, and building energy performance yield greater benefits in terms of both thermal comfort and public health.

## 6. Estimated results of building-level intervention scenarios

The present paper puts forward a proposal for the integration of morphological analysis based on the LCZ classification and the modelling of building energy performance, with a focus on the identification and quantification of anthropogenic heat emissions resulting from building operations. This is to be achieved within a unified methodological framework that provides a replicable decision-making tool for the analysis of urban areas with similar functions and characteristics, located in regions with a continental climate and trends toward rising temperatures and heat waves. The quantitative indicators resulting from the analysis – namely, the proportion of permeable surfaces characterised by high albedo, anthropogenic heat emissions, and specific values for primary energy and $CO_2$ emissions – can be used to develop local climate adaptation strategies and evaluate results in relation to resilience objectives.

## 7. Limitations of the study, future directions for research

About the interpretation of the results, it should be noted that the analysis of urban surfaces was based on reference parameters from the relevant literature without in-situ validation through direct measurements of ground surface temperature or air temperature in the analysed area using remote sensing data or sensor networks. The scenario does not include an assessment of the influence of urban morphology on natural ventilation and the spatial distribution of temperatures, nor does it include dynamic modelling of the long-term degradation of material performance in terms of permeability and reflectivity, which would lead to a reduction in the estimated benefits.

Heat and pollutant emissions resulting from road traffic significantly influence the urban heat balance (Taha, 1997). Therefore, in addition to the benefits of passive measures and green solutions implemented at the building and surface levels, the study can be expanded to include an analysis of the mobility component relevant to the multi-criteria analysis of urban areas.

## CONCLUSIONS

This study confirms and supports the view that reducing the urban heat island effect (UHI) in major urban renewal projects requires more than one type of intervention and can be effectively integrated with building energy performance objectives.

Attempts to recalibrate the area's energy systems so that they meet the performance standards for nZEBs by 2050 contribute to reducing heat emissions into the atmosphere and lessen the anthropogenic impact of buildings (Marin Lazăr, 2021). These two courses of action - the reconfiguration of urban areas and energy-efficient renovation - become interdependent, generating clear climate co-benefits.

Individual measures have limited effectiveness in dense urban areas; tangible results are achieved through the implementation of integrated solution packages that combine green infrastructure, cool surfaces, building solar control, and the reduction of anthropogenic heat (Santamouris, 2015b; Li et al., 2014). The package of solutions proposed following the morphological analysis - by comparing scenarios with the current situation - is based on increasing zonal permeability and albedo, through cool roofs equipped with photovoltaic panels, the conversion of parking lots, as well as targeted interventions to increase green spaces, and has real potential to reduce the UHI effect within the test urban area.

The integrated solutions analysed can serve as a methodological framework for local adaptation strategies aimed at climate resilience, provide quantitative indicators, and highlight the need for integration between public spaces, building performance, and energy infrastructure. The methodological framework, based on the LCZ classification, comparative analysis of scenarios for interventions in urban areas, and integrated energy performance modelling, provides a decision-making tool for climate resilience objectives, replicable for the multi-criteria analysis of renovation projects in similar urban areas.

From the residents' perspective, integrating green infrastructure and public spaces not only provides environmental benefits, but also enhances the appeal of outdoor areas and fosters a reconnection with nature. This approach can also help to improve social cohesion at the urban/neighbourhood level.

This integrated approach, which is based on the understanding that urban climate resilience is a systemic objective, leads to a tangible reduction in the urban heat island (UHI) effect during heatwaves. This contributes to increased urban comfort and climate adaptation, reduced energy consumption and improved quality of life in urban areas.

***Abstract***

*Thermal insulation materials used in construction exhibit diverse structural morphologies that directly influence their thermal performance. Unconventional solutions based on recovered agro-industrial by-products, such as sheep wool mattresses, offer sustainable and eco-friendly alternatives. This paper comparatively analyzes the thermal insulation performance of sheep wool-based mattresses and evaluates the influence of testing methodology on measurement accuracy. Thermal conductivity was determined as a function of density using two complementary approaches: steady-state measurements with the λ-Meter EP500e (guarded hot plate method) and transient measurements with the ISOMET 2114 (dynamic method), both conducted at controlled, variable laboratory temperatures. The results reveal significant differences between steady-state and transient measurement techniques regarding method suitability and accuracy. Polynomial regression models accurately predict thermal behavior under non-compression conditions, enabling complete material characterization across the operational range relevant for building insulation applications. This comparative study provides practical guidance for selecting appropriate testing methods for fibrous insulation materials.*

***Key words****: ISOMET 2114, λ-Meter EP500e, non-woven sheep wool mattress, thermal conductivity coefficient, unconventional thermal insulation materials.*

## INTRODUCTION

In developed countries, people spend approximately 87% of their time indoors (Klepeis et al, 2001). Recent decades have witnessed a shift in urban architecture towards models focused on speed, efficiency, and comfort, often neglecting integration with existing contexts and local resources. Contributing to the achievement of the 17 Sustainable Development Goals requires reducing energy consumption, protecting air quality, and ensuring sustainable resource use (Petrișor et al., 2025). In Europe, the building sector is responsible for approximately 40% of final energy consumption and 36% of greenhouse gas emissions, while about 8% of the population faces energy poverty due to inadequate thermal comfort, highlighting the critical role of high-performance insulation materials (Frasca et al., 2023).

Alongside conventional materials such as polystyrene, mineral wool, and polyurethane foam, environmentally friendly recyclable alternatives are being developed, including those based on sheep wool. These materials offer high thermal insulation, low costs, and minimal environmental impact (Ye et al., 2006; Zach et al., 2012; Corscadden et al., 2014; Mansour et al., 2016). The thermal performance of insulation materials, including sheep wool mattresses, is evaluated through the thermal conductivity coefficient (λ), which quantifies heat transfer reduction capability.

Recent studies conducted according to EN 12667 with strict temperature and humidity control show λ values between 0.0333 and 0.0438 W/(m·K) for sheep wool insulation, influenced by density, applied treatments, and test method consistency (Vėjelis et al., 2024). Statistical analysis confirms that reproducibility and accuracy critically depend on experimental protocol adherence, correct experimental conditions, and method consistency.

A relevant aspect of experimental research concerns thermal conductivity coefficient

variation as a function of temperature range during determination. Other recent studies already demonstrated that humidity significantly degrades the thermal performance of insulation materials, with the thermal conductivity coefficient (λ) increasing by 1.9% for rock wool and up to 33-45% for hygroscopic materials such as wood-based boards and lightweight cellular concrete at 95% relative humidity (Kendzierawska & Trochonowicz, 2023; Petcu et al., 2024). This observation correlates with previous research by Sandberg (1992), who identified a linear equation for thermal conductivity variation as a function of water absorption in cellulose insulation materials. Other research (Talukdar et al., 2007) has indicated that thermal insulation performance quantified by thermal conductivity, measured at temperatures between 10°C and 30°C, varies according to a polynomial function relative to moisture content.

Specialized research (Mazrouei-Sebdani et al., 2022; Lou et al., 2023; Pontinha et al., 2023; Shrestha et al., 2023) indicates thermal conductivity variation in fibrous insulation materials as a U-shaped curve as a function of product density. This behavior is determined by competition between three distinct terms: the constant term representing air conductivity, the term proportional to density due to increased conductivity through solid contacts, and the opposing term having significant contribution at low densities through intense radiant transfer but becoming negligible at high densities due to radiation scattering on a higher number of fibers. The analytical approach to the relationship between thermal conductivity and density enables identification of optimal densities for different insulating material categories and formulation optimization according to specific application requirements (Lakatos, 2018).

Beyond conductivity analysis, recent literature integrates experimental methods and numerical simulations to evaluate sheep wool insulation performance under varying operating conditions. An example is the study on sheep wool-based bio-composites, where thermal tests are complemented by numerical analyses of energy requirements for buildings insulated with these materials, demonstrating significant reductions in heating energy requirements in simulated models (Saaidia et al., 2026). This combined approach - standardized experimental measurements and modeling - allows more complete thermal insulation performance characterization and highlights that rigorous test methodology selection is essential to obtain accurate and relevant data for practical applications, especially when comparing natural materials with conventional alternatives.

The objective of this research is to comparatively evaluate two complementary testing methods - the guarded hot plate (GHP) method using the λ-Meter EP500e and the transient method using the ISOMET 2114 - for characterizing the thermal conductivity of sheep wool insulation across a range of densities from natural (25.5 kg/m³) to compressed states (up to 80 kg/m³), and to validate polynomial regression models derived from steady-state measurements for predicting thermal behavior under operational conditions relevant to building applications.

## MATERIALS AND METHODS

### 1. Material Description

The investigated product consists of sheep wool mattress insulation manufactured from natural wool fibers. The material represents an unconventional solution based on recovered agro-industrial by-products, offering sustainable and eco-friendly characteristics. The natural fiber structure of sheep wool provides inherent thermal insulation properties through its cellular morphology, which creates numerous air-filled cavities that impede heat transfer. The wool samples were tested in both their natural, uncompressed state (density 25.5 kg/m³) and under progressive mechanical compression to achieve higher densities up to 80 kg/m³.

### 2. Guarded Hot Plate Method (λ-Meter EP500e)

The guarded hot plate method represents the reference standard for absolute thermal conductivity measurement of insulating materials, providing traceable measurements without requiring calibration samples (Baldinelli et al., 2019).

The method operates under steady-state conditions based on Fourier's one-dimensional thermal conduction equation. A specimen is placed between two isothermal plates maintained at different constant temperatures. Once steady-state thermal flux is established, thermal conductivity is calculated using the relationship (Baldinelli et al., 2019):

$$\lambda = \frac{q \cdot d}{A \cdot (T_h - T_c)}$$

where $q$ represents heat flux per unit time, $d$ is specimen thickness, $A$ is measurement area, and $T_h$ and $T_c$ are hot and cold plate temperatures, respectively.

The λ-Meter EP500e, manufactured by Lambda-Meßtechnik GmbH Dresden, represents a contemporary single-specimen guarded hot plate apparatus specifically designed for testing thermal insulation and construction materials (Lambda-Meßtechnik, 2023). The defining characteristic of the GHP apparatus is the guarded heating section, consisting of a central measurement zone surrounded by one or more concentric guard zones maintained at identical temperatures. This configuration ensures one-dimensional heat flux through the specimen by eliminating lateral heat losses from the measurement section. Guard temperature is precisely controlled to match the measurement section within millikelvin limits, typically achieved through sophisticated control algorithms monitoring guard thermocouples (Zarr, 2010).

The equipment conforms to standards ISO 8302, EN 1946-2, EN 12664, EN 12667, EN 12939, ASTM C177, and DIN 52612, with thermal conductivity measurement range 0 - 0.5 W/(m·K), thermal resistance range 0.1 - 14 m²K/W, measurement area 200 × 200 mm², specimen thickness 10 - 120 mm, reproducibility < 0.5% (typically < 0.2%), accuracy < 1.0% (typically < 0.7%), and temperature range 10 - 40°C (Lambda-Meßtechnik, 2023). The National Institute for Research and Development in Construction, Urban Planning and Sustainable Spatial Development URBAN-INCERC Romania acquired a λ-Meter EP500e as part of integrated thermal testing infrastructure, utilizing it for research on thermal insulation and certification activities according to European standards.

The GHP method provides absolute measurements without requiring reference materials, while heat flow meter (HFM) methods are secondary techniques requiring periodic calibration using certified reference materials (Baldinelli et al., 2019). A reference Round Robin test conducted by Baldinelli et al. (2019) in six European laboratories demonstrated that both methods produce consistent results for conventional and innovative insulating materials. Testing of aerogel, vacuum insulation panels, expanded polystyrene, and birch fiber boards revealed repeatability < 7% relative standard deviation for most materials and reproducibility ~10% for aerogel, EPS, and wood fiber boards (Baldinelli et al., 2019).

**3. Transient Method (ISOMET 2114)**

ISOMET 2114, manufactured by Applied Precision Ltd. (Bratislava, Slovakia), represents a portable instrument designed for direct measurement of heat transfer properties in a wide range of isotropic materials (Applied Precision, Ltd., 2019). This advanced thermal analyzer has become an useful tool in construction materials research, particularly for characterizing thermal insulation products. The device enables rapid and precise measurements of thermal conductivity (λ), thermal diffusivity (a), volumetric heat capacity (cρ), and temperature (T) using dynamic measurement methods that significantly reduce testing time compared to traditional steady-state approaches (Applied Precision, Ltd., 2019; Czajkowski et al., 2022).

ISOMET 2114 operates based on analysis of the temperature response of analyzed materials to heat flux pulses (Applied Precision, Ltd., 2019). The fundamental principle involves electrical heating of a resistor element introduced into a measurement probe that maintains direct thermal contact with the test specimen. Heat flux is generated through this electrical heating, and evaluation of thermal conductivity and volumetric heat capacity is based on periodically sampled temperature recordings as a function of time, provided that heat propagation occurs in an unbounded medium (Applied Precision, Ltd., 2019).

The ISOMET 2114 system utilizes two distinct probe types to adapt to diverse material

properties: needle probes (IPN 1100 series) for soft materials and surface probes (IPS 1100 series) for hard materials (Applied Precision, Ltd., 2019). The needle probe used in this research requires minimum 20-40 mm of material in all radial directions from the insertion axis to ensure a one-dimensional thermal field according to manufacturer specifications. Thermal conductivity measurement range is 0.015-0.70 W/(m·K) with accuracy ±5% of reading + 0.001 W/(m·K), thermal diffusivity range 0.15-10 mm²/s with accuracy ±15% of reading, and volumetric heat capacity range 0.05-3.0 MJ/(m³·K) with accuracy ±15% of reading (Applied Precision, Ltd., 2019).

Czajkowski et al. (2022) demonstrated ISOMET 2114 application in characterizing straw-based insulation panels, finding thermal conductivity values between 0.025 and 0.075 W/(m·K) depending on measurement method used. The study emphasized the importance of considering temperature influence when determining thermal properties of insulating materials made from agricultural industry by-products (Czajkowski et al., 2022). For mineral wool, Ablaoui et al. (2023) performed extensive thermal analysis of mineral wool with 80 kg/m³ density using ISOMET 2114, examining thermal behavior at elevated temperatures and finding thermal conductivity in the range 0.030-0.046 W/(m·K) at ambient temperature, with values varying according to temperature-specific relationships.

A critical consideration in using ISOMET 2114 involves understanding differences between transient and steady-state measurement techniques. Latif (2023) performed a comprehensive comparison between transient ISOMET 2114 measurements and steady-state Fox 600 guarded hot plate measurements for insulating materials made from agricultural industry by-products. The research revealed that transient methods using surface probes underestimate thermal conductivity values by approximately 14% compared to steady-state measurements, while needle probes tend to overestimate values by the same magnitude. Discrepancy arises from several interrelated factors: contact resistance at the probe-material interface affecting heat transfer and leading to underestimation in surface probe cases; local compression of porous materials following needle insertion modifying apparent density and consequently effective thermal conductivity; reduced measurement duration allowing capture of instantaneous properties without achieving complete thermal equilibrium specific to steady-state methods; and semi-infinite medium assumption which may not be valid for all tested specimen geometries. Latif (2023) concluded that measuring thermal conductivity of materials made from agricultural industry by-products using transient methods requires validation through comparison with steady-state measurements when establishing material properties for design purposes.

## 4. Testing Protocol

The experimental protocol consisted of thermal conductivity determination as a function of density using two complementary approaches. First, systematic steady-state measurements were conducted using the λ-Meter EP500e at three controlled temperature levels (10°C, 25°C, and 40°C) across a range of densities achieved through progressive mechanical compression. For each temperature, polynomial regression models of the form

$$\lambda(\rho) = a\rho^2 + b\rho + c$$

were developed, where $\lambda$ represents thermal conductivity and $\rho$ represents material density. These polynomial functions achieved coefficients of determination $R^2$ between 0.987 and 0.999, indicating excellent agreement between the mathematical model and experimental data.

Second, transient measurements were performed using ISOMET 2114 with the IPN 1100 needle probe at variable laboratory temperatures. For the natural density wool (25.5 kg/m³), measurements were conducted at seven distinct positions to evaluate spatial homogeneity and provide statistical validation. Each measurement position was tested multiple times (n = 21-50 measurements per position) to ensure statistical reliability. For compressed wool configurations (50, 60, 70, and 80 kg/m³), measurements were performed at multiple height levels within the test fixture when geometrically accessible according to the 20-40

mm minimum material requirement around the probe.

The experimental setup for ISOMET measurements utilized a custom-designed test fixture consisting of a rectangular prismatic frame with internal dimensions 108.5 × 111.5 × 600 mm, providing an internal cross-sectional area of approximately 12,097.75 mm² (1.21 × $10^{-2}$ m²). Measurement ports were positioned at five vertical levels (H1 at 100 mm, H2 at 200 mm, H3 at 300 mm, H4 at 400 mm, and H5 at 500 mm from the internal base), allowing systematic evaluation of vertical property and density profiles. Material compression was achieved using a Testometric M350-10AT universal press, enabling controlled density variation while maintaining material integrity.

Environmental conditions during testing were carefully controlled. The λ-Meter EP500e measurements were conducted under precisely controlled temperature conditions at the three specified set points (10°C, 25°C, and 40°C) with relative humidity maintained within standard laboratory conditions. ISOMET 2114 measurements were performed at variable laboratory temperatures typically ranging from 26.9 to 28.3°C, reflecting ambient conditions during the experimental campaign. All measurements were conducted after appropriate equilibration periods to ensure thermal stability of specimens.

The total measurement campaign encompassed 1,235 measurement points across 51 different densities, with 471 points specifically dedicated to wool product characterization across 16 density configurations, yielding an average of 29.4 measurements per density configuration. This extensive dataset provided robust statistical foundation for the comparative analysis of the two measurement methodologies and validation of polynomial regression models.

## RESULTS AND DISCUSSIONS

### 1. Thermal Conductivity and Thermal Resistance: Density and Temperature Effects (λ-Meter EP500e)

The λ-Meter EP500e measurements across the tested density and temperature ranges provide critical insights into the relationships between thermal conductivity, thermal resistance, and material configuration. Figures 1-4 present comprehensive visualization of these relationships, derived from steady-state measurements under controlled temperature conditions.

The experimental results reveal a critical aspect for practical building applications that extends beyond simple thermal conductivity values. Figures 1 and 2 demonstrate that thermal conductivity exhibits a complex behavior with density variation. At higher densities, thermal conductivity values show a tendency to decrease (improve) - for example, at 40°C, λ decreases from 47.21 mW/(m·K) at 30.1 kg/m³ to 36.57 mW/(m·K) at 64.4 kg/m³, representing a 22.5% improvement in material thermal performance.

This improvement results from increased fiber contact and reduced air gaps in the compressed material structure, consistent with the reduction of radiative heat transfer through increased fiber density documented by Shrestha et al. (2023) and Lou et al. (2023).

However, Figures 3 and 4 reveal the critical limitation of this approach: while thermal conductivity improves moderately through compression, thermal resistance ($R = d/\lambda$) decreases dramatically due to the substantial reduction in material thickness. At 25°C, the sample at natural density (22.3 kg/m³) exhibits $R = 1.876$ m²·K/W, while the compressed sample at 64.4 kg/m³ shows only $R = 0.858$ m²·K/W - a reduction of 54.3%.

This dramatic decrease in thermal resistance occurs because the reduction in thickness (approximately 65-70% compression ratio) far outweighs the improvement in thermal conductivity (approximately 20-25% improvement). The physical relationship $R = d/\lambda$ demonstrates that thermal resistance scales linearly with thickness but only inversely with conductivity, making thickness the dominant variable. The temperature variation shown in Figures 1 and 3 further emphasizes that thermal performance must be evaluated across the operational temperature range, as λ increases by approximately 25-50% from 10°C to 40°C depending on density configuration.

This finding has fundamental implications for building envelope design in Romanian and European climatic conditions. For typical building envelope applications, the most cost-

effective thermal insulation strategy involves using materials with acceptable thermal conductivity coefficients (λ = 0.04-0.05 W/(m·K) range) installed at substantial thicknesses, rather than pursuing marginal improvements in conductivity through compression at the expense of reduced installation thickness. Therefore, in practical applications, material thickness remains the dominant factor in achieving effective thermal insulation performance.

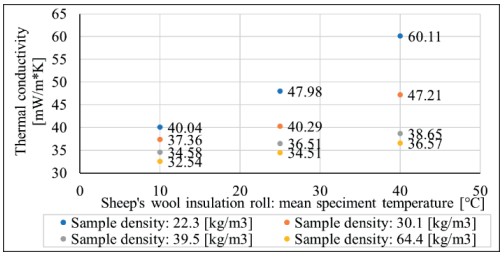

Figure 1. Thermal conductivity variation as a function of mean specimen temperature for sheep wool insulation at four density levels (22.3, 30.1, 39.5, and 64.4 kg/m³), measured using λ-Meter EP500e under steady-state conditions

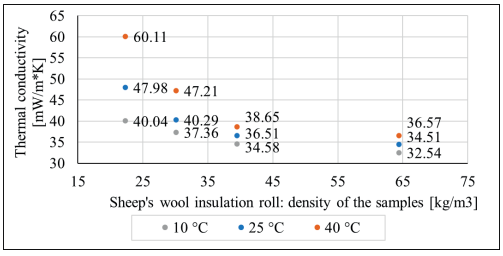

Figure 2. Thermal conductivity variation as a function of sample density for sheep wool insulation at three test temperatures (10, 25, and 40°C), measured using λ-Meter EP500e

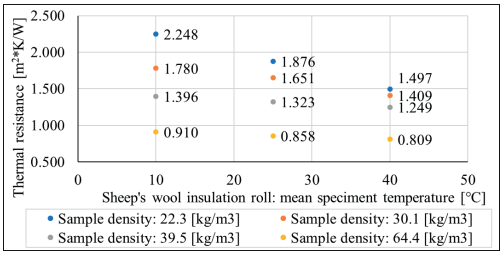

Figure 3. Thermal resistance variation as a function of mean specimen temperature for sheep wool insulation at four density levels, calculated from λ-Meter EP500e measurements (R = d/λ, where d is specimen thickness)

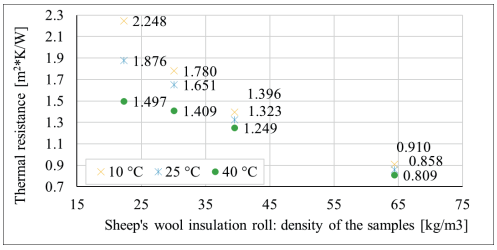

Figure 4. Thermal resistance variation as a function of sample density at three test temperatures, demonstrating the critical role of material thickness in achieving effective thermal performance

This finding aligns with European building physics principles and emphasizes that for sustainable insulation materials like sheep wool, installation at adequate thickness with proper vapor management represents a more effective strategy than pursuing material optimization through excessive compression.

## 2. Natural Density Wool Thermal Conductivity (25.5 kg/m³)

Measurements performed on sheep wool at natural density (25.5 kg/m³) using the ISOMET 2114 transient method revealed remarkably consistent thermal conductivity values across seven measurement positions. Table 1 presents the comprehensive results including thermal conductivity (λ), mean heater temperature (Tmean), coefficient of variation (CV), and number of measurements (n) for each position.

Table 1. Thermal conductivity measurements for natural density wool (25.5 kg/m³)

| Position | λ (W/m·K) | $T_{mean}$ (°C) | STDEV | CV (%) | n |
|---|---|---|---|---|---|
| 1 | 0.0456 | 28.10 | 0.000219 | 0.48 | 28 |
| 2 | 0.0460 | 27.00 | 0.000336 | 0.73 | 50 |
| 3 | 0.0453 | 27.09 | 0.000500 | 1.10 | 30 |
| 4 | 0.0447 | 27.04 | 0.000367 | 0.82 | 42 |
| 5 | 0.0455 | 27.28 | 0.000310 | 0.68 | 21 |
| 6 | 0.0465 | 27.60 | 0.000302 | 0.65 | 22 |
| 7 | 0.0454 | 27.57 | 0.000298 | 0.66 | 24 |

The results demonstrate excellent measurement consistency, with thermal conductivity values ranging from 0.0447 to 0.0465 W/(m·K) across all seven positions. Mean heater temperatures during measurements varied minimally between 27.00 and 28.10°C, reflecting ambient laboratory conditions. Coefficients of variation remained below 1.11% for all positions, with most positions achieving CV < 0.75%,

indicating high precision and low variability in the transient measurement method. The average thermal conductivity across all seven positions was 0.0456 W/(m·K), establishing a baseline reference value for natural density wool insulation.

## 3. Compressed Wool Thermal Conductivity (50-80 kg/m³)

Thermal conductivity measurements were extended to compressed wool configurations at densities of 50, 60, 70, and 80 kg/m³. Measurements were performed at multiple height levels within the test fixture where geometrically accessible according to probe requirements. Table 2 presents the comprehensive results for compressed wool configurations, achieving a balanced equilibrium across this operational density range.

Table 2. Thermal conductivity measurements for compressed wool densities

| Config. | ρ (kg/m³) | λ (W/m·K) | $T_{mean}$ (°C) | CV (%) | n |
|---|---|---|---|---|---|
| 50 kg/m³ - H1 | 50 | 0.0450 | 27.33 | 0.66 | 24 |
| 50 kg/m³ - H2 | 50 | 0.0466 | 27.19 | 0.13 | 30 |
| 50 kg/m³ - H3 | 50 | 0.0446 | 26.96 | 0.50 | 38 |
| 60 kg/m³ - H1 | 60 | 0.0446 | 28.12 | 0.37 | 30 |
| 60 kg/m³ - H2 | 60 | 0.0458 | 28.23 | 0.67 | 28 |
| 70 kg/m³ - H1 | 70 | 0.0455 | 28.40 | 0.42 | 19 |
| 70 kg/m³ - H2 | 70 | 0.0460 | 28.05 | 0.57 | 24 |
| 80 kg/m³ - H1 | 80 | 0.0460 | 28.14 | 0.59 | 24 |
| 80 kg/m³ - H2 | 80 | 0.0458 | 28.14 | 0.58 | 37 |

The compressed wool measurements using ISOMET 2114 revealed a remarkable finding: thermal conductivity remained relatively stable across the density range from 50 to 80 kg/m³ when measured with the transient method. The λ values ranged from 0.0446 to 0.0466 W/(m·K), representing a variation of only approximately 4.5% across this density interval. This apparent stability in the ISOMET measurements contrasts with the more pronounced density-dependent behavior observed in the λ-Meter EP500e steady-state measurements presented in Section 3.1, which revealed the characteristic U-shaped relationship between thermal conductivity and density across a broader range from 22.3 to 64.4 kg/m³. The difference between methodologies may be attributed to the limited density range tested with ISOMET (50-80 kg/m³), which appears to capture only the relatively flat portion near the minimum of the U-shaped curve, whereas the λ-Meter measurements encompassed both ascending and descending portions of this relationship. This density-independent thermal conductivity behavior suggests that the cellular structure of wool fibers maintains excellent insulating performance even under significant compression, with the competing mechanisms of solid phase conduction (increasing with density) and radiative transfer (decreasing with density).

## 4. Method Comparison and Polynomial Model Validation

The steady-state measurements presented in Section 3.1 obtained with the λ-Meter EP500e at controlled temperatures (10°C, 25°C, and 40°C) across the density range enabled development of second-order polynomial regression models of the form $\lambda(\rho) = a\rho^2 + b\rho + c$. These polynomial functions achieved excellent coefficients of determination ($R^2 > 0.987$), validating the characteristic U-shaped relationship between thermal conductivity and density for fibrous insulation materials, as documented in specialized literature (Lakatos, 2018; Lou et al., 2023; Shrestha et al., 2023).

Using the polynomial models, predicted thermal conductivity values for natural density wool (25.5 kg/m³) were calculated: λ = 38.84 mW/(m·K) at 10°C, λ = 44.74 mW/(m·K) at 25°C, and λ = 54.51 mW/(m·K) at 40°C. These predictions, derived from compression testing data extrapolated to natural density conditions, provide a critical validation opportunity when compared with the direct ISOMET 2114 transient measurements at natural density.

Figure 5 illustrates the validation of ISOMET 2114 transient measurements against the polynomial trendline derived from λ-Meter EP500e steady-state testing for natural density wool (25.5 kg/m³). The horizontal dashed line represents the thermal conductivity value predicted by the second-order polynomial

function at 25°C (λ = 44.74 mW/(m·K)), corresponding to the median temperature of the ISOMET measurement range. The scattered data points represent individual ISOMET measurements across four spatial positions within the specimen, plotted as a function of mean heater temperature during each measurement cycle. The tight clustering of all measurement points around the polynomial prediction line, despite temperature variations between 26.9°C and 28.5°C induced by ambient laboratory conditions and equipment operation, demonstrates excellent agreement between the two methodologies. This cross-validation confirms that polynomial functions derived from systematic compression testing at controlled temperatures can reliably predict thermal conductivity values at natural density conditions, with observed scatter attributable primarily to the inherent heterogeneity of natural fibers rather than systematic measurement bias.

Validation of ISOMET 2114 measurements on natural density wool specimens (25.5 kg/m³) demonstrated remarkable concordance with polynomial functions derived from λ-Meter tests. The experimental measurements with the needle probe across seven positions generated a distribution of points with minimal local variations relative to mean specimen temperature, concentrated in the range 26.9-28.3°C and indicating practically constant thermal conductivity of approximately 0.0446-0.0465 W/(m·K). This range corresponds excellently to the values calculated through polynomial functions for the respective density, falling within the expected interval between the 25°C prediction (44.74 mW/(m·K)) and approaching the lower temperature regime predictions.

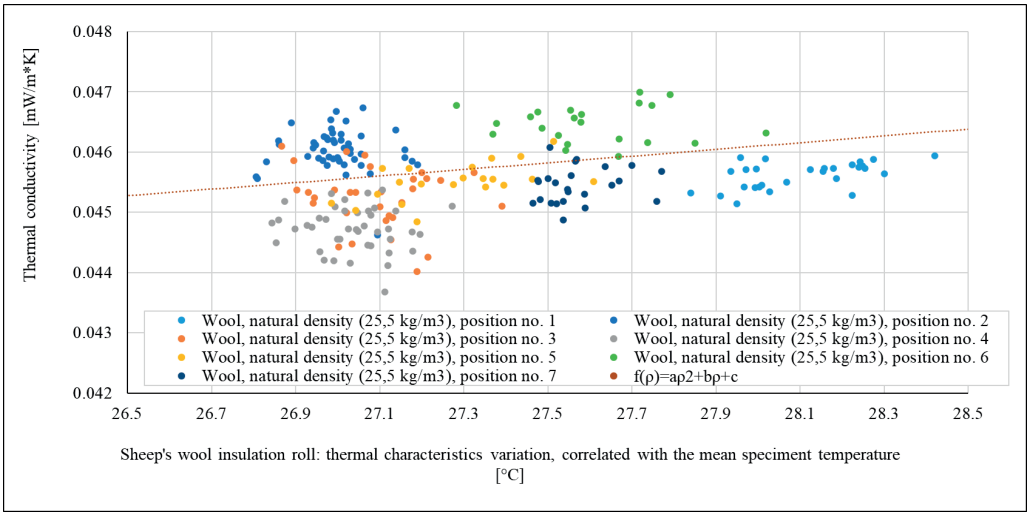

Figure 5. Cross-validation of ISOMET 2114 measurements (colored points) against polynomial prediction from λ-Meter testing (dashed line) for natural density wool (25.8 kg/m³). Measurements were performed at four spatial positions across a temperature range of 26.9-28.5°C

The limited dispersion of experimental points around calculated values, demonstrated through coefficients of variation below 1.11% within the same specimen, validates that second-order polynomial equations obtained through progressive compression in the λ-Meter EP500e can be confidently used for predicting thermal behavior of the material at natural density. Observed differences between measurement positions can be attributed to intrinsic heterogeneity of natural fibers and local temperature variations induced by ISOMET equipment utilization, aspects confirmed through coefficients of variation inferior to 2% within the same specimen. This cross-validation methodology demonstrates that polynomial functions correctly extrapolate thermal behavior even for non-compression conditions, ensuring complete material characterization across the entire operational

domain relevant for thermal insulation applications in construction.

**5. Discussions**

The most significant finding of this research is the remarkable density-independence of thermal conductivity for sheep wool insulation across the tested range of 25.5 to 80 kg/m³. This behavior, while seemingly counterintuitive, can be explained through the fundamental mechanisms of heat transfer in fibrous porous materials. The total thermal conductivity in such materials results from the sum of three components: gas phase conduction (constant for a given pore size distribution), solid phase conduction (increasing linearly with density), and radiative transfer (inversely proportional to density) (Lakatos, 2018; Shrestha et al., 2023).

For sheep wool in the investigated density range, these competing mechanisms appear to achieve a balanced equilibrium. As density increases through compression, the solid phase conductivity increases due to greater fiber-to-fiber contact area and more continuous pathways for phonon transport. Simultaneously, the increasing number of fibers per unit volume provides more scattering centers for thermal radiation, effectively reducing the radiative contribution to heat transfer. The observation that these two effects approximately cancel each other across the 25.5-80 kg/m³ range suggests that this density interval represents a thermal conductivity plateau region for wool insulation.

This finding has significant practical implications for building applications in Romanian climate conditions. It indicates that sheep wool insulation can be compressed for transport and installation convenience without suffering thermal performance degradation, provided the density remains within the 25.5-80 kg/m³ range. This flexibility contrasts with some conventional insulation materials that exhibit more pronounced density-dependent performance variations.

Comparison with literature values confirms the competitive performance of the tested sheep wool material. Vėjelis et al. (2024) reported λ values between 0.0333 and 0.0438 W/(m·K) for sheep wool insulation tested according to EN 12667, while Zach et al. (2012) documented values around 0.0380 W/(m·K) for similar materials. The present study's measurements (0.0446-0.0466 W/(m·K)) fall within the upper range of published values, which may be attributed to differences in wool fiber treatment, manufacturing processes, or measurement conditions. Nevertheless, the obtained values demonstrate adequate thermal insulation performance for building envelope applications.

The influence of moisture and temperature on thermal conductivity represents a critical consideration for hygroscopic materials like sheep wool. Vėjelis et al. (2024) demonstrated that a 1% increase in hygroscopic moisture content causes a 1.25-2% increase in thermal conductivity. The linear relationship identified by Sandberg (1992) and the polynomial dependencies documented by Talukdar et al. (2007) underscore the importance of moisture control in practical applications. While the present study focused on measurements under controlled laboratory conditions, future research should systematically investigate moisture effects on the tested wool material to provide complete characterization for design purposes.

The U-shaped curve theory for density-dependent thermal conductivity, extensively documented for fibrous insulation materials (Mazrouei-Sebdani et al., 2022; Lou et al., 2023; Pontinha et al., 2023), provides a theoretical framework for understanding the observed behavior. The present study's density range appears to encompass the relatively flat region near the minimum of this U-shaped curve, where thermal conductivity remains relatively constant. Extended testing beyond 80 kg/m³ would likely reveal increasing thermal conductivity as solid phase conduction begins to dominate over the decreasing radiative contribution.

Regarding methodology, the successful validation of polynomial regression models derived from λ-Meter EP500e measurements through comparison with ISOMET 2114 transient measurements represents an important methodological advancement. This dual-method approach combines the absolute measurement accuracy and temperature control capabilities of the guarded hot plate method with the rapid, portable convenience of

transient techniques. The excellent agreement between methods (within measurement uncertainty) demonstrates that polynomial extrapolation from compression data reliably predicts thermal behavior under natural density conditions.

The observed systematic differences between measurement methods merit consideration. As documented by Latif (2023), transient methods using needle probes can introduce local compression effects that modify apparent density and consequently measured thermal conductivity. The present study's careful attention to probe insertion technique and multiple measurement positions helped minimize these artifacts. The low coefficients of variation (< 1.11% for natural density measurements) confirm measurement reliability and proper experimental technique.

The methodological trade-offs between the two testing approaches are important for practical applications. The guarded hot plate method offers superior accuracy (< 1% typically < 0.7%), precise temperature control, and absolute measurements without calibration requirements, making it ideal for material certification and reference measurements (Baldinelli et al., 2019). However, it requires specific specimen geometries, longer test durations, and expensive specialized equipment. In contrast, the ISOMET 2114 transient method provides rapid measurements (minutes vs. hours), portable operation, simultaneous multi-property determination, and flexibility for irregular geometries, making it excellent for quality control, field testing, and comparative studies (Applied Precision, Ltd., 2019; Czajkowski et al., 2022).

For Romanian building applications, the present results suggest that sheep wool insulation represents a viable sustainable alternative to conventional materials, particularly for low-rise residential construction and renovation projects where natural, breathable insulation materials offer additional benefits beyond purely thermal performance. The material's hygroscopic behavior, while requiring careful moisture management, can contribute to indoor climate regulation when properly integrated into building envelope systems. Future research should address long-term performance under realistic Romanian climate conditions, including freeze-thaw cycling and seasonal moisture variations.

## CONCLUSIONS

This comparative study of testing methodologies for sheep wool-based thermal insulation has yielded several significant conclusions:

1. The thermal conductivity of sheep wool insulation exhibits density-dependent behavior consistent with the characteristic U-shaped relationship documented for fibrous materials, with λ-Meter EP500e measurements revealing values ranging from approximately 32.54 mW/(m·K) to 60.11 mW/(m·K) across the density range 22.3-64.4 kg/m³ and temperature range 10-40°C. At higher densities, thermal conductivity shows moderate improvement (20-25% reduction) due to increased fiber contact and reduced radiative transfer. However, the critical finding for practical applications is that thermal resistance ($R = d/\lambda$) decreases dramatically with material compression - by 54.3% in the tested range - because thickness reduction (65-70%) far outweighs conductivity improvement. This demonstrates that for building envelope applications, adequate installation thickness (≥100-150 mm for European climatic conditions) with acceptable thermal conductivity (λ = 0.044-0.047 W/(m·K)) provides superior thermal performance compared to compressed materials with improved conductivity but reduced thickness. The apparent stability observed in ISOMET 2114 transient measurements (λ = 0.0446-0.0466 W/(m·K) across 50-80 kg/m³) reflects the limited density range tested with this method, capturing only the relatively flat portion near the minimum of the U-shaped curve.

2. The guarded hot plate method using λ-Meter EP500e successfully enabled development of second-order polynomial regression models ($R^2$ > 0.987) that accurately predict thermal conductivity as a function of density across the operational range. These polynomial functions, derived from systematic compression testing at controlled temperatures (10°C, 25°C, 40°C), provide a robust mathematical framework for material characterization.

3. The transient method using ISOMET 2114 demonstrated excellent precision for natural density wool measurements, with coefficients of variation below 1.11% across seven measurement positions. The method's rapid measurement capability and portability make it highly suitable for quality control and comparative testing applications, despite inherent limitations compared to absolute steady-state methods.
4. Cross-validation between methodologies confirmed that polynomial extrapolation from λ-Meter compression data reliably predicts thermal behavior under natural density conditions. The excellent agreement between steady-state polynomial predictions and transient ISOMET measurements (within combined measurement uncertainties) validates the dual-method approach for comprehensive material characterization.
5. For practical applications, material selection recommendations depend on specific testing requirements. The λ-Meter EP500e guarded hot plate method is recommended for certification testing, reference measurements, and absolute thermal conductivity determination where highest accuracy is required. The ISOMET 2114 transient method is recommended for rapid quality control, field measurements, comparative testing between formulations, and situations requiring portable equipment or irregular specimen geometries.
Future research directions should include systematic investigation of moisture effects on thermal conductivity across the density range, long-term performance evaluation under realistic Romanian climate conditions including freeze-thaw cycling, optimization of wool fiber treatments to achieve lower thermal conductivity values approaching the 0.035-0.040 W/(m·K) range, and integration studies of wool insulation into complete building envelope systems to evaluate hygrothermal performance in actual construction applications.

## ACKNOWLEDGEMENTS

This research was funded by the Romanian Government Ministry of Research Innovation and Digitization, project No. PN 23 35 02 01 "Synergies of innovation and digitalization in the design of eco materials and multifunctional products for sustainable constructions, with an impact on the environment and the circular economy".

***Abstract***

*The European Union's Energy Performance of Buildings Directive (EPBD), as amended by Directive (EU) 2024/1275, mandates the transition from nearly Zero Energy Buildings (nZEB), with very high energy performance and substantial renewable energy coverage, to Zero Emission Buildings, with an annual zero emissions balance. Aquifer Thermal Energy Storage (ATES) offers an environmental-friendly and cost-effective technology for supporting nZEB through seasonal thermal energy storage in groundwater aquifers. This paper assesses ATES feasibility for an office building in Bucharest, Romania (climatic zone 2), using dynamic simulations for both existing and nZEB-renovated configurations. The analysis reveals significant deployment barriers including shallow unconfined aquifers (7-10 m), regulatory constraints on groundwater reinjection, and pronounced heating-cooling demand imbalances characteristic of Romania's continental climate. The proposed system integrates ATES with solar thermal technology to mitigate demand asymmetry and enhance efficiency. Results indicate that successful ATES implementation in Romania requires updated legislation, site-specific hydrogeological assessment, and hybrid renewable configurations enabling balanced seasonal thermal storage.*

***Key words****: aquifer thermal energy storage (ATES), building energy efficiency, ground source heat pump, nearly zero energy buildings (nZEB), seasonal thermal storage.*

## INTRODUCTION

The European building sector accounts for approximately 40% of total energy consumption and 36% of greenhouse gas emissions, making it a primary target for decarbonization efforts (Fleuchaus et al., 2018). The Energy Performance of Buildings Directive (EPBD), recently amended by Directive (EU) 2024/1275, establishes stringent requirements for nearly Zero Energy Buildings (nZEB), mandating that all new buildings comply with zero-emission standard by 2030, with public buildings required by 2028. The directive defines nZEB as buildings with very high energy performance where the nearly zero or very low amount of energy required should be covered to a very significant extent by renewable energy sources produced on-site or nearby. Because the directive sets no numeric thresholds for this definition, nZEB requirements and limit values are interpreted differently across Member States (Magrini et al., 2020).

Aquifer Thermal Energy Storage (ATES) represents a mature technology capable of meeting nZEB renewable energy requirements through seasonal thermal storage in groundwater aquifers. International experience demonstrates that ATES systems achieve thermal recovery efficiencies of 68-87% and reduce building energy consumption by 40-70% while cutting $CO_2$ emissions by up to 74% compared to conventional systems (Fleuchaus et al., 2018; Stemmle et al., 2021). Of the more than 2,800 systems operating worldwide, 85% are located in the Netherlands, with a further 10% in Sweden, Denmark, and Belgium, demonstrating technical maturity and economic viability with payback periods of 2-10 years (Fleuchaus et al., 2018).

Despite proven international success, ATES deployment in Central and Eastern Europe remains limited due to multiple barriers including regulatory constraints, limited hydrogeological data, and heating-cooling demand imbalances characteristic of continental

climates. Despite favourable geological conditions in western regions and substantial geothermal resources documented by Rosca and Antics (2004), Romania has not succeeded yet to fully exploit its ATES potential. The primary obstacles include obsolete groundwater legislation prohibiting thermal reinjection, insufficient aquifer characterization data, and limited institutional capacity in ATES-specific well construction requiring targeted technology transfer.

The continental climate of Romania presents unique challenges for ATES implementation. In Bucharest (climatic zone 2), annual heating demand typically exceeds cooling demand by a large margin (Tache et al. 2024; Petrişor et al., 2025), creating thermal imbalance that reduces ATES efficiency. This asymmetry contrasts with office buildings in temperate maritime climates where heating-cooling loads are more balanced. Recent work demonstrates that integrating high-temperature solar thermal collectors with underground seasonal heat storage can mitigate this thermal imbalance by injecting surplus summer heat into the subsurface, thus partially compensating for the heating-dominant load profile characteristic of continental climates (Bu et al., 2022).

Moreover, long-term numerical simulations indicate that persistent thermal imbalance leads to gradual aquifer temperature drift, reduced recovery efficiency, and potential regulatory constraints related to groundwater protection (Bloemendal & Hartog, 2018; Fleuchaus et al., 2018). In the Romanian context, where seasonal temperature amplitudes are high and heating seasons extend over 5–6 months, maintaining thermal equilibrium is particularly critical for system sustainability. Without corrective measures, thermal recovery efficiency can remain well below the 68-87% reported for well-operated installations: long-term monitoring of a doublet ATES system yielded average recovery efficiencies of only 47% and 60% for the warm and cold stores over the first three storage cycles, with annual energy and hydraulic imbalances producing thermal breakthrough between the warm and cold sides of the aquifer (Abuasbeh et al., 2021).

Hybridization strategies - including integration with solar thermal collectors, photovoltaic-driven heat pumps, or auxiliary low-carbon heat sources - have been shown to restore annual energy balance and stabilize subsurface temperatures (Fleuchaus et al., 2018). The practical relevance of such measures is reflected in regulatory practice: monitored Dutch ATES systems show annual energy imbalances between −22% and +15%, and provincial legislation requires energy balance to be met over a 3-5 year period (Bloemendal & Hartog, 2018). In particular, solar-assisted ATES systems can inject surplus summer heat into the warm well, compensating for the higher winter extraction demand typical of continental climates. Parametric studies suggest that achieving a seasonal storage balance within ±10% significantly improves long-term efficiency and mitigates environmental risks (Bloemendal & Hartog, 2018).

For Romania, the high solar irradiation levels during summer (1,400–1,600 kWh/m²·year) create favorable conditions for such hybrid configurations, especially in urban areas like Bucharest where large roof surfaces are available on commercial and institutional buildings (Năstase et al., 2018; Prăvălie et al., 2022). Therefore, adapting ATES design to continental climatic conditions through hybridization and optimized operational control is essential to ensure technical feasibility, environmental compliance, and long-term performance stability.

This paper investigates ATES application feasibility for an office building in Bucharest, Romania, through hydrogeological assessment, dynamic building energy simulations, and system design analysis. The study evaluates both existing building performance and nZEB level renovation, identifying technical barriers specific to Romanian conditions and proposing solutions including hybrid renewable system integration. The research contributes to understanding ATES deployment potential in heating-dominated continental climates and provides guidance for Romanian policy development.

## MATERIALS AND METHODS

### Case Study Building and Location

The pilot building is an office facility located in climatic zone 2, Bucharest, Romania, constructed in the 1970s with ground floor plus

two levels. The building has a gross floor area of 864 m², with occupied office spaces totalling 366.80 m² (conditioned volume 1,281 m³). The building is currently connected to the district heating system for space heating.

**Hydrogeological Investigation**

Three exploratory wells (45 m depth) were drilled at the pilot site to characterize lithology and aquifer properties through soil sampling and granulometry analysis (Figure 1).

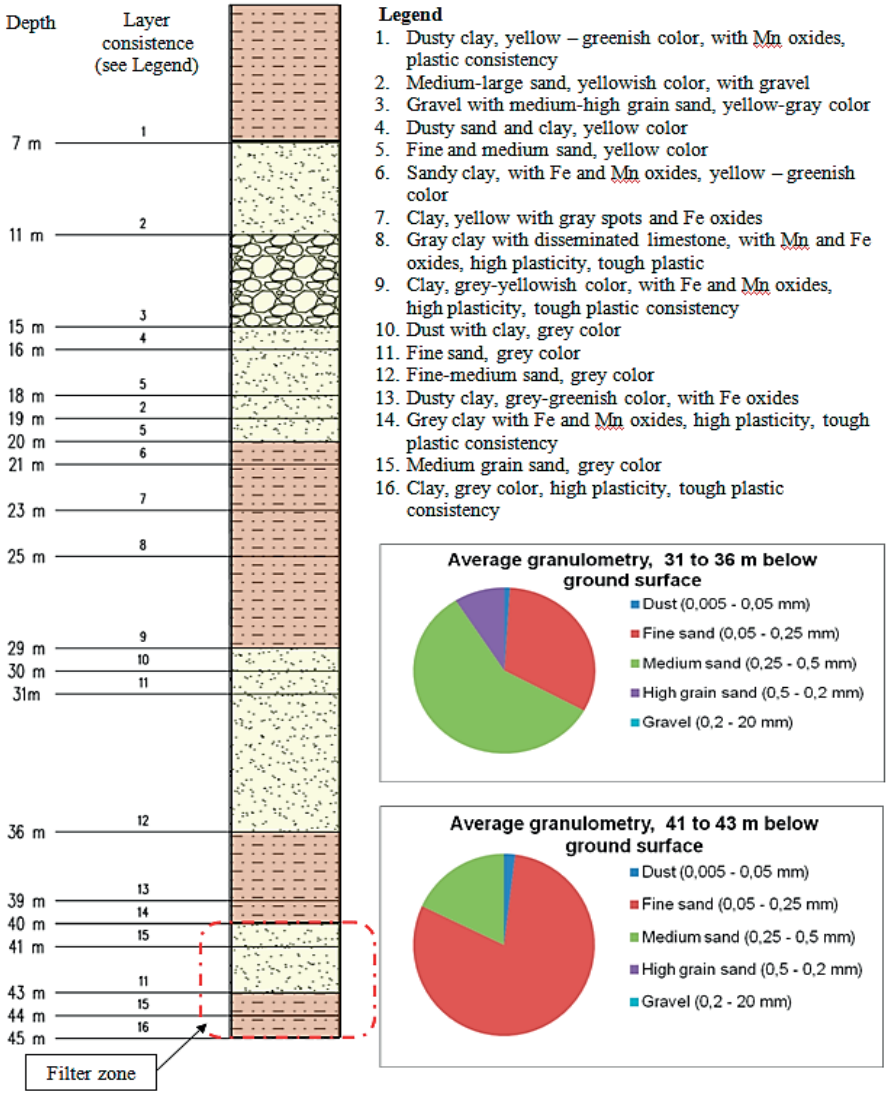

Figure 1. Site lithology, based on the 3 drills executed at the site. Lower right: breakdown for the composition of two different layers of the same aquifer

Site preparation and surface stabilization measures were implemented following erosion control protocols established for infrastructure applications (Olinic et al., 2024) to prevent surface runoff contamination during drilling operations. The investigation documented a confined secondary aquifer system at 30-45 m depth, comprising two distinct layers of 7 m and 3 m thickness respectively, yielding a combined aquifer thickness of 10 m - relatively shallow

compared to typical ATES implementations where 15-40 m are common.

Soil samples were collected during drilling and subjected to granulometric analysis in the laboratory to determine particle size distribution. The analysis revealed a significant presence of fine sand particles alongside coarser fractions, indicating moderate permeability conditions. The confined aquifer exhibits pressurized conditions with static water level rising to 11 m below ground surface, which is characteristic of artesian aquifers.

Groundwater temperature measurements were conducted in static well conditions using a calibrated PT100 resistance temperature detector at 5-meter depth intervals. Recorded temperatures were 13.18°C at 41 m depth and 12.98°C at 46 m depth.

A pumping test was performed with extraction from one well and reinjection distributed between two wells to evaluate aquifer hydraulic response. Due to project constraints including limited expertise availability and time restrictions, well screen placement was not optimally positioned. The filter zone was installed at 37-45 m depth, whereas optimal placement based on the granulometric data would have been at 29-36 m depth where higher permeability was indicated by coarser particle size distribution. The site lithology and aquifer configuration are illustrated in Figure 1.

**Building Energy Simulation Methodology**

Dynamic building energy simulations were performed using the RTU (from Romanian "Răspunsul Termic Unitar") method with one-hour time steps (Constantinescu, 2008; Petcu, 2009). The RTU method characterizes building elements thermal dynamics through the unit impulse response δ(t), enabling the determination of both intensive parameters (indoor temperatures) and extensive parameters (heat flow rates) under arbitrary climatic excitation via convolution with this unit thermal response (Skruch & Długosz, 2019; Constantinescu, 2020). The software tool implementing this method was developed and validated in earlier work (Petcu, 2009), and applied here to both existing and nZEB-renovated building configurations.

Critically for this study, the software operates with a finite heat source model: when available heating or cooling capacity is insufficient to maintain the setpoint temperature (20°C for heating and 25°C for cooling), it calculates the resulting indoor temperature deviation rather than assuming unlimited supply. This capability is essential for ATES feasibility assessment, where system thermal capacity is inherently constrained by aquifer properties and well design.

Hourly standard climate data (test reference year for Bucharest, Mc 001/6-2013) including outdoor air temperature and solar radiation on all building orientations were used as input. Software validation is documented through empirical validation using measured data from the Experimental Building INCERC Bucharest during cold and warm seasons 2008-2010 (Petcu et al., 2010), and numerical validation applying EN 15255:2008, EN 15265:2008, and ISO 13792:2012 for cooling load calculation, dynamic energy needs calculation, and summer internal temperature calculation respectively.

The building was simulated in two configurations: the existing building configuration with current envelope thermal properties, and the building renovated to nZEB standards. The existing building is characterized by limited thermal envelope performance typical of pre-renovation construction. The external walls present a thermal transmittance of 1.3 W/m²K, while the fenestration offers minimal insulation with a window U-value value of 3.2 W/m²K. The floor slab contributes to the thermal performance of the building envelope with a U-value of 2.5 W/m²K and the roof provides 0.77 W/m²K of thermal transmittance. Air leakage assessment indicates moderate infiltration with an airtightness level of $n_{50}$ = 1.5 $h^{-1}$, reflecting gaps and thermal bridges typical of existing building stock. The building is currently serviced by connection to a district heating system for thermal conditioning.

In the nZEB renovation hypothesis, the thermal envelope performance is substantially enhanced across all structural components. The thermal envelope of the renovated building is assumed to reach U-values of 0.28 W/m²K for the insulated external walls, 1.3 W/m²K for the windows, 0.2 W/m²K for the floor slab, and 0.19 W/m²K for the insulated roof, resulting in a more thermally homogeneous envelope with reduced thermal bridging. Airtightness is set to

$n_{50}$ = 0.5 $h^{-1}$, approaching passive building standards and substantially limiting uncontrolled air leakage. The renovated configuration assumes integration of renewable energy systems to meet nZEB requirements, replacing reliance on conventional district heating with technologies capable of meeting heating and cooling demands from renewable sources.

## RESULTS AND DISCUSSIONS

### ATES System Design Considerations

Based on the pilot study findings and international best practices, the confined secondary aquifer at 30-45 m depth with 10 m combined thickness can be accessed through properly designed wells with a minimum spacing of 100 m between warm and cold wells to prevent thermal interference and ensure adequate thermal storage volume (Bloemendal et al., 2018; Birdsell et al., 2021). For small-scale ATES systems in similar geological conditions, international experience indicates design flow rates of 10-15 $m^3/h$ per well (Bloemendal et al., 2014); however, the significant fine sand content and suboptimal well screen placement at the pilot site (installed at 37–45 m depth rather than the optimal 29-36 m depth indicated by granulometric analysis) restrict feasible extraction rates to approximately 2.9-5.8 $m^3/h$ (0.8-1.6 l/s). A temperature differential of 5 K between extraction and reinjection was adopted as the design value for the aquifer circuit, based on hydrogeological assessment and recommendations from the MATES project's hydrogeological partner. This differential ensures reinjection temperatures remain within environmentally safe limits: approximately 8°C during winter (cold storage) and 18°C during summer (warm storage), consistent with the ranges recommended to balance heat pump efficiency with environmental protection and avoid exceeding 25°C, which may impact trace element mobility (Bonte, 2015). At the maximum feasible site flow rate of 1.6 l/s, this differential provides a thermal exchange capacity of approximately 33.4 kW at the aquifer, sufficient to meet the evaporator demand of the proposed heat pump system under design load conditions.

The proposed system employs water-to-water heat pumps with modular scroll compressors, enabling capacity modulation across multiple steps depending on load conditions. Performance analysis indicates COP values of 6.14 for small compressor operation, 5.91 for large compressor operation, and 5.35 at full capacity with both compressors engaged. The seasonal performance factor for the complete system, including circulation pumps and auxiliaries, ranges from 4.65 to 5.01 based on operational scenarios. To protect the aquifer from potential refrigerant contamination and allow controlled flow rate variation, the technological scheme (Figure 2) incorporates an intermediate heat exchanger circuit between the heat pumps and the underground circuit. A buffer tank enables temporary sensible heat storage to accommodate variable building demands without modifying underground water flow rate, while distribution employs low-temperature heating (35/30°C supply/return) and chilled water cooling (7/12°C supply/return) to maximize heat pump efficiency and ensure compatibility with aquifer temperature levels.

### Building Energy Performance Analysis

Dynamic simulation results reveal substantial energy demand reduction through nZEB renovation. For the existing building configuration, annual specific energy consumption totals 181.41 $kWh/m^2 \cdot year$ for heating and 14.75 $kWh/m^2 \cdot year$ for cooling, based on the occupied area of 366.80 $m^2$. The pronounced heating-cooling imbalance characteristic of Bucharest's continental climate is evident, with heating demand exceeding cooling demand by a factor of approximately 12:1.

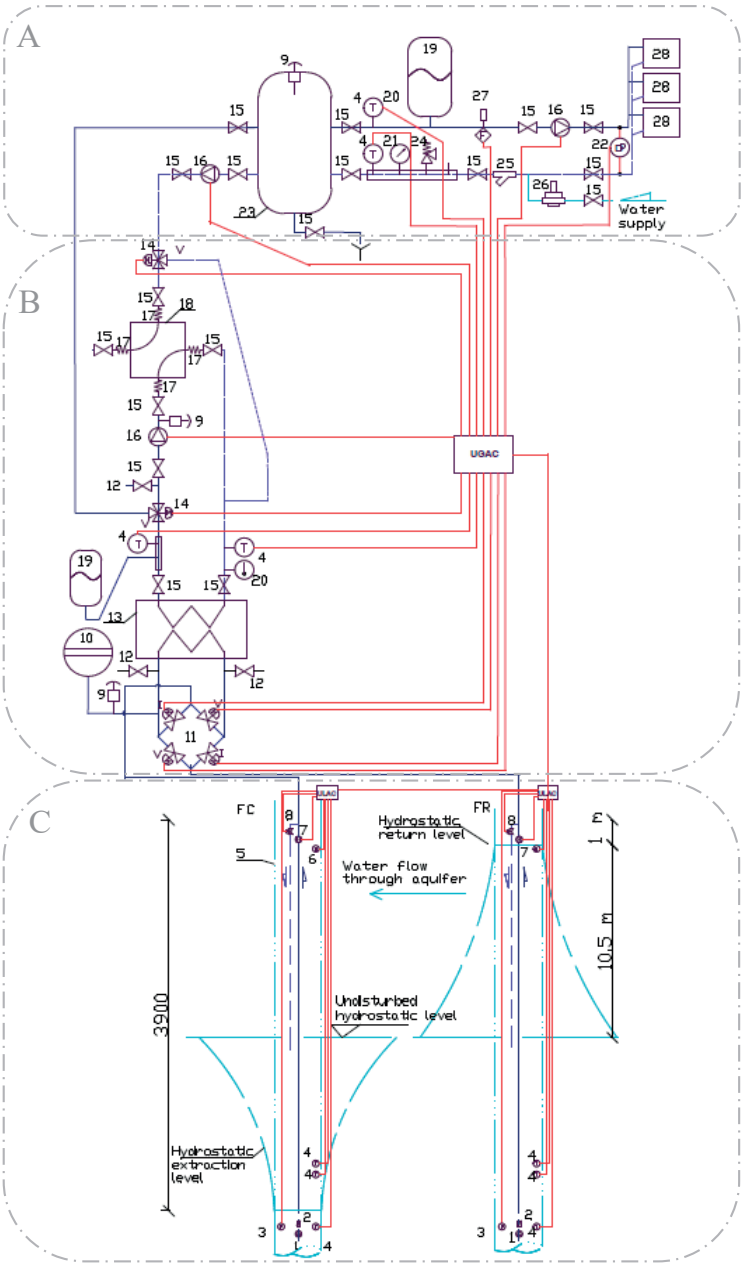

Figure 2. Technologic scheme for a heating / cooling system using ATES (A - distribution system and building related equipment, B - heat pump and other equipment from heat station, C - aquifer)
LEGEND: 1. Immersion water pump; 2. Clapper check valve; 3. Pressure transducer; 4. Temperature transducer; 5. Water well PVC pipe; 6. Water level sensor; 7. Water meter with pulse output; 8. Fan coil unit; FC – Warm well; FR – Cold well; ULAC – Local acquisition and control unit; UGAC – General acquisition and control unit; I – Winter; V – Summer

Following nZEB renovation, annual heating demand decreases to 63.99 kWh/m²·year (65% reduction) while cooling demand reduces to 9.14 kWh/m²·year (38% reduction), though the heating-cooling asymmetry persists at a ratio of 7:1. Peak demands are also substantially reduced, with maximum hourly heating load dropping from 28.5 kW to 12.3 kW and peak cooling load from 9.8 kW to 6.7 kW (Figure 3). These lower peaks make the renovated building suitable for heat pump-based systems, but this suitability comes with a critical design constraint that must be addressed explicitly.

The ATES-coupled system operates as a low-entropy heating and cooling circuit, with thermal agent parameters close to the conditioned space temperature - 35/30°C for heating and 7/12°C for cooling.

This reduced temperature lift is precisely what enables the high COP values (5.35-6.14) reported for the heat pump configuration, as thermodynamic efficiency increases with decreasing temperature differential between source and sink. However, the same characteristic makes the distribution system technically demanding. The small driving temperature difference between the agent and the indoor environment - approximately 14 K on the heating side at design conditions - severely limits the capacity of conventional terminal units. Standard fan coil units are typically rated at higher supply temperatures (40-45°C), and their performance at 35°C supply is not covered by manufacturer specifications; capacity must therefore be estimated through corrected characteristic curves rather than catalogue data. This constraint becomes particularly acute during peak heating loads, where insufficient terminal unit surface area leads directly to failure to maintain setpoint. Radiant heating systems are better suited to these low-temperature conditions but introduce their own thermal inertia challenges in buildings with variable occupancy schedules. Both the engineering calculations and the physical implementation of such a system therefore require specialized expertise - the high system-level efficiency must not obscure the significant technical risk at the terminal unit level.

The annual energy demands for both building configurations are illustrated in Figure 3.

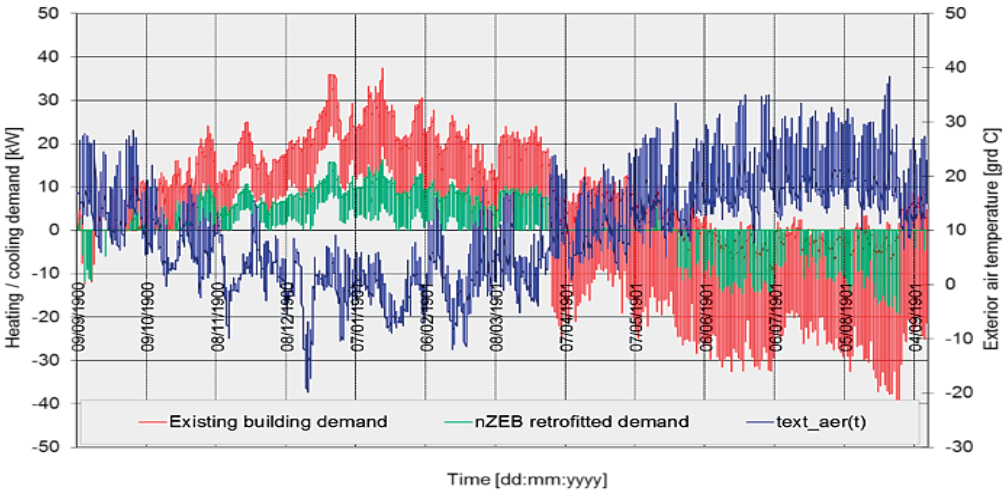

Figure 3. Energy demand of the pilot area, for existing building and the building renovated at a nZEB level

**Aquifer Characteristics and ATES Suitability Assessment**

The hydrogeological investigation identified characteristics that present both opportunities and limitations for ATES implementation. The measured combined aquifer thickness of 10 m falls below the typical 15-40 m thickness recommended for optimal ATES performance (Fleuchaus et al., 2018). Because the plume height is fixed by the aquifer thickness, a thin

aquifer also constrains the plume aspect ratio available for limiting heat losses to the confining layers (Tang & Rijnaarts, 2023), potentially limiting thermal storage volume and requiring careful system design to prevent thermal breakthrough between wells.

The confined aquifer conditions with artesian pressure offer advantages including reduced pumping energy requirements and natural protection from surface contamination. However, the pressurized nature requires careful well design to prevent uncontrolled discharge and ensure reliable reinjection capabilities. The granulometric analysis indicating significant fine sand content increases the risk of well screen clogging through particle migration and potential iron precipitation, which has been documented in other ATES systems (Possemiers et al., 2014). Preventive measures including proper well development, controlled injection velocities, and periodic monitoring would be essential for long-term operation.

The elevated groundwater temperatures (13.18°C at 41 m depth, 12.98°C at 46 m depth) exceed the regional average multiannual temperature of 10.7°C (SR 4839:2014) by approximately 2.5 K. This thermal anomaly is consistent with established patterns of groundwater thermal behaviour: at depths of 10-20 m, groundwater temperatures typically stabilize at 1-2 K above local mean annual temperatures, with further gradual increases below these depths due to geothermal gradient (Lee, 2013). The measured temperatures therefore reflect the combined influence of natural geothermal warming and potentially urban heat island effects documented in other urban areas (Benz et al., 2016; Böttcher & Zosseder, 2022), though the geothermal potential of the pilot area has not been comprehensively characterized. These elevated baseline temperatures provide advantageous conditions for heat pump operation, reducing temperature lift requirements during heating mode.

**Groundwater Quality Assessment**

Water quality analysis performed at the Bucharest pilot site revealed elevated concentrations of dissolved minerals that pose operational challenges for ATES implementation. Iron concentration measured 0.80 mg/l, exceeding the maximum contaminant allowable value by a factor of four and approaching the threshold above which iron oxide precipitation induces significant injection well clogging (Possemiers et al., 2014; Burté et al., 2019). Manganese was measured at 0.42 mg/l, exceeding its allowable limit by a factor of 8.4. While manganese contributes less to clogging than iron, the simultaneous presence of both elevated iron and manganese increases the risk of combined mineral precipitation during thermal cycling. Beyond inorganic parameters, urban aquifers in Bucharest may be subject to persistent organic pollutant contamination from historical industrial activities, though recent monitoring shows declining trends in urban soil contaminants such as polychlorinated biphenyls (Sandu et al., 2025), suggesting gradual improvement in urban environmental quality.

**ATES System Performance Assessment**

For the pilot building with occupied area of 366.80 m², the annual heating energy demand of 63.99 kWh/m²·year translates to approximately 23,470 kWh total annual heating requirement, while cooling demand of 9.14 kWh/m²·year corresponds to approximately 3,350 kWh annual cooling requirement. This pronounced imbalance (ratio 7:1) presents significant challenges for ATES thermal balance.

The heat pump system performance with seasonal performance factor (SPF) of 4.65 to 5.01 demonstrates the potential for highly efficient operation when coupled with ATES thermal storage. The modular compressor configuration allows optimization of part-load performance, with single compressor operation achieving COP values up to 6.14 during low-demand periods. This operational flexibility is particularly valuable for accommodating variable building loads and maximizing energy efficiency throughout the heating and cooling seasons.

The heating-cooling asymmetry has direct consequences for long-term ATES performance. A sustained mismatch between seasonal cooling injection and heating extraction produces a continuous thermal drift of the aquifer around the wells: the storage volume gradually cools until a new quasi-stationary regime is reached, characterized by asymmetric thermal plumes and a progressive reduction of the available

temperature contrast between warm and cold wells (Sommer et al., 2013; Fleuchaus et al., 2018; Godinaud et al., 2025).

From an environmental and regulatory perspective, such imbalance – particularly on the cooling side – is generally permissible in urban contexts. Regulatory frameworks are primarily concerned with excessive groundwater warming rather than moderate cooling, and life cycle assessments confirm that ATES yields substantial greenhouse gas reductions - up to 74% for heating compared with oil- and gas-fired systems, and up to about 59% for cooling relative to conventional techniques under the present electricity mix, rising to some 97% under a projected 2050 electricity mix (Stemmle et al., 2021). The dominant environmental impacts are attributable to operational electricity demand, which is responsible for over 95% of water use, global warming potential and acidification impacts, rather than to aquifer temperature changes (Ni et al., 2020). The critical consequence of persistent imbalance is therefore thermodynamic, not environmental: reduced temperature contrast translates directly into declining heat recovery efficiency and lower heat pump performance over successive annual cycles. Field monitoring of an imbalanced LT-ATES system documented a progressive decrease in the temperature difference on the ATES side - from approximately 3 K down to 1.8 K over four cooling seasons despite an available $\Delta T$ of 8 K - confirming that performance degradation under imbalanced operation exceeds what hydrogeological dispersion alone would produce (Abuasbeh et al., 2021). Numerical simulations corroborate this: thermally balanced doublet operation produces stable, symmetric plumes and sustained performance over decades, whereas imbalanced scenarios show enlargement of the warm plume, reduction of the cold plume, and progressive warming of the screened interval (Bozkaya et al., 2018; Godinaud et al., 2025).

The integration of solar thermal collectors offers a practical solution to achieve thermal balance. International experience demonstrates that ATES systems achieve high seasonal performance in heating-dominated climates, and that supplementary heat injection is the accepted lever for maintaining long-term balance. Vanhoudt et al. (2011) documented three years of monitored operation of an ATES-heat pump system at a Belgian hospital, achieving a seasonal performance factor of 5.9 for heating and a 71% reduction in primary energy use compared with gas boilers and conventional chillers.

For the Bucharest pilot building, evacuated tube collectors could provide supplementary heat injection during summer cooling season to reduce thermal imbalance. The sizing of such a solar thermal system would need to balance the heating-cooling asymmetry, potentially requiring collector areas and storage capacities determined through detailed optimization considering building loads, available roof area, seasonal solar irradiance patterns, and system integration requirements. This hybrid renewable configuration would facilitate meeting EPBD requirements for on-site renewable energy generation while enabling sustainable ATES operation.

Beyond system-level solar thermal augmentation, imbalance can be managed through multi-well configurations and optimized well placement accounting for ambient groundwater flow, aquifer thickness, and urban constraints, which help maintain higher heat recovery factors even under imperfectly balanced loads (Sommer et al., 2013; Li et al., 2024; Petrova et al., 2025) and, in aquifers with high flow velocities (of the order of 100 m/year), an additional upstream extraction well acting as a hydraulic barrier can more than double thermal recovery efficiency relative to a conventional doublet (Ohagen et al., 2025). At urban scale, coordinated planning of multiple ATES systems allows excess cold from individual installations to be offset by excess heat from others, improving overall aquifer balance and increasing deployment density by approximately 30% (Sommer et al., 2015; Bloemendal et al., 2018; Beernink et al., 2022). Contemporary design guidelines therefore treat thermal imbalance as a manageable design variable rather than a hard constraint, emphasizing active balance management through control strategies and additional thermal sources as the key lever for maintaining long-term system viability (Bozkaya et al., 2018; Abuasbeh et al., 2021).

**Regulatory and Institutional Barriers**

The primary impediment to ATES deployment in Romania is Water Law no. 107/1996 (with subsequent amendments), which regulates reinjection of extracted water into aquifers. Contemporary operational experience with discharge quality compliance in Romanian wastewater treatment facilities demonstrates that meeting natural receptor standards requires continuous technological adjustment and monitoring (Dracea et al., 2022), principles equally applicable to ATES thermal discharge management. The legislation was designed primarily for mining and industrial wastewater discharge, establishing strict prohibitions on reinjection into the same aquifer from which water was extracted. This regulatory framework does not differentiate between contaminated industrial wastewater and closed-loop thermal energy storage where groundwater contacts only inert heat exchanger materials.

International regulatory frameworks provide alternative models that could guide Romanian policy development. The Netherlands employs a performance-based permitting system where ATES installations must demonstrate that thermal impacts remain within acceptable limits and that annual thermal balance is maintained (Bloemendal et al., 2014). German regulations, while more restrictive, still explicitly permit ATES systems under appropriate monitoring and control conditions (Stemmle et al., 2021).

The absence of ATES-specific technical standards in Romania creates additional uncertainty for potential investors. Key gaps include lack of well design specifications, monitoring requirements, operational protocols, and decommissioning procedures. The development of Romanian national standards based on established international protocols would facilitate systematic ATES deployment while ensuring environmental protection.

Institutional capacity represents another significant barrier. Limited Romanian experience exists with ATES-specific well construction techniques, and hydrogeological expertise for thermal storage applications is scarce. Professional training programs and technology transfer initiatives modelled on Dutch and German experience would be necessary to build domestic technical capacity for this renewable energy technology.

**Comparison with International ATES Experience**

The Bucharest pilot study findings align closely with recent assessments in other European countries facing similar regulatory and technical challenges. Noethen et al. (2025) identified substantial ATES potential in German regions despite regulatory barriers limiting implementation, while Jackson et al. (2024) report that ATES in the United Kingdom currently meets less than 0.01% of national heating demand although the technology could in principle serve about 61% of it. Similar to the Bucharest case, these studies demonstrate that technical feasibility exists but institutional frameworks remain underdeveloped.

The heating-cooling imbalance documented for Bucharest (ratio 7:1 for renovated building) is more severe than typical Dutch office buildings (ratio 1.5-2.5:1) but comparable to heating-dominated climates in Sweden and northern Germany. The proposed solar thermal integration strategy has precedent in Swedish and Belgian applications where seasonal storage systems achieve thermal balance through coordinated operation with solar collectors.

The shallow aquifer depth identified in Bucharest (10 m combined thickness) presents greater challenges than typical Dutch ATES installations (15-40 m aquifer thickness) but remains within technically feasible ranges. Al-Madhlom et al. (2019) proposed a multi-criteria site selection method (AHP combined with the DRASTIC index) specifically for shallow groundwater conditions, confirming that such settings require more conservative design approaches and careful thermal management.

**Study Limitations**

One should acknowledge several limitations of this pilot investigation. The hydrogeological characterization was based on three exploratory wells within a limited site area, providing insufficient data to fully characterize aquifer heterogeneity and regional groundwater flow patterns. A more comprehensive assessment would require additional wells, long-term pumping tests, and seasonal temperature monitoring to validate ATES feasibility for commercial-scale implementation.

The dynamic building simulations employed standard test reference year climate data and

assumed operational patterns based on typical office occupancy. Climate change projections indicate potential shifts in heating-cooling ratios for Central Europe (Godinaud et al., 2025), which could affect long-term ATES thermal balance. Future studies should incorporate climate scenarios to assess system performance under evolving conditions.

The system design considerations and performance estimates presented in this study are based on simulation results and international best practices adapted for Romanian conditions rather than operational data from a functioning pilot installation. Actual implementation would require comprehensive feasibility studies including detailed performance monitoring, cost-benefit analysis, and long-term operational experience to validate the projected system performance and economic viability.

## CONCLUSIONS

This study demonstrates that Aquifer Thermal Energy Storage (ATES) technology presents technically feasible opportunities for supporting nearly Zero Energy Buildings (nZEB) in Romanian continental climate conditions, though significant regulatory and technical barriers currently impede implementation. The pilot assessment for an office building in Bucharest revealed that nZEB renovation reduces annual energy demand by 65% for heating and 38% for cooling, making the building suitable for integration with renewable ATES-based systems.

The hydrogeological investigation documented a confined secondary aquifer at 30-45 m depth with 10 m combined thickness across two layers (7 m and 3 m) separated by a clay deposit. The aquifer exhibits favorable characteristics including moderate hydraulic conductivity and elevated ambient temperatures (13.2°C) that benefit heat pump operation. However, the aquifer thickness falls well below optimal ranges typical of international ATES installations, necessitating conservative design approaches and careful thermal management.

The elevated iron and manganese concentrations documented at the pilot site illustrate a broader challenge for ATES deployment in Romania. These values were obtained from a single site; Romanian aquifers across different geological regions may exhibit substantially different mineral profiles. Successful ATES deployment at national scale requires a systematic hydrogeochemical pre-screening of candidate aquifers, analogous to the regional water quality survey methodology developed by Allen (1983) for the United States. Recent assessments of groundwater contamination risks in Romania confirm the urgency of such systematic screening, revealing widespread vulnerability to multiple contaminants including nitrates, arsenic, and coliforms affecting over 670,000 individuals in rural areas alone (Ivanescu & Sandu, 2025). Allen's framework identified groundwater chemistry - particularly total dissolved solids, iron content, and carbonate saturation - as the primary determinants of long-term well injectivity and system reliability, concluding that freshwater with TDS below 500 mg/l in quartz sand aquifers represents the most favorable condition for low-temperature ATES. No equivalent national-scale screening exists for Romania, despite the fact that groundwater mineral content likely constitutes the most significant technical challenge for widespread ATES deployment in the country.

The pronounced heating-cooling demand imbalance characteristic of Bucharest's continental climate (ratio 7:1 even after nZEB renovation) represents the primary technical challenge for ATES deployment. This asymmetry would progressively cool the aquifer over multiple annual cycles, degrading system performance unless addressed through supplementary heat sources. Integration of solar thermal collectors offers a practical solution to achieve thermal balance, as demonstrated by successful international implementations in similar heating-dominated climates.

The heat pump system performance analysis indicates seasonal performance factors (SPF) of 4.65 to 5.01, demonstrating potential for highly efficient operation when properly integrated with ATES thermal storage. The modular compressor configuration enables optimization across variable load conditions, achieving COP values ranging from 5.35 to 6.14 depending on operational mode.

Romania's current regulatory framework poses the most significant barrier to ATES implementation, with Water Law no. 107/1996 prohibiting thermal reinjection without differentiation

between contaminated wastewater and closed-loop thermal storage. Development of ATES-specific regulations modeled on international performance-based permitting, combined with technical standards for well design and operation, would facilitate deployment while ensuring environmental protection.

Successful ATES implementation in Romania requires coordinated action on multiple fronts including: (1) legislative revision to permit thermal energy storage with appropriate monitoring requirements, (2) development of national technical standards based on international best practice, (3) pilot demonstration projects to build domestic expertise and generate operational data, (4) professional training programs for ATES design and operation, and (5) hydrogeological assessment campaigns to map aquifer suitability in major urban areas.

The research demonstrates that with appropriate institutional frameworks and hybrid system configurations integrating ATES with solar thermal technology, this renewable energy storage approach can significantly contribute to achieving Romania's nZEB targets and building sector decarbonization goals while providing reliable, cost-effective heating and cooling services.

# CASE STUDY ON THE ASSESSMENT OF THE EFFECTS OF CONTROLLED BLASTING DEMOLITION ON NEARBY BUILDINGS

**Adrian SIMION**

National Institute for Building Research, Town Planning and Sustainable Territorial Development "URBAN - INCERC", 266 Pantelimon Road, District 2, Bucharest, Romania

Corresponding author email: simion_i_adrian@yahoo.com

***Abstract***

*Some of the civil and industrial buildings in Romania have exceeded or will exceed, in the coming period, their expected operating lifespan. This fact requires the establishment of a strategy for their replacement and one of the methods that responds to a high degree to these requirements is the demolition of buildings using explosives. This paper presents a theoretical study assessing the impact of the explosive demolition of an industrial building on an adjacent 10-story residential structure. The evaluated effects included the aerial shock wave, seismic impact, thrown fragments, and environmental pollution. To this end, both pyrotechnic parameters and calculation formulas derived from specific legislation were utilized. The demolition impact assessment was carried out during the design stage, providing the necessary documentation to obtain the demolition permit for the industrial building.*

***Key words****: blast effects, buildings, explosives, explosive demolition, impact assessment.*

## INTRODUCTION

Each structure is designed for a specific service life. After this service life, its existence becomes very dangerous for its occupants and surrounding buildings (Popa et al., 2024).
The demand for demolishing old buildings has increased recently, especially in major cities worldwide, where numerous structures were built during past periods of high economic growth (Silva et al., 2022).
A significant portion of these buildings are demolished using techniques that utilize explosive energy, which are often applied in the USA, Europe, and China (Isobe & Jiang, 2022).
In Romania, urban modernization in recent years has generally provided the pretext for the demolition of numerous old buildings.
In some situations, the demolition of these structures was only possible by applying new methods of controlled demolition using explosives (Laszlo et al., 2022).
Implementing the technique of demolishing structures using explosives aims to achieve the desired results by applying optimal constructive and economic solutions, without disrupting ongoing activities, and ensuring safety for both the personnel involved and the environment (Thomsen et al., 2011). Demolishing structures using explosives poses a series of risks to the environment and to people within the range of the explosion's effects. These works are carried out based on technical projects starting from the hypothesis of minimizing and/or removing these risks. In reality, this state of affairs is not always possible.
Sometimes, it is not possible to determine by calculation the optimal explosive charges to achieve the desired effect while maintaining a satisfactory level of protection. At other times, charges calculated as safe from a protection standpoint cannot achieve the desired blasting effect. For these reasons, implementing a demolition project using explosives - especially in an urban environment - requires a compromise between the amount and placement of explosives used to achieve the desired goal and the actual level of protection for the surrounding environment and individuals within range of the explosion's effects.
Practice in the field has shown that a way to achieve this compromise is to use the explosive charges resulting from the calculation as necessary to achieve the desired effects, while using measures to protect the environment and individuals, by means of means of protection adequately sized to achieve the required level of safety.

## MATERIALS AND METHODS

The study presented below consists of assessment of the effects that the demolition of an industrial structure had on buildings located in the nearby of this demolition area.
These effects consisted of the air shockwave effects, the seismic effect, the effect of thrown fragments and the effect of environmental pollution (Fourney, 1983). The structure demolished through controlled blasting (hereinafter referred to as OD12) was an industrial building located on the premises of the former Titan Factory - Bucharest (Figure 1).

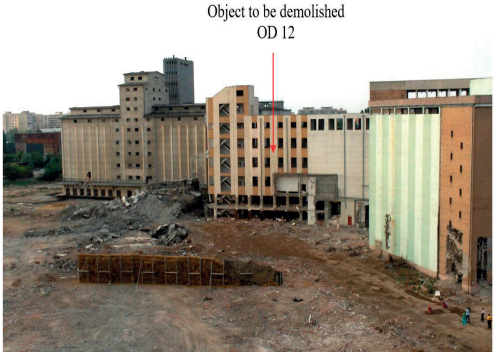

Figure 1. Overview of OD 12 before demolition, taken from the 10th floor of the protected building

Outside the TITAN Bread Factory, to the south, several residential complexes were built approximately 130 m away from the demolished structure (Figure 2).

Figure 2. View from the terrace of the industrial building to be demolished, with the residential blocks which the construction to be protected is part

The demolished building featured a reinforced concrete frame system, with a resistance structure consisting of columns and beams stiffened by floor slabs.
Before demolition, the building had a rectangular footprint measuring 28.20 x 9.25 m and a height of GF+5 floors+2 recessed floors (total height of 31.90 m).
It consisted of two sections without an expansion joint between them: the first section measured 12.20 x 9.25 m (GF+5F+2R), and the second section measured 16.00 x 9.25 m (GF+5F).
The building's structural frame consisted of reinforced concrete frames, with columns (measuring 0.75 x 0.75 m at the ground floor and 1st floor, and 0.65 x 0.65 m at the 2nd floor), beams (0.35 x 1.00 m and 0.45 x 0.70 m at the ground floor, 0.60 x 1.00 m and 0.45 x 1.00 m at the 1st floor), and ribs (0.25 x 0.40 m and 0.20 x 0.30 m). The layout and dimensions of the columns within the industrial building structure are shown in Figure 3.

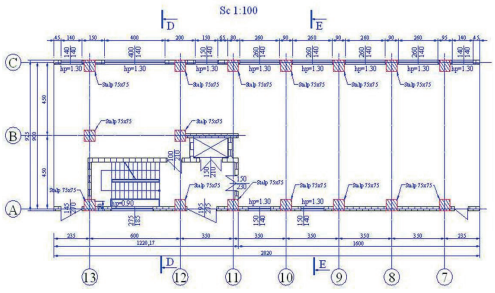

Figure 3. Ground floor plan of the demolished structure

The building's roof consisted of a reinforced concrete coffered slab (waffle slab) for the 5-story section (GF+5) and a reinforced concrete flat slab for the section with a height of GF+5+2R (receded floors), both equipped with thermal and water insulation. Access to the upper floors was provided via stairs.
The building envelope was made of non-load-bearing brick masonry walls and glazed surfaces, which were destroyed once the factory was abandoned (Figure 4). The reinforced concrete technological floors were positioned at the following levels: +3.50 m, +7.00 m, +11.50 m, +16.00 m, +20.50 m, +25.00 m, and +28.70 m.

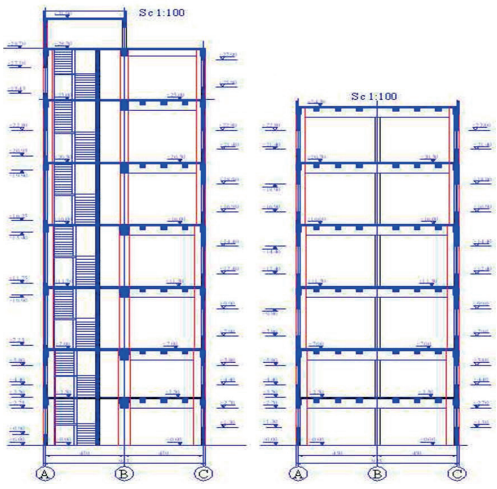

Figure 4. Cross sections of the demolished structure

During the demolition of the industrial building, measures were taken to protect neighboring structures from the effects of the process.
One of the protected buildings was a 10-story residential block consisting of a rigid core and reinforced concrete frames.
The centrally located core, made of shear walls surrounding the elevator, was designed to handle most of the lateral loads, while the reinforced concrete columns were responsible for supporting the gravity loads (Figure 5).

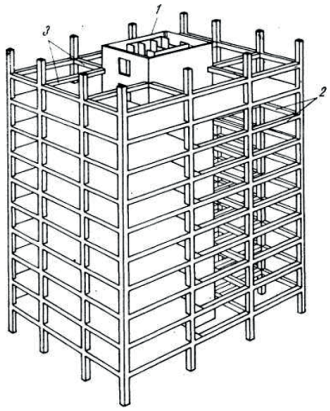

Figure 5. Combined structure made with central core and reinforced concrete frames: 1- central core made of reinforced concrete diaphragms; 2 - marginal reinforced concrete frames; 3 - intermediate reinforced concrete frames

During the demolition works of OD 12 using controlled explosions, the following effects occurred: the air shockwave effect; the seismic effect; the effect of thrown fragments; and the effect of environmental pollution.
*Assessment of the effect of the air shock wave:*
According to the legislation in force in Romania, in HG 536/2002 the value of the overpressure in the shock wave front is determined with the relation:

$$\Delta p_f = 0.84\lambda + 2.7\lambda^2 + 7\lambda^3 \quad [\text{kgf/cm}^2]$$

where λ is the scaled distance and is calculated with the relationship:

$$\lambda = \frac{\sqrt[3]{Q}}{R} \qquad [\text{kg/m}]$$

where $Q$ is the amount of explosive material, expressed in TNT equivalent [kg], that detonates instantaneously and $R$ [m], is the distance measured from the site of the explosion to the protected building.
Compared to OD 12, the nearest building is a residential apartment building located at a distance of approximately 130 m.
The maximum charge per delay interval is 3.3 kg of dynamite. Since a nitroglycerin-based explosive mixture is used for the demolition, which has an equivalence coefficient of 1.3 TNT equivalent and there are 3.3 kg of dynamite per detonation stage, it follows that (HG 536, 2002):

$$Q = 3{,}3 \times 1{,}3 = 4{,}29 \text{ [kg TNT equivalent].}$$

The 4.29 kg of dynamite results from adding the amount of explosive in the holes to the amount of PETN in the detonating cord used to initiate the explosives (10 g/m).
Under these conditions, the value of parameter λ is:

$$\lambda = \frac{\sqrt[3]{Q}}{R} = \frac{\sqrt[3]{4{,}29}}{130} = 0{,}0125 \text{ [kg/m].}$$

The resulting value is negligible; for this reason, the shock wave front overpressure was determined via the direct method, resulting in:

$$\Delta p_f = 0.84x0{,}0125 + 2.7(0{,}0125)^2 + 7(0{,}0125)^3 = 0{,}0111 \text{ [kg/cm}^2\text{]}.$$

This calculation did not account for the fact that the total mass of explosive used in the previous calculation is distributed into small charges placed in blast holes (Olsson & Bergqvist, 1993).

For this reason, specialized literature, such as works by experts from the Swedish Detonic Research Foundation (Persson et al., 1981), considers that the overpressure value in the shock wave is:

$$\Delta p_f^* = 0.2\Delta p_f \text{ [kg/cm²]}.$$

In this case $\Delta p_f^* = 0.00222\,kg/cm^2$ and this value is well below the limit that could cause any damage to the building being protected.

From the analysis of this data, it appears that, to protect the neighboring property during demolition, it is sufficient to install protective measures consisting of used rubber mats or to create screens from straw bales, tarpaulins, etc.

*Assessment of the seismic effect induced by detonation of explosives:*

The seismic effect caused by oscillations produced by the detonation of explosives charges during blasting works subjects nearby structures to spatial movement, which places dynamic stress on their constructive elements.

Depending on the intensity of the oscillations and the condition of the structures, stresses can cause damage over time.

This occurs when the generated oscillations lead to dynamic stresses that exceed the tensile, shear, or bending strength of the structural elements.

To assess the seismic effect of elastic oscillations transmitted through the ground to building foundations, the velocity criterion has been chosen globally in most cases, as it is the only reproducible parameter for the entire range of frequencies characteristic of seismicity produced by blasting works (Persson et al., 1970).

The seismic waves affecting the structure to be protected are generated by the detonation of explosive charges in the blast holes within the structural elements of OD 12 and by the ground impact resulting from the building's collapse (Lupoae, 2016).

*Assessment of the seismic effect induced by explosions inside structural elements:*

When designing blasting works, the size of the concentrated explosive charge that can be detonated instantaneously is determined by the formula:

$$Q_{inst} = \left(\frac{R}{\alpha k}\right)^3 \text{ [kg TNT equivalent)]},$$

where $R$ is the distance between the blast site and the target (m); $k$ is a coefficient based on the properties of the medium being blasted, and α is a coefficient depending on the blast effect index. The quantity of explosive that can be detonated per delay stage is determined by the relation:

$$Q_{tr.itr} = \frac{2}{3} Q_{inst} f(n) K_1 \text{ [kg TNT equivalent)]},$$

where $f(n)$ is a reduction coefficient based on the delay time of the initiation system, and $K1$ is a reduction coefficient based on the number of blasts carried out during a year.

Using the calculation formulas presented above, for objective OD 12, the following is obtained: $R$ = 128 m (the distance between OD 12 and the building to be protected); $K$ = 9 for clay rocks; $\alpha$ = 1 (for an explosion index $n$ = 1); $Q_{inst}$ = 1139 kg TNT equivalent = 876.5 kg dynamite; $f(n)$ = 0.917 for the NONEL-MS system; $K_1$ = 1 (for one blast); $Q_{tr\ itr}$ = 696.5 kg TNT equivalent = 535.8 kg dynamite.

It can be observed that the values obtained from the calculation are very high compared to the maximum explosive charge per delay stage of 3.3 kg dynamite.

Even if the explosive charges were to detonate in boreholes drilled into the ground, the oscillation velocity generated by the explosion shock is below the level established as admissible.

In conclusion, given that these charges detonate above the ground, a potential seismic effect induced through the soil cannot be considered regarding the blasting works performed for the demolition of OD 12.

*Assessment of the seismic effect induced by ground impact during the collapse of OD 12:*

Assessment the seismic effect produced by the collapse of OD 12 on the ground, it must be

noted that the resistance structure consists of reinforced concrete frames.

For these structures, when the chosen demolition method is overturning in a specific direction, the reduction of the main portion of the falling energy is achieved through the large interior spaces of the structure.

These spaces ensure that, at any given moment, only a small fraction of the building's elements are in contact with the ground, while other elements reach their breaking point and subsequently collapse completely (Figure 6; Figure 7; Figure 8).

Figure 6. Space inside the demolished building from a lower floor

Figure 7. Space inside the demolished building from a higher floor

Figure 8. The structural elements of OD 12 collapsed on the ground

*Assessment of the effect of thrown fragments:*

The main consequences of this effect consist of: local destruction resulting from the impact between the thrown fragments and the protected objective; the occurrence of local fires where the thrown fragments land, if they are heated to an appropriate temperature; to minimize these effects, a series of protective measures have been taken, as follows: installing wire mesh with a 0.03 × 0.03 m mesh size on the building to be demolished, directly over the explosive-filled boreholes, to slow down and retain large concrete fragments detached during the explosion (Figure 9);

Figure 9. Wire mesh used in the manufacture of protective screens

installing various types of screens on the construction pillars, adjacent to the boreholes loaded with explosives, to slow down and

contain small fragments detached during explosions (Figure 10); installing protective panels on or near the structures to be protected and identifying any potential fire outbreaks immediately after demolition and extinguishing them.

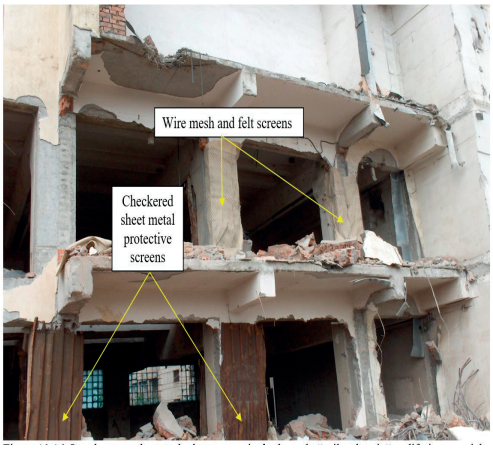

Figure 10. Installation in front of mine holes, the various type of screens for slowing down and retaining large fragments detached from the explosion

*Assessment of the environmental pollution effect:*

This effect is limited in both time and space of action; it is caused by blasting gases and dust resulting from the crushing of the reinforced concrete structure, as well as the interaction of structural elements with each other and upon contact with the ground (Figure 11).

Figure 11. Dust and explosion gas pollution during demolition of OD 12

To reduce dust pollution, the area where the structure collapsed was sprayed with water, both before and immediately after its fall (Figure 12).

Figure 12. Water spraying of the demolition area to limit dust pollution

## RESULTS AND DISCUSSIONS

The results obtained from this study primarily serve a justificatory role. This study can be provided by the demolition contractor to the relevant authorities in the event of complaints from residents of protected properties regarding inconveniences or damage caused by the demolition activity (Simion, 2014).

Thus, to prevent potentiality litigation during the demolition of the industrial structure presented in this paper, monitoring actions were carried out. Monitoring refers to post-event verification methods of the effects generated by this type of demolition. These consisted of filming and photographing the preparatory work performed on the structure to be demolished, filming and photographing the condition of protected buildings before and after the demolition, and measuring blast effects regarding airblast and seismic wave levels, as well as the level of dust dispersed in the air and deposited in the environment.

The non-hazardous level of oscillations caused by explosions during the industrial building demolition is established based on the degree of damage to structures located in the nearby of the demolition area (Singh & Roy, 2010). This threshold varies from country to country and is generally adopted based on the quality of the

constructions and even the manner in which minor repairs are executed for buildings near the blasting area.

It was assessed that the collapse process of the industrial building did not generate ground oscillation intensities capable of damaging neighboring buildings in any way.

During the demolition of the industrial structure, no shrapnel projections or fragments of building materials were observed and recorded, and the overpressure in the shock wave front due to explosions was of short duration and low intensity, and did not cause inconvenience to residents of nearby buildings.

## CONCLUSIONS

The demolition of vast portions of the existing urban structure has been a continuous feature of urban renewal in Romania since the 1990s (Simion & Dragomir, 2014). In this process, many buildings that could have been renovated or otherwise utilized were lost. A large part of these constructions were industrial structures was demolished using one of the most efficient techniques: demolition with explosives. This technique is based on the destructive action of explosions within holes drilled into structural elements to cause the collapse of the building.

This method is particularly effective for large industrial facilities where rapid demolition is required.

However, despite its efficiency, the demolition with explosives requires rigorous engineering analysis and expert supervision to prevent unintended damage to nearby buildings (Yuzbasi, 2025).

Studying the destructive phenomena and actions that occur during explosions requires evaluating, with a certain probability, the scale of destruction and the effects produced on people and various urban buildings.

The destructive effect of explosions on structural elements manifests in a particular way, as the explosive charges detonate in the holes where they are placed, and the transfer of a certain amount of energy from the explosion to the construction material and the environment generates the destructive action and the effects of the explosion.

Controlled demolition projects differ from one construction to another and generate undesirable effects, such as acoustic, seismic, and dust impacts, which must be continuously understood and measured.

To ensure the impartiality and credibility of these effect measurements, they must be carried out by specialists other than those performing the demolition works. These specialists must be accredited for such tasks (possessing proven qualifications and competence) and must use specialized equipment for recording dynamic parameters that has been metrologically verified.

***Abstract***

*In the current context of the implementation of the provisions of the new P118-1:2025 on the fire safety of buildings in Romania, an important role falls to testing laboratories for determining the fire resistance of building elements, in order to increase the fire safety of the built environment. For these reasons, the assessment of the fire behaviour of building elements made of non-load-bearing masonry is an essential component for fulfilling the fundamental requirement of fire safety of buildings. The tests for determining the fire resistance of building elements in Romania, are carried out within the INCERC Testing Laboratory from Bucharest and consist of applying standardized fire resistance testing methods that are harmonized at the level of the countries of the European Union. Recently, researchers from this laboratory conducted several experimental tests to compare the fire resistance of non-load-bearing masonry walls of varying thicknesses.*

***Key words****: cladding systems, compartment fires, experimental research, fire resistance tests.*

## INTRODUCTION

Theoretical studies and experimental research have highlighted that every fire has its own evolution that makes it unique, with no two fires following an identical path. This uniqueness must be understood as referring to the entire set of factors and consequences of a fire (Simion & Dragomir, 2025).
In the Romanian construction sector, autoclaved aerated concrete (AAC) blocks are highly favoured, owing to their superior performance under fire conditions. Autoclaved Aerated Concrete (AAC) is an eco-friendly building material composed of cement, water, lime, silica-based materials (such as sand, ash, or silica fume), an expansion agent (aluminium powder), and other additives (Sherin & Saurabh, 2018; Hammond & Jones, 2008).
Besides its relatively light weight, this material provides benefits like fire resistance, low thermal and acoustic conductivity, and is easy to cut, handle, install, and transport (Mollaei et al., 2022). AAC block masonry utilizes adhesive mortar to bond the blocks (Song et al., 2024). This adhesive mortar behaves differently and can make the AAC masonry vulnerable to fire if not applied in a thin layer.
Researchers at INCERC Bucharest recently conducted experimental studies to assess the fire performance of non-load-bearing masonry walls of varying thicknesses, constructed with autoclaved aerated concrete (AAC) blocks (density: 480 kg/m$^3$, compressive strength: 3.5 N/mm$^2$) and class M2.5 bonding mortar (compressive strength 2.5 N/mm$^2$) (Stanescu et al., 2021).

## MATERIALS AND METHODS

The purpose of this study was to evaluate the fire resistance performance of a single type of AAC masonry wall with the following thicknesses: 150 mm, 200 mm, and 300 mm (Figure 1 and Figure 2).
The experimental tests were conducted at the Fire Safety Laboratory within INCERC Bucharest and consisted of applying a standardized method, harmonized across European Union countries, for testing the fire resistance of non-load-bearing walls.

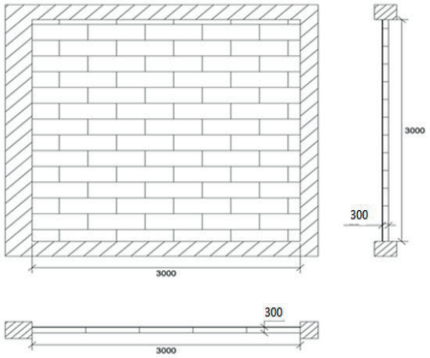

Figure 1. Non-load-bearing AAC masonry wall with a thickness of 300 mm designed for fire resistance testing

Figure 2. Non-load-bearing wall made of AAC masonry with a thickness of 300 mm, prepared for fire resistance testing

The fire resistance testing technology for non-load-bearing walls involved installing the walls (test samples) in the opening of a vertical fire resistance test furnace, conditioning the specimens for a period of 30 days after installation, and testing them under a controlled fire.

This fire followed the ISO 834 standard temperature-time curve, maintained by the furnace's automation system throughout the entire duration of the tests (Figure 3).

During the fire resistance tests, the walls were exposed to a controlled temperature variation regime inside the furnace to evaluate the integrity (*E*) and thermal insulation (*I*) criteria, in accordance with the test method standards "SR EN 1363-1:2020 Fire resistance tests. Part 1: General requirements" and "SR EN 1364-1:2015 Fire resistance tests for non-loadbearing elements. Part 1: Walls" (Figure 4 and Figure 5).

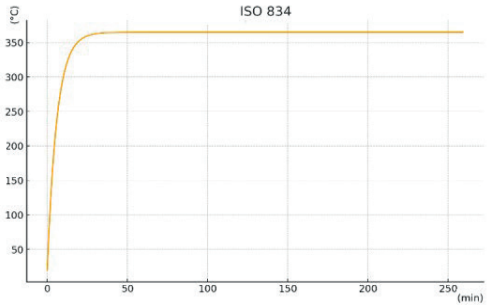

Figure 3. ISO 834 standard temperature-time curve

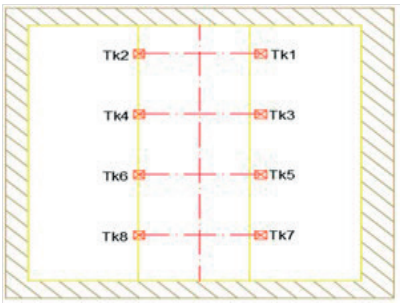

Figure 4. Thermocouple placement inside the furnace

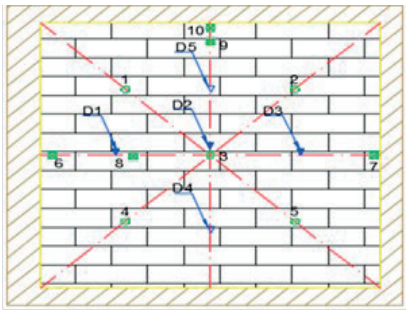

Figure 5. Positioning of thermocouples on the unexposed surface of the sample

## RESULTS AND DISCUSSIONS

After conducting the fire resistance tests on the AAC masonry walls, the testing supervisor prepared the fire resistance test reports for each wall type tested, in accordance with the testing laboratory's internal procedures (a RENAR-accredited laboratory) and the requirements of the harmonized fire resistance testing standards for non-load-bearing walls.

Following the monitoring, recording, and processing of the testing parameters, as well as visual observations regarding the behaviour and

integrity of the specimens during the tests, a series of data was obtained and subsequently included in the fire resistance test reports for the three specimens.

This information consisted of: the temperature evolution inside the furnace compared to the ISO 834 standard curve, as well as on the unexposed surface of the samples; the deformation of the samples during the tests; the moments when the fire resistance criteria samples were lost (expressed in full minutes); the evolution of environmental conditions in the testing hall; the intensity of smoke release on the unexposed surfaces of the samples during the tests; the monitoring of cracks, fissures, and sustained flaming; the ignition time of the cotton pad; the verification of the gap gauge insertion into the cracks formed in the samples; the observation of any material spalling or detachment; the start and end times of the tests, etc.

During the tests, researchers observed the appearance of fissures and cracks on the unexposed surface of the three AAC masonry samples at the following times: at minute 20 for the 150 mm thick sample, at minute 35 for the 200 mm thick sample, and at minute 50 for the 300 mm thick sample. Using a FLIR thermal imaging camera, the temperature variation on the unexposed surface of each sample was measured from the beginning until the end of the fire resistance tests (Figure 6, Figure 7, Figure 8 and Figure 9).

Figure 6. The unexposed surface of the 200 mm thick sample at the beginning of the fire resistance test

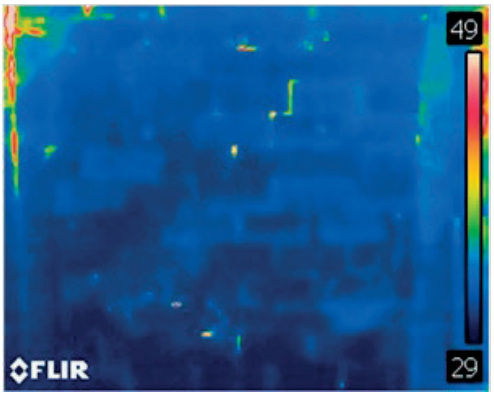

Figure 7. Temperature measurement on the unexposed surface of the 200 mm thick sample at the start of the fire resistance test

Figure 8. The unexposed surface of the 200 mm thick sample at minute 220, at the conclusion of the fire resistance test

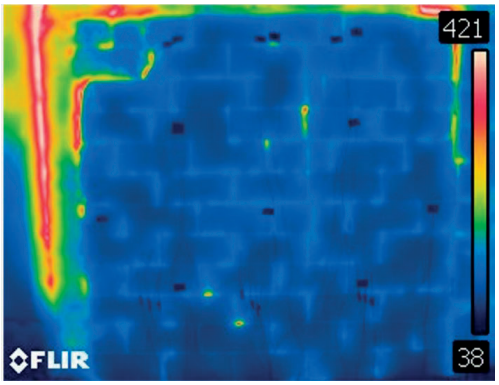

Figure 9. Temperature measurement on the unexposed surface of the 200 mm thick sample at minute 220, upon completion of the fire resistance test

The deformations of the three samples during the fire resistance tests were, as follows (Figure 10, Figure 11 and Figure 12):

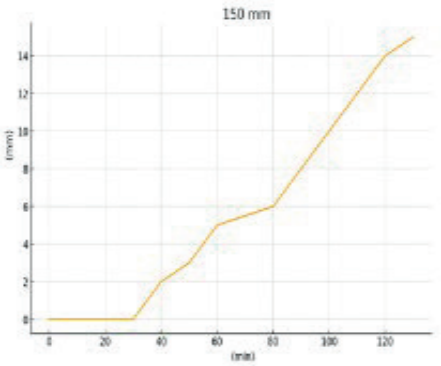

Figure 10. Deformation of the 150 mm thick AAC masonry wall during the test

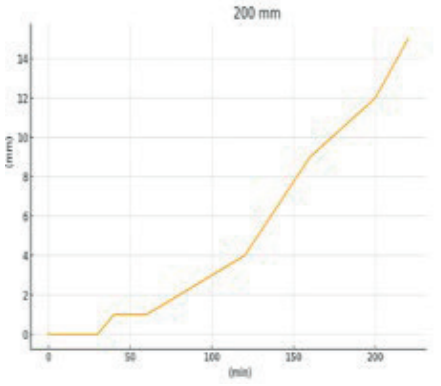

Figure 11. Deformation of the 200 mm thick AAC masonry wall during the test

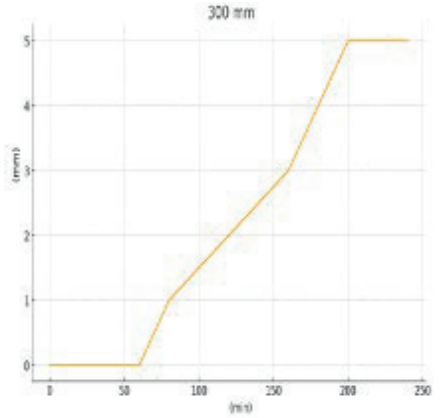

Figure 12. Deformation of the 300 mm thick AAC masonry wall during the test

It is observed that the deformations of the 300 mm thick sample were approximately three times smaller in magnitude than those of the other two samples.

During the fire resistance tests, the three non-load-bearing masonry walls maintained their thermal insulation criterion (*I*) and fire integrity criterion (*E*) as follows:

- For the 150 mm thick wall, criteria *I* and *E* were maintained for 129 minutes and were both lost at minute 130 when criterion *E* failed (Figure 13);

Figure 13. Loss of integrity (E) criterion through the ignition of the cotton pad for the 150 mm thick sample

- For the 200 mm thick wall, the thermal insulation criterion (*I*) and fire integrity criterion (*E*) were maintained for 219 minutes and were both lost at minute 220, when the fire integrity criterion *E* was failed (Figure 14).

Figure 14. Loss of fire integrity criterion (*E*) by ignition of the cotton pad for the 200 mm thick sample

- The 300 mm thick wall did not lose any of its thermal insulation (*I*) or fire integrity (*E*) criteria

until the end of the fire resistance test at minute 244.

The classification of the tested samples into fire resistance classes was conducted by laboratory researchers based on the data from the test reports (total minutes during which the specimens maintained their integrity for fire integrity *E* and thermal insulation *I* criteria) and was performed according to the standard "SR EN 13501-2:2023 Fire classification of construction products and building elements. Part 2: Classification using data from fire resistance and/or smoke control tests, excluding ventilation services".

The fire resistance classes for the three AAC masonry walls were as follows: class *EI 120* for the 150 mm thick AAC masonry wall, class *EI 180* for the 200 mm thick AAC masonry wall, and class *EI 240* for the 300 mm thick AAC masonry wall.

## CONCLUSIONS

Masonry ranks among the oldest structural materials, distinguished by a vast diversity in its units, mortars, and construction techniques. For innovative, affordable, and sustainable building alternatives, Autoclaved Aerated Concrete (AAC) blocks serve as an excellent modern solution (Kałuża, 2024).

This experimental study highlights the importance of laboratory testing in determining the fire resistance of non-load-bearing AAC (Autoclaved Aerated Concrete) masonry walls, which are used in numerous buildings (Daware & Naser, 2021). The research results confirm the applicability and relevance of the testing method in evaluating the fire behaviour of these construction elements, thereby contributing to the consolidation of the national technical framework for implementing the requirements of the new P118-1:2025 Romanian standard regarding the fire safety of buildings (P118, 2025).

Through the experimental research conducted, researchers from INCERC Bucharest contributed to a better understanding of the fire behaviour of these AAC construction elements, ensuring a high level of fire safety for the built environment in our country.

# LONG-TERM CHANGES IN AREAS EQUIPPED WITH DRAINAGE AND DEWATERING SYSTEMS UNDER DIFFERENT LAND USES

**Mihaela BALAN[1], Oana Alina NIȚU[2], Cristian POPESCU[1]**

[1]University of Craiova, Faculty of Agronomy, 19 Libertatii Street, Craiova, Romania
[2]University of Agronomic Sciences and Veterinary Medicine of Bucharest,
59 Marasti Blvd, District 1, Bucharest, Romania

***Abstract***

*This paper examines long-term changes in agricultural and non-agricultural areas equipped with drainage and dewatering systems, which are essential for managing excess moisture and maintaining land functionality. The analysis is based on official national statistical data, complemented by relevant scientific literature, and covers a period of approximately 28 years. The study investigates both the temporal evolution of equipped areas and the influence of different land-use types on hydrological regimes, soil properties, and the operational efficiency of drainage infrastructure. The results indicate an overall declining trend in equipped areas, particularly pronounced for arable land, accompanied by structural shifts among land-use categories. These changes are primarily associated with the progressive degradation of hydrotechnical systems, insufficient financial investment, and land ownership fragmentation. The findings underline the need for integrated drainage and land-use management strategies adapted to current environmental conditions in order to sustain agricultural productivity, protect soil resources, and strengthen the resilience of agroecosystems to climatic variability and the increasing occurrence of extreme weather events.*

***Key words****: dewatering systems, drainage, dynamics, excess moisture, improved land, land reclamation.*

## INTRODUCTION

Soil represents a fundamental component of terrestrial ecosystems and one of the most valuable natural resources for sustaining the existence and development of human society. Through its multiple functions - support for agricultural production, reservoir of water and nutrients, and medium for biological activity - soil plays an essential role in ensuring food security and ecological balance (David et al., 2018; Balan et al., 2024). However, soil is a limited and vulnerable resource, exposed to a wide range of degradation processes that require appropriate protection measures and sustainable management (Musat et al., 2021; Corcheș, 2023; EC Law).

Among the degradation processes with major impact on agricultural productivity is excess moisture, a phenomenon that may occur both at the soil surface, in the form of temporary or permanent waterlogging, and within the soil profile, through groundwater rise or deficient internal drainage. Excess water directly affects the air–water balance in the soil, generating a succession of unfavorable changes in its physical, chemical, and biological properties, with negative consequences for plant growth and development (Lațo et al., 2022; Popescu & Balan, 2024; Yang et al., 2025; FAO, n.d.).

From a pedological perspective, the prolonged presence of excess water leads to the reduction of air-filled porosity and limitation of oxygen diffusion in the root zone, favoring the occurrence of anaerobic conditions (Dollinger, 2016; Baborowski et al., 2021; Nițu et al., 2024). Under such circumstances, processes of gleying and pseudogleying are stimulated, soil structure degrades, and hydraulic permeability decreases (Dollinger, 2016; Birkáš et al., 2021). In advanced cases, excess moisture may contribute to the occurrence of secondary salinization phenomena and to a pronounced decline in the productive capacity of agricultural soils (Manik et al., 2019; Nițu et al., 2024; FAO, n.d.).

The geomorphological diversity and variability of hydrological, hydrogeological, and pedological conditions determine, at national level, a high incidence of land affected by excess moisture, requiring systematic land reclamation interventions. According to

assessments carried out by the Academy of Agricultural and Forestry Sciences, approximately 8.62 million hectares of agricultural land are influenced by this phenomenon: 4.2 million hectares by temporary excess generated by precipitation, 1.97 million hectares by shallow groundwater contribution, and 2.45 million hectares by floods or lateral infiltration from watercourses. Of the total, about 4.55 million hectares require proper drainage, while the remaining areas require differentiated measures depending on irrigation regimes and soil particularities (saline, alkaline). In years with normal pluviometric conditions, excess water affects approximately 5.53 million hectares, predominantly located in floodplains and on heavy clay soils. The major determining factors are: precipitation input under reduced evapotranspiration conditions, deficient natural drainage, and low terrain slopes (De Wrachien & Mambretti, 2012; Lațo et al., 2022).

Under Romania's specific climatic conditions, excess moisture occurs predominantly during spring and early summer, directly interfering with agricultural operations and crop establishment. This leads not only to technological delays but also to quantitative and qualitative production losses (Kulshreshtha & Elshorbagy, 2017). Moreover, global climate change increases the frequency and intensity of extreme meteorological phenomena, raising the risk of floods, prolonged water stagnation, and rapid alternation between episodes of excess moisture and periods of pedological and atmospheric drought (Ilie et al., 2012; Bonea, 2020; Nițu et al., 2025).

In this context, dewatering and drainage works have represented and continue to represent fundamental instruments for managing excess moisture and improving affected agricultural land. Dewatering primarily aims at evacuating stagnant surface water through open channels and land shaping, whereas drainage seeks to remove water from the soil profile and control the groundwater level through subsurface drains or absorbent pipes.

In Romania, dewatering and drainage works experienced significant development over time, reaching a peak in the 1980s, when extensive agricultural areas were integrated into complex hydrotechnical systems. After 1990, however, the existing infrastructure underwent a pronounced degradation process, estimated at 60-80%, due to reduced investments, insufficient maintenance, and land ownership fragmentation resulting from restitution processes (Ursu, 2014). This degradation considerably reduced the efficiency of drainage-dewatering systems and amplified the vulnerability of agricultural land to excess moisture.

Specialized literature highlights that degradation of drainage networks leads to increased frequency of temporary waterlogging, secondary compaction, reduced soil aeration, and diminished microbiological activity, with direct impact on fertility (Skaggs et al., 2012; Ritzema, 2016; de Wit et al., 2022). Furthermore, land-use changes significantly influence water balance, surface runoff, and nutrient transport processes (Blann et al., 2009).

Considering these aspects, the present paper aims to analyze the evolution of areas equipped with dewatering and drainage works, by land-use category at national level, over a 28-year period (1997-2024), based on recent statistical data. The analysis seeks to identify major trends, evaluate the magnitude of changes, and highlight their implications for the functioning and sustainability of agro-systems in Romania, within the current context of climate change and socio-economic pressures.

## MATERIALS AND METHODS

The study regarding the current situation of land equipped with works for combating excess moisture was based on the use of official statistical data series, supplemented by information from specialized literature. The main sources were the National Institute of Statistics, the National Agency for Land Reclamation, and the Ministry of Agriculture and Rural Development.

For characterizing the recent stage of developments, average values corresponding to the 2020–2024 interval were used, while for highlighting the temporal evolution, reference data for the years 1997, 2007, and 2017 were analyzed. The integration of these benchmarks allowed the outlining of a dynamic image of the changes recorded over approximately 28 years.

The processing of information aimed at quantifying the share of different land-use categories within the equipped areas, applying the percentage method for the synthetic expression of results. In parallel, data interpretation was supported by reference to existing scientific contributions, in order to understand the structural and functional framework of dewatering and drainage works.
The analytical methodology included: descriptive statistical analysis, used to highlight levels, distributions, and trends of the equipped areas; as well as comparative analysis, through which differences between reference periods and the directions of evolution of land reclamation infrastructure were evaluated. Through this approach, the performance of dewatering and drainage works was assessed from the perspective of quantitative dimension and transformations produced over time.

## RESULTS AND DISCUSSIONS

According to Table 1, the average values for the 2020-2024 interval highlight the existence of a total area equipped for combating excess moisture of 3,198,803 ha, of which the agricultural component amounts to 2,949,913 ha (92.22%).

Table 1. Situation of land equipped with dewatering and drainage works (Average 2020-2024)

| No. | Land use category | Area* -ha- | % of total equipped** |
|---|---|---|---|
| 1 | Total equipped area | 3,198,803 | 100 |
| 2 | Equipped agricultural area | 2,949,913 | 92.22 |
| 3 | Arable land | 2,553,962 | 79.84 |
| 4 | Natural pastures | 256,820 | 8.03 |
| 5 | Natural hayfields | 109,943 | 3.44 |
| 6 | Vineyards and vine nurseries | 15,676 | 0.49 |
| 7 | Orchards and fruit nurseries | 13,512 | 0.42 |
| 8 | Equipped non-agricultural area | 248,890 | 7.78 |

* http://statistici.insse.ro:8077/tempo-online/#/pages/tables/insse-table (15.12.2025)
**Own calculations

The data confirm the predominantly agricultural orientation of dewatering and drainage infrastructure, while non-agricultural land represents a marginal share of only 7.78% (Figure 1).

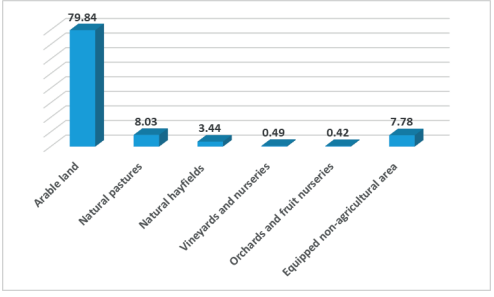

Figure 1. Structure of areas equipped with dewatering and drainage works

Within the equipped agricultural fund, the structure is strongly concentrated in the arable category, which totals 2,553,962 ha, representing 79.84% of the total area. This dominance indicates the historical direction of investments toward land with the greatest contribution to crop production and high exposure to risks generated by water stagnation. Practically, the functionality of dewatering and drainage systems becomes critical for the stability of the major segment of agricultural production.
Natural pastures and hayfields together account for approximately 11.47%, suggesting a secondary importance granted to these uses compared to field crops. At the opposite pole, permanent plantations (vineyards and orchards) hold subunitary shares, each below the 1% threshold. The distribution may be correlated with the frequent location of these categories in hilly or mountainous areas, where natural drainage is more efficient and the necessity for extensive technical interventions is lower.
From a systemic perspective, the overwhelming concentration of developments within the arable area implies a major dependence of national agricultural performance on the technical condition of existing infrastructure. Any process of degradation, underfunding of maintenance, or loss of functionality may generate disproportionate effects on production

volume. The current configuration of areas also reflects the evolution of scientific concepts and development practices, which favored systematic interventions in regions characterized by persistent excess moisture and high agricultural potential.

The evolution of areas equipped with dewatering and drainage works was marked by accelerated expansion in the second half of the twentieth century. If in 1944 approximately 358 thousand hectares were recorded as equipped, infrastructure expansion continued steadily in the following decades, exceeding 0.5 million hectares in the mid-1950s and approaching 0.8 million hectares in 1965. Investment rhythm intensified subsequently, so that by 1975 the area reached nearly 2 million hectares, and in the early 1980s it exceeded 2.5 million hectares. The maximum level of development was reached at the end of the ninth decade, when total developments rose to over 3.2 million hectares.

After this peak period, data indicate a reduction in functional area. At the end of the 1990s, land under the administration of the National Agency for Land Reclamation totalled approximately 3.2 million hectares, with water evacuation carried out both by pumping and gravitational means, the two modalities having relatively similar shares. The system was served by a complex technical ensemble, including hundreds of developments, thousands of kilometres of canals and drains, pumping stations, as well as numerous auxiliary crossing and regulation constructions.

The long-term functionality of these works depended essentially on the operating regime and permanent monitoring of soil property evolution. Institutional transformations after 1990, however, modified the framework of use. The pronounced fragmentation of land associated with property restitution processes did not take into account the geometry of underground networks, many parcels being delimited without correlation to drain positions. In parallel, the lack of maintenance interventions led to accelerated infrastructure degradation. Numerous constructive elements were affected, including slope reinforcements, connections between sectors, and flow control points, which considerably reduced the operational capacity of systems.

Following this background, the comparative analysis of the years 1997, 2007, 2017, and the average of the 2020-2024 period allows capturing the recent trajectory of equipped areas and evaluating the extent to which previous investment legacy was maintained or, on the contrary, eroded over time.

The data synthesized in Table 2 show that, following the high levels recorded at the end of the previous century, infrastructure intended to combat excess moisture entered a process of slow but continuous contraction.

Table 2. Dynamics of land equipped with dewatering and drainage works at national level (ha)

| No. | Land Use Category | Year | | | | | | |

* http://statistici.insse.ro:8077/tempo-online/#/pages/tables/insse-table (15.12.2025)
** Own calculations

Reference to the base year 1997 shows a reduction of total area by over 46 thousand hectares by 2007, a trend confirmed by subsequent evolution, so that the difference compared to the 2020–2024 average exceeds 52 thousand hectares (Figure 2).

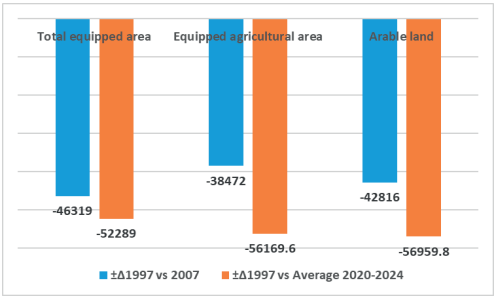

Figure 2. Dynamics of equipped areas – total, agricultural, and arable (ha; ±Δ compared to 1997)

The descending trajectory is also visible in the graphical representation of total, agricultural, and arable areas (Figure 3), where the negative slope is maintained throughout the analyzed interval.

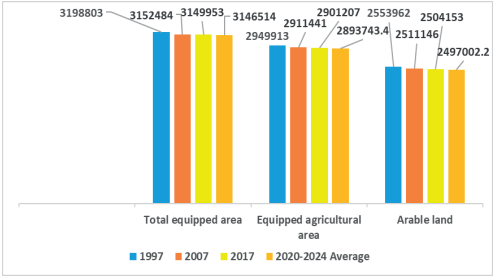

Figure 3. Dynamics of equipped areas – total, agricultural, and arable (ha)

The equipped agricultural area follows the same pattern, indicating that structural adjustments primarily targeted productive land. According to Table 2, the cumulative decrease between 1997 and the recent period exceeds 56 thousand hectares.

The largest contribution to the decline belongs to arable land. The initial reduction, of over 42 thousand hectares in the first decade, is followed by an additional decrease, so that at the level of the 2020-2024 average, total loss approaches 57 thousand hectares compared to the base year (Table 2). The higher intensity of withdrawal in the first part of the interval is clearly reflected in the dynamics presented in Figure 2.

In contrast to this trend, extensive uses show limited variations. Natural pastures mark an increase in the initial stage, followed by minor adjustments, but the final balance remains positive compared to 1997 (Figure 4).

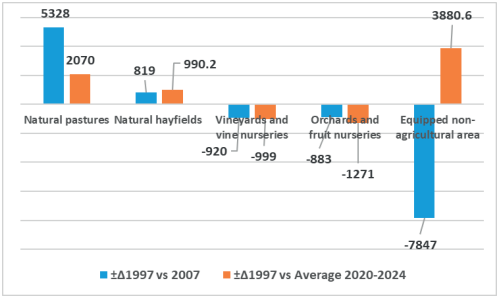

Figure 4. Dynamics of equipped areas – pastures, hayfields, vineyards, orchards, and non-agricultural land (ha; ±Δ compared to 1997)

Natural hayfields indicate similar stability, with small amplitude oscillations. These trends are detailed in Table 2 and graphically represented in Figure 5, where the curves associated with these categories exhibit a relatively stable, near-horizontal trajectory.

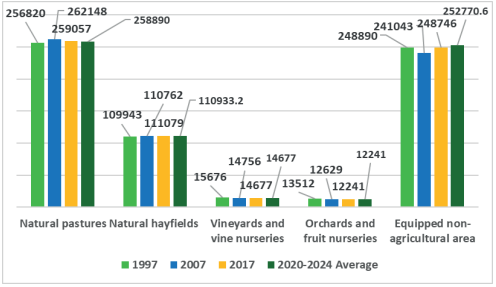

Figure 5. Dynamics of equipped areas – pastures, hayfields, vineyards, orchards, and non-agricultural land (ha)

For permanent plantations (vineyards and orchards), data reveal a constant reduction of equipped areas. Both vineyards and orchards register decreases of close to one thousand hectares compared to the initial level, a trend simultaneously confirmed by the tabular values and the representation in Figure 4.

In the case of non-agricultural areas, dynamics reveal an oscillatory course: after the decrease in the first stage, a recovery follows which, in

the recent interval, exceeds the level recorded in 1997. The interpretation of this evolution, however, requires caution, as it may reflect both the influence of administrative reclassifications and the effects of urban expansion and development of transport, industrial, and residential infrastructure, contexts in which the drainage function shifts from supporting agricultural use to protecting constructions and limiting flood risk or groundwater rise.

Overall, the correlation of numerical information with graphical representations outlines the image of a system undergoing gradual capacity decline, a phenomenon concentrated especially in the arable sector, where dependence on dewatering and drainage functioning is maximal.

Viewed as a whole, the data and graphical representations converge toward the same conclusion: the system has continuously lost area after 1997, with the main impact concentrated on arable land, where dependence on drainage functionality is highest. At the same time, the other categories showed either stability or limited variations, without altering the dominant structure of developments.

## CONCLUSIONS

The long-term assessment of areas equipped with dewatering and drainage works highlights the emergence of a persistent trajectory of declining functionality of hydrotechnical infrastructure.

The identified trends exceed the level of simple statistical adjustments and indicate the manifestation of a cumulative decapitalization process, resulting from the interaction between financial constraints, institutional transformations, and continuous erosion of maintenance capacity.

In this framework, multiple technical evaluations show that after 1990 a major proportion of constructions related to canal networks evolved toward advanced states of degradation. The lack of systematic maintenance interventions and desilting operations led to the deterioration of slope protections, affecting crossing and connection zones, as well as reducing the efficiency of flow regulation and measurement structures. The direct consequence is the progressive restriction of effectively serviced areas and the reduction of overall system performance.

From a conceptual perspective, dewatering and drainage infrastructure must be understood as a determinant of the adaptive capacity of agroecosystems. As its functional area decreases, the ability of the agricultural system to buffer hydrological variability declines, and land users tend to adopt cautious strategies oriented toward risk limitation rather than production intensification.

The persistence of these processes favors the establishment of path-dependence mechanisms, in which each year of underinvestment amplifies the difficulty and costs of potential restoration. In the absence of coordinated interventions, vulnerability becomes a structural rather than conjunctural characteristic.

Looking toward the future, climate projections for Central and Eastern Europe indicate an increase in the frequency of hydrological extremes, with more pronounced alternations between intense precipitation and prolonged water deficit periods. In such a context, existing systems will be subjected simultaneously to the requirement of rapid evacuation of excess volumes and the necessity of conserving resources during drought intervals. For arable land, where development concentration is dominant, this variability may exceed the initial design parameters of infrastructure. Without technological modernization and adoption of flexible operating mechanisms, the efficiency of works risks declining, and exposure of agricultural production to hazard increasing.

At the same time, modification of hydric regimes has the potential to redraw the map of intervention needs, transforming areas considered today relatively stable into future investment priorities.

In the context of increasing climatic variability and the growing frequency of extreme hydrological events, the development of drainage and dewatering infrastructure should be directed toward:

- the systematic rehabilitation of existing networks and the modernization of pumping stations;

- the integration of drainage systems with water retention and reuse facilities;
- the updating of design parameters in accordance with emerging climate scenarios;
- the strengthening of the institutional framework and the provision of multiannual financing mechanisms;
- the implementation of digital water-level monitoring systems.

Drainage infrastructure can no longer be addressed solely as a water evacuation mechanism; rather, it must be integrated into an adaptive water resources management strategy, essential for maintaining agricultural productivity and reducing the vulnerability of agroecosystems.

By integrating statistical evidence with institutional and climatic interpretation, the study provides an analytical framework transferable to numerous regions confronted with aging infrastructure. The central message is clear: passivity does not preserve infrastructure but accelerates its functional decline, leading to more rapid deterioration.

Corresponding author email: sabrina.balanescu1@gmail.com

***Abstract***

*This study investigates the transition from conventional wastewater treatment toward circular water management within the European Union, with a particular focus on the role of mobile and decentralized treatment systems. Despite considerable progress at EU level, major disparities persist in infrastructure coverage, wastewater reuse and resource recovery performance among Member States. A structured literature review and comparative analytical framework were applied to evaluate wastewater treatment technologies, circular economy pathways and implementation indicators, integrating data from Eurostat, the European Environment Agency and national Romanian statistics. The results show that 80–81% of the EU population is connected to at least secondary wastewater treatment, while Romania remains significantly below this level (60.7%), with over 150 non-compliant agglomerations. The analysis indicates that three dominant circular wastewater valorisation pathways can be identified in the EU context: water reuse, agricultural sludge valorisation and thermal nutrient recovery. In contrast, Romania remains in a transitional stage, characterized by limited reuse, low sludge valorisation (21.3% vs. EU average 37.3%) and limited deployment of advanced nutrient recovery systems. The study demonstrates that mobile wastewater treatment systems can function as transitional circular infrastructure, enabling localized treatment, resource recovery and reuse. Their flexibility and rapid deployment capacity position them as potentially strategic solutions for bridging infrastructure gaps and accelerating the implementation of circular water systems in emerging contexts.*

***Key words****: circular economy, resource recovery, mobile wastewater treatment systems, wastewater reuse.*

## INTRODUCTION

Water scarcity and increasing pressure on freshwater resources represent major global challenges driven by population growth, industrialization and climate change. Although freshwater accounts for only approximately 2.5% of global water resources, demand is expected to increase significantly by 2050, particularly due to agriculture, which already accounts for 70% of global freshwater withdrawals (Maniam et al., 2022; Hamam et al., 2024). At the same time, up to 80% of wastewater worldwide is discharged without adequate treatment, leading to environmental pollution and loss of valuable resources (Yang et al., 2020).

In Europe, up to 30-32% of the population experiences seasonal water stress (EEA, 2023b), highlighting the urgency of more sustainable water management approaches. Traditional wastewater management follows a linear model focused on pollutant removal, without fully valorising wastewater as a source of water, nutrients and energy (Van Loosdrecht & Brdjanovic, 2014).

The circular economy framework promotes the transformation of wastewater treatment plants into Water Resource Recovery Facilities (WRRFs), enabling water reuse and resource recovery (Larsen et al., 2016; Smol, 2023). Wastewater reuse supports agricultural, industrial and urban applications, contributing to water security (EEA, 2023a).

In this context, decentralized and mobile wastewater treatment systems represent a key technological extension, enabling on-site treatment and local reuse while reducing

dependence on centralized infrastructure (Capodaglio & Olsson, 2020; Mannina et al., 2022). These systems also support resource recovery pathways, including energy generation and nutrient recycling, positioning them as flexible tools for circular water management.

However, the transition toward circular wastewater systems remains uneven across the European Union, particularly in emerging Member States where infrastructure deficits and limited resource recovery hinder implementation. Romania represents a relevant case study, characterized by gaps in connectivity, treatment performance and circular economy integration.

Against this background, this study analyses mobile wastewater treatment systems as transitional circular infrastructure, integrating technological performance, resource recovery pathways and system-level implementation. The study develops a multi-level analytical framework, compares EU and Romania indicators, and positions mobile systems as enabling solutions for bridging infrastructure gaps and accelerating circular water management.

Figure 1 presents the flow of wastewater from multiple sources (domestic, industrial and agricultural) through treatment processes, enabling water reuse and the recovery of valuable resources such as nutrients, biofuels and bio-based products. The framework highlights the role of wastewater treatment plants as resource recovery hubs within circular economy systems.

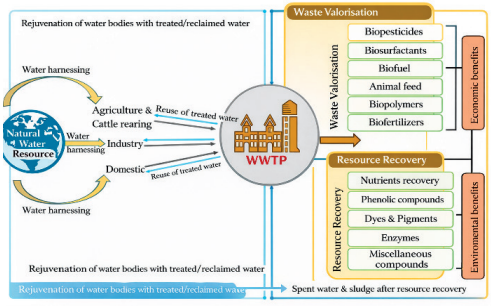

Figure 1. Integrated circular wastewater management framework: water reuse and resource recovery pathways (Singh et al., 2022)

Figure 2 illustrates the conceptual framework of circular wastewater management, emphasizing the integration of treatment technologies, resource recovery pathways, and water reuse applications, with mobile systems serving as a bridge toward circular economy implementation.

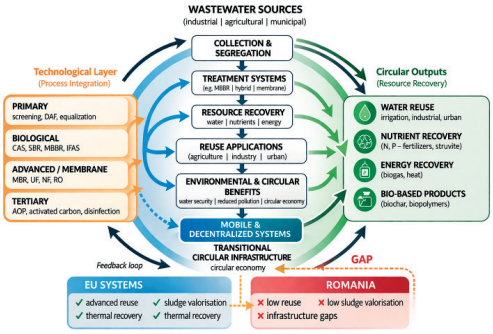

Figure 2. Conceptual framework of circular wastewater management integrating technological processes, resource recovery pathways, and reuse applications. The conceptual illustration was generated with the assistance of ChatGPT (OpenAI) based on the literature synthesized in this review and refined by the authors for visualization purposes

Unlike previous studies that primarily focus on either technological performance or circular economy pathways independently, this research develops a multi-level analytical framework that simultaneously integrates technological efficiency, resource recovery potential and system-level implementation gaps. In addition, the study offers one of the first structured comparative analyses between the European Union and Romania, highlighting the discrepancy between regulatory alignment and practical implementation.

## MATERIALS AND METHODS

This study is based on a structured literature review combined with a comparative analytical framework. The literature review was conducted using major scientific databases, including Web of Science, Scopus and ScienceDirect, covering the period 2000-2025.

The search strategy included combinations of the following keywords: “wastewater reuse”, “circular economy”, “mobile wastewater treatment”, “decentralized systems”, “membrane bioreactor (MBR)”, “resource recovery”, and “nutrient recovery”. Only peer-

reviewed journal articles, official reports (European Commission, Eurostat, European Environment Agency) and highly cited review papers were considered.

The selection process followed three main criteria:

(i) relevance to circular wastewater management and reuse,

(ii) availability of quantitative performance data (removal efficiencies, energy, cost),

(iii) applicability to decentralized or mobile treatment systems.

Studies focusing exclusively on conventional treatment without relevance to circularity or reuse were excluded. In total, over 100 publications were screened, and approximately 70 sources were selected for detailed analysis.

Comparative tables and figures were developed through normalization of reported data ranges and semi-quantitative synthesis. The EU–Romania comparison was conducted using official datasets from Eurostat, the European Environment Agency and National Institute of Statistics (NIS), complemented by European Commission reports on directive implementation.

The reported values represent indicative ranges derived from heterogeneous sources and should be interpreted as comparative benchmarks rather than absolute values.

## RESULTS AND DISCUSSIONS

### *Wastewater reuse and circular economy pathways*

Wastewater reuse is a key strategy for increasing water availability and reducing environmental pollution, providing an alternative resource for agriculture, industry and urban applications (Angelakis & Snyder, 2015; Silva, 2023). Agriculture remains the dominant reuse sector due to its high-water demand and the additional benefit of nutrient supply, reducing the need for synthetic fertilizers (Yang et al., 2020). Industrial reuse further contributes to water savings through applications such as cooling and process water (Nydrioti & Grigoropoulou, 2025).

From a circular economy perspective, wastewater treatment enables resource recovery, including nutrients (nitrogen and phosphorus) and energy through anaerobic digestion, supporting renewable energy production (Kyllönen et al., 2021). Overall, these approaches reduce freshwater withdrawals, limit pollutant discharge and support the transition toward circular water management systems (Hamam et al., 2024).

### *Treatment technologies for circular and mobile systems*

Wastewater treatment technologies for circular reuse and mobile applications must ensure high removal efficiency, operational flexibility and compact design. Biofilm-based systems such as moving bed biofilm reactors (MBBR) and integrated fixed-film activated sludge (IFAS) provide improved biomass retention and resilience under variable loading conditions, making them particularly suitable for decentralized systems (Ştefănescu et al., 2019; Surdu, et al., 2021).

Membrane technologies (MF, UF, NF, RO), particularly membrane bioreactors (MBR), enable the production of high-quality effluent suitable for reuse by ensuring efficient removal of suspended solids, pathogens and organic contaminants. However, membrane fouling and energy demand remain important operational challenges (Gkotsis et al., 2018; Yang et al., 2020). Hybrid treatment systems integrating biological processes, membrane filtration and advanced treatment steps (e.g., adsorption and advanced oxidation) can achieve removal efficiencies exceeding 90% for conventional pollutants and high removal rates for micropollutants, while maintaining compact configurations suitable for mobile applications (Luo et al., 2014; Meng et al., 2017).

Energy consumption remains a critical constraint, with aeration representing a significant share of total energy demand. Process intensification strategies such as partial nitrification–Anammox can reduce oxygen requirements and improve overall efficiency.

From a circular economy perspective, these technologies enable resource recovery through nutrient reuse and energy production via anaerobic digestion, supporting renewable energy generation and reducing sludge volumes.

Mobile systems are designed as compact, modular units integrating multiple treatment stages, including biological reactors, membrane filtration and disinfection, with the possibility of

advanced reuse (Meng et al., 2017). Their main advantages include rapid deployment, operational flexibility and local water reuse, particularly in industrial, agricultural and remote applications (Capodaglio & Olsson, 2020).

However, their treatment capacity is lower than that of centralized systems, and performance may be affected by influent variability and operational complexity (Mannina et al., 2022). Overall, mobile systems represent flexible and scalable solutions supporting localized circular water management and improved resource efficiency (Larsen et al., 2016).

Table 1 summarizes the main technological limitations in livestock wastewater treatment, together with their operational causes, proposed technological solutions, and potential performance improvements.

Figure 3 presents a qualitative technology–wastewater compatibility matrix, illustrating the applicability of different treatment technologies to various wastewater types based on published literature.

Table 1. Comparison of Technological Limitations and Technological Integrations

| Technological Limitation | Measurable Indicator / Effect | Operational Cause | Proposed Emerging Technologies | Quantified Potential Improvement |
|---|---|---|---|---|
| **High energy consumption** | Aeration accounts for 40-60% of total plant energy use | Continuous aeration for biomass maintenance | Energy-efficient aeration systems, real-time DO control, membrane aeration | 15-30% energy reduction (DO optimization & pulsed aeration) |
| **High sludge production** | Increased MLSS & MLVSS | Excess aerobic biomass with limited valorisation | Advanced anaerobic digestion, enzymatic hydrolysis, pyrolysis | 20-50% sludge reduction, conversion to biogas |
| **Sensitivity to flow variations** | Unstable DO, non-compliant BOD/COD | Variable hydraulic and organic loading | Equalization tanks + AnSBR + adaptive control systems | 10-25% improvement in effluent stability |
| **Inefficient nutrient removal** | $NO_3^-$ > 10 mg/L, TP > 1 mg/L | Incomplete nitrification–denitrification | Anammox processes, biofilm systems (IFAS), MBBR | 30–50% total nitrogen reduction without additional aeration |
| **Large footprint** | Space requirement > 5–10 $m^3$/PE | Conventional large-scale tank processes | MBR, SBR, IFAS, modular systems | 40-70% footprint reduction (MBR systems) |
| **Membrane fouling (in MBR)** | Reduced flux, increased TMP | Membrane surface deposition | Automatic backwash, CIP cleaning, advanced hydrodynamic modules | 2-3× increase in cleaning intervals |
| **Poor micropollutant removal** | Presence of compounds > µg/L | Conventional biological processes not adapted | Advanced oxidation processes (AOP), activated carbon adsorption, UV-$H_2O_2$ | 70-95% micropollutant removal |
| **Biological instability (toxic shocks)** | DO fluctuations, non-compliant BOD | Industrial toxic loads | Adaptive AnSBR systems, IFAS hybrid biofilm systems | 2-4× improved performance under shock loads |
| **High maintenance costs** | High OPEX | Traditional mechanical equipment | SCADA/IoT automation, online sensors | 10-25% OPEX reduction |
| **Limitations in advanced water reuse** | Residual N/P/salts concentrations | Lack of tertiary treatment processes | UF/NF/RO + AOP + biofilters | Effluent suitable for potable or industrial reuse |

Figure 3. Technology-wastewater compatibility matrix for circular water reuse systems (1 = the technology is suitable for that type of wastewater, 0 = not suitable)

The matrix was constructed using a binary classification approach (0-1), where each wastewater treatment technology was mapped to its most suitable wastewater types based on reported applications. Technologies were assigned to multiple categories where applicable. The heatmap represents a qualitative synthesis of technological applicability rather than a quantitative performance comparison.

The matrix highlights the heterogeneous applicability of wastewater treatment technologies across different wastewater types. Universally applicable systems such as MBR and MBBR contrast with more specialized technologies such as RO, DAF and membrane contactors, supporting the need for hybrid and modular configurations in mobile wastewater treatment systems.

Technologies were assigned to reuse categories based on keyword identification within the reuse target field (e.g., irrigation, industrial, urban, high-quality). Technologies could be included in multiple categories where applicable.

The reuse distribution was obtained through a qualitative classification of wastewater treatment technologies based on their reported reuse targets. A keyword-based approach was applied to categorize each technology into four reuse pathways (irrigation, industrial, urban and high-quality reuse), allowing multiple assignments per technology. The results represent a comparative synthesis of technological applicability rather than a quantitative performance assessment.

Figure 4 was constructed using a semi-quantitative scoring approach. Mobility levels were classified on a five-point scale (1 = low, 5 = very high) based on system transportability and deployment flexibility. Circular economy output was evaluated using a qualitative scoring system reflecting the potential for water reuse, nutrient recovery and energy generation. Bubble size represents the versatility of each technology, defined as the number of applicable wastewater types identified in the dataset.

To illustrate the versatility of mobile treatment systems, Table 2 presents the main wastewater streams, their characteristic pollutants, suitable treatment technologies, and potential reuse options.

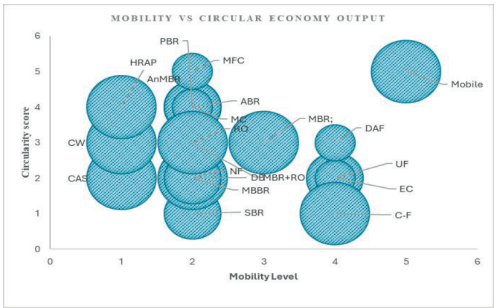

Figure 4. Mobility level versus circular economy output of wastewater treatment technologies

Table 2. Typology of Wastewater Streams Suitable for Mobile Treatment Systems

| Wastewater source | Typical pollutants | Suitable mobile treatment technologies | Potential reuse applications | References |
|---|---|---|---|---|
| **Petrochemical / refinery wastewater** | hydrocarbons, oils, COD, suspended solids | oil separators, DAF, electrocoagulation, MBR, activated carbon, RO | industrial reuse, cooling water, process water | Meng et al., 2017; Yang et al., 2020 |
| **Food industry wastewater** | high COD, BOD, fats, organic matter | DAF, SBR, MBBR, MBR, biological treatment + filtration | irrigation reuse, industrial cleaning water | Maniam et al., 2022; Khaki et al., 2026 |
| **Livestock wastewater** | organic matter, nitrogen, phosphorus, pathogens | biological treatment, MBBR, MBR, anaerobic digestion | agricultural irrigation, nutrient recycling | Obijianya et al., 2025 |
| **Municipal wastewater (small communities)** | COD, BOD, nutrients, pathogens | SBR, MBBR, compact activated sludge, membrane filtration | irrigation, landscape watering, groundwater recharge | Garrido-Baserba et al., 2024 |
| **Construction sites / temporary camps** | suspended solids, organic matter | compact biological treatment, filtration, UV disinfection | local reuse, environmental discharge | Lakho et al., 2020 |
| **Emergency / humanitarian wastewater** | pathogens, organic load | mobile modular treatment units, filtration + disinfection | sanitation reuse, emergency water management | Wolny et al., 2021 |

### *Resource recovery pathways*

Wastewater streams contain multiple recoverable resources, including nutrients, energy, biomass-derived products and valuable metals, positioning wastewater treatment plants as resource recovery platforms rather than solely pollution control systems (Smol, 2023; Wada et al., 2026).

Nutrient recovery represents one of the most established pathways. Wastewater and sewage sludge are significant secondary sources of phosphorus and nitrogen, with phosphorus recovery potential estimated at up to 22% of global demand.

Phosphorus is commonly recovered as struvite, while nitrogen can be extracted via membrane processes or converted into ammonium-based fertilizers. In addition, biosolids can be reused as soil amendments, while thermochemical processes such as pyrolysis enable biochar production and carbon sequestration (Kyllönen et al., 2021; Udu & Okpala, 2025; Wada et al., 2026).

Energy recovery is another key component, with anaerobic digestion converting organic matter into biogas that can be valorized for electricity and heat generation (Sevillano et al., 2021). Advanced processes, including thermal pretreatment and hydrothermal carbonization, further enhance energy recovery by producing energy-rich products such as synthesis gas, while emerging technologies such as microbial fuel cells enable simultaneous treatment and electricity generation (Udu & Okpala, 2025; Wada et al., 2026).

Beyond nutrients and energy, wastewater can support the production of bio-based materials and chemicals. Microalgae systems enable the recovery of nutrients and carbon while generating biomass for biofuels and bioproducts, while agro-industrial wastewater can be used for producing biodegradable polymers such as polyhydroxyalkanoates (Udu & Okpala, 2025; Wada et al., 2026).

Wastewater streams may also contain recoverable metals, particularly in industrial effluents, which can be extracted using biosorption, electrochemical processes, ion exchange or membrane technologies (Udu & Okpala, 2025; Wada et al., 2026).

The integration of these pathways underpins the transition from conventional treatment plants to Water Resource Recovery Facilities (WRRFs), enabling simultaneous pollutant removal, water reuse and resource valorisation (Neczaj & Grosser, 2018; Smol, 2023). In this context, decentralized and mobile systems extend the WRRF concept by enabling localized resource recovery and reuse, particularly in areas lacking centralized infrastructure.

***Romania vs Europe: Implementation Gap***

The analysis reveals significant structural gaps in wastewater management performance in Romania (Mosnegutu et al., 2025). Although approximately 66% of the population is connected to sewerage systems and 60.7% to wastewater treatment plants, only 12% of urban wastewater is treated in compliance with European Union requirements, compared to an EU average of approximately 76%. Wastewater treatment infrastructure remains underdeveloped, with 1,242 treatment plants in operation, of which 847 serve agglomerations larger than 2,000 population equivalents, yet important operational and performance limitations persist.

Resource recovery is also limited, with only around 24% of sewage sludge valorised through agricultural reuse or composting, indicating low circular integration. This aligns with broader circular economy indicators, where Romania records a circular material use rate of 1.3% compared to 12.8% at EU level, and a municipal waste recycling rate of 13.7% versus 48.6% in the EU, highlighting weak integration of circular principles across sectors.

At the European level, wastewater management is characterized by significant heterogeneity, shaped by water availability, climate and infrastructure development. Approximately 11% of the population is affected by water stress, while only around 1 billion $m^3$/year of treated wastewater is reused, compared to an estimated potential of 6 billion $m^3$/year (EEA, 2023b). Water reuse practices vary significantly across Member States, with high reuse rates in water-scarce countries such as Cyprus (>90%) and Malta (>60%), and moderate levels in Spain, Italy and Greece (5-12%), supported by tertiary treatment technologies in line with Regulation (EU) 2020/741.

Circular wastewater management in the EU is structured around three main valorisation pathways: water reuse, agricultural sludge reuse and thermal treatment systems enabling energy and phosphorus recovery. In 2020, the EU generated approximately 6.31 million tons of sewage sludge (dry matter), of which 37.3% was reused in agriculture, with significant national variations - from agricultural reuse-dominated systems (e.g., Estonia 85.9%, France 77.1%) to thermal recovery-oriented systems (e.g., Netherlands 95.6% incineration), where phosphorus recovery can reach 70-90%.

Despite these advancements, infrastructure disparities persist, with approximately 81% of the EU population connected to at least secondary wastewater treatment. The revised

Urban Wastewater Treatment Directive (UWWTD recast) further strengthens requirements by introducing stricter nutrient removal targets and advanced treatment for micropollutants.

Romania remains in a transitional stage within this European framework, with only 60.7% of the population connected to wastewater systems (NIS, 2024) and over 150 agglomerations non-compliant with EU requirements (EEA, 2023a). Although the entire national territory is designated as a sensitive area - requiring enhanced nitrogen and phosphorus removal - circularity indicators remain underdeveloped, with only 21.3% of sewage sludge reused in agriculture compared to the EU average of 37.3%, and no consolidated national data on wastewater reuse.

These findings highlight a gap between legislative alignment and practical implementation, driven by infrastructure deficits, limited reuse deployment and weak resource recovery integration. At the same time, the limitations of conventional wastewater treatment systems - such as high energy consumption, sludge production, sensitivity to variability and incomplete removal of nutrients and micropollutants - further constrain progress toward EU targets. Addressing these challenges requires the integration of advanced technologies, including biofilm systems (IFAS/MBBR), optimized aeration, real-time monitoring and tertiary treatment processes such as filtration, granular activated carbon and advanced oxidation processes.

In this context, mobile systems represent a strategic opportunity due to their high treatment efficiency, flexibility and reuse potential, functioning as transitional circular infrastructure capable of enabling localized treatment, resource recovery and alignment with European wastewater management models.

The conceptual framework from Figure 5 illustrates the main circular wastewater valorisation pathways in the European Union - water reuse, agricultural sludge valorisation and thermal resource recovery - highlighting Romania's transitional position and the role of mobile and decentralized systems as enabling infrastructure for bridging implementation gaps. To provide a regulatory and technological context, Table 3 compares key EU and Romanian indicators related to wastewater treatment and summarizes their implications for WWTP modernization and the integration of advanced technologies.

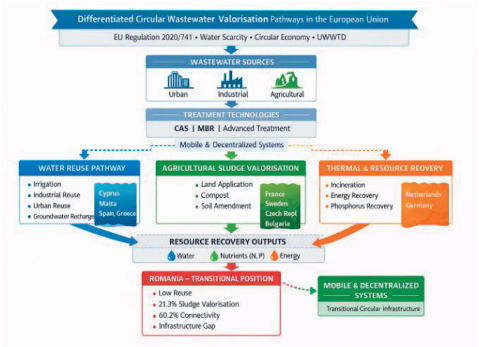

Figure 5. Differentiated Circular Wastewater Valorisation Pathways and the Role of Mobile Systems in the EU–Romania Context (The figure was generated with the assistance of a generative AI tool based on the authors' conceptual design and subsequently reviewed, edited, and scientifically validated by the authors)

Table 3. EU-Romania Indicators Relevant for WWTP Modernization and Integration of Advanced Technologies

| Dimension | EU (Data / Requirements) | Romania (Data / Requirements) | Direct Technological Implication |
|---|---|---|---|
| **Connection to treatment (minimum level)** | ~81% of the population connected to at least secondary treatment (2022) (Eurostat, 2023; EEA, 2022). | Significant disparities between agglomerations; major pressure on collection and treatment in large agglomerations (European Commission, 2023). | Need for network expansion and increased treatment capacity; shock load mitigation through equalization and operational control. |
| **"Secondary" treatment performance (definition)** | ≥70% BOD and ≥75% COD removal required under the Urban Wastewater Treatment Directive (European Commission, 1991). | Uneven compliance; some agglomerations still lack adequate treatment (European Commission, 2023). | Biological process upgrades (IFAS/MBBR, DO control) and improved robustness. |
| **Advanced treatment (nutrients / stricter require-ments)** | Recast strengthens nutrient removal and introduces additional requirements for micropollutants (European Commission, 2022; EEA, 2022). | Application of the "sensitive area" concept → intense pressure on N and P removal (Romanian Government, 2002; European Commissio, 2023). | Integration of optimized nitrification/de nitrification, IFAS/MBBR; Anammox where feasible. |

| Dimension | EU (Data / Requirements) | Romania (Data / Requirements) | Direct Technological Implication |
|---|---|---|---|
| **Non-compliance (large agglomerations)** | — | 150 (collection), 154 (inadequate treatment), 155 (lack of advanced treatment) (European Commissio, 2023). | Investment prioritization: collection systems + biological upgrades + nutrient removal. |
| **Investments (EU context)** | ~€67 billion invested in environmental protection in 2023 (Eurostat, 2024). | Need for accelerated investments, especially in large agglomerations (EEA, 2023b; European Commissio, 2023). | Justification for OPEX/CAPEX optimization: smart control, energy efficiency, resource recovery. |

Source: author's synthesis based on literature review.

Table 4 compares key indicators of wastewater valorisation across the EU, Romania, and selected Member States, highlighting differences in water reuse, sludge management, and nutrient recovery practices.

Table 4. Comparative wastewater valorisation pathways in the EU and Romania

| Indicator | EU Average | Romania | France | Estonia | Poland | Netherlands |
|---|---|---|---|---|---|---|
| Wastewater reuse ($m^3$/year) | ~1 bn | n/a | low | low | low | low |
| Reuse potential | ~6 bn | n/a | — | — | — | — |
| Population connected (%) | ~81% | 60.7% | >90% | >90% | ~75–80% | >95% |
| Sludge production (t DM) | 6.31 mil | 254k | high | low | high | Moderate |
| Agricultural reuse (%) | 37.3% | 21.3% | 77.1% | 85.9% | 38.0% | 3.9% |
| Incineration (%) | Variable | low | low | low | 18.5% | 95.6% |
| Dominant model | Mixed | Transi-tional | Agricul-tural | Agricul-tural | mixed | Thermal |
| Nutrient recovery | Emerging | absent | limited | limited | emerging | Advanced |

*Qualitative descriptors (low, moderate, high) are based on comparative analysis of Eurostat and EEA datasets.

Table 5 summarizes the main EU and Romanian legislative provisions governing wastewater management and highlights the key implementation gaps affecting the transition toward advanced and circular wastewater treatment systems.

The analysis indicates that Romania has largely achieved formal legislative alignment with EU wastewater policy, while significant gaps persist at the implementation level, particularly in infrastructure, compliance, water reuse and resource recovery. While the national regulatory framework is harmonized with European directives, significant gaps persist in infrastructure development, compliance, wastewater reuse deployment and nutrient recovery. These findings indicate that Romania is not primarily limited by regulatory deficiencies, but by implementation constraints, which delay the transition toward circular wastewater management.

Table 5. EU and Romanian wastewater legislation: key framework and implementation gaps (2026)

| Compo-nent | EU frame-work | Romania – legislation | Implementation status and gap |
|---|---|---|---|
| Water policy | Directive 2000/60/EC | Law no. 107/1996 | Objectives not fully achieved, gaps in reaching good ecological status |
| Urban wastewater | Directive 91/271/EEC; Directive (EU) 2024/3019 | HG 188/2002; NTPA-011 | Ongoing non-compliance confirmed by infringement procedure |
| Discharge | UWWTD require-ments | NTPA-001; NTPA-002 | Legally implemented, compliance varies across agglomerations,operational gaps |
| Water reuse | Regula-tion (EU) 2020/741 | Directly applicable | Limited documented implementation, lack of operational reuse systems |
| Sludge | Directive 86/278/EEC | Order 344/2004 | Lower valorisation compared to EU average, limited nutrient recovery |
| Infrastructure | UWWTD obliga-tions | National implementation programs | ~60.7% population connected, significant infrastructure deficit |
| Advanced / circular | Directive (EU) 2024/3019; EU CE policy | No dedicated framework | Limited deployment compared to EU requirements, technological and regulatory gaps |

*Source: Author's synthesis based on EU directives and Romanian legislation (Law 107/1996; HG 188/2002; NTPA-001/002/011; Order 344/2004; Directive (EU) 2024/3019; Regulation (EU) 2020/741); (EEA, 2024a), (EEA, 2024b) (EEA, 2024c), (EEA, 2024d) (EEA, 2024e), (EEA, 2024f).*

Unlike many EU Member States, where circular wastewater management is driven by either water reuse, sludge valorisation or thermal recovery, Romania remains in a transitional stage where none of these pathways are fully developed at scale.

This gap creates a strategic opportunity for mobile and decentralized wastewater treatment systems, which can act as flexible, rapidly deployable solutions to bridge infrastructure deficits and accelerate circular economic implementation.

The comparative analysis shows that conventional wastewater treatment plants

remain economically efficient at large scale, due to lower operational costs and higher biogas recovery. In contrast, mobile and membrane-based systems outperform conventional processes in treatment efficiency, reuse readiness and operational flexibility. Despite higher energy demand and costs, they enable direct water reuse, improved nutrient recovery and stable performance under variable conditions, reflecting a shift from cost-driven to circularity-driven design.

Thus, conventional systems optimize cost and energy recovery at scale, while mobile systems prioritize flexibility, performance and circular economy integration. Table 6 compares the performance of conventional and mobile wastewater treatment systems in terms of treatment efficiency, resource recovery potential, energy demand, and economic indicators.

Table 6. Conventional vs. mobile wastewater treatment systems: performance, resource recovery, energy and cost comparison

| Indicator | Conventional WWTP (CAS) | Mobile / decentralized (MBR / advanced) | Resource recovery potential | Energy (kWh/m³) |
|---|---|---|---|---|
| **Organic matter (BOD/COD)** | BOD: 75-95%COD: 70-90% | BOD: 90-99%COD: 85-98% | 20-40% (biogas) | 0.3-0.6 |
| **Suspended solids (TSS)** | 80-95% | >99% | Sludge → energy | 0.2-0.5 |
| **Nitrogen (TN)** | 40-70% | 70-95% | Limited | 0.4-0.8 |
| **Phosphorus (TP)** | 30-60% | 60-90% | 10–30% (struvite) | 0.3-0.7 |
| **Pathogen removal** | Moderate (needs disinfection) | Very high (membrane barrier) | ≈100% safe reuse | 0.1-0.3 |
| **Water reuse potential** | Low–moderate | High | 50–90% reuse | 0.5-1.0 |
| **Energy recovery** | High (anaerobic digestion) | Moderate | 20–50% | -0.2 to 0.3* |
| **Sludge production** | High | 20-50% lower | Reduced disposal | - |
| **Hydraulic variability** | Low tolerance | High tolerance | - | Stable |
| **Footprint** | Large | Compact (-50-70%) | - | - |
| **CAPEX (€/PE)** | 300-800 | 500-1500 | - | - |
| **OPEX (€/m³)** | 0.2-0.6 | 0.4-1.2 | - | - |

*Negative values indicate energy recovery offset
Source: author's synthesis based on literature review.

At the European level, circular wastewater management is heterogeneous, structured around coexisting pathways including water reuse, sludge valorisation and thermal recovery (Larsen et al., 2016; Smol, 2023). In contrast, Romania remains in a transitional stage, characterized by infrastructure, compliance and circularity gaps. Low connectivity, limited sludge valorisation and the absence of large-scale reuse indicate that constraints are primarily systemic, driven by governance, investment and institutional capacity. While conventional systems remain suitable for centralized applications, their limitations - high energy consumption, sensitivity to variability and limited resource recovery - reduce their effectiveness in decentralized contexts. Mobile systems address these challenges through on-site treatment, operational flexibility and integration of advanced processes. However, they also involve higher costs, lower capacity and increased operational complexity, and should therefore be integrated as complementary components within hybrid systems. From a policy perspective, regulatory frameworks remain insufficiently adapted to decentralized solutions, limiting large-scale implementation, particularly in Romania. Systemic barriers - including weak policy implementation, low public acceptance, infrastructure deficits and limited awareness of resource valorisation - further constrain progress.

In this context, mobile wastewater treatment systems can be conceptualized as transitional circular infrastructure, enabling localized water reuse and resource recovery, particularly in agriculture, where they can reduce freshwater demand and support nutrient and energy recovery.

In contrast to the European examples shown in Table 7, the implementation of mobile wastewater treatment systems in Romania remains limited and fragmented.

Table 7. Examples of mobile wastewater treatment applications in Europe

| Country | Application sector | Technology used | Key performance | Main purpose |
|---|---|---|---|---|
| Spain | Food industry | Mobile DAF + RO | 80-85% TSS removal | Water reuse and compliance |
| Greece | Agro-industrial (fruit processing) | Mobile treatment unit (ULTIMATE project) | Water reuse in process | Resource recovery and reuse |
| Netherlands | Industrial / municipal support | Containerized MBR systems | High effluent quality (reuse standard) | Decentralized treatment and reuse |
| Germany | Industrial / emergency applications | Mobile modular systems | Rapid deployment | Temporary treatment and compliance |

Sources: NSI Mobile Water Solutions (2023); ULTIMATE Project (2022); Water Europe (2023).

Existing applications are mainly restricted to temporary or industrial uses, with no systematic integration into wastewater management strategies. This indicates that, despite technological availability, decentralized and mobile treatment solutions are not yet widely adopted, and wastewater management remains predominantly centralized and treatment-oriented.

## CONCLUSIONS

This study demonstrates a clear transition from linear wastewater treatment toward circular resource recovery systems. Although the European Union has made significant progress in wastewater reuse and valorisation, implementation remains uneven across Member States.

Romania exhibits a structural gap characterized by limited infrastructure coverage, low reuse rates and underdeveloped resource recovery. These challenges are primarily driven by implementation constraints rather than regulatory deficiencies.

Mobile wastewater treatment systems emerge as a viable solution, offering rapid deployment, operational flexibility and high treatment performance. They can be effectively positioned as transitional circular infrastructure.

Rather than replacing centralized systems, mobile technologies should be integrated into hybrid frameworks to support decentralized applications and accelerate infrastructure development, particularly in regions with limited capacity and increasing water stress.

Future research should prioritize improving energy efficiency, reducing operational costs and developing regulatory frameworks that support decentralized deployment. Their integration could significantly accelerate the transition toward circular water management.

Mobile wastewater treatment systems should therefore be considered strategic infrastructure components, enabling localized treatment, resource recovery and water reuse within emerging circular systems.

Despite their advantages, mobile wastewater treatment systems present several limitations that may constrain large-scale implementation. Their operational performance is highly dependent on influent variability and requires advanced monitoring and control systems.

Therefore, mobile systems should not be considered replacements for conventional infrastructure, but rather complementary solutions integrated within hybrid wastewater management frameworks.

***Abstract***

*Livestock wastewater, particularly from pig farming, represents a major environmental challenge due to its high organic load, nutrient content, and strong hydraulic variability. Conventional treatment approaches such as lagoons or activated sludge systems frequently exhibit unstable performance under fluctuating agricultural conditions, resulting in inconsistent effluent quality. This study presents a structured literature review and comparative technological analysis of wastewater treatment systems applicable to livestock farms, focusing on process stability in decentralized environments. The analysis shows that instability in conventional systems originates primarily from biomass washout associated with gravity-based sludge separation. Membrane bioreactors overcome this limitation by physically retaining biomass and decoupling sludge retention time from hydraulic retention time, ensuring stable nitrification and consistent treatment performance. Consequently, MBR technology represents a promising solution for decentralized and mobile livestock wastewater treatment systems.*

***Key words****: decentralized wastewater treatment, livestock wastewater, membrane bioreactor (MBR), pig farming.*

## INTRODUCTION

Growing pressure on freshwater resources and stricter environmental regulations are accelerating the development of decentralized wastewater treatment systems for agricultural environments (European Commission, 2020). Pig farming represents one of the major sources of agricultural pollution, generating large volumes of wastewater rich in organic matter, nutrients and microbial contaminants (Chen et al., 2024). Despite this pollution load, wastewater management in many farms still relies on lagoon storage or simple digestion processes that provide only partial treatment (Ivanciu Popa et al., 2019; Chen et al., 2024).

Conventional biological treatment systems, particularly activated sludge, require stable hydraulic conditions to maintain biomass retention and treatment efficiency (Surdu et al., 2021). However, livestock wastewater is characterized by intermittent flows, high ammonia concentrations and strong seasonal variability, leading to biomass washout and unstable effluent quality (Burton et al., 2003; FAO, 2018).

Membrane bioreactor (MBR) systems overcome this structural limitation by physically retaining biomass through membrane filtration, decoupling sludge retention time from hydraulic residence time and enabling stable treatment under variable loading conditions (Capodaglio, 2017). Consequently, MBR technology represents a promising solution for decentralized and mobile livestock wastewater treatment systems.

Unlike most studies that focus primarily on pollutant removal efficiencies, this paper analyses wastewater treatment technologies from the perspective of process stability under variable hydraulic conditions, identifying biomass retention mechanisms as the key determinant for decentralized livestock wastewater treatment. The relationship between variable agricultural wastewater loading, process instability in conventional activated sludge systems, and the stabilizing role of membrane biomass retention is illustrated in Figure 1.

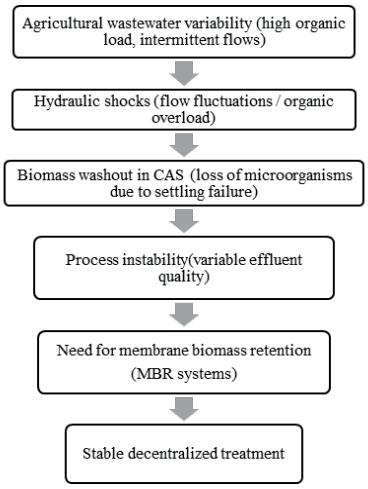

Figure 1. Conceptual framework illustrating the instability of conventional activated sludge systems under variable agricultural wastewater loading and the role of membrane biomass retention in stabilizing decentralized treatment processes.

The technological evolution of livestock wastewater treatment systems from conventional lagoon storage to modern mobile membrane-based systems is illustrated in Figure 2.

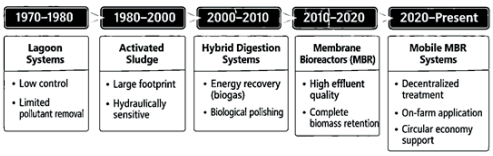

Figure 2. Evolution of wastewater treatment technologies applied in livestock farming, from conventional lagoon storage systems to modern mobile membrane bioreactor installations enabling decentralized treatment and resource recovery

## MATERIALS AND METHODS

This study was conducted as a structured literature review and comparative technological analysis of wastewater treatment systems applicable to livestock farms, focusing on process stability and the suitability of decentralized and mobile treatment technologies.

Scientific publications were identified through systematic searches in the Scopus, Web of Science, and Google Scholar databases, covering the period 2000-2025. The search strategy included combinations of the following keywords: pig wastewater treatment, livestock wastewater, membrane bioreactor (MBR), decentralized wastewater treatment, mobile wastewater treatment systems, agricultural effluents, and nutrient removal technologies.

Selected studies were further analysed and categorized according to the type of treatment process. Studies were selected based on relevance, data availability and applicability for livestock wastewater systems.

For the comparative evaluation, the technologies were analysed based on several key operational parameters frequently reported in the literature.

The collected data were synthesized into comparative tables in order to highlight the technological limitations of conventional treatment approaches and the operational advantages of membrane-based systems in decentralized livestock wastewater management.

## RESULTS AND DISCUSSIONS

### *Characteristics of livestock wastewater*

Wastewater generated in animal husbandry contains high concentrations of organic matter, suspended solids, nutrients and pathogenic microorganisms originating from manure, feed residues and cleaning operations (Burton et al., 2003; FAO, 2018).

Mobile treatment technologies have emerged as an alternative approach for treating high-strength wastewater directly at source, reducing transport requirements and improving process control under variable loading conditions (Libralato et al., 2012; Capodaglio, 2017). These systems commonly integrate multi-stage filtration processes, including pre-filtration, membrane separation and disinfection, enabling the removal of suspended particles, microorganisms, and dissolved contaminants (Iorhemen et al., 2016; Meng et al., 2017).

In many regions, small livestock farms store wastewater in lagoons or reuse it for irrigation, whereas large farms increasingly implement anaerobic digestion to recover energy in the form of biogas (Burton et al., 2003; FAO, 2018).

A comprehensive treatment scheme for piggery wastewater typically includes solid-liquid

separation, anaerobic digestion, aerobic polishing and membrane filtration, followed by advanced polishing steps such as activated carbon or reverse osmosis (Metcalf & Eddy et al., 2014; Meng et al., 2017).

In Romania, most small livestock farms collect their wastewater in a storage basin, for further use as irrigation wastewater, or in aerated or non-aerated lagoons. The large farms, where significant financial investments have been made, have begun to build up their wastewater treatment plants with anaerobic digesters, and the biogas obtained can be used as a source of energy in the farm (Ivanciu Popa et al., 2019).

Historical livestock waste generation coefficients indicate that pigs produce approximately 6 kg total solids and 2 kg $BOD_5$ per 1,000 kg live weight per day. Although absolute values vary in modern intensive systems, the data demonstrate that livestock wastewater is generally characterized by high organic and nutrient loads. The current environmental challenge therefore results not from a change in manure composition but from the scale and hydraulic variability of modern production systems. The typical pollutant loads generated by swine livestock in Romania, compared with European reference ranges, are presented in Table 1.

Table 1. Typical pollutant load generated by swine livestock: Romania vs European reference values ($kg \cdot animal^{-1} \cdot day^{-1}$)

| Parameter | Romania | European typical range |
|---|---|---|
| Total suspended solids (TSS) | 4.48 | 3.0-5.5 |
| Volatile suspended solids (VSS) | 3.50 | 2.0-4.5 |
| Chemical oxygen demand (COD) | 3.94-5.78 | 3.0-8.0 |
| Biochemical oxygen demand ($BOD_5$) | 1.90-2.30 | 1.5-4.0 |
| Total nitrogen (TN) | 0.35 | 0.30-0.60 |
| Total phosphorus (TP) | 0.074 | 0.05-0.15 |

Romanian data: (Chiriac et al., 1977); European ranges: Burton et al., 2003; FAO, 2018; European Commission, 2020. Values are expressed per average pig live weight equivalent (livestock unit).

The comparison between typical Romanian practice and controlled Western European treatment (Table 2) indicates that removal efficiency is not primarily determined by the treatment technology itself but by process controllability. Lagoon-based systems exhibit moderate organic matter removal (30–60% COD), yet nutrient removal remains below 40%, and effluent stability is highly seasonal. In contrast, controlled biological systems achieve >90% removal efficiency and consistent compliance.

This demonstrates that livestock wastewater treatment failure is associated with hydraulic and operational variability rather than insufficient biodegradability of the substrate.

Western European treatment systems achieve higher removal efficiencies not always due to superior technologies but because wastewater is treated as a controlled process rather than stored as an agricultural by-product, resulting in predictable effluent quality and enabling water reuse.

Table 2. Comparative performance of swine wastewater treatment (Romania vs Western European practice)

| Parameter | Romania - typical practice (lagoons / storage / basic digestion) | Western Europe - controlled treatment (biological + advanced) |
|---|---|---|
| COD removal | 30-60% in anaerobic lagoons; highly dependent on retention time | 85-98% in biological reactors; >95% with MBR polishing |
| $BOD_5$ removal | 40-70% (partial stabilization) | 90-99% in activated sludge/MBR |
| TSS removal | 50–80% sedimentation based | >99% membrane separation |
| Nitrogen removal | <20-40% (mostly volatilization and soil uptake) | 70-95% nitrification–denitrification; >90% advanced systems |
| Phosphorus removal | <10-30% natural precipitation | 80-95% EBPR / chemical / struvite recovery |
| Pathogen removal | inconsistent; dependent on storage time | near complete removal after membrane/disinfection |
| Effluent stability | highly variable; seasonal | stable compliance |
| Water reuse suitability | Unsuitable | irrigation reuse feasible |
| Nutrient recovery | indirect via land spreading | controlled recovery (fertilizer products) |
| Treatment philosophy | manure management | wastewater treatment & circular economy |

Livestock wastewater is fundamentally different from municipal wastewater due to its extreme variability in organic loading, nutrient concentration and suspended solids content (Musa & Idrus, 2021; Rahman et al., 2023).

***Limitations of conventional systems***

Conventional activated sludge (CAS) systems are frequently considered an upgrade solution; however, their application in livestock wastewater treatment presents intrinsic limitations (Du et al., 2020).

The process stability of CAS depends on constant influent composition and controlled loading rates; conditions rarely encountered in agricultural effluents (Rahman et al., 2023).

Sudden variations in organic load or ammonia concentration may lead to biomass inhibition and process imbalance (Iorhemen et al., 2016).
Furthermore, gravity sedimentation used for biomass separation represents a structural weakness of the CAS process (Iorhemen et al., 2016).
The treatment process typically involves several stages to effectively treat pig wastewater, as shown in Figure 3.

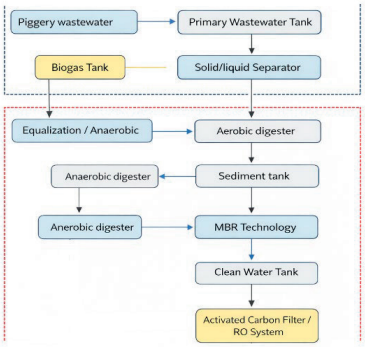

Figure 3. Treatment process of piggery wastewater (adapted and redrawn by the authors based on Hinada, n.d. and literature sources)

Poor sludge settling characteristics frequently observed in high-strength agricultural wastewater led to solids washout (Du et al., 2020). Therefore, achieving consistent compliance with discharge standards becomes difficult without tertiary treatment stages (Ezugbe & Rathilal, 2020).

***Mechanistic origin of process instability***

The instability of conventional activated sludge treatment under variable agricultural loading originates from the dependence of biomass retention on gravity settling.
Animal farms, particularly small and medium units, rarely have sufficient available land for aeration basins and clarifiers (Kesari et al., 2021). This structural difference between gravity-based biomass separation and membrane retention is illustrated in Figure 4.
Consequently, treatment infrastructure is often undersized, leading to chronic overloading conditions (Musa & Idrus, 2021).

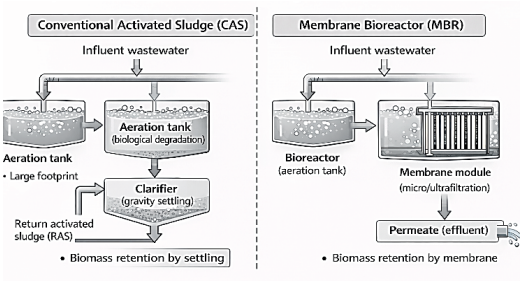

Figure 4. Mechanistic comparison between conventional activated sludge (CAS) and membrane bioreactor (MBR) systems highlighting biomass retention mechanisms and treatment stability under variable hydraulic loading

Cleaning operations, rainfall infiltration and manure removal cycles generate hydraulic shocks that conventional biological reactors cannot buffer effectively (Iorhemen et al., 2016). Additionally, nutrient removal in conventional systems remains limited without advanced process control (Ezugbe & Rathilal, 2020). High ammonia concentrations typical for livestock wastewater inhibit nitrification and reduce biological stability (Iorhemen et al., 2016).
Overall, the main limitation of conventional treatment is not insufficient pollutant removal capacity per se, but the incompatibility between system design philosophy and agricultural wastewater characteristics (Du et al., 2020). Systems optimized for stable municipal flows cannot maintain performance under decentralized, variable and high-strength effluents (Rahman et al., 2023). This structural mismatch explains the increasing interest in compact, modular and physically separated biomass systems such as membrane bioreactors (Iorhemen et al., 2016; Rahman et al., 2023). If manure is treated on-farm to reduce emissions of nitrogen, phosphorus, odours, and microbial pathogens to air and water, as well as to improve storage and land application, Best Available Techniques (BAT) require the application of specific processing methods (European Commission, 2017). These include mechanical separation of slurry, anaerobic digestion in biogas installations, external tunnel drying, aerobic digestion, and nitrification-denitrification of slurry (European Commission, 2017).

***Comparative performance analysis***

The pollutant removal efficiencies reported for several livestock wastewater treatment technologies are summarized in Table 3.

Table 3. Pollutant removal efficiencies of selected livestock wastewater treatment technologies in percentage (Kashyap, 2017)

| Treatment Technology | BOD | COD | SS | TN | TKN | TP | Cu |
|---|---|---|---|---|---|---|---|
| Stabilization Pond | 77.78 | 78.02 | 88.12 | 61.65 | 67.02 | 65.16 | 88.57 |
| Cover Lagoon | 85.18 | 83.06 | 85.43 | 47.61 | 51.88 | 66.42 | 89.28 |
| Fixed Dome | 85.06 | 70.97 | 80.63 | 51.98 | 52.16 | 67.27 | 82.72 |

Note: BOD – biochemical oxygen demand; COD – chemical oxygen demand; SS – suspended solids; TN – total nitrogen; TKN – total Kjeldahl nitrogen; TP – total phosphorus; Cu – copper.

The operational ranges presented in Table 4 show that conventional activated sludge systems require the sludge retention time (SRT) to be maintained through hydraulic stability, whereas membrane systems can maintain long sludge retention times (SRT) independently of the hydraulic retention time (HRT). Under variable loading, conventional systems operate outside the nitrification stability domain (<10-20 days effective SRT), whereas MBR systems maintain 15-40 days due to physical biomass retention. Therefore, process instability in agricultural wastewater treatment is a structural consequence of gravity separation rather than biological kinetics.

The comparative analysis illustrated in Figure 6 is based on a synthesis of representative literature data regarding livestock wastewater treatment technologies. Reported operational ranges and removal efficiencies were extracted from peer-reviewed studies and aggregated to obtain indicative average values for each technology group.

The results highlight clear differences in treatment efficiency and operational stability among the evaluated technologies. Conventional biological systems, such as activated sludge and hybrid biological-physicochemical configurations, can achieve satisfactory pollutant removal under stable influent conditions, but their performance may decline under hydraulic variability typical of agricultural wastewater.

In contrast, membrane bioreactor (MBR) systems demonstrate higher operational robustness due to complete biomass retention and the decoupling of sludge retention time (SRT) from hydraulic retention time (HRT). This allows the maintenance of high mixed liquor suspended solids (MLSS) concentrations and stable nitrification even under variable loading conditions, resulting in consistently higher effluent quality.

Overall, the compact design and process stability of MBR systems make them particularly suitable for decentralized and mobile wastewater treatment applications in livestock farms.

Operational ranges and performance indicators presented in Table 4 were obtained through a synthesis of representative literature data on livestock wastewater treatment technologies. Reported values from peer-reviewed studies were aggregated to illustrate typical operational conditions and treatment efficiencies.

MBR is an efficient wastewater treatment technology that integrates a biological process with membrane filtration.

The membrane bioreactor configuration illustrated in Figure 5 integrates biological treatment with membrane separation, ensuring complete biomass retention and stable effluent quality under variable loading conditions. Aeration supports both microbial activity and membrane fouling control, while sludge recirculation maintains process stability. This configuration enables the decoupling of sludge retention time from hydraulic retention time, which is essential for reliable treatment of livestock wastewater.

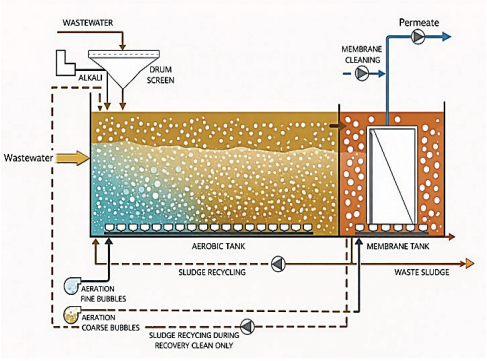

Figure 5. Containerized Membrane Bioreactor (MBR-C) Process Flow (adapted and redrawn by the authors based on literature sources)

Table 4. Comparative operational ranges and process stability of conventional activated sludge (CAS) and membrane bioreactor (MBR) systems for livestock wastewater treatment

| Parameter (units) | Conventional systems (CAS / lagoons) | MBR systems (submerged / containerized) | Process stability mechanism |
|---|---|---|---|
| Influent COD (mg/L) | 500-8000 (high variability typical of livestock wastewater) | Similar influent range; high-strength wastewater commonly treated up to 3000–5000 mg/L | Both systems depend on influent variability, but MBR tolerates higher load fluctuations |
| Influent $BOD_5$ (mg/L) | 200-5000 depending on wastewater strength | Similar influent range; effluent $BOD_5$ typically <5–20 mg/L | Membrane barrier ensures consistent effluent quality |
| Influent TSS (mg/L) | 200-3000 | Similar influent range; permeate TSS typically <1–5 mg/L | Complete physical retention of suspended solids |
| SRT required for nitrification (days) | ≥10-20 required for stable nitrification | Easily maintained at 15–40 due to membrane biomass retention | Decoupling of SRT from HRT stabilizes biological activity |
| HRT (hours / days) | CAS: 6-24 h; lagoons: several days–weeks | Typically 4-12 h; longer for high-strength wastewater | MBR allows shorter HRT with long SRT |
| MLSS (g/L) | 2-5 | 8-15 typical; occasionally higher in pilot systems | High biomass concentration improves treatment robustness |
| Membrane flux (LMH) | Not applicable | 10-30 typical operating range | Membrane filtration replaces gravity settling |
| Transmembrane pressure TMP (kPa) | Not applicable | ~10-40 depending on fouling and operation | Fouling controlled through aeration and cleaning cycles |
| COD removal (%) | 70-90 under stable operation | 85-98 | Higher stability due to retained biomass |
| BOD removal (%) | 85-95 | 90-99 | Membrane barrier prevents solids carryover |
| TSS removal (%) | 80-95 | >99 | Membrane filtration ensures near-complete solids removal |
| Nitrogen removal (%) | 40-80 depending on configuration | 70-95 with nitrification–denitrification | Stable nitrification enabled by long sludge age |
| Phosphorus removal (%) | 20-60 without advanced processes | 60-90 depending on configuration | Enhanced biological or chemical removal possible |
| Energy consumption ($kWh/m^3$) | ~0.2-0.6 | ~0.4-1.0 | Higher aeration demand but compensated by smaller footprint |

Note. Values were derived from reported ranges in peer-reviewed studies and validated against established wastewater engineering references (U.S. EPA, 2007; Judd, 2011; Metcalf & Eddy et al., 2014; Iorhemen et al., 2016; Meng et al., 2017; Nagarajan et al., 2019; Du et al., 2020; Rahman et al., 2023; Vaishnav et al., 2023; Chen et al., 2024).

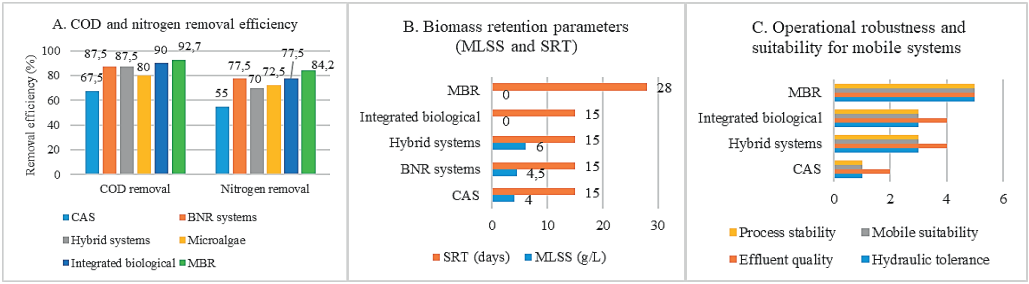

Figure 6. Comparative performance and operational stability of wastewater treatment technologies applied to livestock effluents

(A) Comparison of COD and nitrogen removal efficiencies reported in literature for conventional activated sludge (CAS), biological nutrient removal (BNR), hybrid biological–physicochemical systems, microalgae-based treatment, integrated biological treatment and membrane bioreactors (MBR). (B) Biomass retention characteristics expressed through mixed liquor suspended solids (MLSS) and sludge retention time (SRT). (C) Comparative operational robustness based on hydraulic variability tolerance, effluent quality and suitability for decentralized mobile systems

Membrane bioreactor (MBR) technology, which combines the activated sludge process with micro- or ultrafiltration membranes, is widely regarded as an effective tool for industrial water treatment and water reuse due to its high product water quality and low footprint (Hoinkis et al., 2012). In membrane bioreactor systems, biological degradation is coupled with physical separation through microfiltration or ultrafiltration membranes

(Ezugbe & Rathilal, 2020). The membrane barrier ensures near-complete suspended solids removal and significantly improved effluent quality (Iorhemen et al., 2016).

Consequently, the effluent quality becomes reproducible and independent of sludge settling characteristics (Rahman et al., 2023).

Another structural advantage is the possibility of operating at long sludge retention time and short hydraulic retention time simultaneously (Iorhemen et al., 2016). This condition favors slow-growing nitrifying microorganisms and improves nutrient removal stability (Du et al., 2020).

From a spatial perspective, eliminating secondary clarification significantly reduces the overall footprint of the treatment system, defined as the land area required for reactor installation and operation (Rahman et al., 2023).

The compact configuration of MBR systems makes them particularly suitable for decentralized and mobile installations where land availability is limited (Kesari et al., 2021).

This feature directly addresses one of the primary constraints of agricultural wastewater treatment infrastructure (Musa & Idrus, 2021).

The main drawback of MBR technology is membrane fouling, which reduces permeability and increases operational costs. However, fouling represents an operational challenge rather than a conceptual limitation, and extensive control strategies have been developed (Iorhemen et al., 2016; Du et al., 2020).

The technological barrier has shifted from demonstrating the feasibility of biological wastewater treatment to optimizing its operational stability, treatment efficiency, and adaptability under variable field conditions. In the decentralized agricultural context, where hydraulic loading fluctuates and wastewater characteristics are highly variable, stable biological treatment cannot be reliably maintained because sufficient biomass retention and settling cannot always be achieved. Membrane filtration is then more about securing the process stability than about increasing the performance of the wastewater treatment system. Thus, implementing membrane technology represents a completely new approach to wastewater treatment management in contrast to the incremental evolution from traditional to improved treatment systems.

The expected permeate quality of containerized MBR systems (Table 5) shows ammonium concentrations below 2 mg/L and BOD below 10 mg/L even at influent concentrations typical for agricultural wastewater.

Table 5. Typical influent and permeate water quality in containerized membrane bioreactor systems

| Parameter | Feed Water Quality | Expected Permeate Quality | Removal Efficiency (%) |
|---|---|---|---|
| pH | 6.5-7.5 S.U. | 6.5 - 7.5 S.U. | - |
| Alkalinity (as $CaCO_3$) | 125 mg/L | ≥ 100 mg/L | 20 |
| Temperature Range | 20-30°C | 20-30°C | |
| Total Suspended Solids (TSS) | 200 mg/L | < 5 mg/L | 97.5 |
| Biochemical Oxygen Demand (BOD) | 250 mg/L | < 10 mg/L | 96 |
| Chemical Oxygen Demand (COD) | 400 mg/L | < 50 mg/L | 87.5 |
| Ammonium-Nitrogen ($NH_4$) | 30 mg/L | < 2 mg/L | 93.33 |

*Values are indicative and may vary depending on influent characteristics and system configuration.

This indicates that stable nitrification is maintained despite high organic and nitrogen loads, confirming that decoupling SRT from HRT ensures biological robustness under intermittent inflow conditions.

In Romania, wastewater from farms has a biochemical oxygen demand (BOD) of up to 2000 mg/L, a total nitrogen content of less than 300 mg/L, and a dry matter content of less than 1% (Ministry of Environment, Waters and Forests & Ministry of Agriculture and Rural Development., 2021).

Wastewater passes through a drum screen to remove aggregates of hair and other debris, and to protect the membrane surface. The water then overflows to aeration tank, where air (fine bubbles) is injected to the tank to provide oxygen for microorganisms to decompose organic contents to $CO_2$, $H_2O$, and to convert ammonium/ammonia to nitrate. Membranes are periodically cleaned using chemical agents and air scouring with coarse bubbles in order to reduce fouling and keep the transmembrane pressure (TMP) within acceptable operating limits.

Despite the specific energy demand associated with membrane aeration and flux maintenance (0.4-0.8 kWh/m³), the MBR technology confers strategic benefits regarding compact footprint, high-quality effluent, and operational stability during load fluctuations.

MBR systems provide several advantages compared with conventional biological treatment processes, including improved effluent quality, reduced footprint, and easier process automation. They are typically operated with longer solids retention times (SRT), which contributes to lower sludge production. The treated effluent usually contains extremely low levels of bacteria, total suspended solids (TSS), biochemical oxygen demand (BOD), and phosphorus.

However, the main limitation of MBR technology is the higher investment and operational costs required to achieve treatment capacities comparable to those of conventional systems.

Energy costs are also higher because of the need for air scouring to control bacterial growth on the membranes (U.S. Environmental Protection Agency, 2007).

***Suitability for decentralized systems***

Mobile wastewater treatment systems for pig farms present significant potential, particularly for small and medium-sized farms needing flexible and sustainable solutions. However, addressing weaknesses such as limited capacity and high operational costs, while leveraging opportunities like renewable energy integration and rising regulatory demands, will be crucial for their widespread adoption and success.

Mobile treatment systems can be relocated to address wastewater issues at different farm sites, ensuring flexibility in operations, suitable for small-scale pig farms where permanent infrastructure may not be financially viable. They can incorporate multiple treatment stages (e.g., sedimentation, biological treatment, filtration) to meet specific water quality standards.

Increased regulations for agricultural wastewater management create demand for advanced treatment solutions. Biogas recovery from pig waste can power treatment units, reduce operational costs and create additional revenue streams (Sporea et al., 2023). Innovations in mobile treatment technologies (e.g., compact anaerobic digesters, advanced filtration) can improve efficiency and reliability. Maintenance, energy consumption, and operator training can be expensive. Performance can be affected by variations in wastewater characteristics, such as high solids or fat content from pig farming operations. High initial investment and operational costs may deter small-scale farmers from adopting the technology. Alternative wastewater treatment methods (e.g., centralized treatment plants, permanent lagoons) may be more appealing for certain farms.

The comparative operational characteristics shown in Table 6 demonstrate that the feasibility of decentralized treatment depends more on predictable effluent quality than on nominal removal efficiency. The compact footprint (0.1-0.3 m² per m³·d) and low hydraulic shock sensitivity enable treatment directly at source, transforming wastewater management from storage-based manure handling to a controlled treatment process.

Table 6. The differences between conventional activated sludge and membrane bioreactor systems in decentralized agricultural applications

| Parameter | Conventional activated sludge | Membrane bioreactor (MBR) | Typical implication for mobile systems |
|---|---|---|---|
| Infrastructure requirement | Requires sewer network and storage | Operates directly at source | Suitable for decentralized farms |
| Specific energy demand | ~0.3-0.6 kWh/m³ | ~0.5-1.0 kWh/m³ | Comparable when transport energy included |
| Sludge retention time (SRT) | ≥10-15 days for nitrification | 20-40 days independent of hydraulics | Stable treatment under variable loads |
| Effluent suspended solids | 10-40 mg/L (variable) | <1-5 mg/L (stable) | Reliable compliance |
| Total nitrogen removal | 50-80% (load dependent) | 80-95% (stable) | Better nutrient control |
| Sensitivity to hydraulic shocks | High | Low | Suitable for intermittent flows |
| Footprint | ~0.5-1.5 m² per m³·d | ~0.1-0.3 m² per m³·d | Compact mobile installations |
| Biomass retention | Settling dependent | Complete membrane retention | No washout risk |
| Operational stability | Less predictable performance | More predictable performance | Predictable effluent quality |
| Treatment philosophy | Dilution and discharge | Concentration and recovery | Compatible with circular economy |

*Values represent typical operational ranges reported in literature.

This study is based on literature analysis and therefore does not include experimental pilot-scale validation. Future research should investigate the operational performance of mobile MBR systems under real farm conditions and evaluate economic feasibility for small and medium livestock operations.

## CONCLUSIONS

Pollution generated by pig farms remains a major barrier to sustainable livestock production, not because of insufficient biological degradation capacity, but because centralized treatment concepts require hydraulic stability that livestock effluents inherently lack (Burton et al., 2003; Metcalf & Eddy et al., 2014). Membrane separation provides a different operational approach by decoupling sludge retention from hydraulics, transforming treatment reliability into a structural property of the process (Meng et al., 2017). For mobile and on-farm systems, environmental impact is determined by stability rather than nominal removal efficiency, making consistent effluent quality the primary performance indicator (WHO, 2006; Rahman et al., 2023).

Economic comparisons between conventional systems and membrane bioreactors are incomplete when transport, storage and dilution externalities are excluded from system boundaries (European Commission, 2020). Decentralized treatment preserves nutrients prior to dilution and therefore enables resource recovery and circular water management (Capodaglio & Olsson, 2020). Under this framework, performance must be evaluated by reuse safety and recoverability, not only pollutant removal (WHO, 2006; European Commission, 2020).

MBR systems should be considered a robust baseline technology for variable-load agricultural wastewater treatment rather than merely an advanced tertiary option.

The transition from activated sludge to MBR thus represents an infrastructural adaptation to circular economy requirements rather than a technological upgrade.

***Abstract***

*High salinity lakes harbor halophilic microbial communities with specialized adaptations to osmotic stress. These ecosystems provide important ecological services and biotechnological potential, yet they face increasing threats from climate change and human activities. Understanding their microbial diversity is essential for conservation efforts. The present study aims to characterize cultivable halophiles from three saline lakes located in Durgau-Valea Sarata area, documenting their diversity, salt tolerance and capacity to produce extracellular enzymes.*
*XRF analysis revealed silica, chloride, calcium and titanium throughout all samples, with sporadic traces of bromide, potassium and sulfur. Cultivation on media with different salt concentrations yielded a total of 60 isolates across the three lakes, optimizing recovery of diverse halophiles including both archaea and bacteria. 16S rRNA gene sequencing of representative isolates revealed affiliation to Salinivibrio, Halomonas, Chromohalobacter, Marinococcus, Salicola, Halococcus, Halobacterium, Haloarcula and Halorubrum genera. Bacterial isolates produced exoenzymes (esterase, inulinase, amylase) and five strains demonstrated biofilm formation capacity.*
*Our results provide reference data on diversity of cultivable halophiles and functional traits in these threatened saline ecosystems.*

***Key words:*** *halophiles, anthropo-saline lakes, biofilm formation, cultivable diversity, exoenzymes.*

## INTRODUCTION

Hypersaline habitats shelter diverse microbial communities, including extreme halophiles, moderate halophiles, and halotolerant microorganisms, which have developed strategies to overcome osmotic stress and elevated salinity levels through mechanisms such as accumulation of compatible solutes and efficient ion transport systems (Quesada et al., 1983). Recent studies have revealed that these communities are characterized by specific trophic interactions shaped by high levels of specialization (Saccò et al., 2021).
Hypersaline lakes, which account for almost half (44%) of inland water volume (Saccò et al., 2021), exhibit uniqueness not only in their extreme physicochemical conditions but also in the diversity and metabolic potential of their microbial communities (Paul & Mormile, 2017). These ecosystems offer biotechnological potential, therapeutic uses through heliothermic properties and organic-rich sediments (Alexe et al., 2018; Rus et al., 2020), and microbiological research opportunities, where microbial communities serve as environmental indicators (Oren, 2018; Paul & Mormile, 2017).
However, hypersaline lakes are highly susceptible to climate change, as increased temperatures lead to high evaporation rates, further intensifying salinity levels that challenge microbial survival (Paul & Mormile, 2017), while rising lake surface temperatures affect ecosystem structure and metabolic activities (Dokulil et al., 2021). Since salinity drives microbial diversity, alterations to this foundation affect the entire food web (Baxter & Butler, 2020). Additionally, anthropogenic pressures, particularly intense touristic exploitation through uncontrolled bathing, cause degradation and diminishment of the heliotherm phenomenon (Alexe & Furtună, 2012). Continued loss and degradation of hypersaline habitats will result in the loss of taxonomic and functional diversity, with impacts at multiple scales, making the prevention of ecosystem destruction and the development of sustainable use strategies a pressing issue (Saccò et al., 2021).

Salt lakes in Transylvania are distinctive components of the basin landscape formed by salt dissolution of underground halite deposits (Har et al., 2010; Alexe et al., 2018). These lakes are small and quite deep, offering ideal conditions for stratification and the development of heliothermy (Mera et al., 2010; Sonnenfeld & Hudec, 1980). Previous microbiological research in the Turda region has focused mainly on the characterization of halophilic bacterial communities associated with Turda Salt Mine (Carpa et al., 2014). Several studies have also investigated the microbial diversity of hypersaline meromictic lakes from the Transylvanian Basin, with particular emphasis on archaeal communities and their vertical distribution in the water column (Andrei et al., 2015; Baricz et al., 2014; 2015). Nevertheless, information regarding the diversity of cultivable bacterial populations inhabiting these saline lakes remains relatively limited.

Understanding the composition and physiological capabilities of halophilic microbial communities is essential for both conservation efforts and potential biotechnological exploitation. The present study aims to document the diversity and physiological characteristics of cultivable halophilic microorganisms from three saline lakes in the Durgău-Valea Sărată area (Turda, Romania). By characterizing these communities, their salt tolerance profiles, and enzymatic capabilities, this research provides baseline data necessary for conservation and monitoring as environmental pressures from climate change and anthropogenic activities intensify.

## MATERIALS AND METHODS

### Site description

Water samples were collected from three saline lakes in the Durgău-Valea Sărată area of Turda (46°35'16.8"N, 23°47'14.1"E), Cluj County, Romania (Figure 1). This area is part of Sărăturile Ocna Veche, a protected area of national interest corresponding to IUCN category IV (mixed nature reserve). The salt lakes in Turda developed over the sites of old salt mine chambers used during the 15th and 16th centuries (Mera et al., 2010). These lakes are characterized by stratification (formation of permanent density water layers) and heliothermy, with a surface freshwater layer of variable thickness (0.15 to 0.2 m) (Mera et al., 2010).

Ocnei Lake emerged around 1800 following the collapse of the "Ocna cea Mare" excavation (Mera et al., 2010). This anthropo-saline lake contains chlorinated-sodic mineral waters with mineralization ranging between 19.27 and 225 mg $L^{-1}$ (Rus et al., 2020) and surface salinity varying from 1.78 to 40.42 g Cl/l depending on freshwater input (Munteanu & Munteanu, 2012). The lake is actively used for recreation and therapy, with heavy exploitation during summer since 2009 (Avram et al., 2022). Over time, maximum temperatures in the heliothermic layer have decreased, mainly due to intensive exploitation of the waters for bathing and treatment activities (Alexe & Furtună, 2012).

Rotund Lake was created by the collapse of the "Ocna cea Mica" excavation (Mera et al., 2010). Similar to Ocnei Lake, it is an anthropo-saline lake used for recreation and therapy (Avram et al., 2022), with chlorinated-sodic mineral waters (Rus et al., 2020).

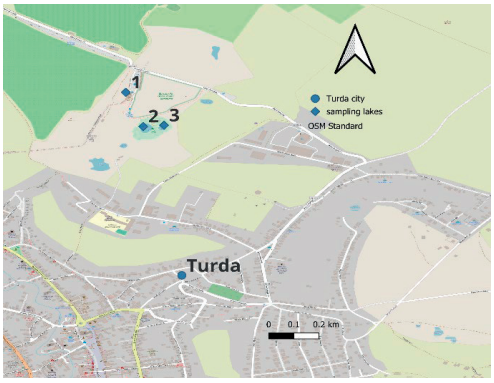

Figure 1. The map with sampling points (QGIS Desktop 3.40.15 with OSM standard)

Therezia Lake is a subterranean lake located at 112 m depth in the Turda Salt Mine, with a water depth of 0.5- 8 m and occupying approximately 80% of the exploitation chamber surface (Kimic et al., 2021). The lake formed through human-induced geomorphological processes: the Theresia chamber, originally a salt extraction site named in honor of Empress Maria Theresa, became structurally unstable following

extensive salt extraction and ultimately collapsed, allowing surface water infiltration that gradually flooded the cavity (Avram et al., 2022). A central island formed by residual salt accumulated after the cessation of extraction activities in 1880 (Kimic et al., 2021). The lake is characterized by a slightly alkaline pH (8.7), specific conductance of 114 mS $cm^{-1}$, and estimated salinity of 90.98 g $L^{-1}$ (Carpa et al., 2014). The subterranean environment maintains relatively constant temperatures (11.8-12.2°C) and humidity (67-70%) with no air flow (Enache, 2010).

**Sampling**

The water samples were collected from the surface layers of the three lakes, about 0.5 m beneath the water surface. The sampling procedure was performed aseptically with sterile utensils and sterilized collection containers, thereby avoiding external contamination. Samples were kept refrigerated and were transported in cooler storage boxes to the laboratory for further chemical and microbiological analysis.

**XRF analysis**

The chemical composition of the water samples was determined using a Supermini X-Ray Fluorescence Spectrometer (Rigaku Corporation, Japan), following the manufacturer's semiquantitative method for light element analysis in a helium atmosphere. SQX software was used to calculate elemental oxide mass percentages (mass %). Weighed 10 mL volumes of each sample were used for analysis.

**Isolation of halophilic microorganisms and estimation of total CFU number** was carried on 3 different nutritive media, with the following compositions (g $L^{-1}$): MH medium - yeast extract, 10; proteose peptone, 5; glucose, 1; NaCl, 100; $MgCl_2$ x $6H_2O$, 7; $MgSO_4$ x $7H_2O$, 9.6; $CaCl_2$ x $2H_2O$, 0.36; KCl, 2; $NaHCO_3$, 0.06; NaBr, 0.026 (Quesada et al., 1983), JCM 168 medium (Japan Collection of Microorganisms) - casamino acids, 5; yeast extract, 5; sodium glutamate, 1; trisodium citrate, 3; $MgSO_4 \cdot 7H_2O$, 20; KCl, 2; NaCl, 200; $FeCl_2 \cdot 4H_2O$, 36; $MnCl_2 \cdot 4H_2O$, 0.36, MR medium - NaCl, 250; $MgCl_2$ $6H_2O$, 13; $MgSO_4$ $7H_2O$, 20; KCl, 4; $CaCl_2$ $2H_2O$, 1; NaBr, 0.5; $NaHCO_3$, 0.2; yeast extract, 5; tryptone, 8; and glucose, 1 (Hedi et al., 2009). A quantity of 20.0 g $L^{-1}$ agar was added to each type of medium for solidification, and the pH was adjusted to 7.2 before autoclaving.

In order to estimate the total CFU number in each sample and isolate the halophilic microorganisms in pure cultures, the serial dilutions method was applied, followed by the pour-plate technique and 3 streak-plate purification passages. The experiments were conducted in triplicate. The cultures incubation was performed at 30°C (MH) or 37°C (JCM 168 and MR) for a period of 30 days.

**The susceptibility to inhibitors (antibiotics/ bile salts)** of the new isolates was tested in order to confirm assignment to the *Bacteria* domain and to differentiate them from halophilic archaea. Two media variants with specific inhibitors were used for this purpose: one containing 0.002% chloramphenicol and the other containing 0.004% sodium deoxycholate. Strains that grew in the presence of the bile salt were considered halophilic bacteria.

**Establishing the salinity range**

The range of salt concentration that allows bacterial growth was determined in MH, JCM168, and MR media containing different NaCl concentrations: 0, 1, 2, 3, 4, and 5 M. The halophilic isolates were classified based on the most widely accepted system defined by Kushner & Kamekura (1988).

**Assessment of extracellular enzyme production**

MH medium with NaCl concentrations adjusted according to previously obtained results was used for establishing the ability of selected isolates to produce extracellular hydrolytic enzymes (amylase, esterase, inulinase). This was qualitatively assessed on solid basal MH (without proteose peptone and glucose) to which the interest substrate was added.

For the amylolytic activity, 2 g $L^{-1}$ starch was added to the basal medium. The selected isolates were inoculated on the surface of agar plates, incubated at 30°C for 48 hours and subsequently flooded with $I_2$ – KI solution (0.1% $I_2$ – 0.2% KI). The presence of a clear zone around the

culture spot indicates the starch hydrolysis and strains were recorded positive for amylase production (Ali et al., 2024).

To determine the esterase activity, the basal medium was supplemented with 0.01% $CaCl_2$. After autoclaving, sterile Tween 80 was added to a final concentration of 1% (v/v). Positive reaction was indicated by the appearance of a white precipitate formed around the growth areas of the bacterial cultures (Ali et al., 2024).

For cellulase activity, basal medium was supplemented with 0.5 g $L^{-1}$ carboxymethylcellulose (CMC). After incubating the inoculated plates at 30°C for 48 hours, they were flooded with 0.1% Congo Red solution for 15 minutes. The dyeing agent was removed by rinsing with 1M NaCl for 5-10 minutes (Rohban et al., 2009; Bambharolia et al., 2024).

The production of inulinase by the investigated isolates was detected by adding 2 g $L^{-1}$ inulin to basal medium. Bacterial growth after 48 hours of incubation at 30°C was considered a positive result (Rohban et al., 2009).

**Molecular identification of the isolates**

Total genomic DNA was extracted using a DNeasy Blood & Tissue kit (Qiagen), according to the manufacturer's protocol. 16S rRNA gene was PCR amplified with the pair of primers 27F (AGAGTTTGATCCTGGCTCAG) – 1492R (GGTTACCTTGTTACGACTT) for bacteria (Miller et al., 2013), while for archaea, the set of primers 20F (AGTTTGATCATGGCTCA) – 1540R (AAGGAGGTGATCCAACCGCA) (Ohnishi et al., 2011) was used. Amplicons were analyzed by agarose gel electrophoresis (1% w/v) with Red Safe staining and visualized under UV light against O'GeneRuler 1Kb Plus DNA Ladder (Thermo Scientific). Following DNA sequencing performed by CeMIA SA (Larissa, Greece), the resulting nucleotide sequences were compared using the Basic Local Alignment Search Tool (BLAST; www.ncbi.nlm.nih.gov/BLAST/).

**Biofilm production** was assessed in five bacterial isolates selected for mucoid/slimy colony appearance, which typically indicates extracellular polysaccharide production.

The experiment was carried out in 96-well U-bottom microplates with following the method described by O'Toole (2011). The experiment was performed with 5 replicate wells per isolate. Plates were incubated for 31 days in static conditions, at 30ºC, and the biofilm formed was quantified periodically by reading the absorbance at 550 nm (BMG LABTECH FLUOstar Omega microplate reader).

## RESULTS AND DISCUSSIONS

**XRF analysis**

Generally, silica, chloride, sodium, calcium and titanium were present in all investigated samples, with slight quantitative variation according to water source. Sporadic traces of bromide, potassium and sulfur were also detected according to data presented in Figure 2. The considerably smaller amounts of silica detected in the Therezia Lake, could be associated with the position of the lake inside the salt mine, unlike the other two surface lakes positioned in open space. As previously stated, silica should not be considered native ions in the salt massifs (Cojoc et al., 2013).

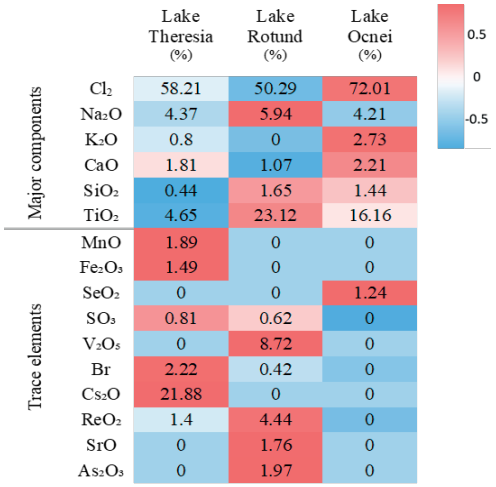

Figure 2. Heatmap of XRF-determined chemical composition of the three salt lakes. Color intensity corresponds to row-wise Z-score normalized values representing relative abundance from low (light) to high (dark). Values indicate measured oxide concentrations (mass %)

High concentrations of titanium and vanadium, both toxic to aquatic organisms and humans, suggest anthropogenic contamination from industrial activities, pigments, cosmetics, and

wastewater entering the lakes via surface runoff or wind (Catana et al., 2022).
The high chlorine concentration observed in all three investigated lakes is reflected in the water's salinity. Sodium chloride, which is a thermophile molecule contributes to an increase in salinity of the warm layer during the daytime (Sonnenfeld & Hudec, 1980).
The performed microbiological analyses proved that the investigated lakes are highly populated by halophilic microorganisms belonging to the *Bacteria* and *Archaea* domains.

**Estimation of the total CFU number and the isolation of halophilic microorganisms**
After 48h of incubation, the number of CFU $mL^{-1}$ on MH medium was estimated as follows: Ocnei Lake – 4.7 x $10^2$ CFU $mL^{-1}$, Therezia Lake – 0 CFU $mL^{-1}$, Rotund Lake – 1.26 x $10^2$ CFU $mL^{-1}$. No colonies grew on JCM 168 and MR media after 48 hours of incubation at 37ºC.
Pink-red and white-cream colonies developed on JCM 168 medium only after 30 days of incubation. The number of CFU $mL^{-1}$ was estimated as follows: Ocnei Lake – 10 CFU $mL^{-1}$, Therezia Lake – 82.33 CFU $mL^{-1}$, Rotund Lake – 13 CFU $mL^{-1}$. On MR medium pink, yellow, and orange colonies developed after 1 month of incubation only from the Therezia Lake sample, the estimated CFU number for this sample being 20 CFU $mL^{-1}$.
A total number of 60 isolates across the three investigated lakes (13 from Ocnei Lake, 25 from Therezia Lake and 22 from Rotund Lake) were obtained and further purified.

**The inhibitor tests performed** showed that all the 25 microbial isolates obtained on MH medium belonged to the *Bacteria* domain, being able to grow in the presence of deoxycholic acid sodium salt.
On JCM 168 medium, 14 of the obtained isolates showed susceptibility to bile salts and were also positive for lysis in sterile distilled water after incubation for one hour at room temperature. The susceptible isolates were thus classified as archaea. The remaining 15 strains resistant to bile salts were selected for further experiments and considered to belong to the *Bacteria* domain. Following the same differentiation test, two of the isolates obtained on MR medium were classified as bacteria and 4 were assigned to *Archaea.* Across the three investigated lakes different domain distributions of the isolates were observed (Figure 3).

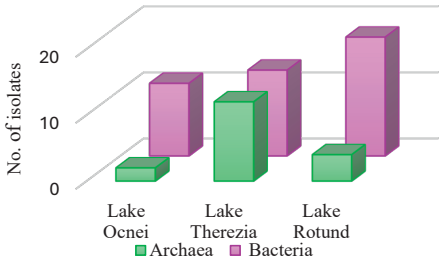

Figure 3. Domain distribution of isolates obtained from the saline lakes

**Establishing the salinity range**
Based on optimal salinity for growth, this study revealed distinct halophilic profiles between surface and subterranean environments.
The two surface anthropo-saline lakes - Ocnei and Rotund - were dominated by halotolerant strains (46% and 61% of the isolates), with moderately halophilic isolates representing 36% and 39%, respectively. Extremely halophilic strains were detected only in Ocnei Lake (18%), whereas they were absent from Rotund Lake. In contrast, the subterranean Therezia Lake exhibited a distinct distribution, with predominant moderately halophilic strains (46%), followed by halotolerant (39%) and extremely halophilic (15%) representatives, suggesting different selective pressures in the isolated subterranean environment.

**Assessing of the capacity of producing extracellular enzymes**
Screening of the bacterial isolates revealed a heterogeneous distribution of extracellular enzymatic capabilities. A considerable number of strains expressed lipolytic (5 isolates) and proteolytic activity (6 isolates), whereas inulin degradation was detected only in three isolates. CMC was not hydrolyzed by any of the isolates. The capacity to degrade complex carbohydrates was less prevalent. Amylolytic activity was detected in a limited number of isolates and showed only partial overlap with lipolytic activity.
A smaller number of isolates (5) demonstrated combined hydrolytic activities, suggesting a

high versatility. The presence of such polyvalent strains may reflect ecological adaptation to fluctuating nutrient availability, highlighting potential candidates for saline bioprocesses.

**Molecular identification of the isolates**

Agarose gel electrophoresis confirmed successful PCR amplification with domain-specific primers, by yielding products of expected size for both bacterial and archaeal 16S rRNA genes (Figure 4).

Representative isolates from the three investigated anthropo-saline lakes were identified by partial 16S rRNA gene sequencing as belonging to bacterial and archaeal genera as presented in Table 1.

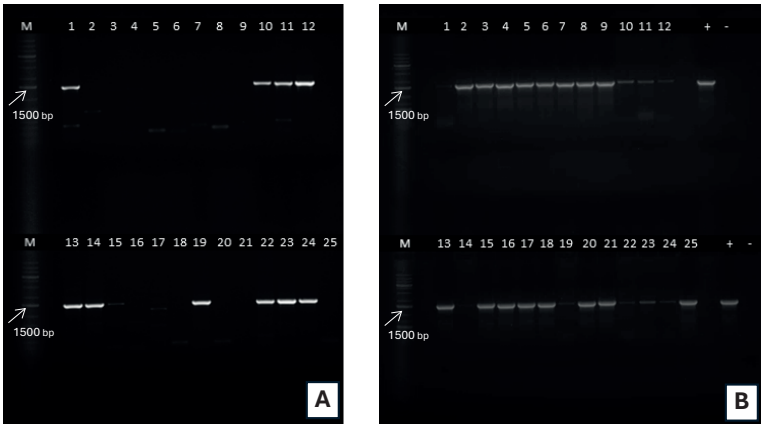

Figure 4. Domain-specific amplification of 16S rRNA genes with (A) Archaeal primers (20F/1540R), (B) Bacterial primers (27F/1492R). Lane identifications: M = 1 kb Plus DNA ladder; 1-25 = isolates from the 3 saline lakes; + = positive control, - = negative control

Table 1. Taxonomic affiliation of sequenced isolates from the three saline lakes

| Sample source | Affiliation to bacterial genera | Affiliation to archaeal genera |
|---|---|---|
| **Ocnei Lake** | *Halomonas* (3), *Marinococcus* (1), *Salinivibrio* (1), *Salicola* (1) | *Halococcus* (1) |
| **Therezia Lake** | *Halomonas* (1), *Salicola* (1), *Chromohalobacter* (3) | *Haloarcula* (2), *Halococcus* (2), *Halobacterium* (3), *Halorubrum* (1) |
| **Rotund Lake** | *Marinococcus* (3) | Not sequenced |

*Numbers in parentheses indicate isolates assigned to each genus.

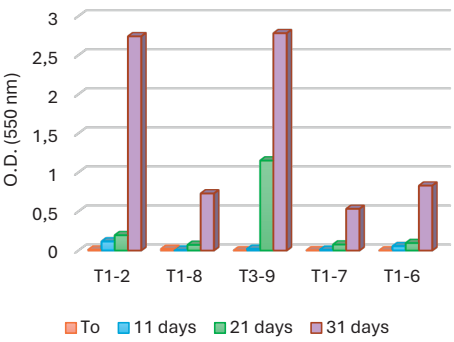

Figure 5. Biofilm production capacity of the investigated bacterial isolates

**Biofilm formation capacity**

Biofilm production was assessed in five bacterial isolates showing mucoid/slimy colony morphology. All five isolates demonstrated biofilm formation capacity, though with varying kinetics and production levels (Figure 5).

Isolate T3-9 showed a significant capacity for biofilm formation after 21 days of incubation, while T1-2 was able to produce notable biofilms only after 31 days. The remaining three isolates also formed biofilms after 31 days of incubation, but at lower levels than T3-9 and T1-2.

## CONCLUSIONS

The three anthropo-saline lakes in the Durgău-Valea Sărată area (Turda, Romania) harbor diverse cultivable halophilic microbial communities comprising both bacterial and archaeal representatives.

Distinct halophilic profiles were observed between surface saline lakes (Ocnei and Rotund) and the subterranean Therezia Lake, with surface lakes dominated by halotolerant strains, while the subterranean environment showed higher proportions of moderately and extremely halophilic microorganisms, suggesting that environmental isolation may create different selective pressures in these habitats.

The presence of elevated titanium and vanadium concentrations detected through XRF analysis indicates anthropogenic contamination associated with intensive bathing activities, particularly from sunscreens and cosmetic product pigments, raising concerns about impacts on microbial community health and ecosystem stability.

The enzymatic capabilities of bacterial isolates, including esterase, inulinase, and amylase production, along with biofilm-forming capacity across multiple strains, highlight the biotechnological potential of halophilic microorganisms from these threatened ecosystems and underscore the economic value of preserving microbial diversity.

This study provides essential baseline data on cultivable halophilic diversity and functional traits in Turda saline lakes, establishing reference information necessary for future monitoring and conservation efforts as these ecosystems face mounting pressures from climate change and anthropogenic activities.

## ACKNOWLEDGEMENTS

This research work was carried out with the support of the Institute of Biology Bucharest of Romanian Academy and was financed from the projects no. RO1567-IBB05/2026 and RO1567-IBB02/2026.

***Abstract***

*Wastewater treatment plants are complex systems designed to deal both with wastewater and with resulting sludge. Physical, chemical and especially biological processes depend significantly on technological factors, the conditions for the development of biochemical reactions having complex dynamics. Due to hourly and seasonal variations in inputs (flows and pollutant concentrations), and to the conditions of the treatment process, continuous technological adjustments are necessary. The economic sizing of wastewater treatment plants can lead to operating situations at the organic pollutant load limit in terms of efficiency, making it necessary to adopt additional technological measures. The paper presents a one-year long case study on adjusting the stabilization processes and reducing the quantity of sludge produced (50% in warm seasons, 10% in cold season) in a wastewater treatment plant based on specialized microbial products. The monitorized parametres are dissolved organic carbon (COD), $N_{total}$, $P_{total}$ The results highlight the need to ensure all technological factors for wastewater treatment and for sludge mineralization, simultaneously with the maintaining of desired efficiency and the corrective measures implementation.*

***Key words:*** *biological processes, biopreparations, sludge stabilization, wastewater treatment plant.*

## INTRODUCTION

Wastewater treatment plants become increasingly important for the environment and human activities in the context of climate change and the major imbalance between water demand and available water quantities.

The technological challenge of management of the sludge quantities was addressed using microbial products by Chinese scientist (Li et al., 2022) isolating strains of *Firmicutes* and *Proteobacteria* confirming the possible use.

The study main objective is the decrease of the sludge quantities by 50% all over the year, independently of temperature, on average flux of 100 $m^3$/h and average COD of 2000 mg/L, by adding microbial products.

Sewage sludge management has historically been achieved (EU, 2024) through methods that did not take into account all environmental factors, with major implications generated over time; Table 1 presents the main methods used and their advantages/disadvantages.

Table 1. Treatment methods for sludge resulting from wastewater treatment processes

| Method | Disadvantages | Advantages |
|---|---|---|
| Spreading on agricultural land | - technological difficulties in transporting and applying for sludges with high moisture<br>- pedological changes in the pH indicator, and the need to monitor soil characteristics over time<br>- high consumption of lime for sludge stabilization and dehydration, respectively for soil amendment<br>- accumulation of heavy metals in soil, cumulative evolution<br>- need for large land areas | - unloading of significant quantities of materials considered waste – circular economy<br>- nutrient supply for agricultural lands<br>- improving soil structure |
| Reduction of sludge quantities through aerobic stabilization | - increase in technological wastewater treatment volumes<br>- additional energy consumption for aeration, | - reducing the sludge volumes generated by wastewater treatment plants |

| Method | Disadvantages | Advantages |
|---|---|---|
| at the technological wastewater flux or in specific compartments | homogenization and recirculation<br>- consumption of coagulants for phosphorus correction<br>- all the aspects mentioned for the previous method | - reducing the amount of stabilization lime<br>- improving sludge management/dewatering processes, including reducing the quantities of dehydrated reagents required<br>- reducing the amount of carbon discharged into the environment with the possibility of generating secondary pollution |
| Anaerobic stabilization | - difficult process to manage due to the range required for feeding the fermenter with raw material, the restricted pH and temperature range necessary to be ensured in the process<br>- significant consumption of electrical and thermal energy even in the case of complete solutions for valorization of the biogas produced<br>- incompatibility between the need to reduce nitrogen in wastewater and biogas production for low C:N ratios<br>- oversizing biological tanks for treating nitrogen and phosphorus generated in fermentation processes<br>-the need for additional stabilization of the fermented sludge compared to an aerobic process | - reduction of the final sludge amount<br>- obtaining energy by utilizing biogas and gaining wastewater treatment plant energy independence<br>- obtaining expensive energy by optimizing cogeneration processes |
| Incineration | - $CO_2$ generation and removal into the atmosphere in contradiction with the concept of carbon storage<br>- need to dehydrate sludge to low moisture levels (35%)<br>- generation of gases and water vapor in the dehydration and incineration process<br>- dust generation<br>- additional fuel requirement | - reducing the quantities of waste that must subsequently be managed<br>- obtaining thermal energy<br>- simplifying the wastewater technological flux and sludge technological flux, by reducing the technological volumes necessary for sludge stabilization |

From the analysis of the advantages and disadvantages listed, the optimal solution seems to be the centralized management of sludge in regional depots (Neamt et al., 2013; Rosiek, 2020), ensuring: centralized collection of sewage sludge from economic operators; quantitative and qualitative control of sludge and application of efficient technologies for each category of sludge and for by-products; storage in plots depending on chemical characteristics; development of specific processing technologies for each type of sludge.

A regional sludge depot can be structured as follows:

- plots for stabilizing good quality organic sludge, with minimal content of toxic substances and heavy metals for agricultural use or composting (mixed with organic waste as organic fertilizers);
- anaerobic fermentation with energy recovery or storage in plots that naturally ensure the process;
- washing and reconditioning of sludge with recovery of some components;
- concentration of leached solutions/solutions resulting from various processes and their valorization;
- treatment and cremation of petroleum products, stable products, etc.

In such a sludge management structure, the technological challenge for economic agents is to reduce the amount of sludge and raw (wet) sludge. Reducing sludge amount can be approached in two technological directions: aerobic or anaerobic biological mineralization and improving dehydration processes. It thus becomes of interest to address aspects related to efficiency and technology in the case of the use of biopreparations intended to reduce the amount of sludge generated in biological wastewater treatment plants.

## CONSIDERATIONS REGARDING BIOLOGICAL PROCESSES IN WASTEWATER TREATMENT PLANTS

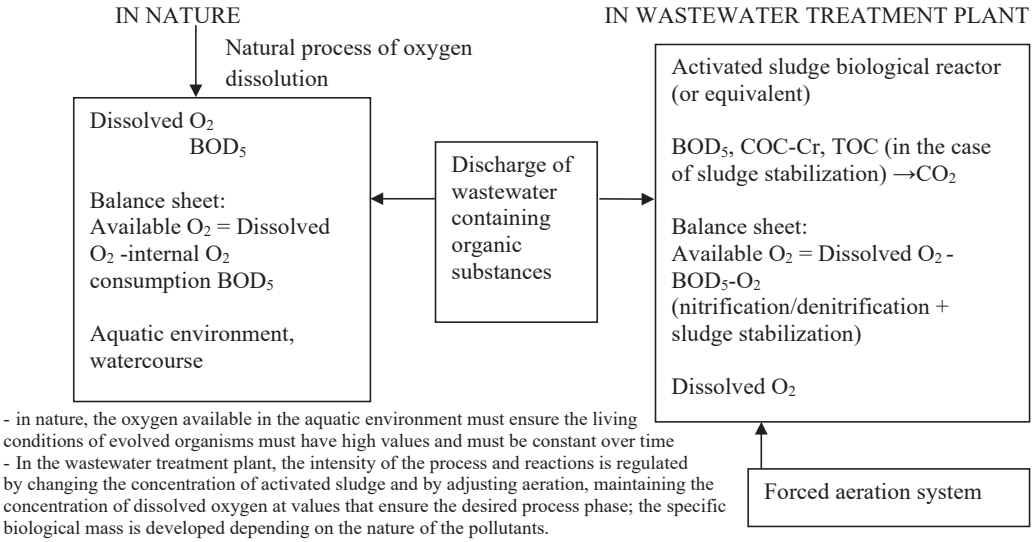
Initially, the treatment plants were sized and constructed to ensure the reduction of $BOD_5$

and suspended matter indicators. It is considered that reducing oxygen consumption in biological processes to a minimum accepted level can eliminate oxygen deficiency situations in the receiving watercourse and maintain environmental factors away from any quality degradation risk. Every study, design and operation recommendation, and treatment efficiency concept took into account $BOD_5$ as indicator. Within biological nitrogen reduction wastewater treatment plants, C:N ratio is the principal efficiency indicator, also governing the sizing of biological nitrification/denitrification compartments.

Within wastewater treatment plants using biological sludge stabilization and/or bioaugmentation, where part of the sludge is biologically mineralized, C:N Kjeldahl indicator became the main parameter for determining the oxygen requirement for the process and also for sizing of additional volumes in the nitrification/denitrification compartments.

Applications designed based on BOD5 indicator recorded increased specific technological consumption indicators due to the processing of larger quantities of COC-Cr or TOC (especially in applications that ensure sludge mineralization/stabilization).

Table 2 presents the degree of carbon reduction for standard design situations corresponding to the standards NTPA 002 (MAPM-b, 2002) treatment influent and NTPA001 (MAPM-a, 2002) effluent. It could be noticed that in the case of plant sizing with the COC-Cr indicator, it is necessary to process additional quantities of organic substances (about 100 $mgO_2/L$). The design process becomes difficult when the BOD5/COD-Cr ratio is low and, also, there are high COC-Cr concentrations. For these specific reasons, the design of wastewater treatment plants with the COC-Cr parameter was adopted.



From a technical point of view, the design model adopted does not reflect the effective situation in the wastewater treatment plant. Figure 1 shows the difference between a wastewater self-treatment process in a watercourse and the wastewater treatment plant process.

Table 2. Minimum treatment efficiencies for domestic wastewater treatment plants (MAPM-b, 2002)

| Indicator | NTPA 002/2002 | Effective reduction | |
|---|---|---|---|
| | (mg/L) | (mg/L) | (%) |
| $BOD_5$ | 300 | 275 | 91.67 |
| COC-Cr | 500 | 375 | 75.00 |
| $BOD_5$/COC-Cr = 0.6, as a result of values in NTPA 002/2002 | | | |

From the point of view of the accuracy of determining the design quality indicators, the $BOD_5$ indicator implies a reduced accuracy due to the dilution required for determination, compared to the COC-Cr determination where the accuracy is high due to the simplicity of the method.

The design standard NP 133/2022 (MDLPA, 2022) provides for the determination of the oxygen requirement depending on the COC-Cr value in the situation where the COC-Cr/$BOD_5$ ratio > 2.2 or $BOD_5$/COC-Cr = 0.45, without specifying the how to do it when the ratio varies in the range (0.6 - 0.45); in this situation the bioaugmentation is a solution, combined with the increase of oxygen added in the process NP 133/2022 requires the calculation of sludge production and oxygen demand with influent COC-Cr values (MDLPA, 2022). Consequently, wastewater treatment plants sized based on the influent $BOD_5$ indicator, without taking into account the critical nitrogen indicator (ammonia nitrogen) or plants with sludge stabilization calculated without the COC-Cr or TOC indicator, encounter operational difficulties in ensuring the oxygen requirement, sludge production and management and, in many situations, do not ensure mandatory discharge conditions. In the design of wastewater plants without sludge stabilization, an activated sludge concentration of 3000 mg/L and a sludge age of (10-20) days is recommended (MDLPA, 2013; DWA, 2000). In the design of wastewater plants with sludge stabilization, an activated sludge concentration of 4500 mg/L and a sludge age of (20-30) days is recommended (MDLPA, 2013; DWA, 2000), resulting in a technological volume 18% higher than in the first situation, which proves in operation that are not enough in cold seasons.

- in nature, the oxygen available in the aquatic environment must ensure the living conditions of evolved organisms must have high values and must be constant over time
- In the wastewater treatment plant, the intensity of the process and reactions is regulated by changing the concentration of activated sludge and by adjusting aeration, maintaining the concentration of dissolved oxygen at values that ensure the desired process phase; the specific biological mass is developed depending on the nature of the pollutants.

Figure 1. Scheme of $O_2$ provision for biological processes in nature and in wastewater treatment systems

For these specific plants or for those with aerobic sludge stabilization in separate compartments, the technological variant with microbial products based on bacterial strains support in sludge digestion can be adopted. For plants having nitrification-denitrification and sludge stabilization at the technological wastewater flux, complex solutions can be adopted by dosing two types of biopreparations, one to improve the mineralization, one to maintain the efficiency of the main treatment process; in both processes, must be ensured the technological factors related the necessary oxygen and re-circulations.

The wastewater treatment technological scheme will be developed so that the process takes place in individual nitrification and denitrification tanks, respectively sludge stabilization tanks, and allows the optimization of each phase of the process (Figure 2).

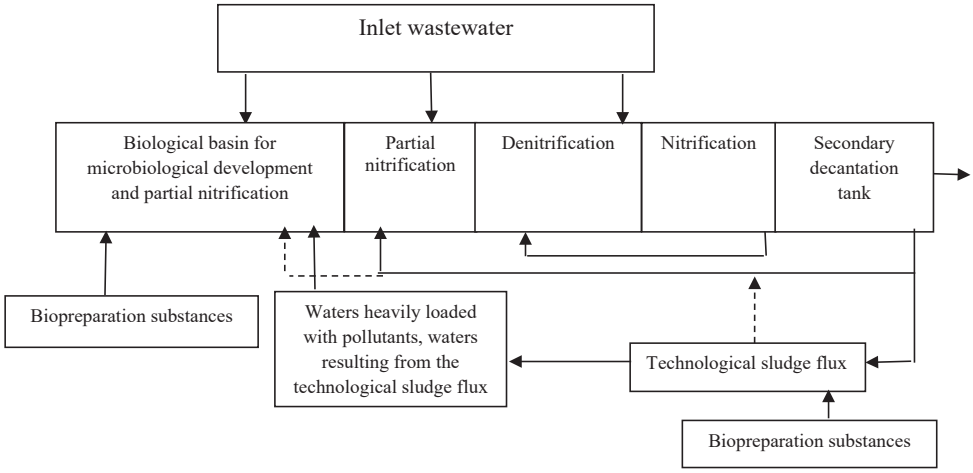


Figure 2. General scheme of an optimized biological stage with specialized biopreparation substances

Efficiency is achieved by maintaining a high biological capacity by dosing microbiological preparation substances, by successive nitrification and denitrification phases, by

appropriate fractional feeding and, in particular, to maintain denitrification capacity, microbiological dosing for sludge stabilization both on the technological wastewater flux and on the technological sludge flux.

## DYNAMICS OF BACTERIAL DEVELOPMENT WITHIN WASTEWATER TREATMENT PLANTS

The calculation models used in the design standard for wastewater treatment plants provide relationships that depend on the temperature and sludge age, which modify the rate of sludge mineralization/stabilization.
In the evolution of biological sludge, four development stages were highlighted, corresponding to process starting (primary bacteria), development and appearance of protozoa, sludge maturation and aging, corresponding to the nematode appearance (Figure 3).
For bacterial development, it is necessary to permanently ensure the needed nutrients and avoid toxic elements. Within wastewater treatment plants operation, both discharges of highly toxic substances and variations in nutrient concentrations are recorded, the dynamics of bacterial development being thus variable. Achieving optimal conditions in specialized compartments lead to obtaining the bacterial base stock that ensures the treatment of consumption peaks.

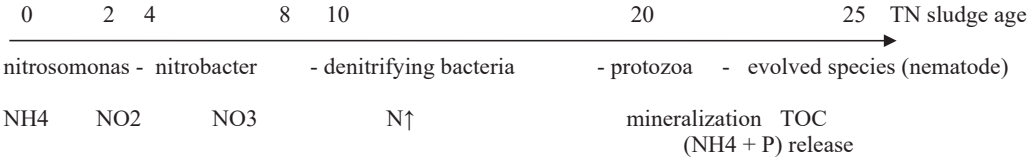

Figure 3. Phases of activated sludge development

When the nutritional conditions are met, depending on the temperature, pure bacterial population can double in a time interval of (20-50) min - bacterial doubling time t.D – under ideal lab conditions (Simionescu, 2009). In Figure 4 the bacterial growth is presented assuming the necessary nutritional conditions are provided; for this model, the treatment plant capacity doubles in a short time, with sufficient adaptability to wastewater load changes: this is the valid model for the priming phase, as there are no nutritional deficiencies. In practice, the need to adapt the biological mass to the quality conditions of the influent wastewater has been highlighted, the period defined as the "lag phase" (Simionescu, 2009).

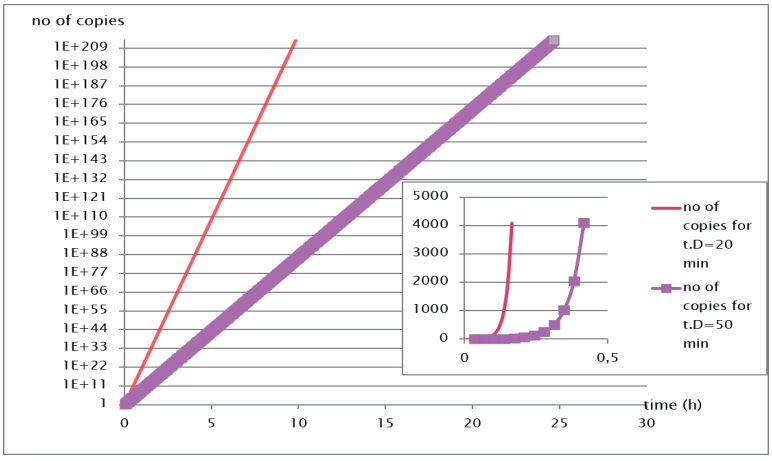

Figure 4. Bacterial development assuming optimal development conditions (t.D - bacterial doubling time)

In the following phases of activated sludge development (development of protozoa and nematodes) the dynamics change significantly, organic matter being hydrolyzed, metabolized and eliminated with secondary products, $CO_2$, $NH_4$ and P. The increase in suspended mass of activated sludge is thus diminished.

The mathematical models adopted in the wastewater treatment standard are based on the "sludge age" indicator, which can be interpreted as the period of development of the activated sludge that ensures the processing of a certain amount of pollutant (carbon, ammonia nitrogen, nitrates, phosphorus, and sludge stabilization), the maturation and stabilization of the activated sludge.

For the development of the bacterial mass capable of processing the corresponding loads of wastewater at the entrance to the treatment plants (MAPM-b, 2002), the proposed relationships depend on the temperature (equation 1):

$$T_{N,aerob} = FS \cdot 3{,}4 \cdot 1{,}103^{(15-T)}(days) \quad (1)$$

where:

$$T_{N,dim} = \frac{T_{N,aerob}}{1 - \frac{V_D}{V}}(days)$$

FS - security factor; 1.45-1.8 - depends on load variations at the inlet of the wastewater treatment plant
V - biological reactor total volume
$V_D$ - denitrification compartment volume

In the case of nitrogen reduction in denitrification processes and biological stabilization of sludge at the technologic wastewater flux, the proposed relationships for sludge age defined as stock compared to daily production, the dynamics depend on sludge production determined with equation 2 (MDLPA, 2013):

$$N_{eC} = C_b(0{,}75 + 0{,}6\frac{c^b_{uz}}{x^b_{5,uz}} - \frac{0{,}102.T_N.F_T}{1+0{,}17.T_N.F_T}\left(kg\ d\frac{s}{day}\right) \quad (2)$$

where:
-$N_{eC}$ - sludge production in kg d.s./day (dry substance/day)
-$C_b$ - the amount of organic matter entering the wastewater treatment plant
-$C^b_{uz}$ - suspension concentration in the influent of the biological reactor
-$x^b_{5,uz}$ - $BOD_5$ concentration in the influent of the biological reactor
$T_N$ - sludge age
$F_T$ - temperature factor for endogenous respiration

Determining the sludge age requires an iterative calculus.

Considering the equations presented and applied for standard situations, a biological reactor of 1 $m^3$ biological, operated with a load Iob (organic load index of the biological tank) in various temperature scenarios, results in the values for the graphs presented in Figure 5.

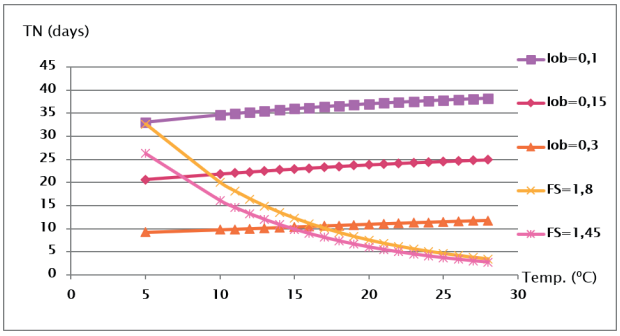

Figure 5. Sludge age determined for different temperature and organic load scenarios in the case of a standard wastewater treatment plant with an activated sludge concentration of 3000 mg/L

The analysis of the determined values results in reduced sludge ages in the case of low loads, Iob = 0.1 kg $BOD_5/m^3$ and day, respectively over 15 days in the case of loads of Iob = 0.3 kg $BOD_5/m^3$ and day.

In the exploitation variant with sludge stabilization, the third term in equation 2, which expresses the mineralization fraction, depends on the temperature and age of the sludge, respectively the bacterial development of the activated sludge.

The values of mineralization factor in Figure 6 are greater than 0.4 (inferior limit doable for operation) in the case of exploitation for

temperature greater than $10^0$C and sludge age over 18 days. At a temperature of $25^0$C, the mineralization factor greater than 0,4 is reached at a sludge age of 6 days.

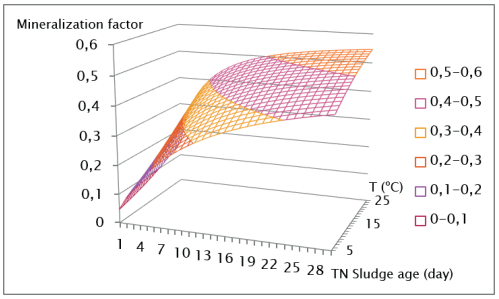

Figure 6. The mineralization factor for activated sludge determined in equation 2

When microbial products for sludge mineralization are used the result is the augmentation with 0.1 of mineralization factor in the case of exploitation for temperature greater than $10^0$C and sludge age over 18 days. At a temperature of $25^0$C and the sludge age of 6 days there is obtained a mineralization factor of 0.6. In operation, improving the mineralization factor becomes important, the values being a function of sludge doses and age.

## CASE STUDY

Operation of wastewater treatment plants highlights the multitude of variants related to pollutant loads. In the case of industrial wastewater treatment plants, the operating range is wide and for these reasons the regulation capacity of the plants must ensure the treatment efficiencies.

Results are presented for a biological wastewater treatment plant in the food industry designed for a flow rate of 100 $m^3$/h and dissolved organic carbon concentrations of 2000 mg/L Technological problems are recorded, due to the sludge decantability, the high sludge volume index of over 200 ml/g the entrainment of suspensions in the treated wastewater, the high sludge production, and its low age. Table 3 presents the calculation of sludge age and sludge production according to equation 2 at maximum load.

According to the operating parameters, the critical section from the point of view of wastewater treatment is the "settlement" due to sludge load high values: the superficial load with total suspended matter of about 215 kg dry matter/$m^2$day (recommended range of 90-140), respectively the superficial volumetric load with sludge of 928 $dm^3/m^2h$ (recommended range of 450-500), limits provided by the national design regulation NP 133/2013 (MDLPA 2013).

Table 3. Sludge age determined for the maximum load situation

| | |
|---|---|
| Q ($m^3$/day) | 2400 |
| BOC influent (mg/L) | 2000 |
| Influent suspensions (mg/L) | 100 |

| Sludge stock (kg/day) | 12000 |
| Calculated T.N. (days)–iterated result | 4.245204 |

*third term – sludge mineralization factor

To improve the settling properties and increase the mineralization degree, microbial products (described in Table 4) were dosed, a mixture of microorganisms (over 3 x 109 microorganisms/g) and enzymes. The product is dosed directly into the aeration area of the wastewater treatment plant, with doses ranging from 3 kg/1000 $m^3$/day for starting de process, to 0.12 kg/1000 $m^3$/day for maintenance phase. The product can be applied in a wide range of temperature and pH indicator (Table 4).

Table 4. Microbial products utilized range of application

| Conditions | Range | Optimum |
|---|---|---|
| dissolved oxygen, ppm | 0-2.0 | >0.5 |
| pH | 6-9 | 7 |
| temperature, $^0$C | 10-40 | 35 |
| toxic heavy metals, ppm | low presence | absent |
| nutrients | | |
| $BOD_5$: $NH_3$-N | 10:1 - 10:0.5 | 10:1 |
| $BOD_5$: $PO_4$-P | 100:1-100:0.5 | 100:1 |

The biological product contains microbiological strains capable of breaking down a wide

range of substances such as: lignocellulose, fats, greases, proteins, fibers, etc., without generating additional cell mass. The synergistic content of microbial strains, oligo-elements, minerals and vitamins improves the quality of wastewater treatment by reducing pollutants, optimizing sedimentation and reducing total costs. The frequency and amount of application dose are related to the influent volume, pollutant loading, biological reactors capacity, hydraulic retention time, physical and chemical parameters, etc.

Testing was carried out starting in the autumn-winter months and continued into the warm season. For the cold season, the minimum temperature in the biological reactors being $12^0$C, sludge production decreased by 10% (estimated on sludge management sheets). During the warm season, at temperatures above $20^0$C, sludge production decreased by 50%, the costs generated by sludge management being very low. These values are valid only for wastewater treatment plants designed for an average flux of 100 $m^3$/h and average COD of 2000 mg/L, by adding microbial products.

The cold period represents the critical operating interval, and in this case the additional biological activity due to the biological product addition generated a reduction in wastewater treatment efficiency. The values of effluent water quality indicators for carbon, nitrogen, phosphorus and suspensions increased as process temperatures decreased. Figure 7 shows the evolution of the biological product doses applied within every phase of the wastewater treatment process in September. A dose of 5.5 kg/day of microbial product is the maximum for the first stage and for the restoring.

Frequently, the phosphorus records increase in the discharged water when the input water loads are reduced and the biological process is unbalanced for sludge stabilization. Important variations in the quantities of pollutants at the entrance imply significant changes for the biological process. Sludge stabilization ensures good sludge decantability and filterability, therefore good mechanical dehydration, these processes are observed in the operation of the wastewater treatment plant. During the testing period, the release of phosphorus was highlighted by increases in concentrations in the discharged water and the need to increase dephosphorization doses (Figure 8).

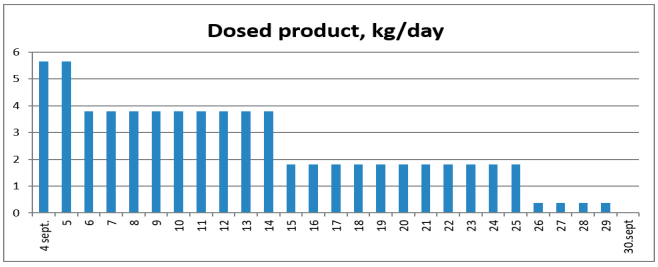

Figure 7. Product doses used in the process starting and maintenance phases

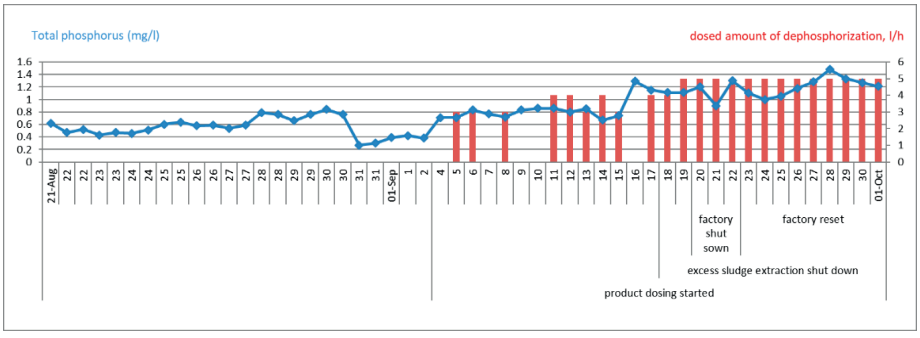

Figure 8. Evolution of the quantities of reagents for dephosphorization and the phosphorus indicator for discharged water

Concerning the biological activity, the decrease in wastewater treatment efficiency (Figures 9 and 10) was caused by: sludge mineralization processes due to the product use; decrease in temperatures decrease; treated wastewater flow rates increase; frequent use of biocidal products in the sterilization processes of the factory's production facilities.

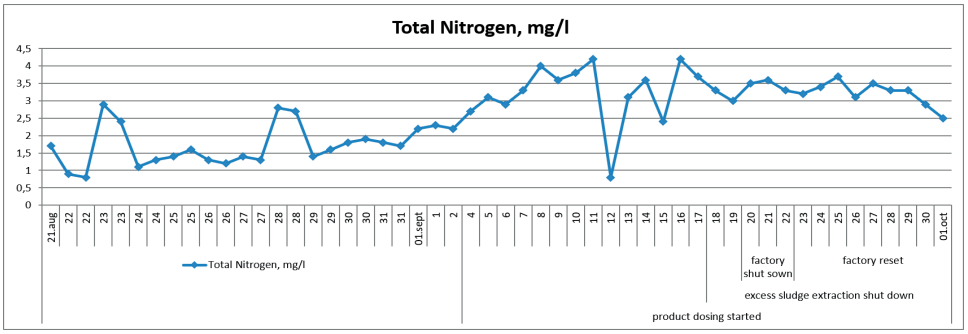

Figure 9. Evolution of the total nitrogen indicator for discharged water

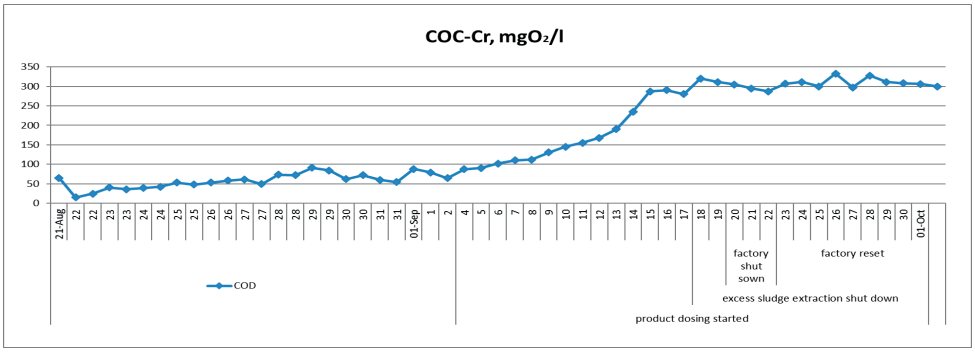

Figure 10. Evolution of the oxidizable organic substances COC-Cr indicator for discharged water

Technologically, the dissolved oxygen was maintained in the range (2-4) mg/L in automatic mode, with aeration reserves of over 100%, and for the external recirculation value, a level of approximately 1000% of the maximum input flow rate were ensured.
During the warm season, the microbial product ensured the sludge reduction by 50%; for the cold period, the use of biological product stimulates the sludge mineralization ensuring the sludge reduction of 50%

## CONCLUSIONS

Industrial and domestic wastewater treatment plants do not always fulfill the tasks related to the stabilization of biological sludge.
The use of microbiological products in the case study shows a decrease of 10% to 50% of sludge quantities, depending on the season. The decreases mentioned above imply also modification of technological volumes, dissolved oxygen and additional dosing of dephosphorization reagents.
When reduced organic pollutant loads (under 50% design COD, namely 1000 mg/L) and temperatures below $10^0$C within the process are present it is necessary to restore the capacity to assimilate and metabolize pollutants through additional dosing of microbial products of maximum 5.5 kg/day.
For industrial wastewater it would be benefic to revise the existing Regulation used for domestic wastewater treatment and adapting it for non-standardized loads.
Products to stimulate biological activity are beneficial, technological compartments are mandatory in order to develop specialized

biological mass and optimize wastewater treatment process.

Changing technological conditions impose modifying the wastewater treatment scheme and the type of products used. The case study and its results demonstrate the importance of the dynamic response in terms of introduction and dosing the microbial products when needed. As future works, the research will focus on using simultaneous two different microbial products, one for sludge mineralization, the second for the bacterial assimilation, in order to compare the results with the present study, for the cold season.

***Abstract***

*Cyanobacteria exert intense ecological pressure within aquatic systems of the Danube Delta, shaping both phytoplankton and zooplankton community dynamics. Their summer intense development can disrupt the balance between phytoplankton and zooplankton functional groups. Cyanobacteria dominated the phytoplankton, often outcompeting other algal taxa. Abundance indicated high concentrations of Cyanobacteria ($10^7$–$10^8$ cells $L^{-1}$), reflecting the high productivity. Their competitive advantage modifies species composition, reducing overall diversity and altering trophic interactions. The zooplankton displayed adaptive responses to shifts in phytoplankton, reflecting changes in food quality and availability. Among the dominant phytoplankton species were Anabaena variabilis, Aphanizomenon spp., and filamentous forms of the genera Microcystis spp., and Oscillatoria spp. In contrast, the zooplankton was predominantly structured by rotifers and cladocerans, among which Keratella cochlearis, Brachionus calyciflorus, and Bosmina longirostris were frequently found, indicating a high ecological tolerance. These temporal patterns highlight a complex interplay between communities, emphasising the regulatory role of cyanobacterial pressure in structuring aquatic community dynamics and influencing the trophic functioning of Delta ecosystems.*

***Key words****: cyanobacterial blooms, Danube Delta, phytoplankton, trophic interactions, zooplankton.*

## INTRODUCTION

*Cyanobacteria* are a prominent group in aquatic phytoplankton that, under prolonged periods of high temperatures, proliferate and become dominant in many continental ecosystems (Paerl & Huisman, 2008). Their competitive success is explained by their functional traits, such as broad tolerance to temperature and light, the ability to efficiently exploit nutrient resources, buoyancy conferred by gas vacuoles and, in some cases, the production of secondary metabolites with allelopathic effect. In addition, adaptations such as the ability to fix atmospheric nitrogen and high tolerance to eutrophic conditions are also added (Reynolds, 2006; Paerl & Otten, 2013). The Danube Delta is a complex network of aquatic ecosystems characterised by high spatial heterogeneity and heightened sensitivity to anthropogenic and climatic pressures. Changes in the hydrological regime, increased nutrient input and climate change have favoured the intensification of eutrophication processes in many deltaic lakes (Dumitran et al., 2020). One of the most visible effects of these transformations is the increase in the frequency and intensity of algal blooms dominated by *Cyanobacteria*, with potential risks for ecosystems (Moza et al., 2021). Studies have shown that in recent decades, *Cyanobacteria* have contributed significantly to phytoplankton biomass with effects on trophic status (Török et al., 2017). This dominance is manifested either by the massive development of several cyanobacterial species or by high densities generated by one or two species (Dumitran et al., 2024). As a result of algal blooms, community structure is simplified, increasing the dominance of a few taxa and reducing evenness, even when overall richness remains relatively high. This imbalance in diversity is characterised by reduced abundances of species from other groups, temporary coexistence with *Cyanobacteria*, and subsequent competitive exclusion (Török, 2011).

The emergence and rapid expansion of *Cyanobacteria* have significant ecological

consequences, affecting both the structure of planktonic communities and trophic relationships in aquatic ecosystems (Moldoveanu & Florescu, 2011). In the lakes of the Danube Delta, these processes manifest differently depending on local environmental conditions, leading to contrasting responses from phytoplankton communities. Thus, studies have shown that in some ecosystems cyanobacterial dominance intensified, whereas in others competition with chlorophytes or diatoms limited the success of this group, generating unstable, seasonal community structures (Török et al., 2017).

The aim of our study is to evaluate the role of *Cyanobacteria* as key factors in structuring phytoplankton communities in Roșuleț, Puiu and Tătaru lakes, representative lakes of the Danube Delta. The objectives of the study are: 1. Analysing the taxonomic structure of phytoplankton communities and highlighting the position of *Cyanobacteria* relative to the main algal groups using multivariate methods; 2. Assessing variations in α and β diversity, in order to identify structural changes in communities between lakes and between seasons; 3. Identifying cyanobacterial taxa responsible for seasonal compositional changes by analysing their contribution to community dissimilarity; 4. Investigating competitive relationships between *Cyanobacteria* and other phytoplankton groups, through quantitative indicators of the competitive replacement rate, in order to highlight ecological hierarchies and community stability.

## MATERIALS AND METHODS

### *Study site*

The Danube Delta is characterised by a complex network of branches, channels and shallow lakes, developed on fluvial and marine beds, with active transformation processes. The inland lakes are generally shallow, with variable connectivity to the channel network, which results in low hydrodynamics and a strong influence on Danube level variations. From an ecological perspective, the Danube Delta is one of the most valuable wetlands in Europe, with high biodiversity and a wide range of aquatic ecosystems, including eutrophic and hypereutrophic lakes with rich phytoplankton communities (Pavel et al., 2009).

The lakes selected in our study, Puiu, Tătaru and Roșuleț (Figure 1), are part of the Danube Delta lacustrine complex, and are characterised by variable hydrodynamics and different connectivity with the river branches and secondary channels. The lakes are shallow, developed on fluvial beds and subject to clogging and morphological remodelling processes, characteristic of inland deltaic lakes. Lake Puiu is a large, relatively deep (2-2.5 m in our sampling campaigns) lake in the Danube Delta, with a moderate fluvial influence that determines the seasonal dynamics of nutrients and planktonic communities (Tudorancea & Tudorancea, 2006; Gâștescu, 2009). Lake Tătaru is shallower (approx. 1 m deep in our sampling campaigns) and less hydrologically connected, favouring nutrient accumulation and frequent eutrophic episodes, with seasonal algal dominance (Coops et al., 1999). Roșuleţul, a shallow lake (1.1-1-6 m in our sampling campaigns), is strongly influenced by internal processes, such as sediment resuspension and phosphorus recycling, which lead to high phytoplankton variability and unstable community structures (Oosterberg et al., 2000; Gâștescu, 2009).

Figure 1. The sampling lakes: Roșuleț, Puiu and Tătaru (Google Earth app, 2026)

### *Phytoplankton sampling and analysis*

Water samples were collected during two field campaigns, in August and September 2015. To capture the spatial variability of the studied ecosystems, 4 sampling stations were established in each lake. Phytoplankton sampling was performed on the entire water column using a Patalas-Schindler (5 litres) and stored in a bucket. From this volume, 500 ml of the water sample was taken, immediately fixed

with 4% formaldehyde, and stored in plastic containers. In the laboratory, the samples were sedimented for 14 days. Quantitative and qualitative analyses were performed according to the Utermöhl method (Edler & Elbrachter, 2010) using an inverted microscope (Zeiss Axiovert 40C, Germany).

Taxonomic identification of organisms was performed to the genus or species level, using specific determination keys for the main taxonomic groups: *Cyanobacteria, Euglenophyceae, Pyrrophyceae, Chrysophyceae, Bacillariophyceae, and Chlorophyceae* (Moldoveanu et al., 2025).

***Statistical analysis***

Statistical analyses were performed using Past 5.2.1 software (Hammer et al., 2001), including Discriminant Analysis (DA), diversity indicators α (Dominance_D, Shannon_H, Equitability_J) and β (Whittaker, Cody, Williams), and the construction of a dendrogram based on the Bray-Curtis coefficient. The structure of the communities was additionally assessed using ANOSIM (Permutation test, N=9999) and SIMPER. The Rate of Competitive Displacement (RCD) was also calculated according to the methodology described by Ji et al. (2017), which estimates the rate at which phytoplankton groups replace one another under competitive conditions. RCD as differences between September versus August, as ln(X1/X2), where: X1- *Cyanobacteria* and X2 – diatoms or green algae – the total abundances of group.

## RESULTS AND DISCUSSIONS

***The structure and distribution of phytoplankton communities***

In the phytoplankton structure, *Cyanobacteria* recorded the highest share, followed by *Chlorophyceae* and *Bacillariophyceae*, with considerably lower abundances (Table 1). In Puiu and Tătaru lakes, all three groups showed significant increases in abundance during the monitoring period, with pronounced blue-green biomass peaks observed (in Tătaru − $9.22\times10^7$ cells/L; in Puiu − $8.04\times10^7$ cells/L). In contrast, at Roșuleț Lake, except for *Chlorophyceae*, most phytoplankton groups showed pronounced declines. *Chlorophyceae*, although the second group in weight, showed low abundances overall, reaching a maximum in Lake Tătaru in the month ($2.79\times10^7$ cells/L). Diatoms recorded lower values than *Cyanobacteria*, but showed notable increases in September. The *Euglenophyceae, Pyrrophyceae*, and *Chrysophyceae* groups were present at low densities, reflected in episodic increases.

Table 1. The abundances of the phytoplankton taxonomic groups in the studied lakes

| | Puiu | | Tătaru | | Roșuleț | |
|---|---|---|---|---|---|---|
| | VIII | IX | VIII | IX | VIII | IX |
| *Cyanobacteria* | $4.05x\ 10^7$ | $8.04x10^7$ | $1.45x10^7$ | $9.22x10^7$ | $4.08x10^7$ | $2.04x10^7$ |
| *Euglenophyceae* | $1.57x10^5$ | $5.80x10^4$ | $4.23x10^5$ | $1.86x10^5$ | $1.52x10^4$ | $6.59x10^3$ |
| *Pyrrophyceae* | $8.98x10^4$ | $1.38x10^5$ | $2.03x10^5$ | $9.81x10^5$ | $4.36x10^4$ | $2.60x10^4$ |
| *Chrysophyceae* | 0 | 00 | 0 | $8.84x10^5$ | $1.23x10^5$ | 0 |
| *Bacillariophyceae* | $1.54x10^6$ | $5.75x10^6$ | $4.89x10^5$ | $2.48x10^6$ | $1.92x10^6$ | $3.94x10^5$ |
| *Chlorophyceae* | $3.21x10^6$ | $6.95x10^6$ | $2.87x10^6$ | $2.79x10^7$ | $2.57x10^6$ | $3.50x10^6$ |

The DA discriminant analysis revealed clear separation between the main phytoplankton groups, along with partial taxonomic overlap, reflecting functional similarities and convergent ecological responses (Figure 2). These indicate that taxonomic structure only partially explains community organisation. Discriminant axis 1 (61.72%), but also an evident separation of *Cyanobacteria* (positioned predominantly on the right side of the axis) from *Bacillariophyceae* and *Chrysophyceae* (located on the left). *Chlorophyceae* present an intermediate position, with a greater dispersion, which indicates a higher heterogeneity than diatoms. This spread suggests the presence of species that display both opportunistic strategies and adaptations to more stable conditions. The partial overlap between chlorophytes, *Cyanobacteria*, and diatoms indicates the

functional flexibility of this group. In contrast, diatom species showed a clearer delimitation compared to the other groups. Also, *Chrysophyceae* showed a strong separation from the other groups (observed on the left side of axis 1). Axis 2 (29.55%) contributes to further differentiation of the communities, especially by the distinct positioning of *Euglenophyceae*, which forms a separate group on the left side of the axis. Groups with reduced representation, such as *Pyrrophyceae* and *Chrysophyceae*, appear more poorly delimited, with limited dispersion and less obvious separation. This positioning suggests either a reduced contribution to the overall community structure or shared ecological features with other major groups. The other groups show a clear overlap on this axis, with no clear demarcations between them. This separation is more pronounced than the differences between ecosystems or months, indicating that the community structure is mainly dominated by the contrast between *Cyanobacteria* and the rest of the phytoplankton. However, habitat overlaps are also evident, especially among *Chlorophyceae*, *Cyanobacteria*, and *Euglenophyceae*, reflecting a complex, partially overlapping community structure.

**α and β diversity traits**

The α-diversity indices revealed clear differences in the structure of phytoplankton communities between the lakes and between the two periods analysed (Table 2). Although total species richness remained relatively high (44-60 species), the Shannon index values indicated differences in community diversity, reflecting changes in the relative distribution of taxa, especially in Puiu and Roșulet lakes. In these two ecosystems, the increase in the dominance index (D), concomitant with the decrease in evenness (J), suggests a more pronounced structuring of the community, characterised by the concentration of abundance within fewer groups or taxa. Thus, between the two periods, the diversity indices showed different changes in the structure of phytoplankton communities in the three ecosystems. Total species richness generally recorded higher values in September, with a maximum in Lake Tătaru (60 species), suggesting seasonal diversification of the communities, especially through increased contributions from

the *Bacillariophyceae* and *Chlorophyceae* groups. Lake Puiu showed an increase in total richness from 45 to 53 species, concomitant with an increase in *Cyanobacteria*, while Lake Roșuleț recorded a decrease in total richness in September, suggesting a possible simplification of the community structure. The Shannon index (H′) ranged from moderate to high (2.08-2.69), with the highest values observed in Lake Tătaru in both months, suggesting relatively well-structured and stable communities.

In contrast, the higher values of the dominance index (D), especially in September in Lake Puiu and Lake Roșuleț, indicate an increase in the dominance of a few taxa, probably favoured by trophic conditions. This trend is also supported by the decrease in evenness (J), which reflects a more unequal distribution of species abundances in the community.

Even if total species richness remains relatively high, the increase in the proportion of *Cyanobacteria*, associated with a decrease in evenness and effective diversity of the community, can lead to an "apparent diversity" in which other groups are present but contribute less to the total biomass.

Table 2. Diversity of phytoplankton in the studied ecosystems

| | **Puiu** | | **Tătaru** | | **Roșuleț** | |
|---|---|---|---|---|---|---|
| | **VIII** | **IX** | **VIII** | **IX** | **VIII** | **IX** |
| *Cyanobacteria* | 15 | 19 | 12 | 12 | 16 | 11 |
| *Bacillariophyceae* | 5 | 6 | 8 | 18 | 6 | 6 |
| *Chlorophyceace* | 17 | 23 | 20 | 25 | 19 | 20 |
| *Euglenophyceae* | 6 | 3 | 5 | 2 | 1 | 1 |
| *Pyrrophyceae* | 2 | 2 | 1 | 2 | 1 | 1 |
| *Chrisophyceae* | 0 | 0 | 0 | 1 | 1 | 0 |
| **Species richness (S)** | 45 | 53 | 46 | 60 | 44 | 39 |
| **Dominance (D)** | 0.11 | 0.30 | 0.11 | 0.11 | 0.14 | 0.26 |
| **Shannon (H′)** | 2.61 | 2.16 | 2.69 | 2.69 | 2.34 | 2.08 |
| **Equitability (J)** | 0.68 | 0.55 | 0.70 | 0.66 | 0.62 | 0.57 |

Spatial beta diversity among lakes (Table 3). showed a moderate to high overall species turnover among the lakes (Whittaker = 0.50; Cody = 46.00; Williams = 0.27). The pairwise comparisons showed the highest compositional dissimilarity between Lakes Puiu and Tătaru (Whittaker = 0.36; Cody = 25.50; Williams = 0.24), followed by the Puiu–Roșuleț pair (Whittaker = 0.31; Cody = 20.00; Williams = 0.19). The lowest beta diversity values were recorded between Tătaru and Roșuleț (Whittaker = 0.30; Cody = 20.50; Williams = 0.16). Similar spatial patterns were observed across all three indices, indicating consistent differences in species composition among the studied lakes.

Table 3. The spatial beta diversity among lakes

| **Global beta diversities** | | | |
|---|---|---|---|
| Whittaker | 0.50 | | |
| Cody | 46.00 | | |
| Williams | 0.27 | | |
| **Whittaker** | **Puiu** | **Tătaru** | **Roșulet** |
| Puiu | 0.00 | 0.36 | 0.31 |
| Tătaru | 0.36 | 0.00 | 0.30 |
| Roșulet | 0.31 | 0.30 | 0.00 |
| **Cody** | | | |
| Puiu | 0.00 | 25.50 | 20.00 |
| Tătaru | 25.50 | 0.00 | 20.50 |
| Roșulet | 20.00 | 20.50 | 0.00 |
| **Williams** | | | |
| Puiu | 0.00 | 0.24 | 0.19 |
| Tătaru | 0.24 | 0.00 | 0.16 |
| Roșulet | 0.19 | 0.16 | 0.00 |

Regarding structural changes during the investigated period, β-diversity indices revealed moderate differences in phytoplankton composition (Table 4). The Whittaker index ranged from 0.40 to 0.47, indicating moderate temporal heterogeneity. The highest value was recorded in Lake Roșuleț (0.47), suggesting that this lake experienced the highest rate of species replacement from summer to autumn among the three. In contrast, the Cody index showed similar values across the lakes (19.5-21.0), suggesting a comparable rate of species replacement between months, with a slight maximum in Lake Tătaru. The Williams index values were relatively low (0.19-0.28), indicating low to moderate turnover (species change) between the two, but with a more pronounced differentiation in Lake Roșuleț.

Table 4. Temporal beta diversity within lakes

| | **Puiu** | **Tătaru** | **Roșuleț** |
|---|---|---|---|
| **Whittaker** | 0.41 | 0.40 | 0.47 |
| **Cody** | 20.00 | 21.00 | 19.50 |
| **Williams** | 0.23 | 0.19 | 0.28 |

The magnitude of structural changes reflected in diversity indices was assessed using a Bray-Curtis similarity dendrogram (Figure 3), which revealed distinct separation of the studied ecosystems, driven by both spatial and temporal factors.

The highest degree of similarity (approximately 67%) was found between Roșuleț and Puiu lakes in August (R-VIII, P-VIII), thus highlighting convergent trophic conditions that favour the same algal associations. In contrast, station Tătaru VIII showed the lowest similarity to the other ecosystems (below 50%), indicating a significant taxonomic divergence during the summer period. Also, in September, an association of Tătaru and Roșulet lakes were observed, forming a distinct cluster indicating a structural convergence of phytoplankton communities towards the end of the vegetation season and marking the transition from highly specialised summer associations to a more balanced structure, characteristic of the early autumn period.

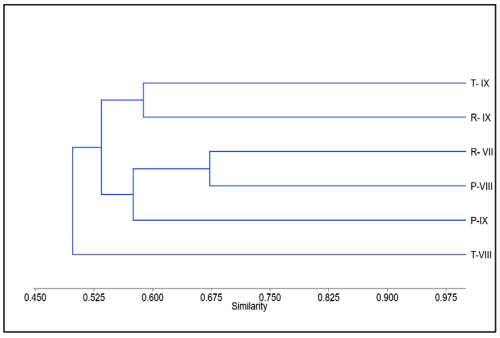

Figure 3. Similarity dendrogram of phytoplankton communities in lakes Roșuleț, Puiu and Tătaru (August-September), based on the Bray-Curtis index (Paired Group method)

### *Compositional shift at the level of phytoplankton groups*

The ANOSIM test applied to identify structural changes during the tested period showed that the differences between the summer (VIII) and autumn (IX) periods were greater than the spatial variations between ecosystems (Table 5). Lake Roșuleț (R = 0.67, $p$ = 0.008) showed the greatest and most significant seasonal change, indicating major structural changes during the investigated period. In Lake Puiu (R=0.47, $p$=0.03), the separation of communities was moderate, while in Lake Tătaru (R=0.30, $p$=0.05), the lowest seasonal differences but the highest spatial variation (12.08) were observed.

Table 5. ANOSIM analysis of structural changes among lakes and periods

| | **Puiu** | **Tătaru** | **Roșulet** |
|---|---|---|---|
| Mean rank within: | 10.67 | 12.08 | 11.75 |
| Mean rank between: | 17.38 | 16.31 | 23.9 |
| R: | 0.47 | 0.30 | 0.67 |
| *p* (same): | 0.03 | 0.05 | 0.008 |

By Simper analysis (Table 6), the species whose turnover was decisive in the phytoplankton structuring were identified. This analysis identifies the taxa that contributed the most to the taxonomic change from summer to autumn. In Puiu Lake the species *Oscillatoria minima* was the dominant species with the highest contribution (34.68%), achieved through a massive development reaching a peak of $1.06x10^8$ cells/L – in autumn. In contrast, other cyanobacterial species, *Aphanizomenon flos-aquae* (7.065) and Oscillatoria sp. (6.27%), showed a significant shift, but through a decline in abundance. In Tataru Lake, the strongest influences in the seasonal changes were also due to *Cyanobacteria*. *Gomphosphaeria lacustris* accounted for 16.84% of the difference, with an increase in the average in September, along with *Microcystis pulverea*, which also made a significant contribution (13.63%) due to its appearance and massive development in autumn. In contrast, *Oscillatoria limosa* showed a significant decline during this period. And in Lacul Roșuleț, *Cyanobacteria* were the taxa that contributed significantly higher values in the changes between the two periods. Thus, we mention, *Microcystis pulverea* (18.44%, with a significant increase in autumn), *Aphanocapsa grevillei* and *Aphanizomenon flos-aquae* (which together explained over 32% of the dissimilarity by completely disappearing in autumn), as well as *Oscillatoria minima* Gicklhom, which also underwent a decline in abundance. ANOSIM and Simper analyses confirm a strong turnover induced by *Cyanobacteria* species. While some summer species (such as *Aphanizomenon* spp. or *Aphanocapsa* spp.) tend to disappear or

decrease in September, others (such as *Oscillatoria minima* in Puiu or *Microcystis pulverea* in Tătaru and Roșuleț) take over dominance, generating changes in diversity.

Table 6. SIMPER analysis results of the major phytoplankton contributors to the average dissimilarity between seasons in: P – Puiu lake, T – Tătaru lake, R – Roșuleț. Av.d. - average dissimilarity, Contrib. (%) – percentage contribution to the average dissimilarity; Mean Aug – mean abundance in August; Mean Sep – mean abundance in September.

Rate of Competitive Displacement (RCD). Although the results showed a decisive role of *Cyanobacteria* in the phytoplankton component in ecosystems, RCD highlighted that, with the arrival of autumn, the other two major groups (green algae and diatoms) showed tendencies toward recovery in their functionality. Thus, the negative values (Table 7) indicate an unfavourable exchange rate for the analysed blue-green algae group relative to the second one, diatoms or green algae. In the *Cyanobacteria* vs. *Chlorophyceae* testing, all ecosystems showed negative values: Puiu (-0.09), Tătaru (-0.43), and Roșuleț (-1.00), indicating that *Chlorophyceae* had a competitive advantage over *Cyanobacteria* in all three locations, with the impact being most pronounced in Roșuleț Lake. Also, the results regarding *Cyanobacteria* vs. *Bacillariophyceae* showed both a negative value in Puiu (-0.64) and positive values in Tătaru (0.22) and Roșuleț (0.89), which indicated that diatoms dominated competitively only in Puiu Lake, while in Tătaru and Roșuleț, *Cyanobacteria* managed to prevail over them even in autumn. Also, in Roșuleț, the most dynamic and unbalanced phytoplankton competition was recorded among all the studied locations, at the point where *Chlorophyceae* exerted the greatest pressure (-1), thus signalling a trend of competitive collapse on *Cyanobacteria*.

Table 7. Rate of Competitive Displacement (RCD) between *Cyanobacteria* and the other main phytoplanktonic groups

| | *Cyanobacteria* vs *Chlorophyceae* | *Cyanobacteria* vs *Bacillariophyceae* |
|---|---|---|
| **Puiu** | -0.09 | -0.64 |
| **Roșulet** | -1 | 0.89 |
| **Tătaru** | -0.43 | 0.22 |

This may indicate that the available resources in Roșuleț were accessed more efficiently by *Chlorophyceae* compared to the other groups, so *Cyanobacteria* could no longer maintain their population as in summer. However, *Cyanobacteria* maintained dominance despite competition with diatoms, even though the diatom replacement rate was the highest (0.89) among the three ecosystems (Table 7). Thus, in Roșuleț, *Cyanobacteria* were subjected to niche pressures.

The structural features of phytoplankton communities were also reflected in the zooplankton composition across the three lakes, indicating adaptive ecological responses shaped by interactions among environmental factors and trophic structure.

Thus, the pressure exerted by phytoplankton on primary consumer communities led to a prevalence of small, opportunistic forms, especially rotifers (*Trichocerca, Polyarthra, Keratella*) and juvenile copepods, along with microcrustaceans such as *Bosmina* spp. (Table 8).

Table 8. Dominant zooplankton species and their distribution in the studied ecosystems

| Spercies | P- VIII | P- IX | T- VIII | T- IX | R-VIII | R-IX |
|---|---|---|---|---|---|---|
| *Bosmina coregoni* (Baird, 1857) | 0.67 | 50.08 | 0.00 | 0.00 | 2.74 | 299.82 |
| *Copepoda* g. sp. St Nauplial | 99.17 | 239.58 | 238.20 | 471.91 | 78.70 | 86.70 |
| *Keratella cochlearis* var. *tecta* (Gosse, 1851) | 8.00 | 229.84 | 0.00 | 5.55 | 2.30 | 32.82 |
| *Lecane closterocerca* (Schmarda, 1859) | 0.00 | 7.54 | 0.55 | 0.66 | 639.13 | 0.70 |
| *Polyarthra remata* Skorikow 1896 | 137.50 | 54.96 | 142.31 | 297.30 | 64.99 | 93.90 |
| *Synchaeta oblonga* (Ehrenberg, 1832) | 100.33 | 0.00 | 1.50 | 23.59 | 6.43 | 11.20 |
| *Trichocerca pussila* (Jennings, 1903) | 167.50 | 86.54 | 0.94 | 2.91 | 185.36 | 1.30 |
| *Trichocerca similis* (Wierzejski, 1893) | 231.50 | 86.82 | 0.00 | 2.00 | 180.80 | 12.32 |
| *Diflugia globulosa* (Dujardin, 1837) Penard, 1902 | 1.33 | 260.42 | 0.00 | 3.04 | 1.30 | 0.00 |
| *Diflugia lobostoma* (Leidy, 1879) | 154.17 | 293.52 | 3.55 | 4.62 | 388.40 | 3.28 |

The Grubbs test identified statistically significant outliers ($p < 0.05$) for several species, indicating higher dominance relative to the rest of the zooplankton community and associated with a temporary reduction in competition. In Puiu Lake, Grubbs showed significant values for *Trichocerca similis* (August - 6.34) and *Difflugia lobostoma* (September - 5.75), indicating punctual dominance. In Tataru Lake, nauplial copepod stages were identified as dominant peaks in both August (9.14) and September (8.48), indicating maintenance of juvenile stages. In Roșuleț Lake, the rotifer *Lecane closterocerca* (August - 8.44) and the cladoceran *Bosmina coregoni* (September - 9.53) reflected pronounced seasonal structural changes as well as an alternation of dominant species. Thus, the results indicate a high spatio-temporal heterogeneity of zooplankton, with dominance patterns related to period and ecosystem, suggesting a differentiated response of taxa to local ecological conditions.

Structure and distribution of phytoplankton communities. The dominance of *Cyanobacteria* in all three lakes studied during the summer period underlines their role as key factors in structuring phytoplankton communities in the Danube Delta. This dominance is consistent with numerous studies showing that, under conditions of high temperatures, hydrodynamic stability and increased nutrient availability, *Cyanobacteria* are favoured over other algal groups (Paerl & Huisman, 2008; Moza et al., 2021; Dokulil & Teubner, 2023). The high cyanobacterial abundance in Puiu and Tătaru lakes, as well as the persistence of this group in Roșuleț, indicate a meso- to hypereutrophic trophic status, characteristic of many deltaic lacustrine ecosystems. In Puiu and Tătaru, the simultaneous increase of *Cyanobacteria*, *Chlorophyceae* and diatoms suggests a general intensification of primary production in the late summer period, while in Roșuleț the decline of most groups, except *Chlorophyceae*, indicates a pronounced structural instability. Such spatiotemporal patterns are frequently reported for shallow lakes, where sediment resuspension and internal nutrient recycling can amplify fluctuations in phytoplankton communities (Oosterberg et al., 2000; Gâștescu, 2009).

Taxonomic structure and interpretation of discriminant analysis. Discriminant analysis revealed a clear separation of *Cyanobacteria* from the other major groups, highlighting the functional contrast between this group and the rest of the phytoplankton. The intermediate positioning and high dispersion of *Chlorophyceae* indicate increased ecological flexibility, reflecting the ability of this group to occupy varied niches and to respond rapidly to environmental changes. Diatoms and *Chrysophytes* showed clearer delimitation, suggesting stricter ecological requirements and greater sensitivity to changes in physicochemical conditions. The overlaps observed among *Chlorophyceae*, *Cyanobacteria*, and *Euglenophyceae* indicate convergent ecological responses and common functional traits, especially in unstable

ecosystems. This type of community structure is typical of eutrophic lakes, where competition for resources is intense, and advantages are quickly redistributed among groups depending on seasonal conditions (Jia et al., 2022; Tóth-Krasznai et al., 2022).

α and β diversity: ecological implications. Although total species richness remained relatively high in most cases, α-diversity indices showed a clear trend toward increasing dominance and decreasing evenness, especially in Puiu and Roșuleț lakes. This combination suggests the emergence of an "apparent diversity", in which numerous taxa are present but their contribution to total biomass is reduced, eclipsed by *Cyanobacteria*'s dominance. The phenomenon is frequently reported in eutrophic ecosystems and is considered an indicator of the functional degradation of phytoplankton communities (Vasconcelos et al., 2020; Ahoutou et al., 2021).

The moderately high spatial β diversity reflects the pronounced heterogeneity of the studied lakes, determined by differences in hydrological connectivity, morphology and nutrient supply. At the same time, temporal β-diversity indicates significant seasonal turnover, especially in Roșuleț Lake, confirming the structural instability of this ecosystem. These results suggest that seasonal variations may have a greater impact on community composition than spatial differences, a finding also confirmed by ANOSIM tests. Seasonal dynamics of *Cyanobacteria*: ANOSIM and SIMPER. ANOSIM results confirm that seasonal differences explain a significant proportion of the variation in phytoplankton communities, especially in Lake Roșuleț. SIMPER analysis showed that these changes are mainly driven by a small number of cyanobacterial species, including *Oscillatoria minima, Microcystis pulverea, Gomphosphaeria lacustris,* and *Aphanizomenon flos-aquae*. The alternation between dominant summer and autumn species reflects the seasonal succession described by the PEG model, where non-nitrogen-fixing *Cyanobacteria* can take over dominance towards the end of the growing season (Moza et al., 2021).

The persistence and dynamics of these taxa indicate a high adaptability to eutrophic conditions and variations in the hydrological regime. At the same time, the disappearance or decline of some species in autumn suggests increased sensitivity to temperature drops and increased water turbulence, factors known to limit cyanobacterial blooms (Jiang et al., 2023; Lenard & Ejankowski, 2024).

Relationships between the main phytoplankton groups. Even though *Chlorophyceae* occupied a secondary position in the phytoplankton structure, they demonstrated a competitive role, especially in Lake Roșuleț, where they exerted the greatest pressure on *Cyanobacteria* during the autumn period. The negative values of the Rate of Competitive Displacement (RCD) for the *Cyanobacteria-Chlorophyceae* comparison across all lakes confirm the competitive advantage of green algae at lower temperatures and under changing light and nutrient conditions. This behaviour is well documented in the literature, showing that many *Chlorophyceae* exhibit high growth rates at moderate temperatures and can efficiently exploit available phosphorus, thereby limiting cyanobacterial development (Briddon et al., 2022; Vasconcelos et al., 2020).

In contrast, the relationship between *Cyanobacteria* and diatoms was more nuanced. In Puiu Lake, diatoms had a competitive advantage in autumn; in Tătaru and Roșuleț, *Cyanobacteria* remained dominant, even as diatom replacement rates increased. This capacity suggests that *Cyanobacteria* exhibit functional adaptations to persistent eutrophic conditions, including tolerance to variations in the N:P ratio and changes in the mixing regime (Zou et al., 2025; Reynolds, 2006).

The Rate of Competitive Displacement analysis adds an important functional dimension to the interpretation of results, highlighting not only the competitive relationships among phytoplankton groups but also the degree of community stability. Strongly negative RCD values indicate unstable competitive hierarchies and reduced cyanobacterial capacity to maintain dominance, while mixed values suggest seasonal resilience, with alternations between dominant groups.

Also, the fact that seasonal differences are more pronounced than spatial ones emphasises the role of seasonality as an integrating factor of physicochemical and biological variations.

This predominance of the temporal signal suggests that climate change and changes in the hydrological regime may have a stronger impact on phytoplankton community structure than local spatial differences between lakes.

Overall, the results confirm the central role of *Cyanobacteria* in structuring phytoplankton communities in the studied lakes, but also highlight a clear dissociation between taxonomic diversity and ecological functionality of the communities. Although the specific richness remains relatively high, the pronounced dominance of *Cyanobacteria* leads to functional simplification, with the effective contribution to biomass and ecosystem processes concentrated in a small number of opportunistic taxa. This situation reflects what can be defined as an "apparent diversity", characteristic of shallow eutrophic ecosystems.

The shallow nature of the analysed lakes amplifies the role of internal sediment-nutrient-phytoplankton feedbacks, favouring the persistence of *Cyanobacteria* even under conditions of seasonal instability. In this context, Lake Roșuleț is characterised by a more unstable community structure, driven by intense internal nutrient recycling and high competitive pressure from *Chlorophyceae*, suggesting an ecosystem in an ecological transition.

The species with high abundances identified by the Grubbs test ($p < 0.05$) reflect episodes of massive development of resistant and opportunistic species, characteristic of shallow, highly dynamic aquatic ecosystems such as the lakes of the Danube Delta. The specialised literature describes the punctual dominance of the rotifers *Trichocerca similis* and *Lecane closterocerca* as opportunistic taxa with high reproduction rates and increased tolerance to eutrophic or unstable conditions (Allan, 1976; Wallace et al., 2006). Regarding the nauplial stages of Copepoda in Lake Tătaru, the persistent outlier values observed in both months suggest an unbalanced stage structure, with juveniles dominating. This pattern is typical of ecosystems where conditions favour continuous reproduction, but the survival of adult stages is limited by stressors or predators (Sommer et al., 2012; Hirst & Kiørboe, 2002). This may reflect another effect of bottom-up phytoplankton pressures. Also, the dominance of *Bosmina coregoni* in Lake Roșuleț in September reflects seasonal changes in the structure of the cladoceran community, which are recognised for their sensitivity to temperature, phytoplankton availability, and grazing pressure (Lampert, 1987). These episodes of dominance of some zooplankton species were directly reflected in the values of diversity indices, in particular the decrease of Shannon and Pielou indices and the increase of dominance (Simpson). The literature emphasises that such temporary imbalances are an intrinsic component of planktonic community function and provide essential information about the processes of community assembly and the stability of ecosystems (Magurran, 2013; Borics et al., 2021).

## CONCLUSIONS

*Cyanobacteria* proved to be the dominant ecological factor in the structure and dynamics of planktonic communities in Puiu, Tătaru, and Roșuleț lakes, profoundly influencing both phytoplankton composition and zooplankton responses. During the summer, blue-green algae reached very high densities, dominating the phytoplankton and affecting the diversity and functional balance of the other communities. Thus, the phytoplankton structure was strongly shaped by the competition between *Cyanobacteria* and the other major groups (chlorophytes and diatoms). With the onset of autumn, recovery trends in diatoms and chlorophytes were observed, reflected in negative values of the competitive replacement rate (RCD). However, the intensity of these processes varied among the lakes, with Roșuleț exhibiting the greatest structural instability and the most pronounced seasonal turnover. Seasonal changes were stronger than spatial ones, and cyanobacterial species were the main contributors to dissimilarity between periods characterised by variations in community structure, either through massive development or sudden disappearances. The impact on zooplankton was evident in the dominance of small, opportunistic forms (rotifers and juvenile copepod stages), indicating the trophic pressure exerted by a phytoplankton community dominated by *Cyanobacteria* and the reduced quality of the food resource. Overall, our study

highlights the central role of *Cyanobacteria* in regulating the functioning of lacustrine ecosystems in the Danube Delta. In the context of climate change and eutrophication, these processes are increasingly common, accentuating the vulnerability of deltaic ecosystems.

***Abstract***

*The Bahlui River, flowing through the urban area of Iași, is subjected to significant anthropogenic pressures that influence its microbial communities. This study assessed the structure and temporal dynamics of microbial populations along a 24 km urban stretch of the river, using six sampling sites distributed from the river's entry into the city to its exit. Water samples collected in April and July 2025 were analyzed for total bacterial counts, Gram-positive bacteria ($G^+$), and micromycetes. Results revealed significant spatial and temporal variations: total bacterial and Gram-positive abundances increased from April to July, with point 3 consistently exhibiting the highest counts, while micromycete abundance was lower but also displayed site-specific and seasonal variation. Two-way ANOVA confirmed that both sampling location and period significantly influenced microbial abundance, with interactions indicating non-uniform temporal changes along the river. These findings highlight the combined effects of urbanization and seasonal dynamics on microbial community structure and provide valuable insights for monitoring and managing urban aquatic ecosystems.*

***Key words****: aquatic microbiology, Bahlui river, DPSIR, microbial communities, spatial variation, urban river.*

## INTRODUCTION

Water bodies, such as rivers that traverse urban areas, constitute vulnerable aquatic ecosystems, as they are subjected to significant anthropogenic pressures resulting from direct or indirect human activities (Teurlincx et al., 2019). Urban rivers are subjected to several categories of anthropogenic pressures (Castro et al., 2021), including chemical pollution, resulting from the input of nutrients, heavy metals, organic compounds, pharmaceuticals, antibiotic residues, and microplastics (Mandaric et al., 2018; Sekudewicz et al., 2021; Tiwari et al., 2022; Mansor et al., 2024); microbiological contamination, associated with wastewater discharges (Olds et al., 2018; Cui et al., 2019; Jing et al., 2024); hydromorphological alterations, caused by channel modifications, embankments, and bank impermeabilization (Ollero et al., 2015; Borek et al., 2022); and thermal pollution, arising from industrial warm-water effluents (Briciu et al., 2020; Chakraborty, 2021).

These types of pressures need to be carefully investigated, as they can cause significant changes in the structure, diversity, and dynamics of aquatic microbial communities. Given the essential role of the watermicrobiota in organic matter decomposition (Liu et al., 2023), nutrient recycling (Ávila et al., 2019), and the regulation of biogeochemical cycles (Pan et al., 2024), its disruption can lead to functional imbalances in the ecosystem, a reduced natural self-purification capacity of the rivers, and impaired health of the aquatic ecosystems (Xie et al., 2021; Singh et al., 2025).

In the urban area of Iași Municipality, the Bahlui River, the municipality's main hydrographic collector, exhibits significant changes in the physico-chemical and biological parameters of the water (Zaharia, 2015; Marcoie et al., 2025). These transformations represent the cumulative result of the expansion of urban infrastructure, wastewater discharges, and inputs originating from industrial, residential, and agricultural activities carried out within the basin corresponding to the urban sector.

The ecological status assessment of the Bahlui River should be conducted through the integration of data within the DPSIR framework (Drivers–Pressures–State–Impact–Response), facilitating the correlation between socio-economic driving forces, the

pressures exerted on the ecosystem, and the associated impacts. Previous studies have demonstrated that the DPSIR framework provides a holistic approach for evaluating the overall ecological effects of polluted urban rivers (Skoulikidis et al., 2009; Lu et al., 2019).
In this context, the Bahlui River represents a relevant case study for the systematic application of the DPSIR framework in an urban environment.
Within this framework, the ecological dynamics of the urban river sector can be structured as follows: **Drivers** are represented by positive demographic growth and the accelerated urban expansion of Iași and its surrounding areas (Holobâcă et al., 2022), reflected in intensified economic activities and the expansion of impervious surfaces, which have significantly altered the hydrological regime. These processes generate **Pressures**, including increased domestic and industrial wastewater discharges (Marcoie et al., 2024), nutrient inputs (nitrates and phosphates) from urban runoff and diffuse agricultural sources (Neamtu et al., 2009; Oiște & Breabăn, 2011), microbiological contamination associated with insufficient or malfunctioning sewage systems, as well as the occurrence of emerging contaminants such as pharmaceutical residues, antibiotics, and microplastics (Apostol, 2008; Zaharia, 2015). Consequently, the **State** of the river ecosystem is altered, particularly through shifts in microbial community structure along the pollution gradient, characterized by reduced diversity and functional modifications of key biogeochemical cycles (e.g., nitrogen and carbon cycling). These changes lead to **Impacts** manifested as ecosystem imbalance, degradation of ecological integrity, and potential public health risks. Therefore, appropriate **Responses** should include continuous microbiological and physicochemical monitoring at the watershed scale, modernization of wastewater treatment infrastructure, and the implementation of integrated urban water management strategies aimed at improving the ecological status of the Bahlui River within the broader framework of sustainable urban development.
The present study investigates changes in microbial communities of the Bahlui River along the sector that crosses the city of Iași. While numerous studies have addressed hydrological, physicochemical, and general water quality aspects of the river, research specifically focused on the dynamics and structure of microbial communities remains limited. This gap in the literature underscores the need for an integrated microbiological approach capable of revealing functional and structural alterations in the river ecosystem. Accordingly, the present research provides a scientific basis for future studies aimed at assessing hydrological sustainability in anthropized environments, contributing to the development of monitoring and management strategies tailored to urban river systems.

## MATERIALS AND METHODS

### *Study area*

The Bahlui River, the main watercourse traversing the city of Iași, has a total length of approximately 119 km. It originates at an altitude of around 500 m in Tudora commune, Botoșani County, and flows into the Jijia River near the village of Chiperești, Iași County (Figure 1).

Figure 1. Hydrographical overview of the Bahlui River, showing the source (red circle), river course (orange line), and confluence with the Jijia River (blue triangle) (map generated from www.openstreetmap.org)

Along its course, the Bahlui River passes through a series of settlements, the most significant of which are Hârlău, Podu Iloaiei, and the municipality of Iași. Within Iași and its surrounding localities, the river spans approximately 28 km, between Lețcani and Chiperești. This stretch represents the focus

area of the present study. Along this segment, the population density is high, economic activities are intensive, and extensive impervious surfaces exist, all of which have increased the river's susceptibility to anthropogenic pressures (Figure 2).

Figure 2. Geographical positioning of the sampling points (1-6) along the Bahlui River (map generated from www.openstreetmap.org)

The sampling points were distributed along a 24 km river course, following the longitudinal course of the Bahlui River through the urban area of Iași. The inter-site distances varied between 2.8 km and 6.5 km, reflecting differences in urban pressure intensity and hydromorphological conditions along the river continuum. This spatial configuration allows for the evaluation of cumulative anthropogenic effects and the identification of potential shifts in microbial community structure along the upstream–downstream gradient (Table 1).

Table 1. Gheographic coordinates of the sampling points sites along the Bahlui rivers and distances between consecutives sites

| Sampling points | Coordinates | | Distance | |
|---|---|---|---|---|
| | Latitude (N) | Longitude (E) | Distance from previous sampling points (km) | Cumulative distance (km) |
| 1 | 47°11'05.6" | 27°24'58.3" | - | 0.0 |
| 2 | 47°10'06.4" | 27°28'13.1" | ≈4.5 | ≈4.5 |
| 3 | 47°10'10.4" | 27°32'20.9" | ≈6.1 | ≈10.6 |
| 4 | 47°09'10.8" | 27°35'46.1" | ≈4.1 | ≈14.7 |
| 5 | 47°09'02.8" | 27°38'31.1" | ≈2.8 | ≈17.5 |
| 6 | 47°08'26.5" | 27°41'30.2" | ≈6.5 | ≈24.0 |

***Sampling***

Water sampling was performed twice in 2025. The first sampling moment took place on April 21, 2025 (T1), followed by a second one conducted approximately three months later, on July 14, 2025 (T2). Water samples were collected from each of the six sampling points for microbiological analyses. At each site, a total of 108 mL of surface water was obtained (six tubes × 18 mL per tube) from approximately 15 cm below the water surface (Figure 3). To ensure spatial representativeness across the river cross-section, subsamples were collected as follows: two near the left bank, two from the mid-channel, and two near the right bank.

Figure 3. Water sampling procedure

Sterile tubes were used for sample collection. After sampling, the tubes were stored in a refrigerated container to ensure optimal transport conditions to the laboratory. Sample processing was performed on the same day as collection.

***Microbiological analyses***

Microbiological analyses of the water samples were performed using conventional culture-based methods (plate technique). For each sample, five replicates were analyzed. For microbial enumeration, 1 mL of river water, as well as 1 mL from serial decimal dilutions (up to $10^{-3}$), was inoculated onto the appropriate culture media using the pour plate method. Total bacterial counts were determined using the $10^{-1}$ dilution, as undiluted samples resulted in overgrown plates (>400-500 bacterial colonies per plate), whereas higher dilutions ($10^{-2}$ and $10^{-3}$) produced low colony numbers (1-20 colonies per plate), outside the optimal counting range. Bacterial counts were determined on Plate Count Agar (PCA, Scharlau, Spain, 23.5 g $L^{-1}$) after incubation at 37°C for 24 h. Colonies were enumerated using an automatic colony counter (Interscience, Scan 1200), and results were expressed as colony-forming units per milliliter (CFU $mL^{-1}$). Selective media were used to differentiate microbial groups.

Gram-positive bacteria ($G^+$) were enumerated on PCA supplemented with streptomycin (35 mg $L^{-1}$) using undiluted river water samples.
Filamentous fungi were determined by inoculating undiluted samples onto Potato Dextrose Agar (PDA, Scharlau, Spain, 39 g $L^{-1}$) supplemented with Rose Bengal (35 mg $L^{-1}$) to limit colony overgrowth and facilitate counting. Fungal plates were incubated at 28°C for 3-5 days and monitored periodically according to colony growth rate.

***Statistical analyses***

Experimental data were analyzed using two-way analysis of variance (ANOVA) to evaluate the effects of sampling point (Sample), sampling moment (Moment), and their interaction on microbial counts. Microbial counts were log-transformed prior to analysis to improve normality. Homogeneity of variances was tested using Levene's test. Statistical analyses were performed using IBM SPSS Statistics 26, and differences were considered statistically significant at $p < 0.05$.

## RESULTS AND DISCUSSIONS

Microbiological analyses revealed significant variations in the total number of bacteria, Gram-positive bacteria ($G^+$), and total number of micromycetes along the six sampling points established on the Bahlui River course, as well as between the two investigation periods.
To further quantify these spatial and temporal variations, the total bacterial abundance at each sampling point and investigation period was determined (Table 2).

Table 2. Total bacterial counts across sampling points and investigation periods on the Bahlui River

| Sampling point | Time | Total number of bacteria (mean±SD) |
|---|---|---|
| 1 | T1 | $1.0 \times 10^3 \pm 0.17$ |
| | T2 | $2.1 \times 10^3 \pm 0.36$ |
| 2 | T1 | $1.2 \times 10^3 \pm 0.16$ |
| | T2 | $2.3 \times 10^3 \pm 0.35$ |
| 3 | T1 | $4.4 \times 10^3 \pm 0.05$ |
| | T2 | $5.7 \times 10^3 \pm 0.43$ |
| 4 | T1 | $0.9 \times 10^3 \pm 0.07$ |
| | T2 | $2.2 \times 10^3 \pm 0.33$ |
| 5 | T1 | $1.2 \times 10^3 \pm 0.06$ |
| | T2 | $2.5 \times 10^3 \pm 0.35$ |
| 6 | T1 | $2.4 \times 10^3 \pm 0.13$ |
| | T2 | $4.0 \times 10^3 \pm 0.45$ |

The results show that total bacterial counts increased at all sampling points from T1 (April) to T2 (July). At T1, counts ranged from $0.9 \times 10^3$ CFU $mL^{-1}$ at sampling point 4 to $4.4 \times 10^3$ CFU $mL^{-1}$ at sampling point 3. By T2, counts rose across all locations, reaching a maximum of $5.7 \times 10^3$ CFU $mL^{-1}$ at sampling point 3 and a minimum of $2.1 \times 10^3$ CFU $mL^{-1}$ at sampling point 1. This indicates a clear temporal increase in bacterial abundance along the river. Two-way ANOVA confirmed that these differences were statistically significant. Significant variation was observed among sampling points ($F(5.48) = 180.70$, $p < 0.001$) and between sampling moments ($F(1.48) = 418.58$, $p < 0.001$). A significant interaction between sampling point and moment ($F(5.48) = 9.44$, $p < 0.001$) further indicates that the magnitude of temporal changes differed across locations (Table 3).

Table 3. Two-way ANOVA results for total bacterial counts across sampling points and investigation periods

| Source | df | F | *p* |
|---|---|---|---|
| Sampling point | 5 | 180.70 | <0.001 |
| Sampling moment | 1 | 418.58 | <0.001 |
| Point x Moment | 5 | 9.44 | <0.001 |

Gram-positive ($G^+$) bacterial abundance was also analyzed at the six sampling points and two investigation periods (Table 4).

Table 4. Gram-positive bacterial counts across sampling points and investigation periods on the Bahlui River

| Sampling point | Time | Gram-positive bacteria (mean±SD) |
|---|---|---|
| 1 | T1 | $3.0 \times 10^1 \pm 0.55$ |
| | T2 | $5.2 \times 10^1 \pm 0.48$ |
| 2 | T1 | $1.3 \times 10^1 \pm 0.35$ |
| | T2 | $3.0 \times 10^1 \pm 0.27$ |
| 3 | T1 | $18.6 \times 10^1 \pm 3.54$ |
| | T2 | $23.5 \times 10^1 \pm 1.02$ |
| 4 | T1 | $2.9 \times 10^1 \pm 0.73$ |
| | T2 | $6.4 \times 10^1 \pm 0.47$ |
| 5 | T1 | $5.7 \times 10^1 \pm 0.45$ |
| | T2 | $8.6 \times 10^1 \pm 0.31$ |
| 6 | T1 | $10.6 \times 10^1 \pm 1.08$ |
| | T2 | $14.9 \times 10^1 \pm 0.76$ |

At T1, counts ranged from $1.3 \times 10^1$ CFU $mL^{-1}$ at sampling point 2 to $18.6 \times 10^1$ CFU $mL^{-1}$ at sampling point 3. By T2, all sampling points showed increases, with a maximum of $23.5 \times 10^1$ CFU $mL^{-1}$ at sampling point 3 and a minimum of $3.0 \times 10^1$ CFU $mL^{-1}$ at sampling

point 2. Sampling point 3 consistently showed the highest abundance, while sampling point 2 exhibited the lowest, indicating strong spatial heterogeneity. Two-way ANOVA revealed significant differences among sampling points ($F$ (5.48) = 337.02, $p < 0.001$) and between investigation periods ($F$ (1.48) = 196.83, $p < 0.001$). A significant interaction ($F$ (5.48) = 7.14, $p < 0.001$) suggests that temporal changes in Gram-positive abundance differed depending on location (Table 5).

Table 5. Two-way ANOVA results for Gram$^+$ bacterial counts across sampling points and investigation periods

| Source | Df | F | *p* |
|---|---|---|---|
| Sampling point | 5 | 337.02 | <0.001 |
| Sampling moment | 1 | 196.83 | <0.001 |
| Point x Moment | 5 | 7.14 | <0.001 |

To assess the fungal component of the microbial community, total micromycete abundance was determined at the six sampling points and two investigation periods (Table 6).

Table 6. Total micromycete counts across sampling points and investigation periods on the Bahlui River

| Sampling point | Time | Total number of micromycetes (mean±SD) |
|---|---|---|
| 1 | T1 | $1.2 \times 10^1 \pm 0.15$ |
| | T2 | $1.2 \times 10^1 \pm 0.15$ |
| 2 | T1 | $1.3 \times 10^1 \pm 0.05$ |
| | T2 | $1.4 \times 10^1 \pm 0.18$ |
| 3 | T1 | $1.2 \times 10^1 \pm 0.25$ |
| | T2 | $1.6 \times 10^1 \pm 0.10$ |
| 4 | T1 | $1.1 \times 10^1 \pm 0.09$ |
| | T2 | $1.3 \times 10^1 \pm 0.36$ |
| 5 | T1 | $1.4 \times 10^1 \pm 0.13$ |
| | T2 | $1.5 \times 10^1 \pm 0.23$ |
| 6 | T1 | $0.7 \times 10^1 \pm 0.15$ |
| | T2 | $1.3 \times 10^1 \pm 0.29$ |

The results show relatively low but significant spatial and temporal variation. At T1, micromycete counts ranged from $0.7 \times 10^1$ CFU mL$^{-1}$ at sampling point 6 to $1.4 \times 10^1$ CFU mL$^{-1}$ at sampling point 5. By T2, counts increased at most points, with a maximum of $1.6 \times 10^1$ CFU mL$^{-1}$ at sampling point 3 and a minimum of $1.2 \times 10^1$ CFU mL$^{-1}$ at sampling point 1. Two-way ANOVA confirmed that these differences were statistically significant (Table 7).

Significant variation was observed among sampling points ($F$ (5.48) = 8.64, $p < 0.001$) and between sampling moments ($F$ (1.48) = 22.09, $p < 0.001$). A significant interaction between sampling point and moment ($F$ (5.48) = 4.25, $p = 0.003$) further indicates that temporal changes in micromycete abundance differed across locations.

Table 7. Two-way ANOVA results for total micromycete counts across sampling points and investigation periods

| Source | df | F | *p* |
|---|---|---|---|
| Sampling point | 5 | 8.64 | <0.001 |
| Sampling moment | 1 | 22.09 | <0.001 |
| Point x Moment | 5 | 4.25 | 0.003 |

## CONCLUSIONS

The present study demonstrated significant spatial and temporal variations in microbial communities along the Bahlui River. Both total bacterial and Gram-positive bacterial abundances increased from April to July, with point 3 consistently exhibiting the highest counts, while micromycetes showed lower overall abundance but also displayed significant temporal and spatial differences. Two-way ANOVA confirmed that both the sampling location and investigation period significantly influenced microbial abundance, and interactions between these factors indicate that temporal changes were not uniform along the river. These findings highlight the impact of local environmental conditions and anthropogenic pressures on microbial dynamics and underscore the importance of multiple spatially distributed sampling points and repeated monitoring for accurate assessment of river water quality. Continuous monitoring of microbial indicators, combined with physicochemical analyses, is recommended to better understand ecological risks and the drivers of microbial variability along urban river systems.

***Abstract***

*Railway embankments represent critical components of railway infrastructure, and water infiltration constitutes a major factor in their degradation. This paper presents methods for modelling water infiltration through embankments, with an emphasis on hydro-mechanical analysis and the implications for the stability and durability of railway structures. The use of fundamental flow equations in porous media and the implementation of numerical models for simulating saturated and unsaturated conditions are discussed, providing a basis for optimizing drainage systems and preventing embankment degradation. Numerical simulations allow for the identification of areas vulnerable to infiltration, the optimization of drainage systems, and the prevention of accelerated ballast deterioration. In embankments with insufficient drainage, water accumulation leads to increased pore pressures, reduced material strength, and the occurrence of differential settlements. Integrating infiltration modelling with field monitoring and predictive maintenance methods can significantly contribute to extending the service life of the railway and reducing operational costs.*

***Key words****: modelling, railway, water infiltration.*

## INTRODUCTION

The structural integrity and operational safety of railway infrastructure are fundamentally governed by the hydro-mechanical behaviour of the underlying geostructures, among which unsaturated soil embankments represent the most critical and vulnerable assets. In modern railway engineering, embankments are continuously subjected to complex, coupled environmental and dynamic stressors, where the phenomenon of meteoric water infiltration acts as a primary driver of structural degradation and premature geotechnical failure. The mechanical response of these engineered earthworks is intrinsically linked to their hydraulic state, which exhibits high spatial and temporal variability driven by local hydrometeorological regimes, rainfall intensity profiles, and evaporation fluxes. When precipitation infiltrates the unsaturated matrix of a railway embankment, it induces a progressive dissipation of matric suction within the soil pores, shifting the hydrologic baseline toward full saturation. From a geotechnical perspective, this reduction in matric suction directly compromises the shear strength parameters of the compacted soil skeleton, while simultaneously altering the effective stress state and triggering a marked decrease in the resilient modulus of the foundation. Consequently, unmanaged infiltration pathways not only accelerate track geometry degradation and differential settlements under heavy cyclic rolling stock loads but also significantly increase the probability of catastrophic slope failures, landslips, and embankment collapse (Apshikur et al., 2026).

To accurately forecast and mitigate these hydro-mechanical feedback loops, modern engineering practice has transitioned from empirical assessments to advanced numerical simulations capable of capturing non-steady saturated-unsaturated water transport. The mathematical simulation of these sub-surface flow processes relies on the numerical solution of the non-linear partial differential Richards equation, coupled with constitutive soil-water characteristic curves that define the non-linear relationships between volumetric water content, suction, and hydraulic conductivity. However, executing high-fidelity predictive modelling remains a significant challenge due to the complex material properties of railway

embankments, which often feature heterogeneous compacted profiles, varying geomorphological gradients, and specialized ballast-subballast drainage boundaries. This numerical complexity is further amplified when capturing the transient boundary conditions imposed by extreme, high-return period precipitation events, where rapid infiltration fronts create sharp hydraulic gradients that can induce localized numerical oscillations or matrix divergence within the computational grid. Furthermore, standard geotechnical design frameworks frequently suffer from a historical deficiency in high-resolution, ground-based hydrologic and suction monitoring data, forcing reliance on remote sensing datasets that lack the discrete spatial resolution required to model localized seepage lines. Therefore, developing an integrated numerical modelling strategy that comprehensively simulates transient infiltration hydrodynamics, validates hydro-mechanical strength reductions, and complies with modern structural infrastructure safety standards which is a critical requirement for ensuring the climate resilience of transboundary railway networks.

This research paper provides a comprehensive hydro-mechanical analysis and numerical simulation of water infiltration processes within unsaturated railway embankments subjected to severe pluviometric configurations. By coupling continuous hydrometeorological forcing series with non-linear finite-element or finite-difference seepage formulations, this study evaluates the progressive advancement of infiltration fronts, the dynamic degradation of matric suction profiles, and the resulting fluctuations in the global factor of safety against slope instability. The predictive framework established herein delivers a validated optimization tool for infrastructure managers, enabling the proactive identification of critical saturation zones and the strategic design of advanced sub-surface drainage perimeters tailored to withstand extreme climate change scenarios.

## MATERIALS AND METHODS

The evaluation of transient water infiltration and the resulting hydro-mechanical feedback loops within the railway embankment was executed through an integrated numerical modelling workflow that couples unsaturated seepage analysis with limit equilibrium slope stability formulations. The geometric profile of the representative railway geostructure was reconstructed based on standard European ballast-subballast infrastructure designs, capturing a symmetric earthwork embankment with side slope gradients engineered to reflect critical operating conditions. The computational mesh discretization was optimized by implementing a highly refined finite-element grid along the atmospheric boundaries and embankment slopes, where the sharpest hydraulic and suction gradients develop during precipitation events, while a coarser grid spacing was maintained within the deep, saturated core to maximize computational efficiency without inducing matrix divergence or numerical locking. To establish a realistic simulation environment, continuous hydrometeorological forcing time series were gathered from regional gauging stations, compiling high-intensity synthetic design storms and multi-seasonal precipitation-evaporation flux sequences that act as dynamic, non-steady boundary conditions on the exposed surfaces of the computational domain (Xiao et al., 2025).

The simulation of water transport mechanisms through the unsaturated soil matrix relied on a formulation of the non-linear partial differential Richards equation, which governs the conservation of fluid mass and non-steady flow in porous media. To capture the non-linear behavioural evolution of the compacted embankment soil, the hydraulic framework was coupled with constitutive soil-water characteristic curves defined by the van Genuchten mathematical model. This approach dynamically links the volumetric water content, matric suction, and relative hydraulic conductivity, allowing the computational engine to simulate how the soil's capacity to conduct water scales non-linearly as pore-water pressures fluctuate. The calibration of these hydraulic functions utilized suction and pressure plate extract data characteristic of compacted silty-clay embankments, which fall under typical intermediate drainage classifications. Initial boundary conditions were established by running a long-term steady-state groundwater flow simulation to derive a realistic baseline suction distribution

and water table phreatic surface across the foundation prior to the onset of the transient rainstorm sequences (Kong et al., 2025).

The hydraulic behavior of the unsaturated railway soils is governed by the constitutive relationships defined by the van Genuchten and Mualem models. ″

Figure 1 illustrates the Soil-Water Characteristic Curve (SWCC) and the corresponding relative hydraulic conductivity ($k_r$) as functions of the matric suction ($\psi$), establishing the baseline parameters utilized in the numerical flow simulations.

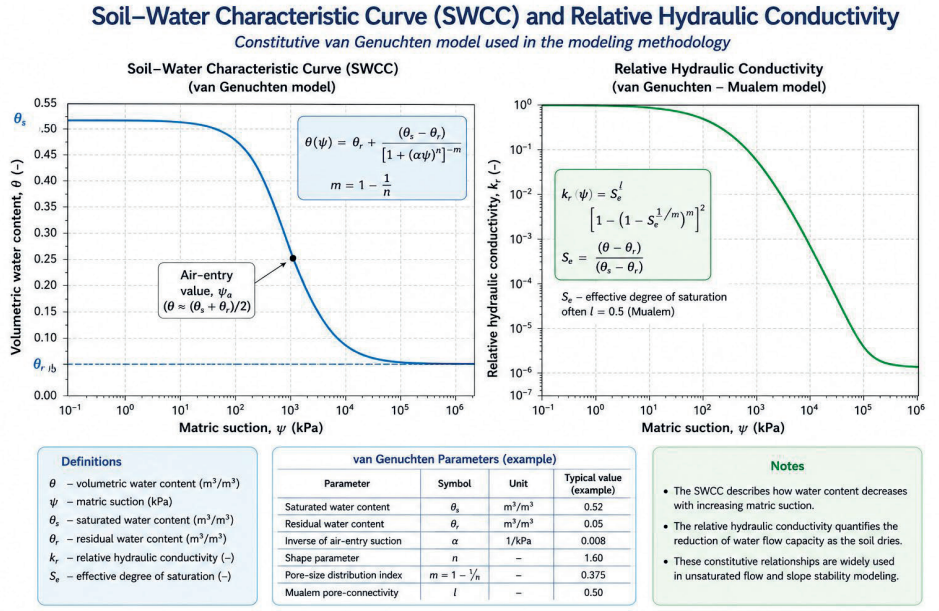

Figure 1. Soil-Water Characteristic Curve (SWCC) and Relative Hydraulic Conductivity (image created by authors with AI assistance)

The mechanical coupling and subsequent slope stability analysis were achieved by mapping the pore-water pressure fields generated from the transient hydraulic solver directly into a 2D slope stability engine at discrete temporal increments. The degradation of the soil's shear strength parameters during the progressive advance of the infiltration front was evaluated using an extended Mohr-Coulomb failure criterion for unsaturated soils. This constitutive framework treats matric suction as an independent stress state variable, where a decrease in suction directly reduces the apparent cohesion component of the soil skeleton without modifying the effective internal friction angle. The global factor of safety against slope failure was calculated continuously across the rainfall timeline using the Spencer limit equilibrium method, which satisfies both force and moment equilibrium along non-circular slip surfaces. This integrated hydro-mechanical workflow successfully quantifies the progressive reduction of embankment stability as the wetting front advances, providing a predictive platform to evaluate structural safety margins under extreme environmental stress (Loku-Pathirage et al., 2025).

## RESULTS AND DISCUSSIONS

The computational execution of the transient hydro-mechanical simulation provided quantitative insights into the temporal and spatial evolution of pore-water pressure fields, matric suction degradation, and overall slope stability margins within the railway embankment during the critical design storm event. Upon the application of the non-steady atmospheric boundary conditions, the

numerical solver tracked the progressive downward migration of a highly defined wetting front through the compacted silty-clay matrix. During the initial hours of the high-intensity precipitation sequence, the infiltration process was restricted to the shallow ballast-subballast interface and the upper crest zones of the embankment slopes, where the initial infiltration rate matched the rainfall intensity due to the high initial suction capacity of the unsaturated soil skeleton. This early phase was characterized by a rapid reduction in matric suction near the atmospheric boundary surfaces, causing the negative pore-water pressures to drop from their baseline values toward near-zero thresholds, which signified the localized elimination of capillary tension and the formation of a shallow, perched water table configuration. As the rainfall progressed, the hydraulic conductivity of the upper soil layers scaled upward by several orders of magnitude in accordance with the calibrated van Genuchten constitutive curves, accelerating the vertical and lateral advance of the wetting front into the core of the embankment (Dodaro et al., 2025).

The mechanical feedback loops resulting from this progressive hydraulic saturation generated a severe structural depreciation of the geostructure's engineering safety margins. By mapping the transient pore-water pressure fields into the limit equilibrium solver at discrete temporal increments, the simulation captured a significant reduction in the apparent cohesion of the soil matrix, driven exclusively by the dissipation of matric suction along the potential non-circular slip surfaces. The spatial analysis of the stress distribution revealed that the critical failure zone shifted from a deep-seated global mechanism under initial steady-state conditions to a series of shallow, slope-parallel failure planes aligned precisely with the maximum depth of the advancing wetting front. The global factor of safety, calculated continuously via the Spencer method, exhibited a non-linear downward trajectory over the rainfall timeline, recording its most abrupt decline during the peak intensity interval of the storm when the rate of suction dissipation reached its maximum.

As demonstrated by the suctions profiles in Figure 2, the advance of the wetting front is strongly dependent on the rainfall duration. At the onset of rainfall (0 h), the initial matric suction remains high near the surface, but a significant non-linear reduction is observed as the infiltration progresses to 6, 12, and 24 hours, with the wetting front penetrating down to 0.7 m after one day. As shown in Figure 3, the slope stability experiences four distinct phases during a hydrometeorological event. Initially, a non-linear decrease of FoS occurs during the rainfall infiltration phase ($t_0$ to $t_1$). Crucially, the minimum FoS is reached after the storm ceases ($t_1$ to $t_2$), during the post-event redistribution phase, where pore water pressures propagate into deeper zones.

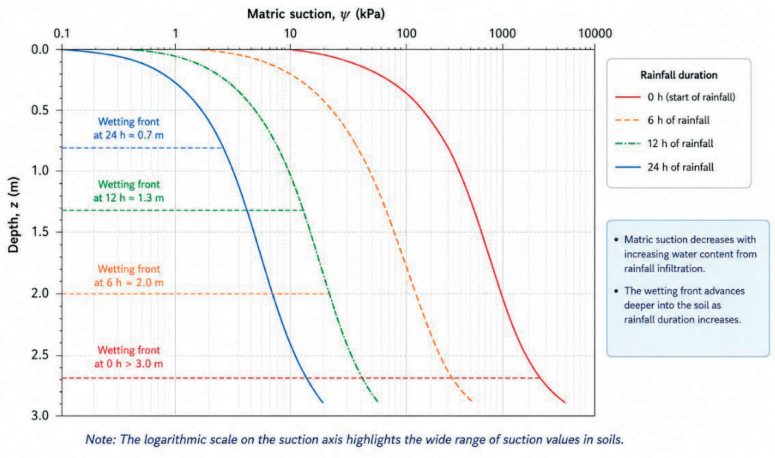

Figure 2. Matric Suction Profile with Depth (Suction Profiles) (image created by authors with AI assistance)

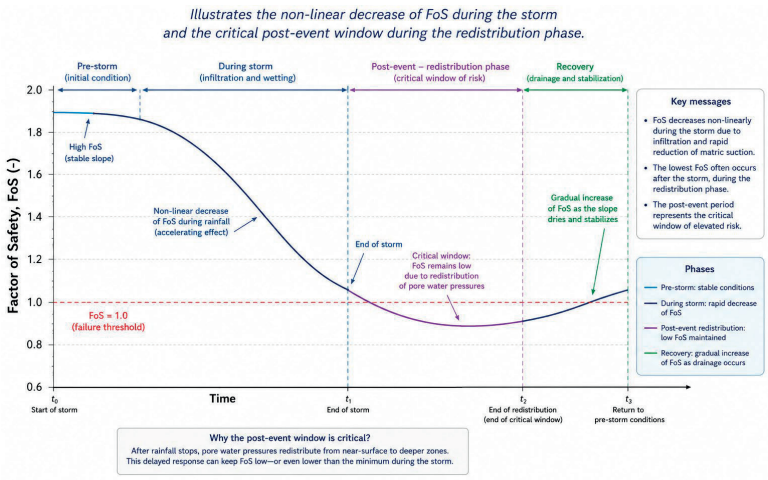

Figure 3. Evolution of the Factor of Safety (FoS) (image created by authors with AI assistance)

This trend demonstrates that embankment stability is not merely a function of cumulative precipitation volume, but is heavily dictated by the transient hydraulic gradients that develop when rainfall intensity outpaces the drainage capacity of the subballast layer, causing water accumulation and sudden shear strength degradation.

Following the termination of the precipitation event, the numerical model tracked the subsequent hydro-mechanical stabilization and drainage phase, highlighting the importance of post-storm monitoring in railway infrastructure management. Although the atmospheric influx ceased, the global factor of safety continued to decline slightly for several hours, a phenomenon caused by the continued internal redistribution and downward gravity-driven migration of the stored water mass toward the deeper, more critical zones of the slope slip surface. This transient delay between the end of the rainfall and the absolute minimum safety margin proves that the critical geotechnical risk window extends into the immediate post-storm period, requiring cautious operational protocols for train speeds during and shortly after extreme weather events. Once the internal drainage and deep seepage processes dominated, driven by the activation of the lower boundary conditions, pore-water pressures began to decline and matric suction registered a gradual, non-linear recovery within the upper slopes, causing the factor of safety to stabilize and enter a long-term upward recovery curve toward its baseline threshold (Aliyu et al., 2024).

## CONCLUSIONS

The comprehensive hydro-mechanical analysis and numerical simulation executed in this research provide a detailed evaluation of transient water infiltration processes and their direct impact on the geotechnical safety margins of unsaturated railway embankments. By coupling the non-linear partial differential Richards equation with the van Genuchten soil-water characteristic framework and Spencer limit equilibrium formulations, this study successfully quantified the time-dependent degradation of structural integrity driven by environmental stressors. The numerical results demonstrate that the progressive advancement of a localized wetting front induces a rapid dissipation of matric suction within the compacted silty-clay matrix, shifting the stress state of the soil skeleton from an unsaturated regime toward a critical condition of localized saturation. From an engineering perspective, this suction dissipation triggers a severe reduction in the soil's apparent cohesion, altering the critical failure mechanism from a stable, deep-seated global configuration to high-risk, shallow, slope-parallel failure planes that develop along the boundary of the maximum infiltration depth. Furthermore, the non-linear downward trajectory of the global factor of safety highlights that geostructural

risk is heavily governed by transient hydraulic gradients and peak precipitation intensity rather than cumulative rain volume alone, which underscores the technical limitations of conventional, simplified hydrological safety thresholds (Liu et al., 2024).

A critical finding of this hydro-mechanical co-simulation is the identification of a distinct post-storm geotechnical risk window, characterized by a continued decline in the global factor of safety even after the cessation of the precipitation event. This phenomenon is driven by the internal hydraulic redistribution and gravity-induced downward migration of the infiltrated water mass toward deeper, more critical slip surfaces, proving that the most vulnerable operational state of a railway embankment extends into the hours immediately following extreme weather. Consequently, this study delivers a validated predictive methodology that infrastructure managers can implement to identify critical saturation boundaries, establish cautious post-storm operational protocols for cyclic rolling stock loads, and design optimized sub-surface drainage arrays. Ultimately, incorporating advanced unsaturated soil mechanics into routine infrastructure assessments provides a scientific pathway to enhance the climate resilience and long-term structural sustainability of transboundary railway networks subjected to severe climate change scenarios.

***Abstract***

*In order to assess the impact of deforestation on the water quality of Lake Buhui, runoff modeling was conducted for the slopes of the lake's tributary catchments, with particular emphasis on the spatial configuration and morphological characteristics of the small hydrographic basins. Lake Buhui, the first artificial lake in Romania, has a storage capacity of approximately 610,000 m³ and is situated at an elevation of 640 m. Lake is additionally supplied by groundwater sources originating from crystalline schists and limestone formations, as well as by four karst springs located in the western sector of the lake, below the mean water level. Runoff generation from the slopes within the studied catchments was simulated using the rainfall–runoff (RR) module of the MIKE 11 modeling system, under the assumption of a representative annual rainfall regime. The simulation results obtained for all tributaries of Lake Buhui are presented in the form of hydrographs corresponding to forested slopes and degraded pasture areas. Furthermore, the results allow for the delineation of the lake's protection zone.*

***Key words****: hydraulic modeling, protection zone, deforestation.*

## INTRODUCTION

The management of surface water resources in specific geomorphological settings, particularly karst landscapes, requires a rigorous understanding of both technical storage capacities and localized hydrographic behavior. On a historical and structural scale, the engineering of artificial reservoirs represents a foundational milestone in regional development. A primary example of this paradigm within the Central and Eastern European territory is the Buhui Reservoir. Situated on a limestone substratum at an altitude of 640 meters above sea level (a.s.l.), it holds historical and technical significance as the first artificial lake constructed in Romania. Engineered and executed between the years 1905 and 1908, the primary objective of this hydrotechnical structure was to secure the continuous public water supply for the mining town of Anina. Geometrically and morphologically, the reservoir extends across a surface area of approximately 11 hectares, bounded by mixed forests of silver fir (*Abies alba*) and European beech (*Fagus sylvatica*). The basin displays a mean longitudinal length of 1.1 km, a transverse width of 0.7 km, and an average operational depth of 8 meters, retaining a total base water volume of approximately 610,000 m³. While the Buhui Reservoir acts as the primary and critical infrastructure backing the municipal drinking water network, the systemic grid relies on a multi-source layout. This network integrates six supplementary sub-surface and karstic spring catchments, namely Colonovățul Mare, Colonovățul Mic, Valea Terezei, Kraksenthal, Grota Morii, and Jitin. Under hydrological drought regimes, the minimal recorded discharge drops to 20 l/s, whereas peak operational flow reaches up to 60 l/s. From a functional standpoint, the infrastructure is entirely decoupled from hydroelectric power generation, serving exclusively as a supply, ecological, and flood-mitigation system. Flood risk management is achieved dynamically via flood-wave attenuation within the storage basin, leveraging a dedicated attenuation volume of 198,706 m³ located between the spillway crest elevation and the maximum water retention level (MWRL). Hydrological calculations indicate that during a high-return period flash flood event with a 1% probability of exceedance (a 100-year flood), the peak upstream inflow reaches 41.3 $m^3/s$. Through basin retention over

the spillway crest, the downstream outflow is mitigated and downscaled to 26 $m^3/s$. This specific flood control framework is designed to protect localized riparian targets, preventing the flooding of the adjacent forest road leading to the Buhui Grotto. To ensure downstream ecological continuity and sustain lower catchments prior to the primary water intake, the dam maintains a continuous mandatory ecological flow calibrated at 150 l/s.

From a technical perspective, the structural behavior of the system is governed by a rigorous set of natural, constructive, and operational elevation parameters: Thalweg: 636.50 m, Bottom Outlet: 637.00 m, Intake: 639.00 m, Minimum Operational: 644.00 m, Spillway Crest/NWRL: 650.00 m, MWRL: 651.80 m (BWBA, 2008).

This research paper provides a modern evaluation of the Buhui Hydrotechnical Node, examining its structural composition, its complex karstic hydrographic basin (including its 3,200-meter underground course through the Buhui Cave), and its long-term operational resilience. By analyzing the interplay between the historical earth-core masonry dam and contemporary water management needs, this study delivers an optimization framework for historic infrastructure operating within vulnerable karstic hydrogeological ecosystems.

## MATERIALS AND METHODS

Our capacity to execute numeric modelling of natural systems has progressed exponentially over the past two decades. Within the last decade, high-performance computing power has scaled to the threshold where desktop supercomputers are a reality, allowing for the inclusion of highly sophisticated parameters and processes within numeric models. The computational tools currently available for data analysis, spatial visualization, and rendering are beyond the imagination of previous generations of engineers. However, as predictive modelling capabilities have expanded, a concurrent reduction in field data collection has occurred, particularly concerning foundational hydrological gauging networks. While modern researchers undoubtedly enjoy access to massive, high-technology spatial datasets - such as multi-spectral satellite remote sensing data - the collection and maintenance of basic, traditional, ground-based historical datasets have severely deteriorated.

A precise quantification of water runoff pathways is essential for resolving practical engineering challenges and ensuring the rational, sustainable utilization of water resources. This principle is a core requirement within complex watershed planning strategies and integrated water resource management (IWRM) frameworks across varying temporal scales. In this context, datasets derived from direct, long-term hydrometric observations remain irreplaceable, as they allow for the empirical definition of characteristic water runoff parameters. Naturally, the water runoff regime displays high spatial and temporal variability across seasonal boundaries and consecutive water years. This variance scales proportionally when comparing catchments with divergent physico-geographical and morphological characteristics. Conversely, within catchments characterized by homogenous physico-geographical conditions, the variations are driven primarily by micro-climatic factors, mean basin altitude, and the forestation density of the drainage basin. Appreciable differences in volumetric discharge can be recorded between hydrometric gauging stations that monitor watersheds situated in entirely different physico-geographical regions. However, when these volumetric values are normalized against catchment surface areas with similar physical and geographic baselines, the resulting variance in specific water runoff indices is minimized.

The formulation of Source Water Protection Plans via integrated catchment-level management and localized resource planning within water intake zones represents a baseline best practice established by the European Union. This policy recognizes that anthropogenic activities inside sanitary protection perimeters can induce severe, long-term negative impacts on public health and downstream municipal consumers (Chapra, 2008).

Within the Romanian legislative framework, sanitary and hydrogeological protection zones are strictly regulated under Government Decision No. 930/2005, which approves the special norms regarding the character and

dimension of sanitary and hydrogeological protection zones for water sources. This legal framework establishes three hierarchical protection tiers:
Zone I: Sanitary Protection Zone with Severe Regime;
Zone II: Sanitary Protection Zone with Restriction Regime;
Zone III: Hydrogeological Protection Perimeter.
For surface water intakes established within natural or artificial lakes (reservoirs), Zone I (Severe Regime) mandates the following minimum strict physical dimensions:
Radial Water Incline: A minimum radial boundary of 100 meters on the water surface, measured outwardly from the exact coordinate of the water intake structure.
Riparian Bank Margin: A minimum radial boundary of 25 meters on the physical shoreline where the active intake infrastructure is anchored.
Lacustrine and Shoreline Perimeter: The entire surface area of the lake matrix must be protected, complemented by a continuous, compulsory 5-meter-wide buffer strip along the entirety of the bounding shoreline.
The integrated hydrological and hydrodynamic modeling framework within the MIKE 11 (DHI) software suite relies on the dynamic, bi-directional coupling between the rainfall-runoff component (MIKE 11 RR), driven by the NAM (Nedbør-Afstrømnings-Model) conceptual core, and the non-steady open-channel routing engine (MIKE 11 HD). Conceptually, this co-simulation architecture transforms discrete meteorological input series, such as continuous temporal arrays of precipitation and potential evapotranspiration stored within .dfs0 time-series files, into physically routed volumetric discharge vectors within the river network. This cross-domain data synchronization is managed by the centralized simulation editor (.sim11), which dynamically couples the spatial river network topology (.nwk11) with the physical catchment parameters parameterized inside the hydrological project file (.rr11), including basin surface areas, initial soil moisture thresholds, and infiltration capacities. Mathematically, the link between the two computational modules is established by injecting the simulated catchment runoff directly into the non-linear Saint-Venant equation of continuity, which governs the conservation of fluid mass in a one-dimensional system. This hydrologic feed is introduced as a dynamic lateral boundary inflow term that is continuously updated at each temporal integration step Delta t by the coupled NAM engine, which mathematically partitions the effective rainfall into three interconnected sub-surface and surface water transport pathways: rapid overland flow traveling across slopes to generate flash-flood hydrograph peaks, interflow moving through unsaturated upper soil layers with a medium structural velocity, and baseflow or saturated groundwater drainage that sustains the baseline ecological and operational drafts of the watercourse during drought periods. In terms of spatial allocation, the engine allows this generated runoff volume to be routed either as a point-source inflow discharged into a single georeferenced junction node simulating a distinct secondary tributary, or as a distributed inflow spread uniformly across a specified longitudinal span of a river branch or reservoir shoreline, where the routing engine divides the cumulative catchment discharge by the length of the targeted reach segment to obtain a continuous lateral flow per linear meter.
A major technical advantage of this integrated software architecture is its ability to perform differentiated temporal harmonization of the computational grid during predictive simulations. While the rainfall-runoff engine processes long-term historical meteorological series using a large, computationally inexpensive time step, the onset of an extreme, high-intensity precipitation event automatically triggers the hydrodynamic core to adjust its runtime temporal resolution via an adaptive time-step configuration. This automatic reduction of the computational interval to seconds or fractions of a second ensures strict compliance with the Courant-Friedrichs-Lewy numerical stability criterion during periods of rapid hydraulic acceleration - such as gravity discharging over frontal spillways or pressurized routing through enclosed subterranean karst conduits - thereby preventing matrix divergence and mass balance errors without inflating the computational cost of the long-term hydrologic background simulation (DHI, 2017).

## RESULTS AND DISCUSSIONS

Lake Buhui is the first artificial lake realised in Romania, retaining a total water volume of approximately 610,000 m³ (Figure 1). Situated at an elevation of 640 m above sea level (a.s.l.), the reservoir spans a surface area of about 11 hectares, with an average longitudinal length of 1.1 km, a transverse width of 0.7 km, and a mean operational depth of 8 m.

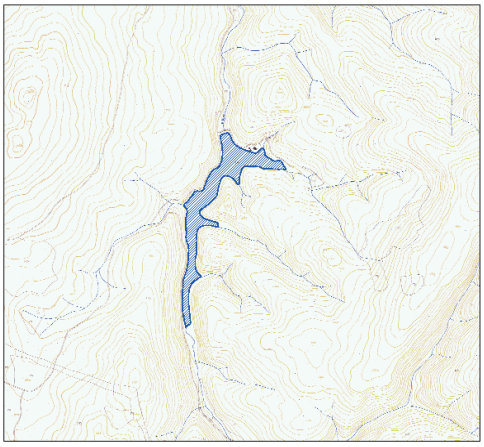

Figure 1. Lake Buhui plan layout

The primary hydrologic inflows sustaining the Buhui Reservoir comprise the following components:

The Buhui Brook: This main watercourse discharges into the Buhui impoundment at a specific location known as "Clocitoare". Originating from a source on the right flank of Lake Buhui, it flows along a surface reach length of approximately 700 m before its confluence with the reservoir.

Secondary Tributaries: In addition to the main brook, five low-discharge streams drain into the perimeter of the lake boundary. Three of these streams are located near the mouth where the Buhui brook enters the reservoir, while the remaining two drain the left flank of the lake, running adjacent to the local forestry road. During summer low-flow periods, several of these minor streams undergo complete drying or exhibit minimal seasonal discharge.

Sub-surface Catchment Inflows: The reservoir is further recharged by subterranean springs originating from crystalline schists and limestone formations. This includes four specific sub-aquatic karst springs located on the western flank of Lake Buhui below the active water surface level.

To execute the numerical hydrological simulations across the catchment, the following boundary conditions and physical boundary parameters were implemented into the computational domain:

Precipitation Distribution: A uniform and constant rainfall intensity was assigned across the entire geographic surface area of the hillslope matrix (Pronk et al., 2006). The monthly rainfall distribution over a one-year period is shown in Figure 2.

Pedological Homogeneity: A single, uniform soil class was mapped across the entire hillslope gradient - specifically categorized as a typical Hapludalfs (comprising multiple sub-types). This soil profile is defined by a medium-to-heavy texture with low permeability, placing it within Hydrologic Soil Group C under standard classification frameworks (Gomi et al., 2002).

Land Use Conditions: Vegetative cover was assumed to be uniform across the hillslope surface area, evaluated under two distinct land-cover scenarios: dense forestry cover versus a post-deforestation state characterized by degraded pastures.

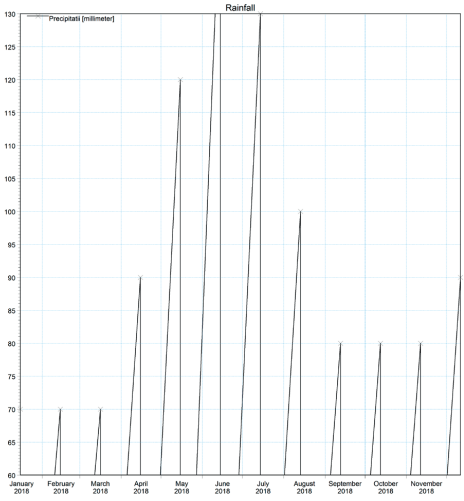

Figure 2. Rainfall one year - 1100 mm

Baseflow Configuration: The continuous background baseline flow was parameterized in accordance with the field-surveyed discharge

data of the sub-surface and karstic tributaries.

Initial Interception Storage: The baseline initial interception and depression storage capacity was set at 20 mm for the forested land-use scenario and downscaled to 1 mm to simulate the low retention capacity of the degraded pastures.

The numerical simulation of hillslope runoff generation across the targeted watersheds was performed using the integrated MIKE 11. The Rainfall-Runoff (RR) module was executed under a non-steady framework based on the regional pluviometric data recorded over a continuous one-year hydrological simulation window.

The simulation results obtained using the MIKE 11 RR module for all the tributaries of Lake Buhui are presented in Figures 3, 4, and 5 through overlaid graphs comparing forested hillslopes and degraded pastures.

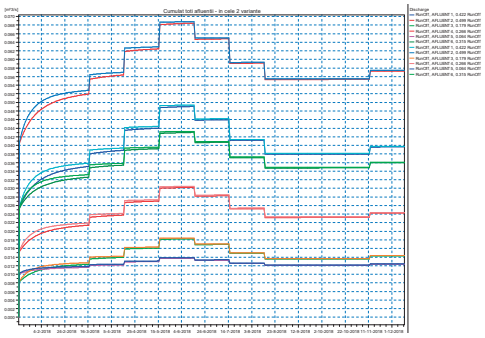

Figure 3. The simulation results

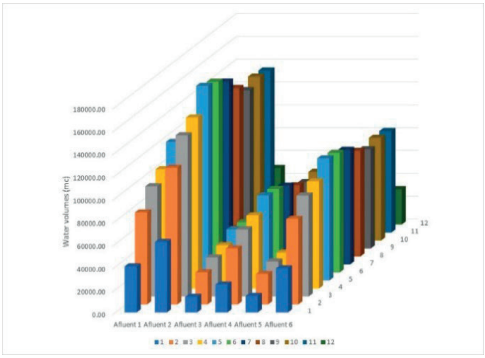

Figure 4. Water volumes - forested hillslopes

To mitigate the risks of accelerated erosion and potential contaminant transport identified in the runoff simulations, a strict spatial delineation of the catchment area is required. Based on these hydrological risks and local karst vulnerability, the critical boundaries around the reservoir perimeter have been mapped (Figure 6).

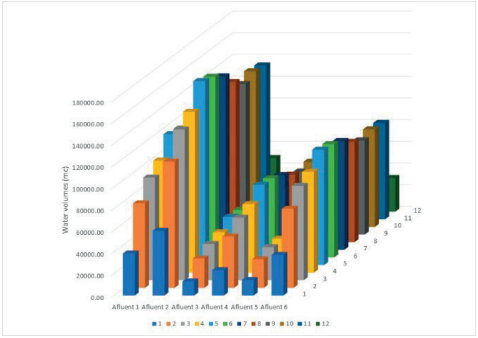

Figure 5. Water volumes - degraded pastures

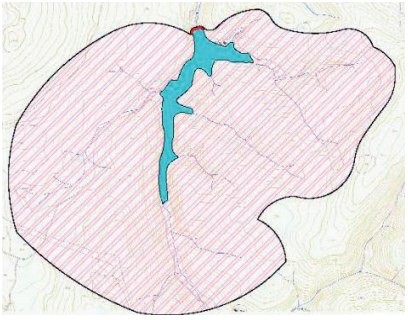

Figure 6. Sanitary and hydrogeological protection zones

The comparative analysis of the simulation scenarios highlights the critical role of vegetative cover in regulating the catchment's water balance. On the forested hillslopes (Figure 4), the high initial interception capacity significantly attenuates peak discharge, ensuring a sustained, gradual baseflow to the reservoir. Conversely, the simulation for the degraded pastures (Figure 5) indicates a rapid hydrological response characterized by accelerated surface runoff and elevated peak volumes, driven by the low retention capacity of the altered terrain. Furthermore, the restrictions implemented within the sanitary and hydrogeological protection zones outlined in Figure 6 are essential to safeguard the subterranean karst springs and surface inflows against anthropogenic degradation, ensuring the long-term ecological stability of the Buhui catchment.

## CONCLUSIONS

The Water Framework Directive (Directive 2000/60/EC-WFD) establishes the foundational European paradigm for water policy, mandating the long-term sustainable management of aquatic ecosystems alongside human and economic water security. While the baseline chemical and ecological status of the raw water matrix within the Buhui Reservoir is categorized as "good" under WFD criteria, this investigation targeted a critical anthropogenic stressor: the qualitative degradation of the lacustrine ecosystem induced by intensive, unregulated forestry exploitation within the catchment area. To evaluate this phenomenon, spatial and temporal field campaigns were executed across varying seasonal and hydro-meteorological regimes to analyze the dynamics of turbidity and Biochemical Oxygen Demand (BOD5) at two strategic monitoring boundaries: the primary upstream reservoir inflow zone of the Buhui Brook and the downstream spillway structure (Directive 2000/60/EC, 2000).

The empirical data collected during the monitoring campaigns reveal a direct causal link between localized deforestation and the disruption of baseline hydrochemical and sediment fluxes:

Sediment Transport and Turbidity Level: A statistically significant increase in turbidity values was recorded at the downstream spillway zone relative to the upstream catchment inflow. This spatial gradient serves as a direct indicator of accelerated mechanical weathering and pluvial soil erosion across the deforested hillslopes. The removal of the root matrix and the canopy layer reduce the initial interception capacity (from 20 mm to 1 mm), leading to enhanced rain-splash erosion and the subsequent gravity-driven transport of fine-grained terrigenous sediments into the lacustrine body.

Organic Loading and BOD5 Kinetics: Conversely, the spatial distribution of BOD5 exhibited a downward trend, with lower concentrations recorded at the spillway zone compared to the primary upstream inflow.

Under the framework of the Water and Wastewater Master Plan for Caraș-Severin County, the Buhui Reservoir is designated as the sole, non-redundant drinking water source for the combined Anina and Steierdorf urban agglomerations, serving a population equivalent exceeding 10,000 PE. Given this high operational dependency, the formulation of an empirical Source Water Protection Plan for the Buhui catchment is a critical public health requirement. Implementing a formalized protection strategy provides the necessary engineering and administrative safeguards to preserve compliant raw water quality parameters, shield the intake infrastructure 639.00 m from shock-loading events, and mitigate medium- to long-term environmental risks to human health.

A critical policy misalignment exists between the empirical findings of this study and current statutory frameworks. The specific regulations governing sanitary and hydrogeological protection zones in Romania, established by Government Decision No. 930/2005 (HG 930/2005), enforce strict physical perimeters for Zone I Severe Regimes (e.g., a 100-meter radial water boundary from the intake). However, this legal framework fails to incorporate restrictive clauses or thresholds regarding commercial forestry operations within the wider hydrogeological boundaries (Government, 2005).

Because this research identifies intensive logging as a severe driver of watershed degradation, relying solely on standard sanitary buffers is insufficient to protect vulnerable karstic aquifers. Therefore, a specialized strategic forestry management plan must be developed for the Lake Buhui perimeter to limit timber harvesting within the catchment. To ensure the sustainability of this resource for future generations, immediate logging bans should be implemented within the catchment, alongside proactive preventative measures to protect this high-quality reservoir.

***Abstract***

*The aim of the study is to assess the levels of Cd and Pb contamination in muscle, skin, and liver samples, to assess the potential ecological risk to ecosystems and the health risk associated with using Roach for human food. The studies were performed using Inductively coupled plasma mass spectrometry. The results indicate higher levels of both elements in the tissues and organs of fish from the Topolnitsa dam. In both ecosystems, the highest values of Pb and Cd were observed in sediment samples, and the lowest in water samples. The RI (potential ecological risk) for all indicators shows a low potential ecological risk for Pb and Cd in the Dushantsi dam ecosystem, and a significant potential ecological risk for Cd in the Topolnitsa dam ecosystem. When consuming R. rutilus from both reservoirs, the fish should be thoroughly cleaned of the entrails and skin. No risk to human health is expected when consuming up to 420 g per week of fish muscle from the two dams.*

***Key words*:** *cadmium, degree of contamination, health risk assessment, lead, potential ecological risk.*

## INTRODUCTION

Dushantsi Dam and Topolnitsa Dam for heavily modified water bodies of the Maritsa River Basin, East Aegean Region, Bulgaria. Dushantsi Dam is of type L13: Medium and small semi-mountainous dams in Ecoregion 7: Eastern Balkans, water body code BG3MA800L180. It is located in the upper reaches of the Topolnitsa River, 2 km from the village of Dushantsi, Sredna Gora. It is a large hydrotechnical facility, determined to be in poor ecological condition, likely related to the region's highly developed industry (River Basin Management Plans (East Aegean Region) 2021-2027). The waters of the dam are mainly used for industrial water supply, fishing, and water sports. No similar studies have been carried out for the freshwater ecosystem of Dushantsi Dam to date. Topolnitsa Dam is located below Dushantsi Dam, towards the middle reaches of the river. It belongs to type L11b: Large deep dams in Ecoregion 7: Eastern Balkans, code of water body BG0001389. The waters of the dam are used for electricity generation, irrigation of large areas of agricultural land, flood control, sport and industrial fishing, tourism, etc. The dam ecosystem is influenced by long-term industrial activities related to mining and mining processing. Fish are one of the main foods for humans. They are sources of high-quality proteins, polyunsaturated fatty acids, vitamins and other essential elements (Stancheva et al., 2012). Heavy metal pollution poses a significant threat to aquatic ecosystems and their biota, especially fish. Fish are sensitive to changes in pollutant concentrations in aquatic environments (Peycheva et al., 2014; Georgieva et al., 2015; Peycheva et al., 2022). They occupy different trophic levels in food chains, but also have a relatively long lifespan, allowing them to accumulate several pollutants in their bodies, including heavy metals, which is why they are sensitive bioindicators of pollution of the aquatic environment (Rashed, 2001; Bervoets &

Blust, 2003; Saeed & Shaker, 2008; Peycheva et al., 2014). The Topolnitsa Dam has been the subject of research by various authors on heavy metal content in fish (Yancheva et al., 2011; Georgieva et al., 2015), but not on *Rutilus rutilus*. The Roach has been studied for heavy metals in other dams (Zhelyazkov et al., 2014), but studies from Bulgarian dams are few. The aim of the study is to assess the degree of anthropogenic loads, the potential ecological risk to ecosystems, and the risk of using the Roach for food based on the levels of Pb and Cd contamination.

## MATERIALS AND METHODS

The objects of the study are thirty specimens of Roach *Rutilus rutilus* (Linnaeus, 1758), each from two freshwater ecosystems: Dushantsi and Topolnitsa dams. The fish were collected with multi-mesh gillnets (BSS EN 14757:2015) and personal permissions from the Executive Agency for Fisheries and Aquaculture, Ministry of Agriculture and Food, Bulgaria. The FishBase database is used to check the scientific and common names of fish (Froese & Pauly, 2020). The fish were collected from the Dushantsi Dam, named as Dushantsi Biotope (42041'49.51''N 24017'27.80''E; 792 m) and from the Topolnitsa Dam, named as Poibrene Biotope (42027'38.88''N 23059'20.81''E; 309 m; Figure 1).

For the ichthyological sample, the following parameters are determined: total number of specimens, total body length (TL, cm), total body width (TH, cm), total body weight (TW, g), biomass in percent (W%), abundance (A%), absolute dominance ($\mathbf{D} = \frac{(A\% + W\%)}{2}$) (Belkinova et al., 2013) and Fulton's condition factor ($\mathbf{K} = \mathbf{100}.\frac{TW}{TL^3}$) (Stavrescu-Bedivan et al., 2023; Zaharieva et al., 2024).

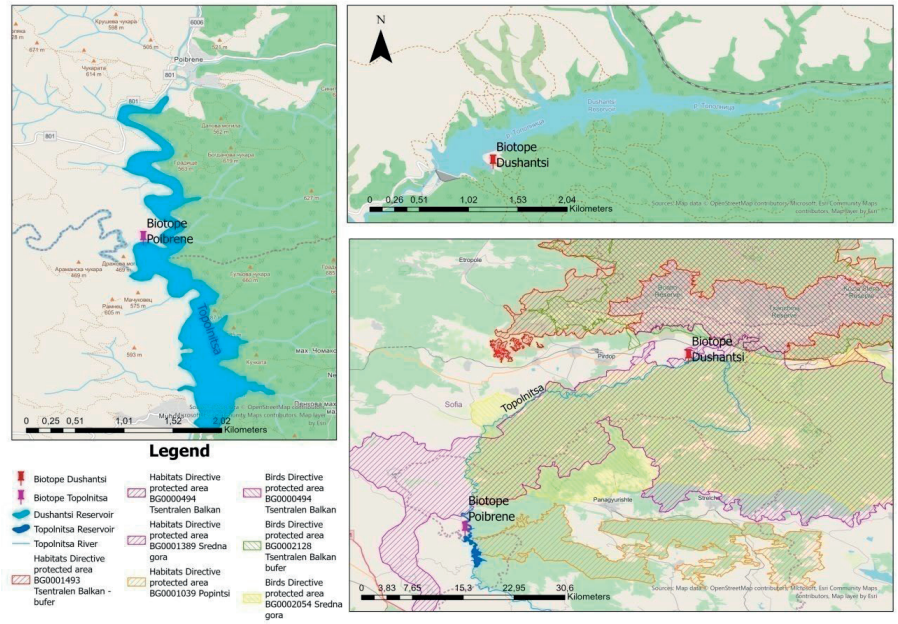

Figure 1. Studied biotopes from the Dushantsi and Topolnitsa dams (Esri Inc. (2023). ArcGIS Pro (Version 3.2.0) https://www.arcgis.com/home/index.html

The requirements of BSS ISO 5667-4:2026 and BSS ISO 5667-12:2017 standards have been used to collect water and sediment samples. BSS EN ISO 5667-3:2024 and BSS EN ISO 5667-15:2009 standards have been applied for the preservation and storage of water and sediment samples, respectively. The standards BSS EN ISO 17294-2:2023 and BSS EN ISO 21424:2020 Milk, milk products, infant formula and adult nutritionals - Determination of minerals and trace elements - Inductively coupled plasma mass spectrometry (ICP-MS)

method (ISO 21424:2018) were used to determine the content of Cd and Pb in samples of water, liver, muscles and skin of the Roach from the two dams, and US EPA Method 3051A for sediment samples. PerkinElmer SCIEX ELAN DRC-e ICP-MS system (MDS Inc., Concord, ON, Canada, Inductively coupled plasma mass spectrometry, Table 1) was used to conduct the elemental analysis.

Table 1. Instrumental parameters and monitored isotopes used for ICP-MS analysis

| Parameter | Value |
|---|---|
| Ar plasma flow rate | 15 L $min^{-1}$ |
| Auxiliary Ar flow rate | 1.20 L $min^{-1}$ |
| Nebulizer gas flow rate | 0.90 L $min^{-1}$ |
| Lens voltage | 6.00 V |
| ICP RF power | 1100 W |
| Integration time | 2000 ms |
| Dwell time | 50 ms |
| Measurement mode | Peak hopping |
| Sample uptake rate | 2 mL $min^{-1}$ |
| Rinse time between samples | 180 s |
| Rinse solution | 3% $HNO_3$ |
| Monitored isotopes | $^{27}Al$, $^{54}Fe$, $^{56}Fe$, $^{57}Fe$, $^{55}Mn$, $^{75}As$, $^{112}Cd$, $^{114}Cd$, $^{52}Cr$, $^{63}Cu$, $^{65}Cu$, $^{202}Hg$, $^{60}Ni$, $^{62}Ni$, $^{207}Pb$, $^{208}Pb$, $^{77}Se$, $^{78}Se$, $^{80}Se$, $^{82}Se$, $^{66}Zn$ |

$HNO_3$ (67-69%, Fisher Chemicals, Ultra Trace Metal Grade, Loughborough, UK), HCl (37%, Fisher Chemicals, Ultra Trace Metal Grade, Loughborough, UK) and $H_2O_2$ (30%, Fisher Chemicals, Ultra Trace Analysis Grade, Loughborough, UK) were used for sample preparation and analysis. All solutions were prepared with double-deionised water. Working standard solutions were prepared by diluting the ICP-MS multi-element calibration standard solution IMS-102 (Ultra Scientific, Agilent, Santa Clara, CA, USA), which contains, among others, Cd and Pb with an initial concentration of 10 mg/L. After collection, water samples were stored at 4°C in dark glass bottles before transport to the laboratory. For ICP-MS analysis, 50 mL of each water sample was filtered through a 25 mm sterile PES syringe filter with a 0.45 µm pore size. The filtrates were acidified with 0.05 mL concentrated nitric acid to pH 2 and subsequently analysed. Biological samples were digested with concentrated $HNO_3$ and then diluted before analysis. A total of 10 tissue, organ, water and sediment samples were examined for each of the two dams, collected during the three seasons (spring, summer, and autumn) in 2025. Skin, muscle and liver samples were weighed twice, once as wet weight and once as dry weight. The degree of accumulation of lead and cadmium in the studied tissues and organs of *R. rutilus* relative to their content in water and sediment samples was estimated using the Bioconcentration factor (BCF): $\mathrm{BCF} = \frac{C}{Cw}$ and $\mathrm{BCF} = \frac{C}{Cs}$, where C is the concentration of the metal in the muscles, skin or liver of the Roach in µg/kg, respectively; $C_w$ is the concentration of the metal in the water samples (µg/L), and $C_s$ is their concentration in the sediments (µg/kg). The calculations are for each organ or tissue and for each metal separately. BCF is an important indicator for assessing ecological risk. The relationship between the concentrations of Pb and Cd in samples of water and sediments and samples of Liver, Muscle, and Skin was presented through Spearman's rank correlation coefficient ($r_s$). The ecological risk ($\mathrm{RI} = \sum E r^i = \sum \mathrm{Tr}^i . \mathrm{Cf}^i$) is defined as the sum of the products of the toxic response factor (specific for each element) and the contamination factor for each of the trace elements. The contamination factor ($\mathrm{Cf}^i$) is defined as the ratio of the actual to the reference concentration of each trace element. The sum of all contamination factor values indicates the contamination level (Cl) (Hakanson, 1980; Tang et al., 2023; Younis et al., 2024). The USEPA (1989) methodology was used to assess the health risk of consuming roach from both dams. A Target Hazard Quotient (THQ) (THQ) was calculated using the formula: $THQ = \frac{(EFr.ED.FIR.C)}{(BWa.AT.RfD)} . 10^{-3}$, where EFr is the frequency of exposure, ED is the average life expectancy for men and women or the duration of exposure, FIR is the average daily intake of fish consumed, C is the concentration of the elements tested in muscle samples (µg.$g^{-1}$, ww), BWa is the average body weight for women and men, AT is the average time of exposure to non-carcinogens, RfD is the reference oral dose (0.001 for Cd and 0,004 for Pb, according USEPA, 2011). The Hazard index (HI) is calculated using the formula: HI = ∑THQ, calculated for each of the two dams in terms of Pb and Cd content. The results are statistically

processed by MS Excel (Microsoft, 2011) with relevant mathematical formulas.

## RESULTS AND DISCUSSIONS

### Characteristics of the studied fish species

Roach, *Rutilus rutilus* (Linnaeus, 1758) (Cyprinidae) is the dominant species in the collected fish samples from both dams. It is a freshwater, benthopelagic, and brackish fish species. Staple food for the Roach are crustaceans, worms, insect larvae, algae, and higher aquatic vegetation (Karapetkova & Zhivkov, 2006; Kottelat & Freyhof, 2007). *R. rutilus* is included in the International Union for Conservation of Nature Red List as a Least Concern species (LC; IUCN) (Kottelat & Freyhof, 2007). The species is widely distributed in various habitats in the country. *R. rutilus* is an object of sport and industrial fishing. In both dams, the Roach is an eudominant species ($D_{Dushantsi}$=47.85; $D_{Topolnitsa}$=22.65). Fulton's condition factor (K > 1 for both dams) indicates that the fish are fatty, well-nourished, with high fat content and developed gonads. The condition factor suggested a favourable body condition (Table 2).

Table 2. Metric data, dominance and status of *Rutilus rutilus* from Dushantsi and Topolnitsa reservoirs

| Fish species *Rutilus rutilus* (Linnaeus, 1758) | Dushantsi | Topolnitsa |
|---|---|---|
| Total length, TL cm | 9.98±2.53 (7.40-21.00) | 16.34±2.52 (9.1-19.5) |
| Total width, TH см | 2.39±0.77 (1.70-5.70) | 4.44±0.94 (2.20-5.90) |
| Weight, W г; W % | 12.50±20.48 (4.00-117.00) 53.92% | 53.24±23.91 (7.00-98,00); 13.30% |
| Abundance, A % | 47.62 | 32.00 |
| Absolute dominance, D | 47.85 | 22.65 |
| Fulton's condition factor, K | 1.26 | 1.22 |

### Concentration of Lead (Pb) and Cadmium (Cd) in Roach and the Environment

The content of Pb and Cd in samples of Skin, Muscle and Liver of R. rutilus, water and sediments are presented in Table 3. Lead (Pb) and cadmium (Cd) are major toxic metals (Liu et al., 2013). Lead is not a natural element in natural waters. It enters natural water bodies from lead ores and industrial wastes, from mines and smelters used for lead processing, and from all production activities that use lead. Lead is a highly toxic metal. Studies have shown that the accumulation of lead by aquatic organisms increases with increasing pH and decreasing water hardness. Lead is transported through the body's bloodstream and accumulates mainly in soft tissues, the liver, and the kidneys. It is permanently deposited in bones. High concentrations of oil in aquatic ecosystems stimulate biodiversity, stimulate fish development and cause other effects (Yablanski & Petkov, 2011). The degree of toxic effects of lead is influenced by the stage of fish development, pH, temperature, water hardness, the presence of dissolved organic matter and other factors. (Hellawel, 1896; Peycheva et al., 2014). The content of Pb and Cd in water samples was assessed in accordance with the requirements of Regulation H-4/2012 and the Regulation on environmental quality standards for priority substances and certain other pollutants of the national legislation. In Bulgaria and the European Union, standards for heavy metals in sediments have not been established; therefore, those approved by the US Environmental Protection Agency (US EPA) were used (Effect Range-Low - ERL) (O'Connor, 2004; Cholakova, 2021). The content of these two elements in fish skin, muscle and liver samples was assessed according to Regulation (EU) 2023/915, FAO (1983), MAFF (1995). For waters, the maximum permissible concentration is 1.20 µg/L (Regulation on EQS, on priority substances and certain other pollutants). For sediments, ERL for Pb is 46.7, and for Cd – 1.20 mg/kg dry weight. According to national legislation, the maximum permissible content (MPC) of Pb in fish muscles is 0.2 mg/kg (Regulation 31/2004), according to FAO (1983), it is 0.5 mg/kg, and according to Regulation (EU) 2023/915 - 0.30 mg/kg wet weight. According to Regulation 31/2004, the MPC for Cd is 0.05 mg/kg, according FAO and MAFF - 0.5 mg/kg and 0.2 mg/kg respectively, and according to Regulation (EU) 2023/915 – 0.05 mg/kg wet weight. Industrial wastewater has been identified as a major source of Cd pollution (Yablanski & Petkov, 2011).

The highest concentrations of Pb and Cd were found in sediments, and the lowest contamination was in water samples for the two elements and dams. The results for the Roach tissues and organs showed the highest values for the two elements in liver samples, followed by

skin samples. The lowest content of Pb and Cd is in the muscle samples. This trend is established for both elements and for the Roach from both dams, in both fresh- and dry-weight samples. The differences in the two dams are in the concentrations of the two elements and the exceedances compared to the established norms. In the Dushantsi Dam, the exceedances in Pb and Cd concentrations are as follows: 9.2 times for Liver>6.7Skin>5.0Muscle for Pb and 3.9 times for Liver>1.40Skin>1.20Muscle for Cd. For the Topolnitsa Dam, the exceedances are: 28.95 times for Liver>7.60Skin>6.90Muscle for Pb. and 11 times for Liver>10.80Skin>1.80Muscle for Cd.

In the Topolnitsa Dam, the exceedances for Pb compared to those in Dushantsi Dam are 3.15 times higher in Liver samples, 1.13 times higher in Skin samples and 1.38 times higher in Muscle samples.

Regarding the exceedances for Cd, which are also higher in Topolnitsa Dam samples: 2.82 times higher for Liver samples, 7.71 times higher in Skin and 1.50 times higher in Muscle. We assume that the higher concentrations of Pb and Cd in the Topolnitsa reservoir are due to river flows passing through areas with intensive mining and ore processing.

The content of Pb and Cd in the studied muscle samples of fish from the Dushantsi Dam is respectively 3.34 and 1.2 times higher, and for the Topolinitsa Dam, 4.6 and 1.8 times higher, compared to the maximum permissible levels of Pb and Cd in fish set by Regulation (EU) 2023/915.

Table 3. Content of Lead (**Pb**) and Cadmium (**Cd**) in tissues and organs of *R. rutilus,* waters and sediments

| **Samples Dushantsi** | **Min-Max Mean±SD** | **Min-Max Mean±SD** |
|---|---|---|
| **Topolnitsa** | **Mean±SD** | **Mean±SD** |
| **Wet weight** | **Pb** | **Cd** |
| Skin *R. rutilus* | 1.52±0.42 (1.22-1.81) | 0.54±0.25 (0.37-0.77) |
| Muscle *R. rutilus* | 1.38±0.06 (1.33-1.42) | 0.09±0.03 (0.07-0.11) |
| Liver *R. rutilus* | 5.79±2.43 (3.86-7.29) | 0.55±0.17 (0.43-0.67) |
| **Water** | 0.02±0.01 (0.01-0.03) | 0.007±0.002 (0.005-0.009) |
| **Dry weight** | **Pb** | **Cd** |

Results of the study show that Cd accumulates at higher concentrations in the liver than in fish tissues. Higher Cd content in liver samples of freshwater fish species compared to skin and muscle has been reported in other studies (Georgieva et al., 2015; Peycheva et al., 2022; Ilieva & Kirin, 2025). Dallinger et al. (1987) indicated that this is related to the higher protein content in the liver. In the study, sediments had a higher Cd content than in water samples. Salomons & Stigliani (1995) explained this result by the fact that heavy metals bind to suspended particles or adsorb to organic matter, leading to their precipitation.

The contamination factor is very high (Cf) for Pb in the muscles of the Roach from both dams and moderate for Cd (Table 3). The contamination level (Cl) is 1.50 times higher in the muscles of *R. rutilus* from Topolnitsa dam than in Dushantsi dam. The risk of Pb and Cd loading in the muscles is 1.49 times and 1.5 times, respectively, higher for *R. rutilus* from Topolnitsa dam than for those from Dushantsi dam. The RI (potential ecological risk) for all indicators indicates a low potential ecological risk for Pb and Cd in the Dushantsi dam ecosystem, and a significant potential ecological risk for Cd in the Topolnitsa dam ecosystem (Table 5). When consuming *R. rutilus* from both reservoirs, the fish should be thoroughly cleaned of the entrails and skin.

Table 5. Risk assessment and degree of contaminations

| Factors | Tissues/Sediments | Pb Dushantsi | Cd Dushantsi | Pb Topolnitsa | Cd Topolnitsa |
|---|---|---|---|---|---|
| Cf | Skin | 10.65 very high | 2.20 moderate | 9.80 very high | 17.60 very high |

The health risk assessment was made assuming equal intake and adsorbed doses of pollutants, an average fish food intake rate of 60 grams per day (FIR), an assumption of an average body weight (BWa) of 65 kg for women and 85 kg, an average lifetime (ED) of 79 for women and 72 for men, reference oral dose for Pb 0.004 and 0.001 ($mg.kg^{-1}.day^{-1}$) for Cd, the Target Hazard Quotient (THQ) is as follows (Table 6):

Table 6. THQ and HI of Dushntsi (Dishantsi Dam) and Poibrene biotopes (Topolnitsa Dam)

| THQ | Dushnatsi Biotope | | Poibrene Biotope | |
|---|---|---|---|---|
| | Pb | Cu | Pb | Cu |
| Women | 0.230 | 0.055 | 0.318 | 0.083 |
| Men | 0.176 | 0.067 | 0.243 | 0.063 |
| Total | 0.406 | 0.122 | 0.561 | 0.146 |
| HI | 0.528 | | 0.707 | |

The obtained values for the HI are below 1. Therefore, according to USEPA (2011) no risk to human health is expected when consuming up to 420 g per week of fish muscles from the two dams.

## CONCLUSIONS

The studied *R. rutilus* specimens from both dams are healthy. Fulton's condition factor (K) indicates favourable conditions in both habitats. The chemical analyses showed that Pb levels were 3.15 times higher in liver samples, 1.13 times higher in skin samples, and 1.38 times higher in muscle samples in the Topolnitsa dam than in the Dushantsi dam. The excesses for Cd are also higher in the samples from the Topolnitsa dam: 2.82 times higher in liver, 7.71 times higher in skin and 1.50 times higher in muscle. The use of Roach no risk to human health is expected when consuming up to 420 g per week of this species of fish from the two dams.

## ACKNOWLEDGEMENTS

The authors thank the NIGGG, BAS, the AU-Plovdiv and the Scientific Centres for the financial support received under the research project, as well as in connection with the work of PhD students Ilieva and Paskaleva. The authors thank Assoc. Prof. Mihaylova, PhD, for her assistance and consultations on the chemical analyses.

***Abstract***

*The study aims to monitor the ecological state and anthropogenic load of the Luda Yana River, part of the Maritsa River catchment. For this purpose, five biotopes of the Luda Yana River and its tributary Strelchanska Luda Yana (Strelcha, Popintsi, Svoboda, Rosen and Pazardzhik) were visited in 2025. A total of 711 specimens of 23 taxa of macroinvertebrate organisms belonging to Oligochaeta, Mollusca, Crustacea, Plecoptera, Ephemeroptera, Trichoptera, Odonata, Heteroptera, Coleoptera, Diptera, Chironomidae and Hydracarina were collected from all biotopes. Basic metrics and indices concerning the abundance and number of the collected indicator macrozoobenthos were calculated. The ecological state of the Luda Yana River is presented and discussed. The ecological state has been reported to range from moderate (Popintsi biotope) to very bad (Strelcha, Svoboda and Rosen biotopes). The content of Al, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Cd, Hg, and Pb in samples of macrozoobenthos, waters and sediments from two biotopes (Svoboda and Pazardzhik) was determined. The highest content of Fe, Al and Mn was found. The bioconcentration factor was considered. National and international legislative norms were used to compare the results of the chemical analyses.*

***Key words****: bioindication, Bulgaria, ecological indices, heavy metals and metalloids, river ecosystem.*

## INTRODUCTION

The Luda Yana River rises in the Sashtinska Sredna Gora under the name Panagyurska Luda Yana and flows through the Panagyurska Valley. After the village of Buta it flows under the name Luda Yana, enters the Pazardzhik-Plovdiv Plain, and flows into the Maritsa River. Tributaries of the river are the Banska Luda Yana River, the Strelchanska Luda Yana River and others. The waters in the lower reaches of the Luda Yana River are used for irrigation (Kiradzhiev, 2013; Gartsiyanova et al., 2021; 2023). The Luda Yana River flows through the Panagyurishte Ore Region, which extends between the central Srednogorie and Stara Planina Mountains and includes several ore deposits, including Assarel, Medet, Elshitsa, Tsar Asen, and Radka (Popov et al., 2003). Pollution of the Luda Yana River is a result of industry, wastewater discharge from urban sewage systems, and agriculture (livestock farms) (Gartsiyanova et al., 2021; 2023). Mining (from exploration through exploitation to deposit closure) impacts the environment, leading to land degradation, air, surface water, and soil pollution, loss of biodiversity, and more (Jhariya et al., 2016). Mineral extraction is associated with the release of large amounts of waste material. Tailings dams, which store a variety of mining waste, are among the most environmentally damaging pollutants (Agboola et al., 2020). Water resources are among the most affected by mining (Jhariya et al., 2016). The importance of rivers as water resources lies in their provision of water for household, industrial, and agricultural needs, as well as various activities (including fishing), which is why their protection from pollution is extremely important (Shanbehzadeh et al., 2014). Heavy metals are characterised by significant toxicity, persistence, bioaccumulation and biomagnification (Garai et al., 2021). About 99.9% of heavy metals

accumulate in sediments, while about 0.1% are dissolved in water (Pradit et al., 2013; Hacısalihoğlu & Karaer, 2016). Aquatic organisms are exposed to the effects of dissolved heavy metals in water on the one hand and those in sediments on the other (Garai et al., 2021). Macroinvertebrates are characterised by low mobility and long lifespan, which is why they can reflect changes in the aquatic environment. Pollution of the aquatic environment leads to changes in the composition and structure of aquatic organism communities (Varadinova et al., 2022). Few authors have investigated the water quality of the Luda Yana River based on the biological quality element (BQE) macrozoobenthos (Vidinova et al., 2008; Georgieva et al., 2014; Zaharieva et al., 2024). Rabadjieva et al. (2009) investigated heavy metal concentrations in waters from the Luda Yana River. No studies were found that affected the circulation of heavy metals in waters, sediments and macrozoobenthos of the studied river ecosystem.

The present study aims to monitor the ecological state and anthropogenic load of the Luda Yana River using the abundance and numbers of indicator macroinvertebrate fauna, and the concentrations of heavy metals and metalloids in macrozoobenthos, water, and sediments.

## MATERIALS AND METHODS

In the spring of 2025, five sites (designated as biotopes) were visited along the Luda Yana River and its tributary, the Strelchanska Luda Yana River (Figure 1).

Figure 1. Map of the studied biotopes

The Strelcha biotope falls within a section of the Strelchanska Luda Yana River named “The Strelchanska Luda Yana River from its sources to the town of Strelcha” of Type R03 Mountain Rivers in Ecoregion 7 Eastern Balkans. The Popintsi biotope is located within a section of the Luda Yana River named “The Panagyurska Luda Yana from Panagyurishte to the confluence of the Strelchanska Luda Yana” of Type R05 Semi-mountainous Rivers in Ecoregion 7. The Svoboda, Rosen and Pazardzhik biotopes fall within a section of the Luda Yana River named “The Luda Yana River from its confluence of the Strelchanska Luda Yana to its mouth” of Type R05. Strelcha biotope (42°29'52.7"N 24°19'31.5"E; 515 m above sea level) is located along the Strelchanska Luda Yana River to the town of Strelcha. The bottom substrate of the river section in this biotope consists of silt, sand, and stones. Popintsi biotope (42°25'28.6"N 24°16'00.7"E; 373 m above sea level) is located along the Luda Yana River, northwest of the centre of the village of Popintsi. Svoboda biotope (42°23'59.1"N 24°17'31.2"E; 370 m above sea level) is located along the Luda Yana

River, in proximity to the Radka mine. Rosen biotope (42°18'45.7"N 24°21'56.1"E; 293 m above sea level) is located along the Luda Yana River, south of the centre of the village of Rosen. Pazardzhik biotope (mouth) (42°09'38.8"N 24°22'52.0"E; 228 m above sea level) is located along the Luda Yana River, in proximity to the wastewater treatment plant (WWTP) of the town of Pazardzhik, shortly before the river flows into the Maritsa River. The bottom substrate in the four biotopes is sand and stones.

Sampling of macroinvertebrates was carried out according to standard methods (Cheshmedjiev et al., 2011; BDS EN ISO 10870:2012; Regulation No. H-4, 2012; Belkinova et al., 2013; BDS EN 16150:2026). The taxonomic affiliation of the collected macrozoobenthos was determined in laboratory conditions using a Stereo Zoom Microscope KERN OZL 464T24. According to Regulation No. H-4 (2012) and Belkinova et al. (2013), the following were calculated:

- total number of macroinvertebrate taxa;
- number of taxa from orders Ephemeroptera, Plecoptera and Trichoptera (EPT);
- Oligochaeta & Diptera in percentage;
- Filter feeders in percentage;
- EPT taxa in percentage;
- German trophic index Rithron Feeding Type Index;
- saprobiological index – Pantle & Buck (SPUB);
- biotic index (BI).

Basic ecological indices have been determined (Table 1).

Table 1. Main ecological indices

| *INDEX* | *FORMULA* | *INTERPRETATION* |
|---|---|---|
| ***Shannon Index (H')**** | $H' = -\sum_{i=1}^{S}(p_i \ln p_i)$ where $p_i=n_i/N$; $n_i$ is the number of specimens of each i species; N is the number of specimens of all species. | Index values ≤1.99 show very low diversity; 2.00-2.49 – low diversity; 2.50-2.99 – moderate diversity; 3.00-3.49 – high diversity; ≥3.50 – very high diversity. |
| ***Simpson's Index (D)**** | $D = \frac{\sum_i n_i(n_i-1)}{N(N-1)}$ | Index values range from 0 to 1. A value close to 0 indicates infinite diversity. A value close to 1 indicates no diversity. |
| ***Simpson's index of diversity (1-D)***** | $1 - \frac{\sum_i n_i(n_i-1)}{N(N-1)}$ | Index values range from 0 to 1. A value closer to 1 indicates greater diversity and vice versa. |
| ***Berger Parker Dominance Index (d)****** | $d = \frac{n_{max}}{N}$ where $n_{max}$ is the number of specimens of the most common species. | Index values range from 0 to 1. Higher values indicate lower diversity. |
| ***Pielou's evenness index (J')******* | $J' = \frac{H'}{H_{max}} = \frac{H'}{ln\, S}$ where S is the number of species; H' is the Shannon Index. | The index has a maximum value of 1, which indicates an even distribution of specimens and higher diversity. |

Legend: * - according to Kim et al., (2017); Baliton et al., (2020); ** - according to Okpiliya, (2012); Arzamani et al., (2018); *** - according to Okpiliya, (2012); **** - according to Patrício, (2009); Arzamani et al., (2018); ***** - according to McDonald, (2010); Roy & Bhattacharya (2024)

Water and sediment sampling were carried out in accordance with BDS EN ISO 5667-6:2016 and BDS ISO 5667-12:2017, respectively. The samples of surface water, sediments and biological element macrozoobenthos were collected from two biotopes – the Svoboda biotope, in a region with mining activity, and the Pazardzhik biotope, before the confluence of the Luda Yana River into the Maritsa River (before the mouth). All samples were analysed for 12 heavy metals and metalloids (Al, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Cd, Hg and Pb) using an Inductively Coupled Plasma Mass Spectrometer (ICP-MS DRC-e, Perkin Elmer) according to BDS EN ISO 21424:2020. The chemical analysis was carried out in an accredited laboratory. The heavy metals content in the samples of water, sediments and

biological elements is compared with the norms of national and international legislation (Dutch target values, 2000; Regulation No. 31, 2004; Regulation No. 3, 2008; Regulation No. 18, 2009; Regulation on environmental quality standards, 2010; Regulation No. H-4, 2012; Commission Regulation (EU) 2023/915). The Bioconcentration factor (BCF) was presented as the ratio of the pollutant concentration in the tissues or organs of aquatic organisms (macrozoobenthos) to the pollutant concentration in the aquatic environment (waters and sediments) (Sabljic & Protic, 1982; Yarsan & Yipel, 2013).

## RESULTS AND DISCUSSIONS

### *Ecological state based on the BQE macrozoobenthos*

In the present study, a total of 22 taxa (including Hydracarina) and 711 macroinvertebrate specimens were found in the five biotopes of the Luda Yana River and its tributary (Table 2).

Table 2. Taxonomic composition and number of macrozoobenthos from the Luda Yana River and Strelchanska Luda Yana River (Nt – number of taxa; Nsp – number of specimens)

| *Taxonomic composition* | *Strelcha* | | *Popintsi* | | *Svoboda* | | *Rosen* | | *Pazardzhik* | |
|---|---|---|---|---|---|---|---|---|---|---|
| | Nt | Nsp | Nt | Nsp | Nt | Nsp | Nt | Nsp | Nt | Nsp |
| Oligochaeta | 1 | 93 | 2 | 2 | - | - | 1 | 1 | - | - |
| Mollusca | 1 | 1 | 1 | 6 | 1 | 1 | - | - | - | - |
| Crustacea | - | - | - | - | - | - | - | - | 1 | 35 |
| Plecoptera | - | - | 1 | 1 | - | - | 1 | 1 | - | - |
| Ephemeroptera | - | - | 3 | 94 | 3 | 39 | 2 | 12 | 2 | 9 |
| Trichoptera | - | - | 3 | 8 | 1 | 2 | 1 | 1 | 1 | 32 |
| Odonata | - | - | 1 | 19 | 2 | 4 | 1 | 2 | 2 | 18 |
| Heteroptera | - | - | - | - | - | - | 1 | 1 | - | - |
| Coleoptera | - | - | - | - | 1 | 2 | 1 | 1 | - | - |
| Diptera | 2 | 6 | 3 | 5 | - | - | 2 | 2 | 2 | 3 |
| Chironomidae | 1 | 184 | 2 | 22 | 2 | 101 | 1 | 1 | 1 | 2 |
| Hydracarina | - | - | - | - | - | - | - | - | - | presence |

In the present study, the highest number of taxa was found in the orders Ephemeroptera (4 taxa: *Baetis* sp., nymph; *Cloeon* sp., nymph; *Caenis horaria* (Linnaeus, 1758), nymph; *Serratella ignita* (Poda, 1761), nymph), Trichoptera (3 taxa: *Hydropsyche ornatula* McLachlan 1878, larvae; *Anabolia nervosa* (Curtis, 1834), larvae; *Limnephilus rhombicus* (Linnaeus, 1758), larva) and Diptera (3 taxa: *Simulium* sp., larvae; *Tabanus* sp., larvae; Diptera, pupae). Taxa from the orders Ephemeroptera and Trichoptera are more sensitive to anthropogenic load.

The greatest taxonomic diversity was found in the Popintsi biotope (15 taxa). In the Popintsi, the dominant taxon is *Baetis* sp. nymph (74 specimens; Ephemeroptera); in the Svoboda biotope – Chironomidae (85 specimens); in the Rosen biotope – *C. horaria*, nymph (10 specimens; Ephemeroptera); in the Pazardzhik biotope – *Gammarus pulex* (Linnaeus, 1758) (35 specimens; Crustacea: Malacostraca). From the Strelchanska Luda Yana River, in the Strelcha biotope, *Chironomus plumosus* (Linnaeus, 1758), larvae (184 specimens; Chironomidae) dominate. The highest number of EPT taxa was found in Popintsi, with 7 taxa. The ecological state of the Luda Yana River, as measured by the total number of macroinvertebrate taxa and the number of EPT taxa, varies from good in the Popintsi biotope to moderate downstream in the Svoboda, Rosen, and Pazardzhik biotopes. The ecological state of the Strelchanska Luda Yana River in the Strelcha biotope was found to be poor in terms of the total number of macroinvertebrate taxa and very poor in terms of the number of EPT taxa (Table 3). The share of Oligochaeta & Diptera is highest in the Strelcha biotope from the Strelchanska Luda Yana River – 97.89% of the total abundance, followed by the Svoboda biotope from the Luda Yana River – 67.79%. The share of Filter feeders is highest in the Strelcha – 1.76% of the total abundance. Representatives of the Filter feeders ecological group were not found in the Svoboda and Rosen. The percentage of EPT taxa was highest in the Popintsi biotope, followed by the Rosen

biotope (Figure 2). Higher EPT taxa in percentage indicate less pollution.

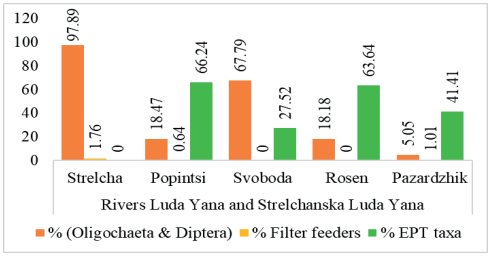

Figure 2. Basic macrozoobenthos abundance metrics

The distribution of indicator macrozoobenthos in the Luda Yana River and its tributaries, grouped by feeding type, was examined. Based on this distribution, the Rithron Feeding Type Index was calculated. In the Strelcha, Svoboda and Rosen biotopes, deposit feeders predominate ($DF_{Strelcha}$=97.54%; $DF_{Svoboda}$=30.20%; $DF_{Rosen}$=50.00%), while in the Popintsi and Pazardzhik biotopes, scrapers ($SC_{Popintsi}$=52.87%; $SC_{Pazardzhik}$=41.41%) (Figure 3).

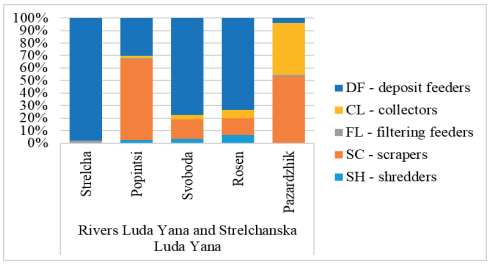

Figure 3. Distribution of macrozoobenthos by trophic groups (in percentages of the total number)

The calculated Rithron Feeding Type Index shows a good ecological state in the Popintsi and Pazardzhik biotopes and a very bad one in the other three biotopes. In addition, Rithron Feeding Type Index values <0.5 indicate an imbalance in the ecosystem, including organic pollution (Table 3).

In the Strelcha biotope, the indicator macrozoobenthos comprises four saprobic groups: xeno-oligosaprobic, β-mesosaprobic, polysaprobic, and poly-α-mesosaprobic (each with one taxon). In the Popintsi, the indicator macrozoobenthos, indicating oligo-β-mesosaprobic conditions (with four taxa), dominates. In the Rosen and Pazardzhik, the indicator macrozoobenthos for β-α-mesosaprobic conditions (with 3 taxa each) was established. In the Svoboda, an equal number of taxa of macroinvertebrates (indicating oligo-β-mesosaprobic conditions) and β-α-mesosaprobic conditions (with 2 taxa each) were established. Based on the saprobic importance, the indicator weight and the abundance of the macrozoobenthos indicator taxa, the saprobic index was calculated and a bad ecological state of the waters of the Strelchanska Luda Yana River in the Strelcha and a change in the ecological state of the waters of the Luda Yana River from good in the Svoboda and Popintsi to very good in the Rosen and Pazardzhik were found (Table 3).

The indicator macrozoobenthos from both rivers belongs to A, B, C, D, and E groups, respectively, sensitive, less sensitive, relatively tolerant, tolerant, and most tolerant organisms. In all investigated biotopes from the Luda Yana River, group C taxa dominate, except the Strelcha biotope from the Strelchanska Luda Yana River, where groups C, D and E are represented by an equal number of taxa (1 taxon). In the Strelcha biotope, the largest numbers of tolerant macrozoobenthos specimens were found (Figure 4). The calculated biotic index (BI) indicates a moderate ecological state in the Popintsi biotope, a bad ecological state in the Svoboda and Pazardzhik biotopes, and a very bad ecological state in the Strelcha and Rosen biotopes (Table 3).

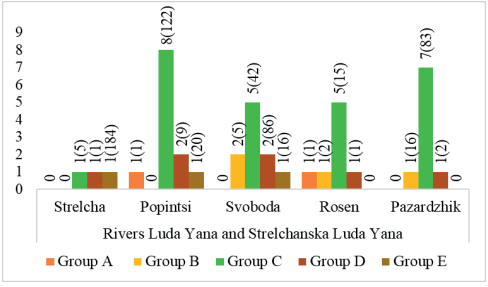

Figure 4. Distribution of established macrozoobenthos by sensitivity groups (number of taxa/number of specimens)

Table 3. Ecological state of the studied river ecosystem
(red – very bad; orange – bad; yellow – moderate; green – good; blue – very good)

| *Metrics*<br>*Biotopes* | *Total number of taxa* | *Number of EPT taxa* | *Rithron Feeding Type Index* | *SPUB* | *BI (nEQR)* |
|---|---|---|---|---|---|
| | **Luda Yana River and tributary** | | | | |
| ***Strelcha*** | 5 | 0 | 0.004 | 3.73 | 1(0.3) |
| ***Popintsi*** | 16 | 7 | 0.67 | 2.09 | 3(0.6) |
| ***Svoboda*** | 10 | 4 | 0.19 | 2.10 | 2(0.4) |
| ***Rosen*** | 11 | 4 | 0.20 | 1.50 | 2(0.2) |
| ***Pazardzhik*** | 10 | 3 | 0.53 | 1.81 | 2(0.4) |

Shannon Index (H') values range from 0.76 to 1.92, which indicates very low diversity in all studied biotopes, with the lowest values found in the Strelcha biotope (Strelchanska Luda Yana River) and Svoboda biotope (Luda Yana River). In the Strelcha biotope, the Simpson's Index (D) value is the highest (D=0.53), and the Simpson's index of diversity (1-D) value is the lowest (1-D=0.47), indicating lower diversity in this biotope, followed by the Svoboda biotope. Berger Parker Dominance Index (d) is highest in Strelcha biotope (d=0.65), followed by Svoboda biotope (d=0.57), which again shows lower diversity in these two biotopes. Pielou's evenness index (J') has the lowest values in the Strelcha and Svoboda biotopes (J'=0.47 and J'=0.59, respectively), which indicates a lower evenness in the distribution of taxa (Table 4).

Based on the calculated metrics and indices for the indicator macrozoobenthos in the Luda Yana River and the Strelchanska Luda Yana River, a moderate ecological state was established in the Popintsi biotope, a bad state in the Pazardzhik biotope, and a very bad state in the Strelcha, Svoboda, and Rosen biotopes.

Vidinova et al. (2008) assessed water quality in the Luda Yana River after Rosen village using physicochemical parameters and macroinvertebrates. According to the calculated indices, the authors report that the Luda Yana River, after Rosen, belongs to the III category of waters. In the present study, a very bad ecological state was found for the Rosen biotope. Zaharieva et al. (2024) conducted hydrobiological monitoring of the Luda Yana River near the village of Popintsi based on BQE macrozoobenthos. The authors report a moderate ecological state in this section of the river, findings confirmed by the present study.

***Content of heavy metals and metalloids***

In the macrozoobenthos samples from the Luda Yana River, Svoboda biotope, the content of heavy metals and metalloids decreases in the order: Fe > Al > Mn > Cu > Zn > Cr > Pb > Co > Ni > As > Cd > Hg; in the water samples – in the order: Al > Fe > Mn > Cu > Zn > Ni > Cr > Co > Pb > Cd > As; in the sediment samples – in the order: Fe > Al > Mn > Zn > Cu > Pb > Co > Cr > Ni > As > Cd. In the macrozoobenthos samples from the Luda Yana River, Pazardzhik biotope, the content of heavy metals and metalloids decreases in the order: Al > Fe > Mn > Cu > Zn > Co > Cr > Pb > Ni > As > Cd > Hg; in the water samples – in the order: Fe > Mn > Cr > Zn > As > Cu > Al > Ni > Hg > Co > Cd > Pb; in the sediment samples – in the order: Fe > Al > Mn > Cu > Zn > Pb > Cr > Co > Ni > As > Cd. In general, in both studied sections (Svoboda and Pazardzhik) of the Luda Yana River, the highest

concentrations of Fe, Al, and Mn, and the lowest concentrations of Cd and As, were found. A higher content of Al, Cr, Fe, Cu, Zn, As and Pb was reported in macrozoobenthos samples from the Svoboda biotope compared to the Pazardzhik biotope. The content of all investigated heavy metals and metalloids is higher in the samples of waters from the Svoboda biotope compared to the Pazardzhik biotope. At the same time, the content of the investigated heavy metals and metalloids was higher in the sediment samples from the Pazardzhik biotope compared to the Svoboda biotope, except for Zn and Cd (Figures 5 and 6).

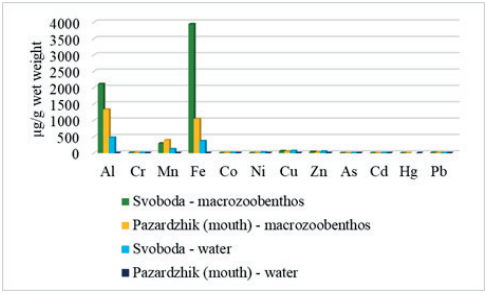

Figure 5. Content of heavy metals and metalloids in macrozoobenthos (µg/g wet weight) and water (µg/g wet weight) from the Luda Yana River

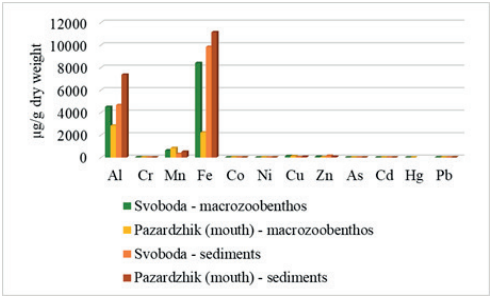

Figure 6. Content of heavy metals and metalloids in macrozoobenthos (µg/g dry weight) and sediments (µg/g dry weight) from the Luda Yana River

Bioconcentration factors (BCF) in the macrozoobenthos compared to Svoboda biotope waters have the highest values for Pb ($BCF_{Pb}$=38.04) and Fe ($BCF_{Fe}$=10.87), and the lowest for Ni ($BCF_{Ni}$=0.15).

The macrozoobenthos accumulated 253.6 times more Pb and 72.47 times more Fe from the waters compared to Ni. The values of the bioconcentration factor in the macrozoobenthos compared to sediments from the Svoboda biotope are the highest for Cu ($BCF_{Cu}$=3.97) and Cr ($BCF_{Cr}$=2.94), and the lowest for Zn ($BCF_{Zn}$=0.51). The macrozoobenthos accumulated 7.78 times more Cu and 5.77 times more Cr from the sediments than Zn. The values of the bioconcentration factor (BCF) in the macrozoobenthos compared to waters from the Pazardzhik biotope have the highest values for Al ($BCF_{Al}$=1329805.20) and Pb ($BCF_{Pb}$=132536.54), and the lowest for Hg ($BCF_{Hg}$=75.00). The macrozoobenthos accumulated 17730.74 times more Al and 1767.15 times more Pb from the waters compared to Hg. Bioconcentration factors in the macrozoobenthos compared to sediments from the Pazardzhik biotope are highest for Cd ($BCF_{Cd}$=2.67) and lowest for Fe ($BCF_{Fe}$=0.20). The macrozoobenthos accumulated 13.35 times more Cd from the sediments than Fe. According to the reported BCF values, the macrozoobenthos from the Pazardzhik can be determined as highly bioaccumulative (BCF>5000; Khan et al., 2022) of the elements Al, Pb, Co, Mn, Cu, Zn and Ni (Table 5). The obtained extremely high BCF values for Al (over 1.3 million) and for Pb (over 130 thousand) are due to a potential short-term dilution of the dissolved metals in the water samples at the river mouth during the sampling period (spring season) in contrast to the stable, long-term accumulation within the macrozoobenthos tissues.

Monitoring the content of heavy metals and metalloids in biota, waters and sediments from the Svoboda biotope is justified by the nearby suspected source of anthropogenic load - the Radka mine and the existing risk of pollution of the river ecosystem in this area. While the choice of the Pazardzhik biotope is related to the need to monitor the ecological state of the river ecosystem and the load with heavy metals and metalloids downstream, before the confluence of the Luda Yana River into the Maritsa River.

In the present study, excesses of six heavy metals and metalloids were found in macrozoobenthos samples, in accordance with the norms specified in Regulation No. 31 (2004), Dineva (2023), and Commission Regulation (EU) 2023/915. In the macrozoobenthos samples from the Svoboda, higher excesses of Al, Cr, Cu and Pb were

found compared to the macrozoobenthos from the Pazardzhik. Higher excesses of Ni and Cd were found in the macrozoobenthos samples from the Pazardzhik. In both biotopes from the Luda Yana River, no excesses of Zn, As and Hg were detected in the macrozoobenthos samples (Figure 7).

The results of the chemical analyses of surface water samples from the Luda Yana River, Svoboda biotope, show an excess of Al, 18.76 times above the maximum permissible concentrations (MPC) specified in Regulation No. H-4 (2012), and an excess of Cd – 0.18 times above the MPC specified in the Regulation on environmental quality standards (2010). In the surface water samples from the Pazardzhik, no excesses of the examined heavy metals and metalloids were found according to the norms specified in Regulation No. H-4 (2012), Regulation No. 18 (2009) and Regulation on environmental quality standards (2010). In sediment samples from the Luda Yana River, Svoboda, an excess was reported only for Zn, 1.05 times above the Dutch target values (2000). In the sediments from the Luda Yana River, Pazardzhik, exceedances were found for Co (1.25 times), Cu (1.79 times) and Pb (1.51 times) compared to the Dutch target values (2000). In both biotopes, the content of the examined heavy metals and metalloids did not exceed the norms specified in Regulation No. 3 (2008).

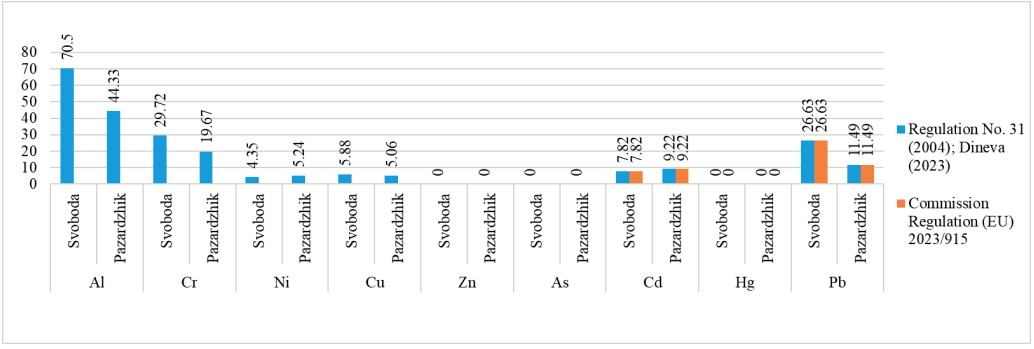

Figure 7. Excesses (in times) of the investigated heavy metals and metalloids in macrozoobenthos samples from the Luda Yana River

Gartsiyanova et al. (2020) investigated spatio-temporal changes in water quality of the Luda Yana River (at Rosen and before the mouth) and the Strelchanska Luda Yana River (after Strelcha) for the period 1981-2018 using complex indices to assess water quality status. The authors report that during the study period, the waters of the Luda Yana River did not meet

the requirements for good chemical status under Regulation No. H-4 (2012). The worst and critical values of the Water Quality Index were established for the Luda Yana River near Rosen. Gartsiyanova et al. (2021) investigated the state of the water in the Luda Yana River (at Rosen and at the mouth) using various indices. The authors define the waters as slightly polluted according to the Bavarian Surface Quality Index (CJ) and as polluted and highly polluted according to the Water Pollution Index (WPI) at Rosen; as well as absent to lightly polluted by CJ and moderately to heavily polluted by WPI at the mouth. The authors explain the bad quality of the water with increased levels of Fe, Mn, and Cu, as well as with high values of the indicators BOD5, ammonium, and nitrate nitrogen. In the present study, a very bad ecological state was found for the Rosen, and a bad state for the Pazardzhik biotope (mouth). In the waters of the Luda Yana River at Pazardzhik, the highest Fe and Mn content was also found, which, however, does not exceed the norms of national and international legislation. Gartsiyanova et al. (2022) investigated the water quality of the Strelchanska Luda Yana River (after Strelcha); on the Luda Yana River (near Popintsi and near Chernogorovo) through the use of physicochemical parameters and heavy metals (Cu, Fe, Mn, Pb, As, Zn, Cd and Ni). The authors indicate that the Luda Yana River in the section near Popintsi is the most polluted, and the one near Chernogorovo is in the best quality, and report persistent and significant pollution with heavy metals (Fe, Mn, Cd and Cu). In the current study of the Luda Yana River, the best ecological state (moderate) was recorded in the Popintsi compared to the other investigated biotopes. Gartsiyanova et al. (2023) analysed the water quality by physicochemical parameters in the catchment basin of the Luda Yana River for the period 2018-2021. The authors defined the waters of the Luda Yana River as highly polluted due to long-term anthropogenic impacts and reported elevated levels of some heavy metals. The authors identify the most favourable conditions for the Luda Yana River from mouth to source.

## CONCLUSIONS

The ecological state of the waters of the Luda Yana and Strelchanska Luda Yana Rivers was assessed based on the taxonomic diversity and abundance of the indicator macrozoobenthos. The values of the calculated metrics and indices show a moderate ecological state of the Luda Yana River upstream (Popintsi biotope – BI(nEQR)=3(0.6)), very bad for the Strelchanska Luda Yana River at the Strelcha biotope (Number of EPT taxa – 0; Rithron Feeding Type Index=0.004; BI(nEQR)=1(0.3)), for the Luda Yana River at the Svoboda (Rithron Feeding Type Index=0.19) and Rosen (Rithron Feeding Type Index=0.20; BI(nEQR)=2(0.2)), as well as bad ecological state of the Luda Yana River before its confluence with the Maritsa River (Pazardzhik biotope – BI(nEQR)=2(0.4)). In addition, the chemical analyses performed on samples from the Svoboda and Pazardzhik biotopes revealed high contents of Fe, Al and Mn. More than half of the investigated heavy metals and metalloids have higher concentrations in the macrozoobenthos from Svoboda than in those from Pazardzhik (mouth). The content of all investigated heavy metals and metalloids was higher in the waters from Svoboda and higher in the sediments from Pazardzhik (mouth), except for Zn and Cd. According to the reviewed legislative documents, the highest exceedances were found for Al (70.5 and 44.33 times), Cr (29.72 and 19.67 times), Pb (26.63 and 11.49 times) and Cd (7.82 and 9.22 times) in the macrozoobenthos samples (from Svoboda and Pazardzhik, respectively), and for Al (18.76 times) in the water samples from Svoboda. Based on the monitoring carried out, permanent and more in-depth studies of the ecological state of the waters of the Luda Yana River and its tributaries, as well as the content of heavy metals and metalloids in river ecosystems, especially in areas with potential sources of anthropogenic load, are recommended in order to protect biodiversity, habitats and ensure a favorable environment for the life of hydrobionts.

## ACKNOWLEDGEMENTS

This work has been carried out within the framework of the National Science Program "Critical and strategic raw materials for a green transition and sustainable development", approved by the Council of Ministers' Resolution № 508/18.07.2024 and funded by the Ministry of Education and Science (MES) of Bulgaria. We express our gratitude to Assoc. Prof. Veronika Mihaylova, PhD, for the assistance and consultations provided in connection with the chemical analyses.

***Abstract***

*Urbanisation strongly influences water quality and the structure of microbial communities in aquatic ecosystems. This study investigates seasonal variations in physicochemical parameters and microorganisms in three urban lakes in Bucharest (Tineretului, Titan 1 and Titan 2) and one peri-urban lake (Comana). Samples were collected from five stations per lake during summer and autumn. Physicochemical parameters (temperature, pH, ORP, dissolved oxygen and TDS) were measured in situ, and bacterial communities were assessed by determining heterotrophic bacteria, total and faecal coliforms, and faecal streptococci, respectively.*
*The results revealed clear differences between urban and peri-urban lakes. The lakes in Bucharest presented increased TDS values (up to 738 ppm) and an alkaline pH (up to 10 in Titan 2), reflecting anthropogenic pressure. Bacterial abundance was higher in Titan 1 and Titan 2, where heterotroph density exceeded $10^3$ CFU·mL$^{-1}$. Faecal coliforms were sporadically detected in urban lakes, but were absent in Comana, indicating point sources of contamination. The findings suggest that urbanisation causes significant changes in water quality and microbial load, highlighting the need for integrated monitoring for sustainable management of urban lakes.*

***Key words****: anthropogenic impact, microbial contamination, physicochemical parameters, urban lakes, water quality.*

## INTRODUCTION

Freshwater ecosystems, especially urban and peri-urban lakes, are critical components of regional biodiversity and provide essential ecosystem services, but are increasingly threatened by anthropogenic activities (Kapetanović et al., 2024). These aquatic environments are highly susceptible to environmental change and serve as indicators of landscape health due to their vulnerability (Roguet & Lucas, 2012). Their ecological integrity is frequently compromised by pollution, nutrient enrichment and habitat degradation, often resulting from human activities in adjacent areas (Lazăr et al., 2017; Mititelu-Ionuș et al., 2020).
The microbial communities in these lakes are particularly sensitive to such disturbances, reflecting changes in water quality and overall ecosystem health (Kiersztyn et al., 2019). Microorganisms play a central role in the functioning of aquatic ecosystems, being involved in the biogeochemical cycles of carbon, nitrogen and phosphorus, as well as in the degradation of organic matter. Bacterial communities in lakes respond rapidly to environmental changes, making them important indicators of ecological status and water quality (Marcondes et al., 2024). Added to this is the escalating impact of global change and land-use changes, emphasising the need for comprehensive studies focused on bacterial populations in urban lake environments to identify reliable indicators of ecological status and emerging pathogens in water (Orel et al., 2022).
Classical microbiological indicators, such as heterotrophic bacteria, total coliforms, faecal coliforms and faecal streptococci, are widely used to assess water quality and identify sources of faecal contamination. The presence of these microorganisms is often associated with risks to human health and deterioration of

ecosystem health, especially in recreational lakes (Lazăr et al., 2017; Lew et al., 2023).

Globally, extensive research has focused on the application of these microbiological indicators to assess water quality in diverse aquatic environments (Loucif & Chenchouni, 2024). For example, studies in lakes in Turkey have correlated bacterial diversity with environmental factors, indicating the presence of wastewater and agricultural runoff even when coliform counts were not exceptionally high (Mercan & Arslan, 2023). Similarly, in Brazil, investigations in urban aquatic systems have used these bacterial indicators to assess the efficiency of wastewater treatment plants and to identify sources of pollution affecting recreational waters, highlighting their broad utility in environmental monitoring. In the Romanian context, research has similarly used these microbial indicators to assess water quality in various freshwater bodies, revealing contamination patterns influenced by urban development and agricultural practices (Lazăr et al., 2017).

In Romania, information on the structure of microbial communities and their relationships with water physicochemical parameters in urban lakes remains limited, especially in the southern region. Given the accelerated expansion of urban areas and the importance of lakes in Bucharest for recreation and local ecological balance, an integrated assessment of water quality from this perspective was of interest.

This study aims to address this knowledge gap by investigating microbial patterns in urban and peri-urban lakes in southern Romania, focusing on how these patterns reflect water quality and ecosystem health under varying degrees of anthropogenic pressure.

Therefore, the main objectives were: (i) assessing seasonal variations of physicochemical parameters and microbiological indicators in urban and peri-urban lakes in southern Romania, (ii) evaluating the relationship between microbiological indicators and physicochemical factors contributing to a better understanding of the impact of urbanisation on the health of aquatic ecosystems.

## MATERIALS AND METHODS

### Study site

Four representative ecosystems were selected in the study: 3 urban lakes in Bucharest (Tineretului, Titan 1 and Titan 2) and a peri-urban lake, as part of the Comana Natural Park (Balta Comana), Giurgiu County in southern Romania, in order to capture how these models reflect water quality and ecosystem health under varying degrees of anthropogenic pressure (Figure 1). Five stations were established for the urban lakes Titan 1, Titan 2, and Tineretului, and three for Balta Comana.

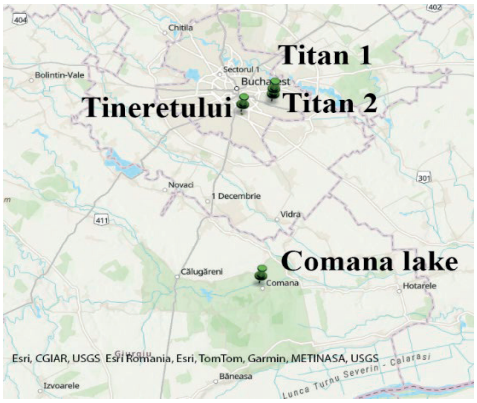

Figure 1. Study site with sampling ecosystems

### Water sample collection

Water-column samples were collected in the summer and autumn of 2024. Using GPS, five sampling points were selected for Lake Tineretului, Titan 1 and Titan 2, whereas three sampling points were selected for Lake Comana. The samples collected into sterile containers, stored, and transported at 4°C were analysed within 24 hours of sampling.

### Measurement of physicochemical parameters

From the water column, a series of physicochemical parameters (oxidation–reduction potential, temperature, percentage saturation of dissolved oxygen, pH, and turbidity) was measured *in situ* with a HI 9828 multi-parameter probe (Hanna Instruments, Woonsocket, RI, USA).

**Microbial analysis**

To perform the quantitative analyses, a serial dilution was prepared.

Using the pour plating method to quantify *heterotrophic bacteria*, sterile Petri plates were inoculated with 1 mL aliquots from each dilution for every replicate. After inoculation, 15 ml of nutrient agar medium (sterile broth media with 20 $g \cdot L^{-1}$ agar), molten and cooled at 45°C, was poured onto the plates and incubated at 37°C. After 48 hours, heterotrophic bacteria counts were determined (Jackson et al. 2000; Sanders, 2012).

The most probable number (MPN) technique was used to determine the number of *faecal coliforms* and *faecal streptococci*. For each dilution and each sample, three tubes were inoculated. MacConkey broth (bile lactose bromcresol purple medium) was added for the cultivation of faecal coliforms, while sodium azide broth containing bromcresol purple was added for the cultivation of faecal streptococci. The inoculated tubes were incubated at 45 °C for 24 h for faecal coliforms and 48 h for faecal streptococci (Berg et al., 1978; Maul & Block, 1983; Sinton et al., 1998; Gronewold &Wolpert, 2008).

To determine the colony-forming units (CFU) of total coliforms, 1 mL of each serial dilution for each duplicate was added to eosin-methyl blue media. The plates were incubated at 37°C for 24 hours (An et al., 2002).

**Data processing**

Violin plots and boxplots were used to display the data distribution. Boxplots were used to highlight the essential statistics of the sample (median and quartiles), while violin plots visualised the full shape of the distribution, including any multimodality and density variations. The width of the violin plot reflects the local density of the data, providing a more detailed picture of the distribution's structure than the quartile representation alone. Combining the two types of graphs provided a more comprehensive characterisation of the data, integrating both central tendency and distributional peculiarities relevant to the interpretation of the results (Hu, 2020).

Heatmaps are powerful visualisation tools for displaying two-dimensional data, effectively revealing patterns shared across subsets of rows and columns. This package excels at connecting multi-source information, making it broadly applicable in diverse data analysis fields, particularly in bioinformatics and genomics (Gu, 2022).

The two-factor ANOVA method examines the simultaneous influence of two qualitative independent variables (factors), in this case, months and lakes, on a quantitative dependent variable, along with their possible interactions. This factorial design allows investigation of the main effects of each factor (month and lake) and detection of a statistical interaction, in which the effect of one factor is modified by the levels of the other factor. A factorial design analyses the effects of two independent variables on a single continuous dependent variable, yielding three results: a main effect for each independent variable and an interaction between the two (Andrade, 2024).

Redundancy Analysis (RDA) is a constrained ordination method used to quantify the relationships between microbial community composition and environmental variables. The technique models variation in abundance data as a function of explanatory factors, allowing the significance of interaction terms to be assessed within a linear framework. RDA extends multivariate regression to multivariate response sets, estimating explained variance and facilitating direct comparison between the community matrix and the environmental variable matrix (Legendre et al., 2010). The software used was Past version 5.2.1, Xlstat add-in 2014 and R-studio R 4.5.2.

## RESULTS

**Physicochemical characterisation of urban and peri-urban lakes**

The temperature boxplots showed a relatively wide distribution of temperatures across all lakes (Figure 2 – Temperature). The water temperature varied across the lakes, with mean values of approximately 17.58-21.74°C, indicating a moderate-to-warm thermal regime during the study period. The minimum values recorded ranged from 6.23°C (Titan 2) to 14.76°C (Comana), and the maximum values ranged between 28.52°C (Titan 2) and 32.23°C (Comana). The means were 21.74°C (Comana), 21.74°C (Tineretului), 17.58°C (Titan 1) and

18.75°C (Titan 2). Also, the boxplots of the lakes showed distinct thermal regimes in Tineretului and Comana, compared to the two Titan lakes, indicating that, in the dynamics of summer and autumn temperatures, the two ecosystems showed lower exposure to extreme values. The two lakes exhibited a stable thermal regime, characterised by progressive warming and cooling of the water without sudden fluctuations.

Regarding pH, the values generally indicated an alkaline range, with minimum values between 8.63 (Titan 1) and 8.91 (Tineretului), and maximum values between 9.53 (Titan 1) and 10.30 (Comana). The averages were 9.58 (Comana), 9.41 (Tineretului), 9.27 (Titan 1) and 9.43 (Titan 2). The differences in the profile of the violin-type boxplots (Figure 2 – pH) suggested that Comana and Tineretului presented a more homogeneous and stable pH, while the Titan lakes, especially Titan 1, exhibited more pronounced chemical fluctuations, reflected by the asymmetry and shape of the distributions. A stable alkaline pH may reflect intense photosynthetic activity and a relatively well-buffered system, whereas more pronounced pH fluctuations may indicate temporary chemical imbalances, with potential implications for microbial community structure and water quality.

The redox potential (ORP) showed very high variability (Figure 2 – ORP), with a general trend towards more oxidising conditions in the urban lakes than in Comana. Negative minima ranged between -82.90 mV (Comana) and -33.50 mV (Titan 1), and positive maxima up to 138.20 mV (Titan 1). The averages were 21.65 mV (Comana), 48.25 mV (Tineretului), 52.82 mV (Titan 1) and 54.15 mV (Titan 2). The boxplots indicated in Comana a frequent alternation between oxidative and reductive conditions, suggesting a more unstable redox dynamic. The relatively broad distribution shape reflected the influence of natural processes, such as the input of organic matter and microbiological activity, characteristic of a less anthropized system. In contrast, urban lakes showed a tendency to exhibit higher ORP values, with higher averages (48.25 mV - Tineretului < 52.82 mV in Titan 1 < 54.15 mV in Titan 2). Thus, the distributions were more concentrated in the oxidative range, with fewer negative values and less extensive negative values. This profile suggested dominant oxidative conditions, associated with better oxygenation and frequent water mixing, typical of managed urban lakes.

Dissolved oxygen (%DO) presented wide ranges, with minimums between 45.10% (Titan 1) and 64.10% (Tineretului) and maximums between 92.90% (Titan 2) and 156.50% (Comana). The averages were 90.48% (Comana), 97.56% (Tineretului), 70.63% (Titan 1) and 65.51% (Titan 2), suggesting generally good to very good levels of oxygenation, with distributions slightly elongated towards high values in Comana. Differences between urban and natural lakes were also observed in oxygen levels. In Lake Comana, the variations were greater, indicating pronounced fluctuations in oxygenation, including frequent episodes of supersaturation. In contrast, in urban lakes, the distributions were more compact and better centred, which explains moderate levels of dissolved oxygen and a lower variability (Figure 2 – DO).

TDS values revealed pronounced differences between urban lakes and Lake Comana, as clearly reflected in the boxplot (Figure 2 – TDS). In Lake Comana, TDS ranged from 381 to 619 mg/L, with an average of 500.33 mg/L, and the relatively wide distribution indicated moderate variability in water mineralisation. The boxplot of the lake highlights seasonal fluctuations in dissolved salt supply, typical of natural ecosystems. In contrast, in urban systems, the boxplots indicate high values, within much lower limits. Lake Tineretului presented the highest values (614-738 $mg \cdot L^{-1}$), with an average of 672.90 $mg \cdot L^{-1}$, and was characterised by a high and constant mineralisation, typical of urban areas. In Titan 1, TDS ranged from 512 $mg \cdot L^{-1}$ to 591 $mg \cdot L^{-1}$, with an average of 547.10 $mg \cdot L^{-1}$ and a relatively compact distribution. In Titan 2, although the average was lower (474.70 $mg \cdot L^{-1}$), the wide range (258-558 $mg \cdot L^{-1}$) suggested greater variability, likely associated with episodic water intakes with varying mineralisation.

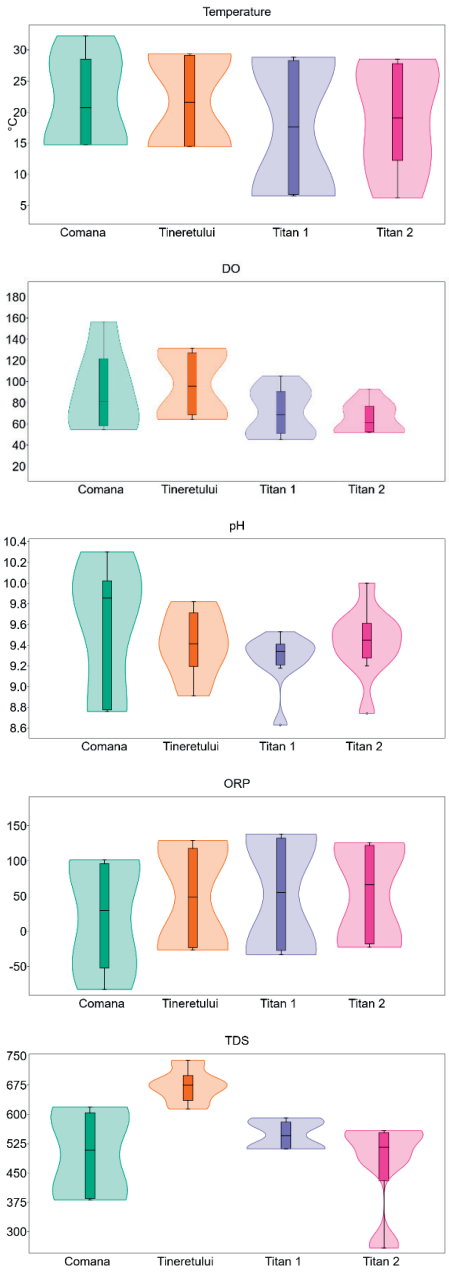

Figure 2. In situ variations of measured physicochemical parameters

**Features of microbial communities in the studied ecosystems**

Microbiological evaluation using general indicators of microbial load (heterotrophic bacteria - HB, total coliforms - TC) as well as specific indicators of faecal contamination (faecal coliforms - FC, faecal streptococci - FS) highlighted varying degrees of anthropogenic pressure on urban lakes.

In Lake Comana, faecal contamination was absent, whereas in urban lakes it was present at varying intensities, indicating episodes of faecal pollution (Figure 3). In Lake Comana, established as a reference system for anthropogenically unaffected conditions, the absence of faecal indicators (FS and FC) and the high productivity of HB confirm the characteristic resilience of these systems. Microbiological values recorded in Comana revealed a stable natural bacterial background, with HB ranging between 2400–8300 CFU·mL$^{-1}$ (mean 5033±1959), low TC (range 2–6, ± 2.53 CFU mL$^{-1}$) and the complete absence of FC and streptococci (0 in all samples), indicating optimal conditions of relatively stable aquatic biota, possibly related to the productivity and organic matter specific to the natural lake (Figure 3).

This ecosystem contrasts sharply with urban lakes, where anthropogenic pressures have produced much more variable microbiological patterns. The high variability in urban lakes underscores the stark contrast between the stability of the natural Comana ecosystem and the disturbed dynamics of urban lakes under anthropogenic pressure.

In Tineretului, the overall microbial load was the highest among all urban ecosystems, with TC reaching 28 CFU·mL$^{-1}$ (mean 7.2 ± 7.87), while faecal contamination remained low (FC 0-0.4, FS average 0.9-0.98), suggesting non-faecal organic inputs (from typical park sources - leaves, sediments, human activity).

Titan 1 and Titan 2 presented the most intense episodes of faecal contamination, with maximum FC of 25 CFU·mL$^{-1}$ (means 4.8 and 4.1, ± 7.7) and FS with maxima between 2.5-4.5 CFU·mL$^{-1}$, indicating irregular inputs of faecal origin.

From the perspective of heterotrophic bacteria, Titan 1 showed intermediate values (300-2600), while Titan 2 showed the greatest ecological instability, with HB ranging from 109 to 8500 CFU·mL$^{-1}$ (average 2550.9), reflecting episodes of intense bacterial proliferation and possible local eutrophication.

The high variability of HB in Titan 2 indicated a pronounced ecological instability, possibly

related to irregular nutrient inputs and unfavourable conditions.

In these ecosystems, the development of coliforms, associated with high levels of heterotrophic bacteria, highlighted differences in the microbiological features of urban lakes compared to those of the natural Lake Comana.

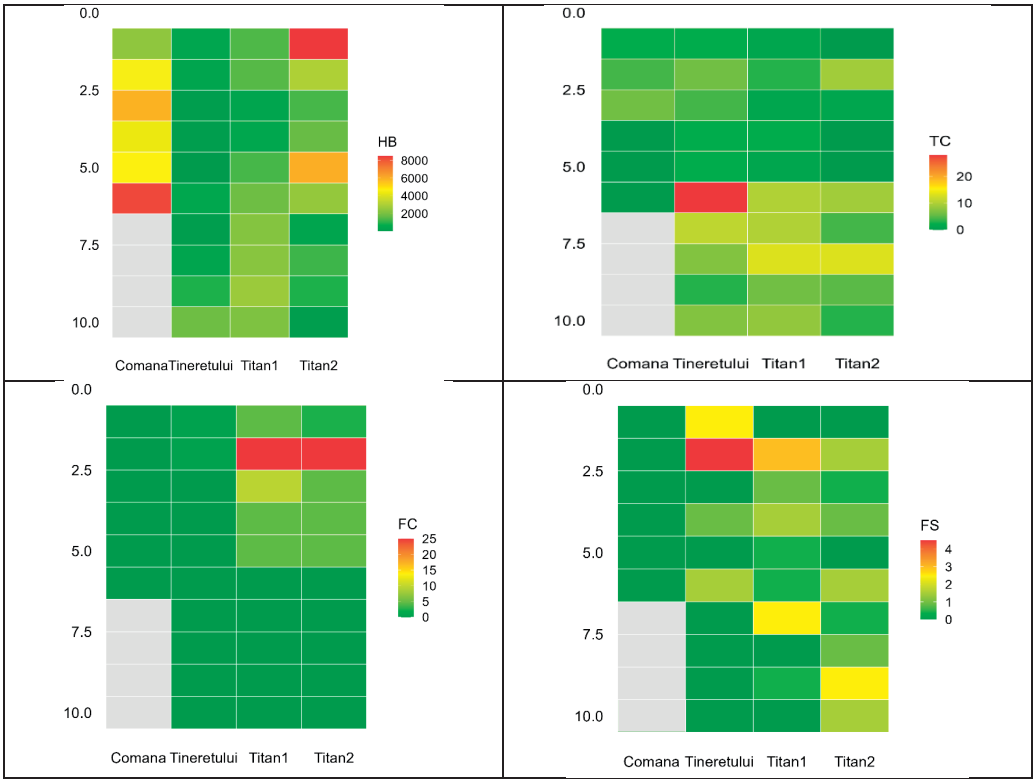

Figure 3. Heatmaps of the abundance of the investigated microbial communities

**Seasonal dynamics and interaction with anthropogenic pressure**

HB bacteria showed distinct spatial and seasonal variations (Table 1), so during the summer the abundances were higher (mean values $5.77\times10^3$ CFU·mL$^{-1}$ - Comana > $2.20\times10^3$ CFU·mL$^{-1}$- Titan 1 > $1.00\times10^3$ CFU·mL$^{-1}$ - Titan 2 > $7.00\times10^2$ CFU·mL$^{-1}$ - Tineretului), compared to the autumn values (mean values - $4.30\times10^3$ CFU·mL$^{-1}$ - Comana > $4.10\times10^3$ CFU·mL$^{-1}$ - Titan 2 > $9.80\times10^2$ CFU·mL$^{-1}$ - Titan 1> $1.77\times10^2$ CFU·mL$^{-1}$ - Tineretului).

TC were absent in Comana in summer (0.00), but were detected in autumn (4.00 CFU·mL$^{-1}$), while in Tineretului the values were higher in summer (11.20 CFU·mL$^{-1}$) compared to autumn (3.20 CFU·mL$^{-1}$).

In Titan 1 and Titan 2 lakes, total coliforms also recorded a decline from summer (9.40 and 6.80 CFU·mL$^{-1}$, respectively) to autumn (means values 1.60 and 2.00 CFU·mL$^{-1}$) (Table 1).

FC, absent in both seasons in Comana, were detected in urban ecosystems, in high abundances in autumn in Titan 1 (9.60 CFU·mL$^{-1}$) and Titan 2 (8.20CFU·mL$^{-1}$).

FS were also present in urban ecosystems, with distinct trends across the three ecosystems investigated.

They were characterised by increases from summer to autumn in Tineretului and Titan 1, whereas in Titan 2, the values were higher in summer (1.36 CFU·mL$^{-1}$) than in autumn (0.56 CFU·mL$^{-1}$) (Table 1).

Table 1. Descriptive statistics and seasonal changes in microbiological indicators (s - summer; a - autumn)

| Type | | Minimum | Maximum | Mean | SD (n-1) |

Two-way ANOVA analysis revealed significant differences in microbial community structure by ecosystem type and season, with effect sizes varying across the analysed microbiological indicators (Table 2).

For HB, the model explained a high proportion of the total variation ($R^2 = 0.71$) and showed a strong overall effect ($F = 10.02$, $p < 0.0001$). Spatial differences were dominant, with values being significantly more different between urban and natural lakes ($F = 17.09$, $P < 0.0001$). The lake × season interaction was also significant ($F = 6.11$, $p = 0.00$), suggesting that HB seasonal dynamics were influenced by ecosystem type, with distinct responses in urban versus natural lakes.

For TC, the ANOVA model explained 69% of the total variation ($R^2 = 0.69$), indicating a significant overall effect ($F = 9.02$, $p < 0.0001$). TC showed both spatial ($F = 5.00$, $p = 0.01$) and seasonal ($F = 7.57$, $p = 0.01$) differences, also reflected in the lake×season interaction (F

= 10.57, $p < 0.0001$). The results show that seasonal amplitude varied across ecosystems, highlighting the indicator's high sensitivity to environmental changes.

For FC, the model had the highest explanatory power ($R^2 = 0.8$, $F = 26.84$, $p < 0.0001$). Both the ecosystem factor ($F = 18.21$, $p < 0.0001$) and the period ($F = 60.63$, $p < 0.0001$) significantly influenced FC concentrations, indicating a pronounced variability also in the lake×season interaction (Table 2). In contrast, FS showed reduced variability, with the model explaining only 30% of the total variation ($R^2 = 0.30$) and no significant overall effect ($F = 1.73$, $p = 0.14$). No significant spatial or temporal differences in the FS distribution were found, highlighting a uniformity of FS across ecosystems and seasons, reflecting a good ecological stability or reduced sensitivity to the analysed factors.

Table 2. Two-Way ANOVA results for microbiological indicators by lake and season

| | **HB** | **TC** | **FC** | **FS** |
|---|---|---|---|---|
| $R^2$ | 0.71 | 0.69 | 0.87 | 0.30 |
| F | 10.02 | 9.02 | 26.84 | 1.73 |
| p | < 0.0001 | < 0.0001 | < 0.0001 | 0.14 |
| Lake | 17.09 | 5.00 | 18.21 | 2.23 |
| | < 0.0001 | 0.01 | < 0.0001 | 0.11 |
| Season | 0.59 | 7.57 | 60.63 | 0.23 |
| | 0.45 | 0.01 | < 0.0001 | 0.64 |
| Lake×Season | 6.11 | 10.57 | 18.21 | 1.70 |
| | 0.00 | < 0.0001 | < 0.0001 | 0.19 |

RDA analysis indicates a separation of microbial communities based on physicochemical water conditions (Figure 4). RDA results indicated an $R^2$=0.23 (23% total explained variation) and $R^2$adj=0.10 (10%), indicating a moderate effect of physicochemical factors on microbial communities, but significant ($F$=1.85, $p$=0.03 at 999 permutations). Axis 1 dominates (69% of the explained variation), explaining the clear separation Titan/Tineretului vs. Comana; Axis 2 (21%) details the differences TC vs. FC/FS/HB. FS and FC were associated with Axis 1 and were influenced by ORP and pH in the anthropogenic conditions of Titan 1 and Titan 2 lakes, indicating recent faecal inputs. In contrast, HB was positioned in the opposite plot to FC and FS, favoured by oxygenated conditions (% DO) with lower temperatures, indicating distinct niches of heterotrophic bacteria compared to faecal indicators. On the other hand, TC, separated from the other microbial communities, was associated with Axis 2, influenced by increases in temperature and oxygen, and, to a lesser extent, by TDS, indicating distinct ecological conditions. The analysis also shows that, depending on environmental conditions and trends in microbial communities, the studied ecosystems were clearly separated. Thus, urban ecosystems are found in the upper part of the plot, whereas Lake Comana is located in the opposite part; faecal indicators (FC/FS) were the main drivers of ecosystem separation and also validate sources of anthropogenic pollution in urban sites.

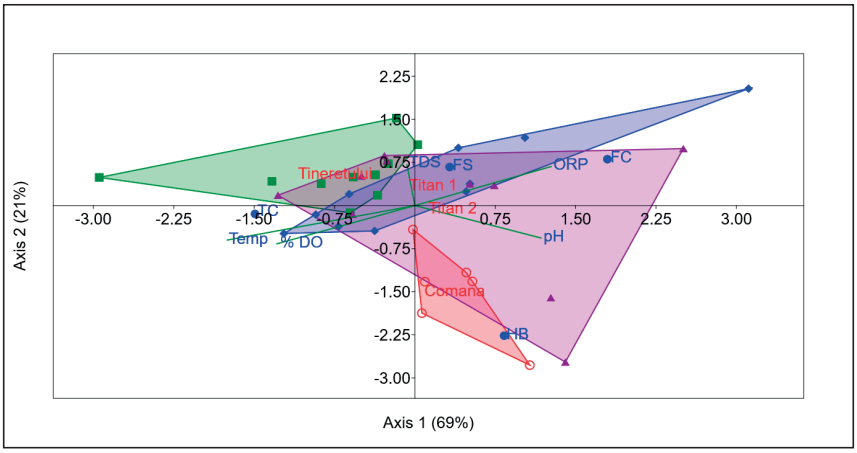

Figure 4. Redundancy analysis (RDA) reveals the relationships between microbial communities and environmental parameters in the investigated aquatic systems

## DISCUSSIONS

The results of our study highlighted a close relationship between the structure and dynamics of microbial communities and environmental conditions in the investigated lakes, demonstrating the impact of the urbanisation gradient and seasonal variability on these communities. Unlike classical descriptive microbiological approaches, the integrated analysis of environmental parameters and microbiological indicators highlighted the ecological mechanisms that control the dynamics of HB communities, as well as those of TC, FC, and FS. Higher values in the warm season were associated with increased abundances of HB across all ecosystems (Figure 2 and Table 1), highlighting the role of temperature in intensifying organic matter degradation. However, the response of microbial communities to this factor varied across ecosystem types. At the peri-urban Lake Comana, HB growth in summer was relatively uniform and correlated with the natural availability of organic matter, indicating a system predominantly controlled by internal processes. In contrast, in urban lakes, especially Titan 2, the high variability of HB suggests an amplified response to episodic nutrient inputs, probably associated with urban runoff and sediment resuspension. Thus, water temperature has been shown to be a primary factor regulating microbial activity, directly influencing metabolic processes and bacterial growth rates (White et al., 1991; Nedwell, 1999). In addition, the alkaline and relatively stable pH created a favourable framework for the development of bacterial communities, but differences in variability between lakes indicate distinct control mechanisms (Wetzel, 2001; Dippong et al., 2023). The stability of pH in Comana and Tineretului suggests a well-buffered system, whereas the more pronounced fluctuations in Titan lakes may reflect temporary imbalances induced by anthropogenic processes, affecting the selection of bacterial taxa tolerant to chemical variations. These differences may contribute to more homogeneous microbial structures in peri-urban lakes and more heterogeneous in urban ones. Instead, redox potential and dissolved oxygen played a central role in the differentiation of microbial niches (Baqué, 2006; Fenchel et al., 2012). In Lake Comana, the alternation of oxic and suboxic conditions (Figure 2 - ORP and DO) favoured the coexistence of microbial communities adapted to variable micro-niches, which explains the general stability of the communities and the absence of faecal indicators. The pronounced fluctuations in dissolved oxygen in the peri-urban Lake Comana reflect a natural ecological control dominated by the circadian cycles of photosynthesis and respiration, amplified by algal and macrophytic biomass and by the mineralisation of organic matter in sediments (Cristini et al., 2017). This dynamic indicates both an intrinsic self-purification capacity and

an increased susceptibility to episodes of benthic hypoxia or anoxia, with direct effects on the distribution and activity of microbial communities and on redox-dependent biogeochemical processes (Tolu et al., 2017). In contrast, the relative stability of dissolved oxygen in urban lakes suggests a more strongly anthropogenically controlled system, influenced by active management, shallow depth, and frequent water-column mixing, which limit stratification and the accumulation of hypoxic zones (Carnohan, 2021; Maier et al., 2021). However, during warm periods, local persistence of low oxygen in the lower layers can favour the release of phosphorus from sediments and intensify eutrophication, with implications for microbial community structure (Radu et al., 2019). In contrast, the predominantly oxidative and more uniform conditions in urban lakes favoured aerobic processes and the persistence of bacteria associated with recent contamination, reflected by the presence of FC and FS (Figure 3). The high and constant TDS values in urban lakes indicate a persistent chemical pressure, which may act as an ecological filter, favouring bacterial communities adapted to increased mineralisation and osmotic stress (Paul & Meyer, 2001; Ghervase et al., 2011). In Comana, moderate TDS variability suggests natural control of mineralisation, without inducing major changes in microbial community structure.

The spatial distribution of microbial communities (Figure 3) clearly reflects the urbanisation gradient, as reported in other urban and peri-urban aquatic ecosystems (Newton et al., 2011; Staley et al., 2013). Lake Comana presented a microbiological profile characteristic of natural ecosystems, dominated by indigenous HB and lacking indicators of faecal contamination. This structure suggests a predominance of autochthonous organic matter and an efficient control of self-purification processes. In contrast, urban lakes showed much more heterogeneous spatial patterns. Titan 1 and Titan 2 were characterised by recurrent episodes of faecal contamination, indicating active or intermittent local sources. The differences between these two lakes, especially the extreme variability of HB in Titan 2, suggest a higher degree of ecological instability, possibly related to morphometry, water residence time and intensity of anthropogenic inputs. Lake Tineretului occupied an intermediate position, with high overall microbial loads but low faecal contamination, indicating a dominance of non-faecal organic sources.

Seasonality amplified differences between ecosystems (Table 1), in agreement with patterns observed in temperate lakes under anthropogenic pressures (Sommer et al., 2012; Lazăr et al., 2017). In urban lakes, increasing temperatures and warm-season rainfall events were followed by higher total coliform levels, and, in some cases, by an increase in faecal contamination until autumn. This seasonal lag suggests the accumulation and persistence of faecal bacteria in sediments, followed by resuspension and remobilisation. In Comana, seasonal variations were less pronounced and were not associated with the appearance of faecal indicators, indicating a more resilient system to seasonal fluctuations. The presence of TC only in autumn can be interpreted as due to sediment resuspension or natural inputs, with no direct link to faecal pollution.

The ANOVA results (Table 2) confirm that ecosystem type is the main determinant of microbial community structure, with season having a secondary but significant role in urban ecosystems. The lake × season interaction indicates that the response of microbial communities to seasonal variations is modulated by the degree of urbanisation. Here, the RDA biplot (Figure 4) integrates these observations, highlighting the clear separation of urban lakes from Comana based on the association of faecal indicators with ORP, pH and TDS, a pattern frequently encountered in aquatic ecosystems influenced by urbanisation (Borcard et al., 2018; Dimpor et al., 2024). The positioning of HB relative to dissolved oxygen and temperature suggests that natural microbial communities follow ecological trajectories distinct from those influenced by anthropogenic factors. Overall, our results indicate that urbanisation not only influences the level of microbiological contamination but also the stability and predictability of microbial communities. Urban ecosystems are characterised by more dynamic communities, with pronounced fluctuations and rapid

responses to environmental changes, whereas peri-urban ecosystems exhibit more stable communities, driven by internal ecological processes. A relevant observation is the potential role of sediments as a microbiological reservoir, especially in urban lakes, where seasonal remobilisation can significantly contribute to the dynamics of bacterial communities (Jamieson et al., 2005; Pachepsky & Shelton, 2011). Also, differences between urban lakes suggest that geomorphological features of ecosystems can significantly modulate microbial responses to anthropogenic pressure.

## CONCLUSIONS

The natural lake Comana presents stable physicochemical parameters and balanced microbial communities, without faecal contamination, while the urban lakes (Tineretului and Titan) record higher and more variable TDS, ORP, and pH values, associated with the presence of FC and fluctuating number of HB, reflecting anthropogenic pressure. The distribution of microbial communities is correlated with the physicochemical conditions, highlighting clear ecological differences between natural and urban ecosystems and underlining the need for an adapted management of water quality.

***Abstract***

*Our study uses X-ray fluorescence spectroscopy to assess element accumulation in Phragmites australis across three distinct aquatic environments. We identified spatial patterns reflecting both the natural background and varying levels of human influence. Natural freshwater exhibited moderate concentrations of geogenic elements, including calcium (Ca), strontium (Sr), barium (Ba), manganese (Mn), and titanium (Ti). In contrast, urban freshwater showed higher levels of iron (Fe), aluminium (Al), copper (Cu), zinc (Zn), and lead (Pb). This indicates an anthropogenic signature associated with runoff, wastewater, and urban infrastructure. Saline lakes exhibited distinct elemental profiles, characterised by elevated levels of sodium (Na), potassium (K), calcium (Ca), and chloride (Cl). These patterns suggest mineralisation processes and physiological adjustments to cope with salinity stress. Rare elements (astatine (At), found in deltaic and urban locations) indicate localised geochemical traits. The accumulation patterns across ecosystems highlight the dual ecological role of the reed. It acts as a natural filtration system, and it can also serve as a potential vector for transferring elements within food webs. These findings support the use of Phragmites as a bioindicator for assessing environmental quality.*

***Key words****: aquatic ecosystems, element accumulation, environmental risk, natural filtration, Phragmites australis.*

## INTRODUCTION

Aquatic ecosystems are subject to increasing geochemical and anthropogenic pressures from industrial activities, agriculture, urbanisation, and climate change. In these systems, geochemical processes are dynamic, and thus common elements and potentially toxic metals are mobilised, transported, and transformed in water bodies through complex interactions. Under these conditions, emergent vegetation acts simultaneously as a biogeochemical interface, a biological filter, and a bioindicator of environmental conditions. The species *Phragmites australis* (Cav.) Trin. ex Steud, it is extremely widespread and adaptable to different conditions, with a remarkable capacity to colonise diverse habitats, from freshwater ecosystems to hypersaline waterbodies or urban systems. The species is characterised by high biomass production and stress tolerance, which is why it is frequently used in phytoremediation and pollution monitoring studies (Chapligin et al., 2022). In addition, its ability to accumulate elements from sediments, water, and atmospheric deposition makes it a valuable bioindicator of metal contamination and local geochemical processes (Weis & Weis, 2004; Chitimus et al., 2023). The sediment composition, water chemistry, salinity,

hydrological dynamics, and anthropogenic pressures influence the distribution and uptake of elements in aquatic biota. For example, lithogenic elements generally reflect the natural geochemical background and sedimentary features and transport, thus indicating aspects of mineral fractions and detrital processes (Taylor & McLennan, 1995; Cullers, 2002). In saline and hypersaline environments, salinity plays a major control factor, influencing the mobility and bioavailability of elements through complex geochemical processes such as chloride complexation, flocculation, and authigenic precipitation. These processes can significantly modify the distribution of elements, affecting their availability to aquatic organisms and emergent vegetation (O'Day et al., 2004; Warren, 2006; Acosta et al., 2023).

A major focus is on potentially toxic elements such as As, Pb, Cu, Zn, and Ni, which are frequently associated with industrial activities, road traffic, and atmospheric deposition (Pacyna & Pacyna, 2001; Thorpe & Harrison, 2008; Charlesworth et al., 2011). Recently, there has been a particular interest in rare earth elements (REE), which are increasingly used as geochemical tracers due to their conservative behaviour and sensitivity to sedimentary fractionation and transport processes (Piper & Bau, 2013; Song et al., 2023; Hatje et al., 2024). Studying the accumulation of REE in plant biomass can provide valuable information about sedimentary sources, redox conditions and biological uptake mechanisms. In the context of increasing anthropogenic pressure on wetlands, assessing plant elemental uptake offers an integrative approach to understanding biogeochemical processes. X-ray fluorescence (XRF) analysis offers a rapid and robust method for the simultaneous determination of a wide spectrum of elements in biological and sedimentary material (Jenkins, 1999; Mondal et al., 2021).

The aim of the study is to evaluate elemental accumulation in *Phragmites australis* from deltaic, urban, and saline aquatic ecosystems using XRF analysis, and to determine the role of the species as a geochemical bioindicator and natural filter of contaminants. The objectives are: the determination of the elemental composition, the comparison of geochemical traits between *deltaic*, *saline* and urban ecosystems, the identification of potential sources of elements and the evaluation of the influence of ecosystem conditions on the bioavailability of elements.

Despite the extensive use of *Phragmites australis* as a bioindicator, comparative assessments across freshwater, urban, and saline ecosystems remain limited. Existing studies rarely integrate geogenic, anthropogenic, and rare earth element signatures into a unified ecological interpretation. This study addresses this gap by providing a multi-environmental evaluation of elemental accumulation patterns using XRF.

## MATERIALS AND METHODS

***Study site.*** The sampling of *Phragmites australis* specimens was carried out, including both aboveground and belowground biomass from each sampling point from ecotonal areas associated with different types of aquatic waterbodies as follows (Figure 1):

• Brackish/*saline* ecosystems: Braila Salt Lake, Techirghiol Lake and Musura Bay.

• *Urban* freshwater ecosystems: Fundeni and Cernica lakes.

• Danube Delta freshwater ecosystems: Eracle Canal, Sulina Branch and Rădăcinos, La Amiază, Miazăzi, Matița and Bogdaposte lakes.

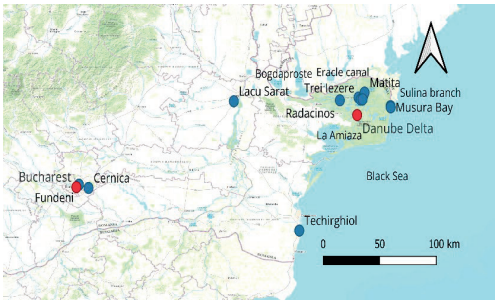

Figure 1. The map of the sampling stations (the red dots-Danube Delta and Bucharest, blue dots - sampling points) - (QGIS 3.40.15- an open-source Geographic Information System)

At each site, three independent *Phragmites australis* specimens were collected to ensure spatial representativeness. Both aboveground and belowground tissues were sampled from individuals located at least 5 meters apart to avoid clonal redundancy. All samples were

collected during the same season to minimize phenological variability.

***Laboratory analysis***. Leaves and roots were separated and prepared for laboratory analysis. The plant material was dried for 2 hours at 60°C, then mechanically ground with a porcelain mortar and pestle. 20 g were taken from each sample, which were subsequently subjected to a calcination process for 2 hours at 550°C in a muffle furnace (Nabertherm LE 6/11/B150). The obtained ash was analysed for elemental composition using a wavelength-dispersive X-ray fluorescence spectrometer (Rigaku ZSX100e, Supermini model). The equipment allows the identification of elements at concentrations of 0.1-100%. For analysis, 1 g of ash was introduced into 30 mm-diameter sample cells, sealed on both sides with 6 μm polypropylene foil, and fixed with a Snap-On ring. The method principle consists of irradiating the sample with X-rays and recording the characteristic reflection angle (θ) for each element. The instrument software converts the signal intensity into mass percentages of elementary oxides (Jenkins, 1999). The percentage values obtained were transformed into absolute concentrations (mg $kg^{-1}$ dry weight) (Mondal et al., 2021). The XRF method may underestimate volatile elements such as Hg, Se, and S due to partial loss during calcination at 550°C. Additionally, elements present near the detection limit (0.1%) may exhibit higher analytical uncertainty. These limitations were considered when interpreting trace and rare element concentrations.

The detected elements were grouped into functional categories based on their predominant ecological role and environmental origin. Classification criteria included geogenic background versus anthropogenic contribution, biological relevance, and toxicity. Thus, elements were assigned to (1) geogenic/macronutrients, (2) anthropogenic and potentially ecotoxic metals, (3) rare earth elements (REE), and elements identified in low/trace concentrations.

***Data processing***. Principal Component Analysis (PCA) was used to explore relationships among the identified elements and to reduce the dataset's dimensionality while preserving most of the total variation (Legendre & Legendre, 2012). Agglomerative Hierarchical Clustering (AHC) was applied to identify similar groupings between elements based on the analysed characteristics (Kassambara, 2017). Analysis of Similarities (ANOSIM) was used to test differences in elemental composition among ecosystem types (Clarke, 1993). The data were transformed by log(n+1). The statistical processing was performed using the XLSTAT add-in (version 2014) and PAST 4.16c (Hammer et al., 2001).

## RESULTS AND DISCUSSIONS

***Elemental composition of Phragmites australis across ecosystem types***.

The results are presented according to the three functional groups of elements: geogenic/macronutrients, anthropogenic metals, and rare/trace elements. Differences among deltaic, saline, and urban ecosystems are highlighted to identify the dominant environmental drivers shaping elemental accumulation in *Phragmites australis*. Analysis of the elemental composition of *Phragmites australis* samples revealed differences in element content across the ecosystems investigated. 58 elements were identified, which varied spatially as follows: 55 *deltaic* > 48 *urban* > 45 *saline* ecosystems. The *urban* environment showed enrichment in metals of anthropogenic origin; the natural *deltaic* ecosystems were dominated by elements indicative of lithogenic input; and the *saline* environments were characterised by elements influenced by the geochemistry of mineralised waters (Table 1, Table 2, and Table 3).

The *deltaic* environment was characterised by elevated concentrations of Fe, Rb, Zr, and elements from the REE category (Table 1, Table 2), indicating the influence of fluvially transported detrital matter and fine sediments rich in mineral fractions. Thus, the composition of the reed in this sector mainly reflected the natural geochemical background and less anthropogenic pressure. In addition, the high variability in Fe, Zn, and Cr may indicate heterogeneous sources and variable conditions for mobilisation and bioaccumulation.

In contrast, in the *saline* lakes, higher concentrations of Hg, Ba, Sr and Mo were recorded (Table 1, Table 3), an association that

may suggest specificities in the mobilisation of elements under conditions of high salinity and a specific redox potential, reflecting the hydrogeochemical characteristics of this type of habitat.

Table 1. The geogenic group elemental concentrations (mg/kg DW) in *Phragmites australis* across *deltaic*, *saline*, and *urban* ecosystems

Elements indicating anthropogenic activity showed an obvious enrichment in the *urban* environment, with higher values recorded for As, Pb, Mn, and Tl (Table 3), as well as Br, suggesting the influence of pollution sources associated with traffic, industrial activities, and atmospheric deposition (Wei & Yang, 2010).

Recent studies have shown that Phragmites australis can effectively bioaccumulate Fe, Mn, Cd, Cr, Ni and Pb, with most metals being retained in belowground tissues, highlighting its phytostabilization potential (Samadi et al., 2024). This distribution supports the reed's ability to retain and integrate metal contaminants from the water column and

sediments, functioning as a biological filter of *urban* pollution.

ANOSIM analysis indicated a statistically significant difference between ecosystems (R = 0.0786, $p$ = 0.0179), with distinct elemental content between at least two of the analysed habitat types. Although the analysis highlights a reduced separation between groups, paired tests indicate that the significant difference is primarily driven by the contrast between *deltaic* and *urban* areas ($p$ = 0.0015). There were no significant differences between *deltaic* and *saline* ($p$ = 0.37) or between *saline* and *urban* ($p$ = 0.29).

Regarding the weight of the groups in the sample (Figure 2), the results showed that geogenic elements (Fe, Ba, Mn, Ti, Ca, K) were dominant, reflecting their structural role and their availability in sediments. The identified elements also varied slightly depending on the habitats evaluated, such as in *deltaic* (Fe>Ba>Mn>Ti), in *saline* (Fe>Ba>Ti>Mn), but in *urban* (Ba>Mn>Ti>Fe) (Table 1, Table 2, Table 3) ecosystems. This predominance reflects the availability of elements, which varies across ecosystems and with plant assimilation under different environmental conditions. In contrast, elements of anthropogenic origin (As, Cr, Zn, Cu, Ni, Pb, Sb) were present at lower levels, but their clear presence indicated external contributions from human activities. This was observed through the dominance of these elements, which varied slightly depending on the type of ecosystem, in the delta (As>Cr>Zn>V), while in the *saline* (As>V>Hg>Pb) and *urban* ecosystems (As>Cr>Pb>V) (Table 1, Table 2, Table 3). N/A values in the tables indicate concentrations below the detection limit of the XRF instrument or signals that could not be reliably quantified due to matrix interferences.

The share of elements with a very low content (trace) as well as of rare earth elements (REE - La, Ce, Nd, Pr or Dy) (Figure 2), may reflect local lithological particularities, but the ability of the reed to accumulate selectively. The REE distribution revealed a differentiated pattern of fractionation across environments (Table 2), suggesting variations in sedimentary sources, redox conditions, and biological absorption mechanisms, providing an ecological indicator (Song et al., 2023). This selective accumulation is essential, as REEs form a chemical group that can facilitate understanding of aquatic or terrestrial conditions, whether natural or anthropogenic (Hatje et al., 2024).

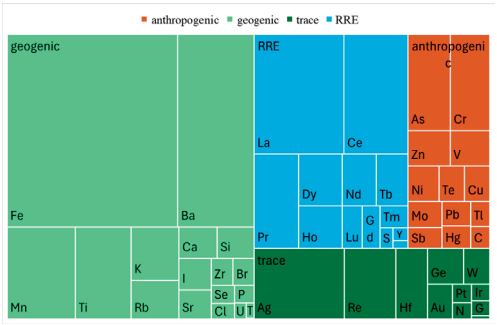

Figure 2. Elemental composition of *Phragmites australis* samples

PCA based on elements indicative of anthropogenic pollution (Figure 3) revealed a close relationship between the *deltaic* and *urban* environments, suggesting common anthropogenic influences or the transport of contaminants into the *deltaic* system, while the *saline* ecosystems remained distinct due to the dominant natural geochemical control. PCA analysis of elements related to anthropogenic sources revealed a cumulative weight of approximately 94% across the two axes. These elemental features confirm the major influence of anthropogenic sources on the reed's elemental composition, especially through contributions from heavy metals from industrial activities, road traffic, and combustion processes. PC1 groups elements of mixed origin, associated with traffic and fuels (Sb, Cu, Ni), fossil-fuel combustion (V, Mo), and industrial activities (Cr, Co, Tl, Te).

The biplot also shows a strong negative association for Sb, Te, Cu, Ni, Co, Mo, and Tl, elements that are frequently correlated with industrial emissions, wear of metallic materials, road traffic, and fossil fuel combustion. This association indicates anthropogenic inputs through atmospheric deposition, industrial effluents or fluvial transport of contaminated particles.

In contrast, As presents a high positive loading, suggesting a distinct source or a different biogeochemical behaviour in the analysed

system. The elements Cr and V, with moderate positive loadings, indicate additional influences related to metallurgical processes and liquid fuels. Hg, V, and Pb were associated with PC2, suggesting a secondary factor driven by atmospheric deposition and fuel combustion. Overall, the three ecosystems exhibited distinct geochemical fingerprints. Deltaic sites reflected lithogenic inputs, saline sites showed signatures of mineralized waters, and urban sites displayed clear anthropogenic enrichment. These patterns confirm that *Phragmites australis* integrates both natural and human-derived geochemical signals.

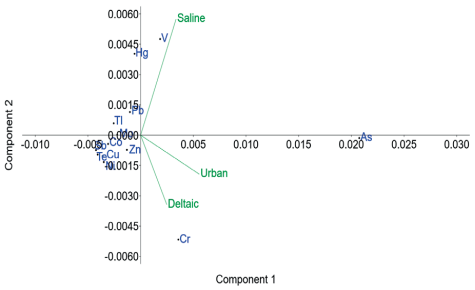

Figure 3. PCA - with elements indicating anthropogenic activities - in the three types of ecosystems

For elements of natural origin (Figure 4), PCA indicates a clear dominance of the first principal component, which explains 90.41% of the variance, while PC2 contributes 9.16%. The elemental composition is dominantly influenced by the geological substrate, *deltaic* sediments and natural processes of plant assimilation. This distribution suggests strong control by a major geochemical factor, highlighted by PC1, which separates lithophile elements from those associated with heavy minerals derived from sediments or deposited on leaves. Fe, Ba, Mn, and Ti, elements characteristic of oxides and detrital minerals, were grouped opposite Al, Si, K, Ca, Zr, Th, and U, indicating their association with the aluminosilicate fraction and resistant minerals in sediments. This component reflects lithogenic input, determined by alluvial transport, basin erosion, and sedimentary deposition. PC2 captures secondary variations in the mobility of elements (Ba, Mn, Ti) that reflect hydro-geochemical conditions, redox, salinity, and sediment availability.

The PCA analysis of rare and trace elements (Figure 5) shows that PC1 explains 87.46% of the variance, followed by PC2 (8.89%), indicating a clearly defined structure. It separates *urban* from natural environments through anthropogenic inputs with low trace-element content.

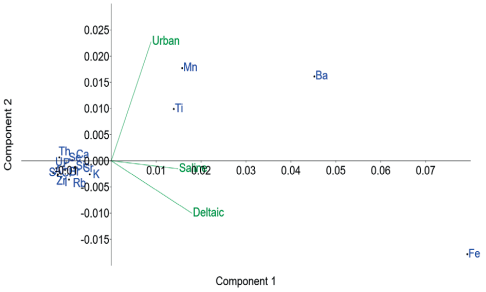

Figure 4. PCA - with elements indicating natural origin - in the three types of ecosystems

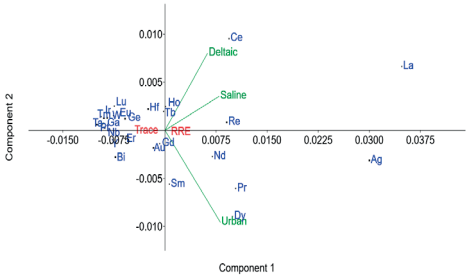

Figure 5. PCA - with elements indicating REE and Trace - rare elements

The *deltaic* ecosystems were subject to natural processes of uptake from sediment, slightly differently from *saline* ecosystems, indicating the influence of salinity, mineral characteristics, and plant availability. The distribution of REE and trace elements reflected the interactions among geogenic inputs (mineralogy, sediment composition), the ecological dynamics of the analysed ecosystems, and anthropogenic influences. PC1 highlighted a gradient in element separation of La, Ce, Pr, and Nd (light rare earth elements-LREE), with elements predominantly associated with stable mineral fractions of lithogenic origin and platinum-group metals

(Ta, Nb, W, Pt, Ir). This distribution reflects the geochemical fractionation and mineralogical control of the sediments. In contrast, PC2 highlights the differentiation of ecosystems: the *deltaic* and *saline* environments showed positive loadings, whereas the *urban* ecosystem exhibits a strong negative loading, suggesting anthropogenic influences on the distribution of trace elements. The detection of rare elements such as At, Ir, and Ta likely reflects localized mineralogical features or the presence of fine sediment fractions adhering to plant tissues. Their low concentrations suggest geogenic origins rather than biological uptake.

The PCA identified the major geochemical gradients, separating *deltaic*, *saline*, and *urban* systems based on dominant elemental features. In addition, AHC dendrograms allow the identification of element associations reflecting complex sediment/water processes. Hierarchical analysis based on Agglomerative hierarchical clustering (AHC) of the elements identified in *deltaic* ecosystems, highlighted a geochemical organisation structured into four major element associations, suggesting mineralogical mechanisms and other physical, chemical and biological processes taking place in the sediments (Figure 6). The first cluster (blue) groups predominantly lithogenic elements, associated with heavy minerals, including light and middle lanthanides (La, Eu, Gd, Tb), actinides (Th, U), high-field elements (Zr, Ta), as well as noble metals (Pt, Ir, Au), along with Sr and Ba. Their association indicates a common source related to the transport of fine particles, possibly enriched by anthropogenic input and distinct from the natural lithogenic background, a feature frequently reported in fluvial and *deltaic* sediments (Taylor & McLennan, 1995; Cullers, 2002). A second cluster (brown), much smaller, is dominated by Zn, Ag, and W, with Ti and Ce added. Zn and Ag are known as markers of metallurgical activities and fluvial transport of contaminated particles, and their association with W has been reported in sediments affected by industrial discharges (Förstner & Wittmann, 2012). The third group (pink) brings together elements characteristic of the clay fraction and oxides such as K, Rb, Si, Mn, V and Cr, together with potentially toxic metals (Cu, Pb, Hg) and part of the REE (Nd, Pr, Sm, Y). This association reflects the role of fine phases as a geochemical support for adsorbed metals. The last group (green), defined by Ca and Fe, correlated with P, As, Se, and Tl, indicating a carbonate- and redox-sensitive association characteristic of reactive sediments from environments rich in organic matter. This covariability reflects natural ecological processes of element fixation and release in iron oxides, controlled by oxidation-reduction cycles and interactions with carbonate and organic matter (Belzile & Tessier, 1990).

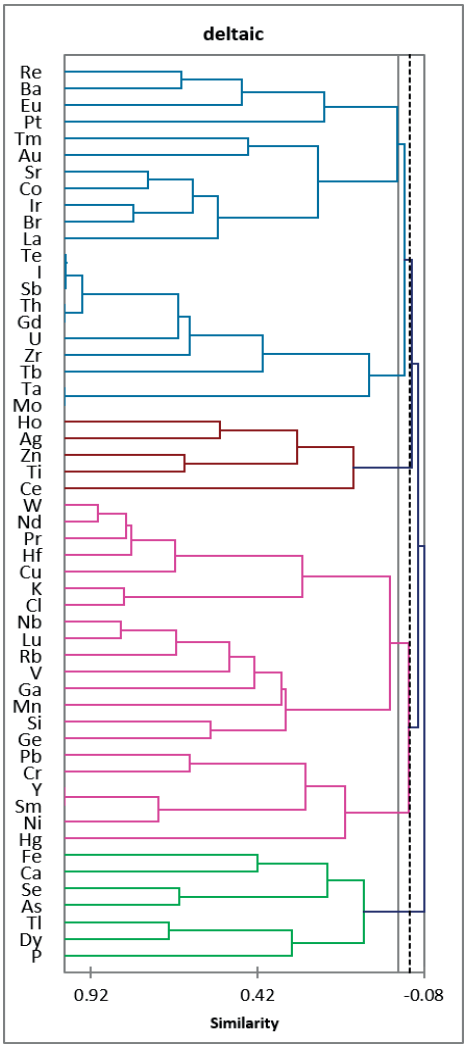

Figure 6. Agglomerative hierarchical clustering (AHC) of elements identified in *deltaic* ecosystems

In *saline* environments, AHC analysis revealed a more compact organisation into three distinct clusters, reflecting the typical chemistry of these ecosystems (Figure 7).

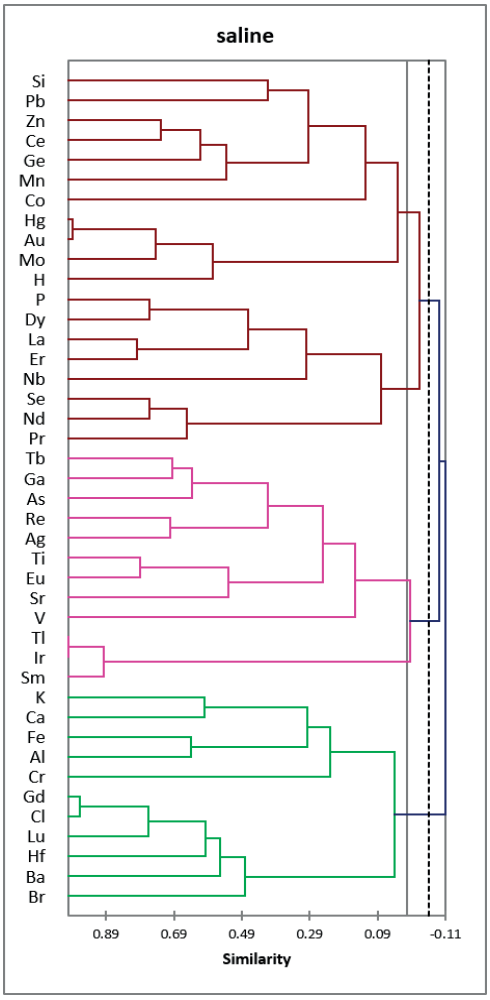

Figure 7. Agglomerative hierarchical clustering (AHC) of elements identified in *saline* ecosystems

A first cluster (brown) groups Si together with Pb, Zn, Ge, Mn, Co, Hg and Mo, indicating an association between the detrital fraction and contaminated metals. The cluster composition suggests that pollutants are transported and retained on mineral particles. Such associations have been reported in *saline* environments where salinity-induced flocculation favours metal retention (Acosta et al., 2023). The second cluster (pink) comprises metalloids and redox-sensitive metals, such as As and Tl, correlated with Sr, V, Ag and neighbouring some of the REE (La, Nd, Pr, Tb, Eu). This association indicates increased mobility in the dissolved phase, followed by re-fixation. Chloride complexation and redox variations enhance the mobility of elements, followed by their re-fixation via adsorption or co-precipitation (O'Day et al., 2004), thereby influencing the availability of nutrients and metals to microbial and benthic communities. Their correlation with Sr and REE indicates the involvement of authigenic phases, a common natural process in lakes and *saline* environments, reflecting active interactions between sediment chemistry and local ecological dynamics (Jones et al., 2005). The third cluster (green) is characterised by evaporitic and carbonate elements: Cl and Br correlated with Ca, Ba, K, Fe, and Al, suggesting authigenic precipitation under conditions of intense evaporation, a process that shapes sedimentary structure and influences the microhabitats of organisms adapted to *saline* environments. Cl/Br ratios are widely used to distinguish marine from continental sources, and the Ba-Ca correlation indicates barite and carbonate precipitation under conditions of intense evaporation (Holland et al., 1987). Therefore, *saline* ecosystem markers reflect three major processes as the input of potentially contaminating fine particles, the mobilisation of metals in *saline* waters, and authigenic precipitation of salts, a pattern commonly found in many *hypersaline* systems (Warren, 2006).

The *urban* dendrogram highlights a structure organised into three distinct clusters (Figure 8). A first major cluster (brown) brings together Zn, Cu, Ni, Mn, Pt, Hg, P, Ba and Sr, indicating a strong anthropogenic association. The high correlations among these elements suggest a common source related to traffic and industrial activities.

The second cluster (pink) was defined by Fe and Cr, and correlated with Se, Ag, and Si, indicating reactive oxide phases associated with *urban* fine particles.

The third, much broader cluster (green), included K, Rb, Ca, Ti, Nb, Th, As, V, Tl, Br and numerous REE (Pr, Gd, Tb, Sm, Dy, Y), suggesting a mixed origin related to *urban* dust and construction materials.

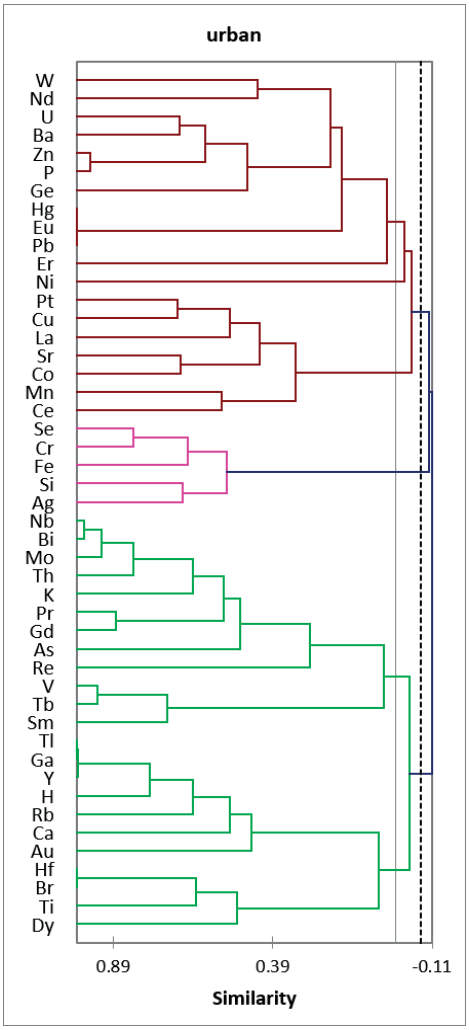

Figure 8. Agglomerative hierarchical clustering (AHC) of elements identified in *urban* ecosystems

The *urban* geochemical signature was dominated by multiple anthropogenic sources. The Zn–Cu–Ni association is considered a robust indicator of tire wear and brake systems, while Pt is an established marker of emissions from automotive catalytic converters.

Clustering with Mn and Ba has been reported in numerous studies on road dust, being attributed to fuel additives and friction materials (Thorpe & Harrison, 2008; Rauch & Pacyna, 2009). The Fe–Cr–Se cluster reflects the role of Fe–Mn oxides as sorbent phases for toxic metals (Lu et al., 2009). In *urban* aerosols and road sediments, Cr and Se are frequently bound to these phases, and their correlation with Si indicates the mineral support of the particles.

The broad association, including K, Ca, Ti, and REE, is typical of construction dust and resuspended *urban* soils. Vanadium and arsenic, present in the same cluster (pink), are indicators of fossil fuel combustion, especially fuel oil and diesel, a pattern reported in *urban* sediments from port and industrial areas (Pacyna & Pacyna, 2001).

Thus, *urban* marker elements reflect three major sources: road traffic, industrial emissions, and construction dust/atmospheric resuspension (Charlesworth et al., 2011).

Our study highlights *Phragmites australis*'s ability to integrate distinct geochemical features across ecosystem types (*deltaic*, *saline*, *urban*), confirming its role as both a bioindicator and a potential natural filter for lithogenic and anthropogenic elements.

The differences identified between habitats (assessed by ANOSIM, R = 0.0786, $p$ = 0.0179) indicate a distinct elemental structure, mainly driven by the contrast between deltaic and urban ecosystems ($p$ = 0.0015), reflecting the influence of anthropogenic pressure on the chemical composition of plant biomass.

Thus, in *deltaic* ecosystems, a lithogenic contribution was observed, evidenced by the dominance of geogenic elements (Fe > Ba > Mn > Ti; Table 1), resulting from detrital inputs and sediments rich in mineral fractions. The Fe–Ba–Mn–Ti association and the distribution of rare earth elements (REE) (Table 2) reflect the control of the geological substrate and fluvial transport, consistent with the geochemical model of continental sediments described by Taylor & McLennan (1995) and Cullers (2002). The differential fractionation of REE between habitats (Table 2, Figure 7) suggests variations in sedimentary sources and redox conditions (Piper & Bau, 2013).

The association of As–Fe elements in AHC in the *deltaic* environment is due to the role of iron oxides in fixing metalloids in sediments rich in organic matter, a mechanism described by Belzile & Tessier (1990). Therefore, in *deltaic* ecosystems, elemental accumulation in *Phragmites australis* predominantly reflects the natural geochemical background, with a

secondary anthropogenic influence. In contrast, under *saline* conditions, geochemical processes exhibited a distinct element profile absorbed by the reed. The elevated concentrations of Hg, Ba, Sr, and Mo (Table 1 and Table 3) indicate mobilisation and redistribution under high-salinity conditions and variable redox potential. *Saline* AHC revealed three major processes: contaminated detrital input, metal mobilisation under *saline* conditions and mineralisation induced by high salinity. The Cl–Br–Ca–Ba clustering in the dendrogram suggests intense evaporitic processes, described in other *saline* systems (Warren, 2006), with chloride complexation and mobilisation of As and Tl (O'Day et al., 2004), and metal retention on fine particles (Acosta et al., 2023).

The clear separation of the *saline* ecosystem in the PCA for natural elements (Figure 6) and for REE/trace (Figure 7) confirms that salinity constitutes a major geochemical control factor, influencing bioavailability and accumulation mechanisms in reeds.

In *urban* environments, anthropogenic influences were evidenced by obvious enrichments in As, Pb, Mn and Tl (Table 3), as well as in Br (Table 1), suggesting the influence of traffic, fossil fuel combustion and industrial activities, elements also mentioned in other studies (Wei & Yang, 2010). The dominance of Ba > Mn > Ti > Fe (Tables 1-3) indicates a modification of natural ratios by external input. PCA for anthropogenic elements (Figure 2) by the association Sb–Cu–Ni–Mo–Tl–Te reflects sources related to traffic and industry (Thorpe and Harrison, 2008; Rauch & Pacyna, 2009). Also, the presence of Pt in the *urban* cluster supports the presence of a road-pollution marker. The elemental grouping Fe, Cr, Se indicates the involvement of Fe and Mn oxides in the retention and immobilisation of potentially toxic metals in sediment (Lu et al., 2009). The association of V and As suggests external inputs specific to the *urban* environment, including contributions from fossil fuel combustion, which modify the geochemical background and increase metal pressure in the ecosystem (Pacyna & Pacyna, 2001). Thus, the elemental composition of *urban* reeds reflects a mixture of multiple sources: road traffic, industrial emissions and construction dust (Charlesworth et al., 2011).

The ability of *Phragmites australis* to accumulate both lithogenic elements and potentially toxic metals demonstrates its dual role as both a bioindicator of local geochemical conditions, highlighted by the integration of sedimentary and hydrogeochemical signatures and as a biological filter of contaminants, especially in *urban* environments, where it retains heavy metals from the water column and from atmospheric deposits (Alghanem et al., 2024). However, the accumulation of Hg, Pb, As, or Tl in aerial biomass may pose a secondary risk through trophic transfer or biomass decomposition. Therefore, the use of reeds in phytoremediation systems requires biomass management strategies to prevent the reintroduction of contaminants into the biogeochemical cycle. Moderate but statistically significant differences between ecosystems indicate that *Phragmites australis* responds sensitively to variations in anthropogenic pressure and natural geochemical control, confirming its usefulness as a sentinel species in ecological risk assessment.

## CONCLUSIONS

**Salinity as a major geochemical control factor**. In saline ecosystems, the association of Hg, Ba, Sr, and Mo, together with the structure of the agglomerative hierarchical clustering (AHC), highlights the role of salinity-driven geochemical processes. These include element mobilisation, complexation, and evaporite-related precipitation, demonstrating the strong influence of mineralised waters on elemental distribution and bioavailability.

**High capacity for bioaccumulation and integration of geochemical signatures**. *Phragmites australis* effectively records habitat-specific geochemical characteristics, reflecting both natural variations in substrate composition and the impacts of anthropogenic activities. Its elemental composition provides an integrated signal of environmental conditions across contrasting ecosystems.

**Dual role as a bioindicator and natural filter**. The species serves not only as a reliable bioindicator of geochemical and environmental conditions but also as a natural biological filter, contributing to the retention and sequestration

of heavy metals, particularly in ecosystems exposed to urban pressures.

**Implications for ecological risk**. The accumulation of potentially toxic elements such as Hg, Pb, As, and Tl may pose ecological risks through trophic transfer and the subsequent re-release of contaminants into the biogeochemical cycle during biomass decomposition. These findings underscore the need for appropriate management and monitoring strategies in affected ecosystems.

**Environmental management applications**. The elemental patterns identified in this study provide valuable information for environmental assessment and wetland management, especially in areas influenced by urbanisation or salinisation. Monitoring *Phragmites australis* can serve as an effective early-warning tool for detecting metal contamination, alterations in sediment provenance, and changes in hydrogeochemical conditions, thereby supporting informed conservation and remediation efforts.

***Abstract***

*This paper analyses the impact of global factors on the availability and quality of water resources, highlighting the need for sustainable management. In the context of climate change, population growth and intensification of economic activities, water resources are subject to significant pressures, such as pollution, overexploitation and unequal distribution. The study uses a narrative review, based on bibliographical-analytical research, comparative analysis and a case study of the Danube River Basin. The case study illustrates the complexity of managing a transboundary resource, affected by upstream pollution, hydrological variations and multiple uses. European policies and integrated management strategies applied to protect water quality and its sustainable use are analysed. The results highlight the importance of international cooperation, infrastructure modernization and the implementation of innovative solutions. In conclusion, efficient management of water resources is an essential condition for sustainable development and the prevention of future water crises.*

***Key words:*** *Danube, management, resources, sustainability, water.*

## INTRODUCTION

Water is one of the most important natural resources on the planet, indispensable for the existence of life and for the functioning of modern economies. Recent European assessments show that water bodies remain under significant pressure from agriculture, pollution and climate change, while drought and flood risks are expected to intensify in the coming decades (European Environment Agency, 2024).

In Europe, the Danube River represents one of the most complex examples of transboundary water management. The Danube River Basin covers approximately 800,000 km² and includes territories from 19 European countries, making it one of the most international river basins in the world. Recent studies indicate shifts towards wetter winters, drier summers and increased high-flow and low-flow risks, which directly affect water-resource availability in the basin (ICPDR, 2021; Probst & Mauser, 2023; Pekárová et al., 2023).

The aim of this paper is to analyse the impact of global factors on the availability and quality of water resources and to highlight how European policies and integrated management strategies contribute to the protection and sustainable use of water resources.

Recent Danube-specific assessments also underline the growing importance of emerging pollutants, including PFAS, and the need for coordinated responses across the basin (Liu et al., 2025; European Commission, 2026).

## MATERIALS AND METHODS

This paper is a narrative review supported by bibliographical-analytical research, comparative analysis and a Danube case study.

Literature search strategy. Sources were identified in ScienceDirect, Scopus, Web of Science and Google Scholar, together with

official documents from the European Commission, the European Environment Agency and the ICPDR. The search covered the period 2000-2026, with priority given to 2019-2026 publications on climate change, water scarcity, nutrient pollution, PFAS, microplastics and transboundary river-basin management.

Selection criteria. The search terms used were "Danube River Basin", "water management", "climate change", "nutrient pollution", "PFAS", "microplastics", "flood risk", "drought risk" and "transboundary river basin", combined with Boolean operators. Included sources were peer-reviewed articles, technical reports and official strategies in English or Romanian that addressed basin-scale hydrology, pollution, governance or management. Duplicates, opinion pieces without clear evidence base and records unrelated to basin-scale water management were excluded.

Comparative analysis. The selected publications and official documents were compared in terms of source of pressure, management response, policy instrument and expected environmental outcome.

**Case study**

The Danube River was analysed as a representative case study for the management of a complex transboundary resource. The following were evaluated: anthropogenic pressures on water, pollution from upstream, hydrological variations, multiple uses of the resource and management measures implemented at regional level.

Overall, more than 25 scientific papers and technical reports were synthesised through tables, graphic representations and descriptive interpretation of hydrological and water-quality indicators, with emphasis on the relationships between climatic, economic and social drivers.

## RESULTS AND DISCUSSIONS

### 1. Global factors influencing water resources

The synthesis of the reviewed literature confirms that water resources are being reshaped by a combination of climatic, demographic and economic pressures. Climate change remains the most pervasive driver because it alters the timing, intensity and spatial distribution of precipitation, increases evapotranspiration and amplifies the frequency of compound extremes. In river basins such as the Danube, these changes translate into wetter winters, longer dry spells in summer, more erratic flow regimes and higher uncertainty for water allocation, flood protection and ecological continuity (Probst & Mauser, 2023; Pekárová et al., 2023). The practical implication is that historical hydrological averages are becoming less reliable for planning, particularly for multi-country basins where upstream and downstream conditions are tightly coupled.

Beyond climate forcing, land-use change and population growth increase the pressure on both surface water and groundwater. Urban expansion concentrates demand, increases impervious surfaces and accelerates stormwater runoff, while industrial growth raises the risk of point-source contamination through incomplete treatment and accidental releases. Agriculture exerts a dual pressure: it is the largest user of water in many European catchments and simultaneously one of the main sources of diffuse pollution through nitrates, phosphorus, pesticides and suspended solids. The European Environment Agency has repeatedly identified agriculture as a dominant pressure on European waters, and this is consistent with the Danube Basin, where nutrient enrichment remains a persistent management challenge (European Environment Agency, 2024).

Table 1 illustrates that the pressures affecting water resources are not isolated.

Table 1. Synthesis of major global drivers, dominant pressures and basin-scale implications

| Driver | Typical pressure pathway | Main hydrological or ecological effect | Management implication |
|---|---|---|---|
| Climate change | Altered precipitation, higher evaporation, longer dry periods | More frequent floods and droughts; lower predictability of river discharge | Scenario-based planning, drought preparedness and flood-risk adaptation |
| Urbanization | Impervious surfaces, wastewater generation, storm runoff | Flash floods, sewage overloads, urban contamination | Modern sewerage, retention systems and advanced treatment |
| Industrialization | Effluents, accidental releases, legacy deposits | Local hotspots, persistent contamination, sediment risk | Strict permitting, monitoring and emergency response |
| Agriculture | Fertilizers, pesticides, | Eutrophication, nitrate loading, | Nutrient management, |

| Driver | Typical pressure pathway | Main hydrological or ecological effect | Management implication |
|---|---|---|---|
| | irrigation abstraction, manure | groundwater stress | precision farming and riparian buffers |
| Emerging pollutants | PFAS, microplastics, pharmaceuticals | Low-concentration chronic contamination | Targeted monitoring and treatment upgrades |

In practice, a single basin may experience simultaneous climate stress, diffuse agricultural pollution and industrial legacy burdens. This convergence increases the probability of threshold effects, in which ecological degradation becomes visible only after the system has already lost resilience. For the Danube, this means that management should be designed as an integrated risk-reduction framework rather than as a set of sector-specific interventions.

## 2. Sustainable management of water resources

The literature reviewed in this study supports the view that sustainable water management must be understood as an adaptive governance process rather than as a static set of technical measures. The Water Framework Directive established a basin-oriented logic by requiring planning at the level of river basin districts, monitoring of ecological and chemical status, and coordinated action across administrative boundaries (European Commission, 2000). This approach remains highly relevant because it links environmental objectives with the use of water for drinking supply, agriculture, navigation, industry, recreation and ecosystem protection.

In the Danube context, governance is especially complex because the basin extends across a large number of countries with different economic capacities, monitoring systems and policy priorities. The Danube River Basin Management Plan and the work of the International Commission for the Protection of the Danube River provide the institutional backbone for coordination, data sharing and joint action (ICPDR, 2021). However, the review shows that good formal coordination is not sufficient by itself. Effective management also depends on implementation capacity, financing, infrastructure quality, real-time monitoring and the ability to respond to transboundary incidents before they spread downstream.

The analysis further indicates that the most robust management strategies combine regulatory instruments with technical modernization. Wastewater treatment upgrades, nutrient reduction at source, hydromorphological restoration, floodplain reconnection and digital monitoring platforms are complementary rather than competing measures. This is important because point-source control alone cannot address diffuse pollution, and river restoration alone cannot compensate for persistent chemical loading. The strongest results are obtained when policy instruments are aligned with ecological processes and when each intervention targets a clearly defined pressure-response pathway.

Table 2 highlights that resilience depends on the combination of measures rather than on a single dominant solution. Digitalization improves detection and forecasting, but it does not remove pollution sources. Likewise, structural measures such as treatment plants or embankments improve control, but they do not replace basin-wide cooperation. A sustainable framework therefore requires a layered approach that combines prevention, monitoring, restoration and adaptation.

Table 2. Policy and technical responses for improving water resilience in the Danube Basin

| Response category | Operational focus | Expected outcome | Implementation challenge |
|---|---|---|---|
| River-basin planning | Coordinated targets for water quantity and quality | Reduced conflict between users | Different national priorities |
| Monitoring and early warning | Dense sampling and digital alert systems | Faster detection of pollution or hydrological stress | Data harmonization across borders |
| Wastewater modernization | Collection, secondary and advanced treatment | Lower nutrient and micropollutant loads | High capital and operating costs |
| Agricultural best practice | Precision fertilization and buffer strips | Reduced diffuse runoff | Adoption at farm level |
| Nature-based solutions | Wetland restoration and floodplain reconnection | Improved retention and ecosystem services | Land availability and governance |

## 3. Case study - the Danube

The Danube is a particularly instructive case because it concentrates almost all of the management challenges discussed above. It is

one of Europe's largest transboundary rivers, links highly urbanized, industrial and agricultural zones, and ultimately delivers water and sediment to the Black Sea. Its basin-scale significance means that local disturbances are rarely local for long: pollutants, hydrological changes and land-use pressures can propagate over long distances and across national borders.

The case-study evidence indicates that the river is exposed to three interacting pressure fields. First, climatic variability affects seasonal discharge, water temperature and the occurrence of low-flow or flood events. Second, point-source pollution from urban wastewater, industrial discharges and accidental releases can create acute contamination hotspots. Third, diffuse pollution from agriculture and urban runoff contributes chronic nutrient and chemical loading, which is often more difficult to reduce because it arises from many distributed sources rather than a single discharge point.

The Danube's historical pollution events demonstrate the basin-wide consequences of upstream incidents. The Baia Mare cyanide spill and the Baia Borşa tailings release remain emblematic examples of how mining accidents can create severe downstream ecological damage with long recovery times (ICPDR, 2000). Likewise, the Ajka red-sludge accident showed that industrial failures in one part of the basin can trigger water-quality emergencies hundreds of kilometres away. These cases are not merely historical references; they reveal structural vulnerabilities in basin governance, especially where prevention, emergency communication and remediation are uneven across borders.

At the same time, the review shows that the Danube cannot be interpreted only through spectacular accident cases. The dominant long-term burden is diffuse nutrient transport. Model-based work has repeatedly found that agricultural and mixed diffuse sources are the principal contributors to nutrient loading, while point sources and legacy hotspots require targeted local control (Malagó et al., 2015; 2017). This pattern matters because chronic eutrophication and sediment contamination produce slow but cumulative ecological damage, including altered food webs, reduced oxygen availability and increased pressure on biodiversity.

The emerging PFAS evidence strengthens this interpretation. The 2025 Upper Danube Basin study reported contamination across environmental compartments and highlighted the combined role of industrial hot spots, wastewater pathways and groundwater-linked transport (Liu et al., 2025). The European Commission's 2026 assessment reinforced the same message by showing that PFAS pollution in the basin is widespread and that conventional wastewater treatment is often insufficient to stop downstream dispersal (European Commission, 2026). Taken together, these findings suggest that the Danube is entering a new phase of chemical-risk governance in which the challenge is not only to reduce a few legacy pollutants but also to manage complex mixtures of persistent, mobile and partly unregulated substances.

The discussion also points to the importance of hydromorphological pressures. Bank erosion, river training works, damming and navigation infrastructure alter sediment transport, connectivity and habitat structure. Although such interventions can support navigation, flood control or energy production, they may also reduce ecological continuity and fragment habitats. In a large basin such as the Danube, hydromorphological alteration is particularly significant because it interacts with climate-driven flow variability: where water levels are already more variable, rigid channelization can further reduce ecological buffering capacity.

From a management perspective, the Danube case study shows that resilience should be assessed at multiple scales. Local measures such as upgrading a wastewater plant may improve water quality in the immediate area, but basin-level resilience depends on whether upstream activities are also controlled. Similarly, flood-protection works can reduce immediate hazard exposure, yet if they are not integrated with floodplain restoration and ecological connectivity, they may transfer risk downstream or accelerate habitat loss. This is why the ICPDR framework remains central: it provides the institutional platform for translating scientific evidence into coordinated basin action (ICPDR, 2021).

Another important result is the growing role of monitoring technologies. Traditional periodic sampling is no longer sufficient for a river basin

of the Danube's scale and complexity. The literature increasingly supports hybrid systems that combine laboratory measurements, automatic stations, remote sensing, model-based forecasting and digital alerts. Such systems are particularly useful for drought forecasting, flood preparedness and early detection of contamination peaks. They also improve transparency, because data can be shared among riparian states more quickly and used to support joint decision-making.

Overall, the Danube demonstrates that transboundary water management is not only a matter of environmental protection but also of economic stability and social resilience. Navigation, hydropower, tourism, drinking water supply, fisheries and ecosystem services all depend on the same river system. Therefore, every major management decision involves trade-offs. The central finding of this study is that the best outcomes are achieved when governance tools, infrastructure investments and ecological restoration are treated as a single integrated policy package rather than as separate sectoral agendas.

**4. Integrated discussion and implications**

The synthesis of the reviewed literature and the Danube case study led to three broader implications. First, water scarcity and water pollution should be analyzed together, because they are often produced by the same pressures and they reinforce each other. For example, drought conditions concentrate pollutants, while polluted water reduces the amount of water that can be safely used for supply or irrigation. Second, basin-scale resilience depends on prevention more than on reaction: once pollutants move downstream or groundwater is contaminated, remediation becomes slower, more expensive and often incomplete. Third, innovation is most effective when it is paired with strong institutions; digital tools, for instance, cannot substitute for cross-border cooperation, but they can make such cooperation timelier and evidence-based.

In practical terms, the Danube Basin would benefit from four priorities. The first is a stronger control of diffuse agricultural inputs, especially through nutrient budgeting, precision fertilization, buffer strips and stricter manure management. The second is wastewater modernization, including the gradual deployment of advanced treatment where micropollutants and PFAS are relevant. The third is restoration-oriented river management, because wetlands and floodplains can attenuate floods, improve water retention and support biodiversity. The fourth is basin-wide digital monitoring, which would allow authorities to identify trends earlier and respond more quickly to incidents.

These priorities are consistent with the growing European emphasis on water resilience. Recent official assessments stress that Europe's waters remain under intense pressure and that climate-related extremes are likely to become more disruptive in the coming decades (European Environment Agency, 2024). Accordingly, the Danube should be viewed not only as a regional case study, but also as a model system for testing integrated adaptation, advanced pollution control and cooperative governance in a large, shared river basin.

## CONCLUSIONS

Water resources in the Danube Basin are under increasing pressure from climate change, urbanization, industrialization and intensive agriculture. The review shows that diffuse agricultural pollution is the dominant nutrient source, while urban wastewater and industrial discharges remain significant point pressures.

The Danube case study highlights specific priority hotspots and hazards, including the historical mining accidents at Baia Mare and Baia Borșa, the Ajka red-sludge accident, and the emerging PFAS contamination detected in the Upper Danube Basin. These findings confirm that upstream events can have basin-wide and long-term effects.

The management response should focus on stronger transboundary cooperation, modernized wastewater and monitoring infrastructure, better control of agricultural inputs, and faster deployment of digital tools for forecasting and pollution detection. These measures are essential for improving resilience to droughts, floods and emerging pollutants in the Danube Basin.

The Danube can serve as a European model of adaptive and integrated water management only if policy, science and implementation remain aligned.

The review also indicates that emerging pollutants have moved from a marginal topic to a central one in water governance. PFAS are of particular concern because they are extremely persistent, mobile in aquatic environments and difficult to remove using conventional treatment. Recent basin-scale evidence from the Upper Danube Basin shows widespread PFAS occurrence across rivers, groundwater, wastewater and landfill-related pathways, confirming that legacy contamination and current industrial inputs can overlap within the same catchment (Liu et al., 2025; European Commission, 2026). Accordingly, the management of water quality can no longer focus solely on conventional indicators such as nutrients and oxygen demand; it must also address chemical mixtures, chronic low-level exposure and long-range transport.

***Abstract***

*The study aims to examine the content of Cr, Mn, Fe and Al in liver and muscle samples of Perca fluviatilis Linnaeus, 1758 and its parasite Proteocephalus percae (Müller, 1780) Railliet, 1899, in samples of Chironomidae, water and sediments from the anthropogenically influenced ecosystem of Topolnitsa Dam (East Aegean Basin, Bulgaria). The highest exceedance was observed for Mn content (171.58 times) in Chironomidae samples. In the studied perch samples, the highest exceedances were recorded in liver samples for Cr (32.27 times), followed by Mn (5.68 times) and Fe (3.85 times) compared to the maximum permissible concentrations by national legislation. The exceedances in Al values were found only in Chironomidae samples (22.94 times). Bioaccumulation, bioconcentration, and biomagnification coefficients were analysed. The bioindicator significance of perch (Pr. percae), its parasite Pr. percae, and chironomids was assessed. The liver of European perch is a bioindicator of Cr pollution, and Chironomidae are bioindicators of Cr and Fe pollution, as well as Pr. percae, for Mn.*

***Key words:*** *benthos macroinvertebrates*, *bioindication, European perch, heavy metals, parasites.*

## INTRODUCTION

Topolnitsa Dam is located in the southern part of a deep valley, on the border between Ihtimanska and Saschinska Sredna Gora, at the boundary between the Balkan Mountain and Vitosha-Ihtiman subregions of the Mountain biogeographic region, and the Upper Thracian Lowland subregion of the Central Bulgarian biogeographic region (Gruev & Kuzmanov, 1994). The Dam was built in 1963 on the Topolnitsa River, 600 m from the village of Muhovo, Ihtiman Municipality, Sofia Region and after the village of Poibrene, Panagyurishte Municipality, Pazardzhik Region. The Topolnitsa River is the longest in the Sredna Gora Mountain. Topolnitsa Dam belongs to type L11b: Large deep dams in Ecoregion 7: Eastern Balkans, with water body code BG3MA800L160. The area around the dam ecosystem is distinguished by rich biological diversity. For its protection, the Protected Area BG0001389 Sredna Gora and Protected Area BG0001039 Popintsi under the Habitats Directive (Directive 92/43/EEC), as well as the Protected Area BG0002054 Sredna Gora, under the Birds Directive (Directive 79/409/EEC), have been declared. In the immediate vicinity of the Dam Wall near the village of Muhovo, the Topolnitsa Hydroelectric Power Plant is located. The waters of the Topolnitsa Dam are used for electricity generation, irrigation of arable land, flood control, sport and industrial fishing, tourism, etc. At the same time, the Topolnitsa Dam is located in an area with significant historical and contemporary industrial activity, including mining, metallurgy, raw material processing, and agricultural pressure in the peripheral territories. This necessitates complex ecological studies to assess interactions among physicochemical, geochemical, biological, and hydrological factors. One of the main pollutants that negatively impacts organisms and ecosystems is metals/metalloids, which, in addition to being pollutants, are also natural components of rocks.

As a result of anthropogenic activities such as mining and metal smelting, these elements are removed from their natural environments and become pollutants (Walker et al., 2006). A characteristic feature of metals is that they are neither created nor destroyed by humans, and, at high concentrations, they can pose a threat to living organisms and ecosystems. The heavy metals are characterised by toxicity, persistence and accumulativeness (Sauer & Watabe, 1989; Castro-Gonzales & Méndez-Armenta, 2008).

Scientific publications indicate that dams under conditions similar to those at the Topolnitsa Dam often exhibit signs of eutrophication, elevated concentrations of toxic metals, disrupted biological structures, and unstable ecosystem processes.

Dams, as anthropogenically created water bodies, have complex dynamics that make them both strategic resources and environmentally sensitive systems (Walker et al., 2006; Li et al., 2019).

The Topolnitsa dam has been identified as a repository of pollutants, with high As and Cu concentrations in the bottom sediments (Kolchakov et al., 1994). Exceedances of Fe, Mn, Ni, Cu, Ba, Mo, Al, Zn, Cd, Pb, Co, Ti, Sr have been reported (Dak et al., 2008).

Other authors have examined elements of the Dam ecosystem, such as water and fish (Velcheva, 2001; Velcheva & Nikolov, 2009; Georgieva et al., 2015; Valkova et al., 2022).

However, the majority of studies concern the state of the waters of the Topolnitsa River (Yancheva et al., 2011; Varbanov & Gartsiyanova, 2015; Gartsiyanova et al., 2021; Mihaylova et al., 2021; Park et al., 2022).

The studies characterise the state of one or another element in freshwater ecosystems, but do not track the circulation of heavy metals between the abiotic and biotic environments.

The study aims to present results on the content of aluminum (Al), chromium (Cr), manganese (Mn) and iron (Fe) in samples of water, sediments, bottom macroinvertebrates from Chironomidae, in muscles and liver of perch (*Perca fluviatilis* Linnaeus, 1758) and its parasite *Proteocephalus percae* (Müller, 1780) Railliet, 1899, for ecological characterisation and conservation of natural resources.

## MATERIALS AND METHODS

The research was carried out in the tail of the Dam after the village of Poibrene, designated as the Poibrene Biotope, with coordinates $42^0$27’38.88’’ N $23^0$59’20.81’’ E (Figure 1).

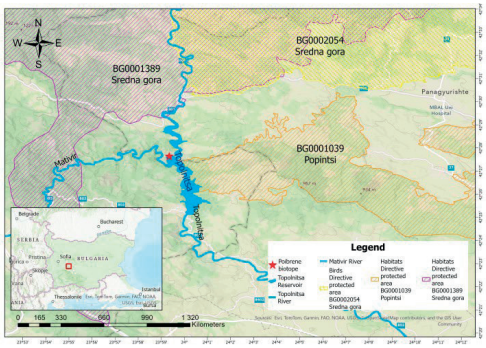

Figure 1. Topolnitsa Dam, Poibrene Biotope

The content of the heavy metals Al, Cr, Mn and Fe was monitored in samples of water, sediments and Biological Quality Elements (BQE) - macrozoobenthos, fish and fish parasites. The studies on BQE macrozoobenthos have been carried out in accordance with the standard BSS EN ISO 10870:2012. The samples were collected using a standard hydrobiological net and a Van Veen dredger in the littoral zone of the Dam ecosystem (Belkinova et al., 2013). The fish were collected after obtaining personal permits for scientific research fishing from the Executive Agency for Fisheries and Aquaculture of the Ministry of Agriculture and Food, in compliance with the BSS EN 14757:2015 standard. The ecological structure, condition and assessment of the condition of the ichthyofauna were analysed based on the indicators number of specimens, abundance (A), percentage of abundance (A%), weight (W g), percentage of weight (W%), maximum body width (TW cm), maximum body length (TL cm), and absolute dominance (D):

$$D = \frac{(A\%+W\%)}{2},$$

where A% is abundance in % and W% is weight of fish in % (Belkinova et al., 2013; Regulation H-4, 2012), Fulton condition coefficient (K):

$$K = 100.\frac{W}{L^3},$$

where W is the weight of fish, and L is the maximal body length (Golub et al., 2019).

Water sampling was carried out in accordance with BSS EN ISO 5667-1:2026, and sediment sampling in accordance with BSS ISO 5667-12:2017. The main Physicochemical Quality Elements: temperature (0C), pH, dissolved O2 mg/l, electrical conductivity (μS/cm), hardness (ppm), N-NH4 mg/l, N-NO3 mg/l, N-NO2 mg/l, TOC mg/l, P-Ortho-PO4 mg/l, BOD5 mg/l and Secchi transparency m, were monitored according to Regulation H-4/2012 from National legislation. A portable system for rapid analysis of organic pollutants in water, the ENOVA Insta Sense O2 model, and a HANNA HI83399 Photometer were used to determine physicochemical water quality indicators under field conditions.

Among the Biological Quality Elements, dominant groups and representatives have been selected. Among the established macrozoobenthos, the dominant Chironomidae were studied for the contamination of Al, Cr, Mn, and Fe. In the ichthyocomplexes, the dominant fish species is the European perch, Perca fluviatilis Linnaeus, 1758 (30 specimens). Samples of perch muscle and liver were isolated. The digestive system was examined for endoparasites. The studies on parasites were conducted in accordance with Zashev & Margaritov (1966) and Moravec (2013). Species differentiation was carried out according to the criteria of Bauer (1987) and Moravec (2013). Dominant helminth species in the helminth communities of perch is the cestode species Proteocephalus percae (Müller, 1780) Railliet, 1899. Pr. percae was also examined for contamination of the four heavy metals. The samples were collected from April to October 2025.

In total, 9 samples each of water, sediment, Pr. percae and Chironomidae, 10 samples each of fish muscle and liver were processed and analysed for Al, Cr, Mn, and Fe content. Sample pretreatment and acid digestion were performed according to EPA- and ISO-approved procedures: BSS EN ISO 21424:2020 for biological samples, BSS EN ISO 5667-14:2016 for water samples, and US EPA Method 3051A for sediment samples. After collection, water samples were stored at 4°C in dark glass bottles before transportation to the laboratory. For ICP-MS analysis, 50 mL of each water sample was filtered through a 25 mm sterile PES syringe filter with a pore size of 0.45 μm. The filtrates were acidified with 0.05 mL concentrated nitric acid to pH 2 and subsequently subjected to instrumental analysis.

Biological samples were dissolved with concentrated $HNO_3$ and then appropriately diluted before analysis. Sediment sample preparation was performed in accordance with US EPA Method 3051A. The aqua regia digestion was performed using 0.5 g of the sediment sample and an acid mixture containing 9 mL of $HNO_3$ and 3 mL of HCl. After the digestion, the supernatant was decanted and diluted to a final volume of 50 mL with double-deionised water. Before ICP-MS analysis, 1 mL of each sample solution was diluted to 10 mL with double-deionised water. Elemental analysis was performed using a PerkinElmer SCIEX ELAN DRC-e ICP-MS system (MDS Inc., Concord, ON, Canada).

Bioconcentration factors have been determined:

$$BCF=\frac{Cb}{Cw},$$

where *Cb* was the concentration of examined heavy metals in the biological samples and *Cw* - concentrations in the water samples, and

$$BCF=\frac{Cb}{Cs},$$

where *Cb* was the concentration of the examined heavy metals in the biological samples and *Cs* - concentrations in the sediment samples.

Bioacumulation factor was determined for the fish parasite *Pr. percae* for the accumulation of examined heavy metals:

$$BAF=\frac{CPr.percae}{Cfish\ muscle \text{ or } Cfish\ liver},$$

The biomagnification factor was determined as:

$$BMF=\frac{Cfish\ muscle \text{ or } Cfish\ liver}{CChironomidae},$$

Statistical processing of the results was performed using MS Excel (Microsoft, 2010).

## RESULTS AND DISCUSSIONS

### Macrozoobenthos

The samples of bioindicator macrozoobenthos collected in 2025 are distinguished by the presence of 5 taxa in the Poibrene Biotope.

Representatives of Chironomidae Newman, 1834, larvae (Insecta, Diptera) dominate, followed by Baetidae (*Baetis* Leach 1815, larvae; Insecta, Ephemeroptera) and Gerridae (*Gerris* Fabricus, 1794; Heteroptera). Coleoptera is represented by two taxa (Gyrinidae and Haliplidae). 286 specimens of Chironomidae were isolated and studied. Representatives of Chironomidae are bioindicators for p-saprobic conditions and belong to the sensitivity group D (tolerant forms) (Belkinova et al., 2013). Scientific studies by other authors show reduced biodiversity in the benthos, dominance of tolerant groups (Chironomidae) and periodic "blooms" of cyanobacteria - typical of reservoirs with combined pressure from toxic metals and eutrophication (Li et al., 2019), also found in this study. Modern methods for complex assessment include physicochemical analyses and biological indicators (Li et al., 2019).

**Fish and basic biological indices**

Freshwater fish in the Poibrene biotope are represented by 5 species: European perch *Perca fluviatilis* Linnaeus, 1758 (Percidae); Roach *Rutilus rutilus* (Linnaeus, 1758) (Cyprinidae); Bleak *Alburnus alburnus* (Linnaeus, 1758) (Cyprinidae); Orpheus dace *Squalius orpheus* Kottelat & Economidis, 2006 (Cyprinidae); Pumpkin seeds *Lepomis gibbosus* (Linnaeus, 1758) (Centrarchidae).

*P. fluviatilis* in the Poibrene Biotope is distinguished by the highest abundance (A%=46.0; 30 specimens) and absolute dominance (D=26.5). It is eudominant in the ichthyocomplexes from the researched biotope of the Topolnitsa Dam. The main metric data of the studied perch specimens were also determined (TL cm 13.58±2.17 (10.4-17.5); TW cm 3.42±0.67 (2.2-4.5); W/W% 28.14±12.28 (11.0-51.0)/7.0). The European perch, *P. fluviatilis*, is distributed throughout Europe and is found across almost all of Bulgaria. It inhabits rivers, lakes, brackish and semi-saline waters. It prefers reservoirs overgrown with aquatic vegetation. It is tolerant of high-water acidity. Young feed on zooplankton, and the adults feed on bottom invertebrates and small fish. The species is the subject of sport fishing.

The perch (*P. fluviatilis*) is recommended as an indicator species for assessing the degree of pollution of aquatic ecosystems (Karapetkova & Zhivkov, 2006; Kottelat & Freyhof, 2007). The species is not threatened (LC, IUCN).

The Fulton condition coefficient for P. fluviatilis in this study was K=1.20, indicating fat fish in the studied biotope of Topolnitsa Reservoir. The Fulton condition coefficient is a widely used indicator for assessing the health, fitness or completeness of fish populations. This tool is vital for monitoring fish health, assessing the impact of the environment on wild populations and for the sustainable management of fish resources. At K values around 1, K indicates an average condition. When K>1.2 indicates fat fish, and K<0.8 indicates slim fish. Furthermore, K>1 values indicate favourable environmental conditions (Radkhan & Eagderi, 2015; Zaharieva et al., 2024). Similar studies were conducted by Stavrescu-Bedivan et al. (2023) on Lake Mostiștea in Romania. They found K values above unity for Prussian carp (*Carassius gibelio*), indicating a favourable state of the species in the ecosystem.

**Parasites of *Perca fluviatilis* from Topolnitsa reservoir, Poibrene Biotope**

The parasite communities of perch are represented by two species: *Proteocephalus percae* (Müller, 1780) Railliet, 1899 (Proteocephalidae, Cestoda) and *Contracaecum* sp., larvae (Nematoda). The dominant species is *Pr. percae*. In the study, the species was represented by a prevalence of P%=43.34, a mean intensity of MI=7.85, and a mean abundance of MA=3.4. The species is the core for the parasitic communities of perch. The definitive hosts of *Pr. percae* are European perch (*P. fluviatilis*), Ruffe (*Gymnocephalus cernua*, Linnaeus, 1758), Northern pike (*Esox lucius*, Linnaeus, 1758), and others. Intermediate hosts are crustaceans of the genus *Cyclops* Müller, 1785 (Kakacheva-Avramova, 1983; Bauer, 1987).

**Physicochemical Quality elements**

Under field conditions, the main physicochemical quality elements were determined according to Regulation H-4/2012 for dams of type L11b in Ecoregion 7: Eastern Balkans, to which the studied dam ecosystem, Poibrene Biotope, also belongs (Table 1).

According to Regulation No. H-4/2012, for lakes of type L11b, the obtained quality elements indicate a moderate water state in the studied biotope.

Table 1. Physicochemical quality elements, Topolnitsa Dam, Poibrene Biotope

| Physicochemical elements | Water stateL11b/ Regulation № H-4/2012 | | | Topolnitsa dam L11b |
|---|---|---|---|---|
| | Excellent | Good | Moderate | |
| Temperature, $^0$C | | | | 20.08 |
| pH | - | 6.7-8.7 | - | 9.00 |
| dissolved $O_2$mg/l | 10.5-8.00 | 8.00-6.00 | <6.00 | 6.80 |
| Electroconductivity µS/cm | <650 | 650-750 | >750 | 410 |
| Hardness | | | | 270Class 5 |
| N-$NH_4$mg/l | <0.03 | 0.03-0.08 | >0.08 | 0.49 |
| N-$NO_3$mg/l | <0.06 | 0.06-1.80 | >1.80 | 0.60 |
| N-$NO_2$mg/l | <0.01 | 0.01-0.025 | >0.025 | 0.058 |

| $BOD_5$mg/l | <1 | 1-2.5 | >2.5 | 0.50 |
| Secchi transparency, m | >3 | 3-2 | <2 | <2 |

**Heavy metal content**

The prepared samples of water, sediments, fish muscles and liver, and samples of *Pr. percae* and Chironimidae were subjected to chemical analyses for the contents of Al, Cr, Mn, and Fe (Table 2). According to Regulation H-4/2012 and Regulation EQS/2010 of national legislation, the maximum permissible values for Al in surface waters are 25 µg/L at pH < 6.5; for Cr, 32 µg/L. The annual average norm for Mn in surface waters is 50 µg/L, and for Fe, 100 µg/L. For fish muscle, according to FAO/WHO (1972), the maximum permissible limit is Mn e 0.5 mg.kg-1, and for Cr – 0.15 mg.kg$^{-1}$ wet weight. According to WHO (1996), the maximum permissible limit of Fe in fish muscles is 0.05 mg.kg$^{-1}$ dry weight. For Al content, the maximum permissible limit of 0.2 mg kg$^{-1}$ wet weight is accepted for marine fish muscles, because there are no officially approved norms by FAO, WHO, and others for freshwater fish (Ranau et al., 2001). The highest concentrations of Al, Mn, and Fe were found in the Chironomidae samples, while the highest concentrations of Cr were found in the liver samples of perch. The change in the concentrations of the trace elements in the studied samples (wet weight) is in the following descending order: CAl_Fe_Chironomidae>CAl_Fe_Liver>CAl_Fe_*Pr.percae*>CAl_Fe_Muscle>CAl_Fe_Water; CCr_Liver>CCr_Chironomidae>CCr_Muscle>CCr_*Pr.percae*>CCr_Water;CMn_Chironomidae>CMn_*Pr.percae*>CMn_Liver>CMn_Muscle>CMn_Water (Table 2).

Higher excesses in Al concentrations were recorded in water samples (80.67 times) than in Chironomidae (22.94 times). In the liver and muscle samples of perch, as well as in the samples from *Pr. percae*, no excesses in Al concentrations were recorded. Regarding the Cr content, excesses were not found only in water samples.

Table 2. Concentration of heavy metals

| Concentration of heavy metals, wet weight | | | | | |
|---|---|---|---|---|---|
| µg/g | *Perca fluviatilis* µg/g | | *Pr.percae* µg/g | Chironomidae µg/g | Water µg/ml |
| | Liver | Muscle | | | |
| **Al** | 14.13±7.50 (8.83-19.44) | 3.48±0.72 (2,97-3.99) | 5.07±0.27 (4.92-5.3) | 688.21±5.25 (684.49-691.92) | 1.21±0.03 (1.19-1.23) |
| **Cr** | 9.68±2.41 (7.98-11.39) | 2.64±0.25 (2.46-2.82) | 1.62±0.01 (1.61-1.63) | 8,45±4,49 (11.62-5.27) | 0,004±0,001 (0,003-0,005) |
| **Mn** | 5.68±0.13 (5.78-5.59) | 0.85±0.63 (0.40-1.29) | 10.21±0.03 (10.19-10.23) | 171.58±2.16 (170.05-173.10) | 0.24±0.03 (0.22-0.26) |

Of the biological samples, the highest Cr exceedances were found in perch liver samples (32.27 times), followed by Chironomidae samples (28.17 times) and perch muscle samples (8.8 times). The lowest Cr exceedances were observed in samples from *Pr. percae* (5.4 times). Mn concentrations showed exceedances in all the studied samples, but were highest in those from Chironomidae (171.58 times), followed by those of *Pr. percae* (10.21 times), of perch liver samples (5.68 times), and in water samples (4.80 times). The lowest exceedances are of perch muscle samples (0.85 times). Regarding Fe content, the highest exceedances were found in Chironomidae samples (12.49 times), followed by water (8.4 times), and were lowest in perch liver samples (3.85 times). No exceedances were found in perch muscle samples and in *Pr. percae* (Table 2).

There are no uniform standard values for heavy metals in sediments in the environmental legislation of Bulgaria and the European Union. For the presented studies, we used Regulation

3/2008 of the national legislation and those approved by the US Environmental Protection Agency (US EPA). Other authors have also used these regulatory documents to assess heavy metal content in sediments in Bulgaria (Cholakova, 2021). When comparing the concentrations of the studied elements to those in the sediment samples (dry weight, μg/g), the highest concentrations of Al, Cr and Mn were recorded for the sediments, the lowest in the muscle samples for Al, Mn, and in Pr. percae for Cr, respectively. The highest values for Fe were recorded in the Chironomidae, followed by those in the sediments, in the perch liver, and in Pr. percae. They were the lowest again in the perch muscle. The change in the concentrations of the studied elements in the samples (wet weight) is in the following descending order:

CAl_Fe_Sediments>CAl_Fe_Chironomidae>CAl_Fe_Liver>CAl_Fe_*Pr.percae*>CAl_Fe_Muscle;CCr_Liver>CCr_Sediments>CCr_Chironomidae>CCr_Muscle>CCr_*Pr.percae*;CMn_Sediments>CMn_Chironomidae>CMn_*Pr.percae*>CMn_Liver>CMn_Muscle;CFe_Chironomidae>CFe_Sediments>CFe_Liver>CFe_*Pr.perca.*

In aquatic environments, Al is present in inorganic and organic complexes. Given its abundance, studying its impact on aquatic organisms and the aquatic environment, especially in dam ecosystems, is of great importance. In the National legislation (Regulation 3/2008), as well as in the ERL (Effect Range-Low; Long et al., 1995) no limit values for the content of this element are determined. The total Al concentration should not exceed 74.4 μg/L to protect freshwater organisms (Botté et al., 2021). Studies have shown that sedimentary forms of Al can be toxic to freshwater organisms, especially fish. Potentially hazardous concentrations of dissolved Al in the environment are considered more harmful to freshwater organisms (Botté et al., 2021). The impact of Al on freshwater organisms is reported to depend on pH, habitat type, total hardness, and DOC (US EPA, 2018).

Chromium (Cr) is a widespread metal in soils and waters. $Cr^{3+}$ accumulates poorly in organisms and is excreted mainly in the urine. Much more toxic is $Cr^{6+}$, which accumulates in much higher concentrations. It accumulates mainly in the liver, spleen and bone marrow. Cr6+ in the body is reduced to Cr3+ , which forms complexes with biomolecules, explaining the long retention of Cr in cells. It is excreted in the urine. According to Regulation 3 of the national legislation, the maximum permissible concentration is 200 μg/L, against which no excesses were found in the sediment samples we examined. According to the ERL US EPA, the norm is 81 mg/kg Cr, against which we also found no exceedances in the sediment samples we examined. Manganese (Mn) plays an important role in the development of aquatic plants. At high concentrations in water, Mn is toxic to fish. Iron (Fe) occurs in the form of inorganic and organic compounds. Fe deficiency leads to anaemia, including in fish. Organisms can accumulate Fe, which is why it is found in them at higher concentrations. At a concentration of 0.2 $mg \cdot l^{-1}$ in water, mass fish deaths have been reported (Yablanski & Petkov, 2011).

BCF values from 1000 to 5000 indicate that the corresponding chemical element is bioaccumulating (European Chemicals Agency, 2017). Such values were found for BCFCr-Liver-Water, BCFCr-Chironimidae-Water and BCFFe-Chironimidae-Water (Table 3). BAF showed higher bioaccumulation values in *Pr. percae* than in perch muscles for Al, Mn and Fe.

Table 3. Bioconcentration factor (BCF), Bioaccumulation factor (BAF), and Biomagnification factor (BMF)

| **BCF[$C_b/C_w$] wet weight** | **BCF_Al** | **BCF_Cr** | **BCF_Mn** | **BCF_Fe** |
|---|---|---|---|---|
| Liver - Water | 11.68 | 2420.00 | 23.67 | 458.57 |
| Muscle - Water | 2.87 | 660.00 | 3.54 | 16.13 |
| *Pr. percae* - Water | 4.19 | 405.00 | 42.54 | 33.59 |
| Chironomidae - Water | 568.77 | 2112.50 | 714.92 | 1486.61 |
| **BCF [$C_b/C_s$] dry weight** | **Al** | **Cr** | **Mn** | **Fe** |
| Liver - Sediments | 0.002 | 0.56 | 0.02 | 0.05 |
| Muscle - Sediments | 0.0006 | 0.18 | 0.004 | 0.0001 |
| *Pr. percae* - Sediments | 0.001 | 0.09 | 0.05 | 0.004 |
| Chironomidae - Sediments | 0.079 | 0.34 | 0.52 | 0.12 |
| **BAF $C_{Pr.\ percae}/C_{fish}$ wet weight** | **BAF_Al** | **BAF_Cr** | **BAF_Mn** | **BAF_Fe** |
| Liver | 0.36 | 0.17 | 1.79 | 0.07 |
| Muscle | 1.46 | 0.61 | 12.01 | 2.08 |
| **BMF $C_{fish}/C_{Chironomidae}$ wet weight** | **Al** | **Cr** | **Mn** | **Fe** |
| Liver | 0.02 | 1.15 | 0.03 | 0.31 |
| Muscle | 0.005 | 0.31 | 0.005 | 0.01 |

Highest BAFMn-*Pr.pertsae*_Muscle=12.01 gives reason *Pr. percae* to be determined as a bioindicator for Mn. When the values of BCF and BAF are < 250, the risk is low; the risk is moderate from 250 to 1000; and the risk is high and bioaccumulative from 1000 to 5000 (European Chemicals Agency, 2017). When

BMF>1, the contaminant increases and accumulates much more (biomagnification) (Fremlin et al., 2025), in this case, in perch than in food, Chironomidae. We establish it for the accumulation of Cr in the perch liver. The results obtained provide reason to declare the European perch a bioindicator of Cr pollution and Chironomidae bioindicators of Cr and Fe pollution (Table 3).

## CONCLUSIONS

The results obtained for the Topolnitsa Dam, Poibrene Biotope, show poor species diversity in the benthic macroinvertebrate fauna, ichthyocenoses, and parasitic communities of perch. According to the study, the liver of European perch is a bioindicator of Cr pollution, and Chironomidae are bioindicators of Cr and Fe pollution. BAF showed higher bioaccumulation values in *Pr. percae* than in perch muscles for Al, Mn and Fe. The highest BAFMn-*Pr. percae*_Muscle=12.01 determined *Pr. percae* as a bioindicator for Mn.

***Abstract***

*The present study aims to evaluate the water quality of five lakes formed as a result of mineral aggregate extraction (sand and gravel) located in the administrative area of Ineu de Criș, Bihor County, Romania. To achieve this objective, two were carried out in May and October 2025, focusing on relevant physicochemical parameters commonly used to characterize the water quality of post-extraction lakes, including pH, dissolved oxygen (DO,), biochemical oxygen demand ($BOD_5$), chemical oxygen demand (COD), total nitrogen (TN), total phosphorus (TP), and potassium ($K^+$). The obtained results indicated relatively small differences in water quality among the five analysed lakes. Based on the measured concentrations of total nitrogen (TN) and total phosphorus (TP), all lakes were classified in Quality Class I according to Romanian Order No. 161/2006. Regarding dissolved oxygen (OD), lake L3 exhibited the highest values, corresponding to Quality Class I, whereas the remaining lakes showed moderate spatial variability with the lowest values recorded in lake L2. Slight differences were also observed for the $BOD_5$, with most lakes falling within Quality class I, while lake Camelot was classified in quality class II. Overall, the investigated lakes exhibited good to very good physicochemical water quality, with no evidence of significant degradation during the monitoring period These findings suggest that the studied post-extraction lakes have developed relatively stable hydro chemical conditions and may represent valuable aquatic ecosystems within the local landscape, although a comprehensive ecological status assessment would require the inclusion of biological and hydro morphological quality elements in accordance with the European Water Framework Directive (European Parliament and Council, 2000).*

***Key words****: gravel pit lakes, physicochemical parameters, post-exploitation lakes, water quality, water quality assessment, Water Quality Index (WQI).*

## INTRODUCTION

Water represents a fundamental resource at the planetary level, being the essence that sustains life and a critical element in the functioning of geosystems (Popa et al., 2019). Covering approximately two thirds of the Earth's surface, water is not merely a physical compound but an indispensable biological factor, participating in cellular structure, metabolic processes, and the maintenance of the thermal balance of all living organisms. At the macro scale, it acts as a driving force of natural cycles, shaping landforms, influencing climate, and representing the essential link connecting the atmosphere, soil, and biosphere. Water is a fundamental requirement for all forms of life, playing a significant role in sustainable development and the circular economy (Sandu & Vîrsta, 2021).

From a socio-economic perspective, the availability and quality of water are directly linked to food security, public health, and sustainable economic development. However, the relationship between humans and this vital resource has become increasingly complex and strained. The intensification and diversification of anthropogenic activities ranging from industrialization and urbanization to the intensive exploitation of natural resources have generated significant pressures on the hydrological cycle and aquatic ecosystems. At the European scale, recent assessments continue to identify substantial pressures on water quantity and quality and emphasize the need to strengthen water resilience and integrated management (European Environment Agency, 2024; Costa et al., 2025). At the local scale, land-use changes, may also support ecological restoration; for example, the conversion of former pasturelands into community forest in Ineu illustrates a local rehabilitation pathway relevant to landscape stabilization (Timofte & Racz, 2025).

In this context, lakes formed as a result of mineral aggregate extraction (stone and sand) can be considered emerging aquatic systems resulting from anthropogenic transformations of the

hydrographic landscape. At the global level, the exploitation of freshwater sand resources is increasingly associated with issues related to natural resource governance and pressures on aquatic ecosystems, being recently identified as a major challenge for sustainable resource management (United Nations Environment Programme, 2022; Yasmin et al., 2024). In this context, post-extraction lakes represent relevant examples of ecosystems resulting from anthropogenic interventions, which can gradually evolve into functional aquatic systems. Although artificially created, these water bodies may progressively develop into new lacustrine ecosystems in which water reflects both residual anthropogenic impacts and ecological regeneration processes, including the development of new trophic chains. These environments provide an excellent natural laboratory for studying secondary ecological succession and natural self-purification processes.

The main objective of the present study is to evaluate the water quality of lakes formed as a result of mineral aggregate extraction, based on the determination of physic-chemical and biochemical water quality indicators, in order to classify these water bodies according to the quality classes established by the national regulation regarding the classification of surface water quality (Order No. 161/2006, 2006).

The commune of Ineu is located in the central part of Bihor County (Figure 1) and represents the easternmost locality within the Oradea Metropolitan Area.

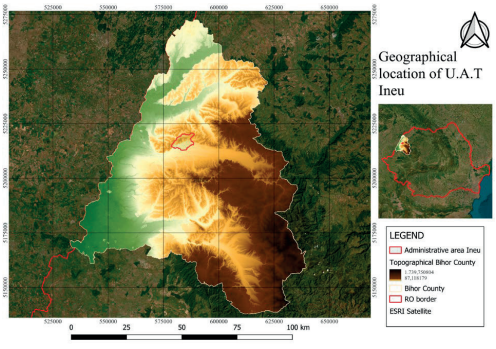

Figure 1. Map of the geographical location of the commune of Ineu using QGIS

The total surface area of Ineu commune is 49.51 km², and the locality is situated at a distance of approximately 20 km from the municipality of Oradea. The geographical coordinates are (47°06′05″ N, 22°06′10″ E). The evolution of the hydrographic landscape in the Ineu area provides an illustrative example of the long-term dynamics of the human-water relationship. The analysis of a historical map from 1782 (Figure 2), georeferenced using QGIS (Bellezza et al., 2014), demonstrates that the original course of the Crișul Repede River crossed the area where part of the present-day locality is currently situated. Naturally, the river branched into two main channels in the area of the locality of Tileagd, forming a complex and unstable hydrographic system. In response to the risks associated with flooding and to support urban development, hydraulic engineering works were implemented to regulate the river course, including the construction of diversion channels aimed at reducing flood risk and protecting the local population. Following the economic transformations that occurred after the 1990s, the upstream agricultural lands were increasingly used for extractive activities, particularly for gravel and sand exploitation, as well as for the expansion of urban areas. These interventions in the river system illustrate the progressive anthropogenic transformation of the landscape and have contributed to the formation of post-extraction lakes, which represent the main focus of the present study.

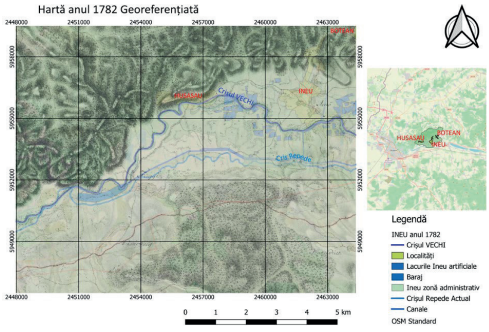

Figure 2. Georeferenced historical map location of the commune of Ineu 1782 using QGIS

The present research aims to:

a) assess the water quality status of lakes formed as a result of mineral aggregate extraction, based on the analysis of physicochemical parameters and their classification into the quality classes established by the applicable legislation;

b) analyze the influence of anthropogenic activities on these ecosystems and highlight their potential for ecological restoration and sustainable use.

## MATERIALS AND METHODS

Specific quality standards are available to indicate the quality of different water sources, such as groundwater, springs, rivers, lakes, and streams, and there are specific water quality criteria for agricultural, industrial, domestic, or other water uses. For example, drinking water must be fresh and free from pollution, while irrigation water should not be excessively saline or toxic, and standards for industrial water use vary depending on the nature of the industrial processes involved. Various human practices and activities, industrial processes, and natural processes significantly and alarmingly affect the quality of water resources, particularly with respect to human well-being.

### Study area

The research was conducted on five surface lakes formed as a result of mineral aggregate extraction (sand and gravel) (Bendixen et al., 2019), located in north-western Romania, in Bihor County, within the administrative area of Ineu. Gravel- pit lakes commonly maintain close hydraulic continuity with surrounding alluvial aquifers, so groundwater-lake exchanges may become a major control on their water balance and hydrochemistry (Jost et al., 2023). The analyzed lakes are arranged approximately along an east-west direction and are identified as follows: L1 - Utopia, L2 - Valer, L3 - Kings Land, L4 - Fildan, and L5 - Camelot Resort.

These water bodies represent anthropogenic lakes formed as a result of mineral aggregate extraction activities (Bendixen et al., 2019; Hackney et al., 2021). Some of them have subsequently been developed and integrated into areas with recreational and tourism functions, while others have remained in a post-extraction state, where natural regeneration processes and ecological succession are gradually shaping new aquatic ecosystems. The hydrological and ecological characteristics of these lakes are influenced both by natural processes and by anthropogenic activities carried out in the surrounding area.

Water samples were collected during two sampling campaigns conducted in May and October 2025. The first sampling campaign took place in May 2025, while the second was carried out in October 2025. During both campaigns, the following physicochemical parameters were determined: pH, water temperature, dissolved oxygen (DO), chemical oxygen demand (COD), biochemical oxygen demand ($BOD_5$), total nitrogen (TN), total phosphorus (TP), and potassium (K). This sampling strategy allowed the evaluation of seasonal variations in water quality between the spring and autumn monitoring periods.

Water samples were collected from the surface layer of the lakes at a depth of approximately 0-0.5 m, corresponding to the warm season when biological activity and biochemical processes in aquatic ecosystems are more intense.

### Water sampling

Water sampling was carried out in accordance with the standardized procedures of the SR EN ISO 5667 series (Figure 3).

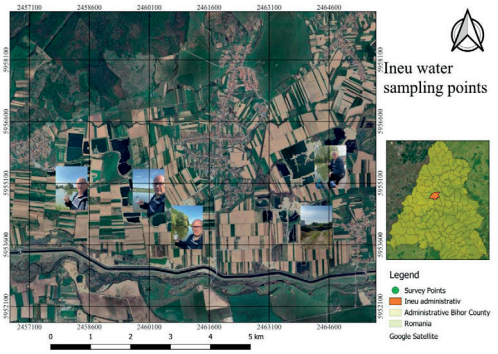

Figure 3. Water Sampling Map of Ineu, created using QGIS

The samples were collected in pre-cleaned glass and polyethylene containers suitable for physicochemical analysis and transported under controlled conditions to the laboratory, where they were analysed on the same day. The procedures for sampling, transport, and preservation were performed in accordance with the following standards:

- SR EN ISO 5667-3:2018 - Preservation and handling of water samples;
- SR EN ISO 5667-4:2016 - Sampling of lakes and reservoirs.

Compliance with these procedures ensures the representativeness of the samples and the integrity of the analyzed parameters until the laboratory analyses are performed.

**Water quality analysis**

For the evaluation of water quality, the following physicochemical parameters were determined:

• pH - determined in the laboratory according to SR EN ISO 10523:2012 PSLU-01;

• Dissolved oxygen (DO, mg $O_2$ $L^{-1}$) - determined by electrochemical method using a membrane electrode (ISO 5814:2012);

• Chemical oxygen demand (COD, mg $O_2L^{-1}$) - determined by the dichromate oxidation method (SR ISO 15705:2022 PSLU-3N);

• Biochemical oxygen demand ($BOD_5$, mg $O_2L^{-1}$) - determined using the 5-day incubation method (SR EN ISO 5815-1:2020 PSLU-04);

• Total phosphorus (TP, mg $L^{-1}$) - determined by molecular absorption spectrometry (SR EN ISO 6878:2005 PS-III-05);

• Total nitrogen ($TN_t$ mg $L^{-1}$) - determined by the chemiluminescence method (SR EN ISO 20236:2024 PS-III-06);

• Potassium ($K^+$, mg $L^{-1}$) - determined by flame photometry (ISO 9964-3:1993 PS-V-04);

• Water temperature (°C) - measured in situ.

The expanded relative uncertainty of the analytical methods was calculated using a coverage factor k = 2, corresponding to a 95% confidence level.

Laboratory analyses were carried out by accredited laboratories of Oradea Water Company S.A. and the Crișuri Water Basin Administration, in accordance with the applicable national and European standards for the determination of water quality parameters.

Water samples were collected by the beneficiary in strict accordance with the sampling protocols and instructions provided by the laboratories to ensure the representativeness and validity of the analyses. Each stage was documented to ensure traceability and quality control.

**Water quality classification**

The interpretation of the physicochemical analysis results was carried out in accordance with Order No. 161/2006, approving the Normative regarding the classification of surface water quality for the determination of the ecological status of water bodies, in its updated form. The classification was performed by comparing the obtained values with the threshold limits corresponding to the quality classes established by the applicable legislation.

**Water Quality Index (WQI*)**

To obtain an integrated assessment of the overall water quality of the investigated lakes, a synthetic Water Quality Index (WQI*) was developed based on the ecological quality classes established by Order No. 161/2006 regarding the classification of surface water quality in Romania. Unlike internationally standardized Water Quality Index models, the proposed WQI* represents a comparative tool specifically adapted to the objectives of this study by integrating the ecological quality classes assigned to selected physicochemical parameters into a single numerical value.

Synthetic water quality indices are widely applied in environmental studies to simplify the interpretation of multiple physicochemical variables and facilitate comparisons among different aquatic ecosystems (Iticescu et al., 2019; Uddin et al., 2021; Georgescu et.al., 2023; Muhammad et al., 2025; Das, 2026).

The WQI* was calculated using the following parameters: pH, dissolved oxygen (DO), biochemical oxygen demand ($BOD_5$), total phosphorus (TP), and total nitrogen (TN). These indicators were selected because they represent key physicochemical variables used in the ecological assessment of surface waters and could be unequivocally assigned to the quality classes defined by Order No. 161/2006.

Chemical oxygen demand (COD) was determined during laboratory analyses and is presented in the results section; however, it was not included in the WQI* calculation because four of the five investigated samples were reported as below the analytical reporting limit (<12 mg $O_2$ $L^{-1}$).

Consequently, the corresponding ecological quality class could not be assigned with sufficient certainty, and its inclusion would have introduced additional uncertainty into the synthetic index.

Potassium ($K^+$) was also excluded from the WQI* calculation. According to Order No. 161/2006, potassium belongs to the group of salinity-related parameters and represents a

naturally occurring constituent rather than an indicator of anthropogenic pollution or ecological degradation. Nevertheless, $K^+$ concentrations were analyzed separately because they may provide useful information regarding groundwater inputs, mineral weathering processes, and local hydrogeochemical conditions.
Total nitrogen concentrations were below the analytical limit of quantification (LOQ) in all investigated samples. Since this value is substantially lower than the threshold corresponding to Quality Class I (1.5 mg $L^{-1}$) established by Order No. 161/2006, all TN measurements were considered to comply with Quality Class I and were assigned the corresponding numerical score in the WQI* calculation.
For each analyzed parameter, the ecological quality class was determined according to the threshold values established by Order No. 161/2006 and subsequently converted into a numerical score (Table 1).

Table 1. WQI* scoring system

| Quality class | Ecological status | Value WQI |
|---|---|---|
| I | very good status | 100 |
| II | good status | 80 |
| III | moderate status | 60 |
| IV | poor status | 40 |
| V | bad status | 20 |

The synthetic WQI* was calculated as the weighted average of the parameter scores using the following equation:

$$WQI^* = \frac{\sum_{i=1}^{n}(w_i \cdot S_i)}{\sum_{i=1}^{n} w_i}$$

where:

- ($S_i$) represents the numeral score assigned to parameter i according to its ecological quality class;
- ($w_i$) represents the weight assigned to parameter i;
- (n) represents the number of parameters included in the calculation.

In the present study, all parameters were assigned equal weights ($w_i = 1$), assuming that each physicochemical indicator contributes equally to the overall assessment of water quality. This approach was adopted to ensure a straightforward and objective comparison among the investigated lakes while avoiding subjective weighting of individual parameters. The proposed WQI* does not replace the official ecological classification established by Romanian legislation. Instead, it serves as a synthetic comparative index designed to integrate multiple physicochemical indicators into a single numerical value, thereby facilitating the overall evaluation and comparison of water quality among the analyzed lakes.

**Statistical analysis**

The obtained data were analyzed using descriptive statistical methods, including the calculation of the arithmetic mean, standard deviation (SV), and coefficient of variation (CV), in order to characterize the variability of the investigated physicochemical parameters.
To evaluate the relationships between the analyzed variables, the Pearson correlation coefficient (r) was calculated according to the following equation:

$$r = \frac{\sum(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\Sigma(x_i - \bar{x})^2 \Sigma(y_i - \bar{y})^2}}$$

where:

- $x_i$ represents the observed values of the first variable;
- $y_i$ represents the observed values of the second variable;
- $\bar{x}$ represents the arithmetic mean value of x;
- $\bar{y}$ represents the arithmetic mean value of y.

The Pearson correlation coefficient ranges from - 1 and +1 where values close to +1 indicate a strong positive linear relationship, values close to −1 indicate a strong negative linear relationship, and values around 0 indicate little or no linear correlation between the analyzed variables.

**Remote sensing analysis (NDVI and NDMI)**

Spatial environmental changes were analyzed using Sentinel-2 satellite imagery provided by the Copernicus Programme for the years 2015 and 2025. Based on these images, the Normalized Difference Vegetation Index (NDVI) and the Normalized Difference Moisture Index (NDMI) were calculated to assess vegetation dynamics and variations in surface moisture content in the area surrounding the analyzed lakes (Șerban et al., 2022).

## RESULTS AND DISCUSSIONS

**Physicochemical parameters**

The results of the physicochemical analyses performed on the five investigated lakes are presented in Table 2. Overall, most of the

analyzed parameters exhibited only minor variations among the lakes, indicating relatively similar water quality conditions. The pH values ranged from 7.0 to 9.0, indicating near neutral conditions in most of the investigated lakes. Lake L3 (Kings Land) recorded the highest pH value (9.0), suggesting a slightly alkaline water conditions. Similar pH ranges (7.2-8.8) have been reported for post-extraction gravel pit lakes in Germany and the Netherlands, where water chemistry is largely controlled by carbonate buffering and biological productivity rather than by anthropogenic pollution (Schultze et al., 2010; Mollema et al., 2016). Likewise, Karlović et al. (2023) reported pH values ranging from approximately 7.0 to 10.7 in Croatian gravel pit lakes, with the highest values being associated with active phytoplankton communities and enhanced photosynthetic processes. Similarly, dissolved oxygen concentrations exceeding saturation levels have been observed in productive gravel pit lakes as a consequence of oxygen release during photosynthesis.

Dissolved oxygen (DO) concentrations varied between 5.65 and 13.70 mg $L^{-1}$, with the highest value recorded in Lake L3 (Kings Land) and the lowest in Lake L2. The DO concentration measured in Lake L3 (13.70 mg $L^{-1}$) substantially exceeded the theoretical oxygen saturation concentration expected at the measured water temperature (18.8°C), which is approximately 9.1 mg $L^{-1}$ under standard atmospheric pressure, indicating oxygen supersaturation of nearly 150%. This phenomenon is commonly associated with intense photosynthetic activity by phytoplankton and submerged aquatic vegetation, which consume dissolved $CO_2$ while simultaneously releasing oxygen into the water column. The elevated pH value (9.0) observed in the same lake further supports this interpretation, as $CO_2$ uptake during photosynthesis shifts the carbonate equilibrium toward more alkaline conditions. Similar patterns of oxygen supersaturation accompanied by elevated pH values have been reported in productive gravel pit lakes and other shallow aquatic ecosystems in the Netherlands and Croatia, where high biological productivity and groundwater–surface water interactions strongly influence hydrochemical conditions (Mollema et al., 2016; Karlović et al., 2023).

The biochemical oxygen demand ($BOD_5$) values ranged from 3.85 to 5.12 mg $L^{-1}$, indicating a low to moderate biodegradable organic load in the investigated lakes. Similar $BOD_5$ values have been reported for European gravel pit lakes, reflecting generally good ecological conditions and limited organic pollution. Total phosphorus concentrations (TP) ranged between 0.045 mg/L and 0.070 mg/L, indicating relatively low nutrient, while total nitrogen (TN) remained below. the limit of quantification (<LOQ) in all analyzed samples. The combination of low phosphorus and nitrogen concentrations suggests limited nutrient enrichment and a low risk of eutrophication. Comparable findings have been reported for gravel pit lakes, where biological uptake by algae and microbial communities contributes to nutrient removal and the maintenance of good water quality. Research on quarry and gravel-pit lakes indicates that many such novel ecosystems may develop comparatively favorable chemical and ecological conditions, although their evolution depends strongly on hydrological connectivity, nutrient availability, lake morphology, and surrounding land use (Mollema & Antonellini, 2016; Seelen et al., 2021; Hetmański et al., 2023). In addition, Karlović et al. (2023) highlighted the potential role of gravel-pit lakes in modifying groundwater chemistry, particularly through processes associated with nitrate removal, including biological uptake and denitrification. Such processes may contribute to lower nitrate concentrations in lake water compared with the surrounding groundwater and illustrate the potential of these systems to provide natural attenuation functions.

Potassium ($K^+$) concentrations exhibited the greatest spatial variability among the analyzed parameters, ranging from 2.00 to 22.55 mg $L^{-1}$, with the highest concentration recorded in Lake L4 (Fildan). In contrast, the remaining lakes showed relatively low potassium concentrations, ranging from 2.00 to 4.90 mg $L^{-1}$. The elevated $K^+$ concentration observed in Lake L4 may reflect local geological characteristics, mineral weathering processes, groundwater inflows, or site-specific anthropogenic influences within the surrounding catchment.

Previous studies have shown that potassium concentrations in gravel pit lakes and post-

extraction water bodies are strongly influenced by the mineral composition of the excavated sediments and by groundwater–surface water interactions rather than by in-lake biological processes. Mollema et al. (2015; 2016) reported that hydrochemical conditions in gravel pit lakes are primarily controlled by geological substrates and groundwater recharge, resulting in spatial differences in dissolved ion concentrations. Jost et al. (2023) further emphasized the close hydrodynamic coupling between gravel-pit lakes and adjacent aquifers. Similarly, Hetmański et al. (2023) highlighted that the chemical composition of gravel pit lakes may vary considerably depending on local lithology, hydrological connectivity, and land-use practices in the adjacent areas.

To provide an integrated visualization of the physicochemical variability among the investigated lakes, the measured parameters are summarized in the heatmap presented in Figure 4.

Table 2. Physicochemical parameters determined of the investigated lakes and their classification according to Order No. 161/2006

| Parameter | L1 (Utopia) | L2 (Valer) | L3 (Kings Land) | L4 (Fildan) | L5 (Camelot Resort) | Quality class according to Order No. 161/2006 |
|---|---|---|---|---|---|---|
| pH | 7.2 | 7.4 | 9.00 | 7.00 | 7.00 | Class I/all lakes |
| DO (mg/L) | 8.32 | 5.65 | 13.70 | 8.47 | 9.41 | L1, L3, L4, L5 – Class I; L2 – Class II |
| COD (mg $O_2$ $L^{-1}$) | <12 | <12 | <12 | 17.40 | <12 | L4 – Class II; others: ≤ Class II (exact class cannot be determined due to censored values) |
| $BOD_5$ (mg $O_2$ $L^{-1}$) | 3.85 | 3.95 | 4.21 | 4.58 | 5.12 | L1–L4 – Class II; L5 – Class III |
| TP (mg P $L^{-1}$) | 0.067 | 0.051 | 0.045 | 0.048 | 0.070 | Class I (all lakes) |
| TN, (mg N $L^{-1}$) | <LOQ | <LOQ | <LOQ | <LOQ | <LOQ | - |
| $K^+$ (mg $L^{-1}$) | 2.00 | 4.90 | 3.20 | 22.55 | 4.40 | Not classified (natural salinity parameter under Order No. 161/2006) |
| Temperature, ℃ | 18.20 | 18.30 | 18.80 | 18.70 | 18.80 | - |

**Note.** COD = chemical oxygen demand; $BOD_5$ = biochemical oxygen demand; TP = total phosphorus; TN = total nitrogen; LOQ = limit of quantification. The physicochemical parameters presented in Table 2 were determined from water samples collected during two monitoring campaigns conducted in May and October 2025.

Potassium ($K^+$) is not included in the ecological quality classification established by Order No. 161/2006, as it belongs to the salinity group and represents a naturally occurring constituent. For COD values reported as "<12 mg $O_2$ $L^{-1}$", an exact quality class cannot be assigned because the analytical result falls below the reporting limit but above the Class I threshold (10 mg $O_2$ $L^{-1}$). Therefore, these values may correspond to either Class I or Class II.

The classification of total nitrogen assumes that the analytical limit of quantification (LOQ) is lower than the Class I threshold established by Order No. 161/2006.

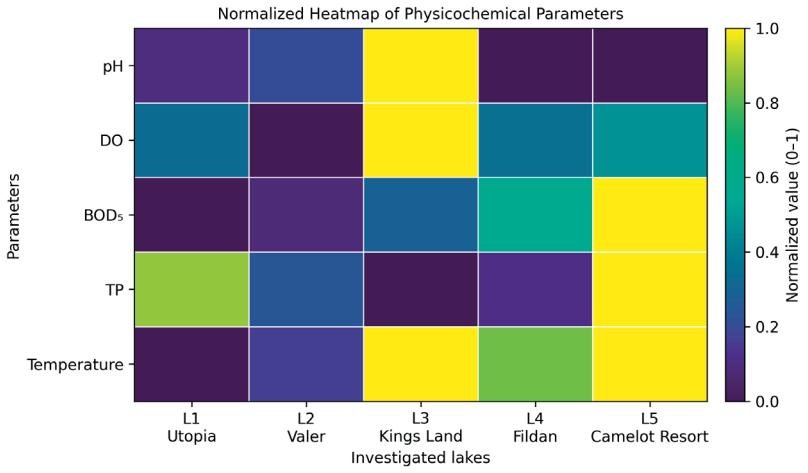

Figure 4. Heatmap of physicochemical parameters across the investigated gravel-pit lakes

The comparison of the obtained values with the threshold limits established by Order No. 161/2006 indicates that most of the analyzed parameters fall within good or very good quality classes. The physicochemical characteristics of the five investigated lakes and their corresponding ecological quality classes according to Order No. 161/2006 are presented in Table 2. Overall, the results indicate that the investigated post-extraction lakes are characterized by generally good physicochemical conditions, with most parameters corresponding to Quality Classes I and II.

The pH values generally fall within Quality Class I, with the exception of Lake L3, where the slightly alkaline value leads to classification in Quality Class II. The pH values ranged from 7.00 to 9.00, indicating neutral to slightly alkaline conditions in all lakes and corresponding to Quality Class I. Dissolved oxygen (DO) concentrations varied between 5.65 and 13.70 mg $L^{-1}$. Four of the five lakes (L1, L3, L4, and L5) were classified as Quality Class I, whereas Lake L2 corresponded to Quality Class II due to its lower oxygen concentration.

Chemical oxygen demand (COD) values were generally low, with concentrations below the analytical reporting limit (<12 mg $O_2$ $L^{-1}$) in four lakes. Lake L4 recorded the highest COD value (17.40 mg $O_2$ $L^{-1}$), corresponding to Quality Class II, while the exact classification of the remaining lakes could not be determined because the reported values were below the analytical threshold.

Biochemical oxygen demand ($BOD_5$) ranged from 3.85 to 5.12 mg $O_2$ $L^{-1}$. Lakes L1-L4 were classified as Quality Class II, indicating a low to moderate biodegradable organic load, whereas Lake L5 slightly exceeded the Class II threshold and was therefore assigned to Quality Class III.

Nutrient concentrations were generally low across all investigated lakes. Total phosphorus (TP) values ranged between 0.045 and 0.070 mg P $L^{-1}$, corresponding to Quality Class I for all sampling sites. Total nitrogen (TN) concentrations were below the analytical limit of quantification in all samples.

Potassium concentrations exhibited the greatest spatial variability, ranging from 2.00 to 22.55 mg $L^{-1}$, with the highest value recorded in Lake L4 (Fildan). However, potassium is classified as a naturally occurring salinity-related element under Order No. 161/2006 and is therefore not used for ecological status assessment. The observed variability is more likely associated with local geological conditions and groundwater–surface water interactions than with anthropogenic pollution.

Overall, the classification according to Order No. 161/2006 indicates that the investigated lakes maintain a predominantly very good to good ecological status, with only isolated deviations observed for $BOD_5$ in Lake L5 and COD in Lake L4. These findings suggest that the post-extraction lakes investigated in the present study have preserved favourable physicochemical characteristics and currently exhibit a low degree of anthropogenic disturbance.

**Calculation of the WQI* index**

The calculated WQI* values for the five investigated lakes are presented in Table 3. The index integrates the quality classes assigned to the analyzed physicochemical parameters (pH, dissolved oxygen, biochemical oxygen demand, total phosphorus, and total nitrogen) into a single comparative value, providing an overall assessment of water quality.

Table 3. Water Quality Index (WQI*) values and interpretation.

| Lake | WQI* | Water quality status |
|---|---|---|
| L1 - Utopia | 95 | Very good |
| L2 - Valer | 83 | Good |
| L3 - Kings Land | 93 | Very good |
| L4 - Fildan | 95 | Very good |
| L5 - Camelot | 90 | Very good |

The calculated WQI* values ranged from 83 to 95, indicating good to very good overall water quality across all investigated lakes. Lakes L1 (Utopia) and L4 (Fildan) achieved the highest index values (95), reflecting the predominance of physicochemical parameters classified within Quality Class I, with only biochemical oxygen demand ($BOD_5$) corresponding to Quality Class II.

Lake L3 (Kings Land) recorded a WQI* value of 93, primarily due to the excellent quality of most analyzed parameters. The slight reduction in the overall score was associated with the pH value, which was assigned to Quality Class II because of its slightly alkaline character.

The lowest WQI* value (83) was obtained for Lake L2 (Valer) and was mainly influenced by

the dissolved oxygen concentration, which corresponded to Quality Class II, while the remaining parameters were generally classified within the highest quality categories.

Lake L5 (Camelot Resort) achieved a WQI* value of 90, indicating very good overall water quality despite the biochemical oxygen demand being classified as Quality Class III. This result demonstrates that the favorable values recorded for the remaining physicochemical parameters compensated for the moderate reduction associated with $BOD_5$.

Overall, the WQI* assessment confirms that the investigated post-extraction lakes exhibit predominantly very good ecological conditions, with only minor differences among sites. The results further indicate that these anthropogenic water bodies have developed stable physicochemical characteristics and currently maintain a generally favourable water quality status.

**Statistical analysis**

The descriptive statistical analysis of the physicochemical parameters is summarized in Table 4. Overall, the results indicate relatively homogeneous water quality conditions among the five investigated lakes, although some parameters exhibited noticeable spatial variability.

Table 4. Descriptive statistics of the investigated physicochemical parameters

| Parameter | Mean | Standard deviation (SD) | Coefficient of variation (CV%) |
|---|---|---|---|
| pH | 7.520 | 0.844 | 11.22 |
| DO (mg $L^{-1}$) | 9.110 | 2.922 | 32.08 |
| COD (mg $O_2$ $L^{-1}$) | 10.704 | 6.362 | 59.44 |
| $BOD_5$ (mg $O_2$ $L^{-1}$) | 4.342 | 0.518 | 11.94 |
| TP (mg P $L^{-1}$) | 0.056 | 0.011 | 20.42 |
| $K^+$ (mg $L^{-1}$) | 7.410 | 8.538 | 115.22 |
| Temperature (°C) | 18.560 | 0.288 | 1.55 |

**Note.** Total nitrogen (TN) concentrations were below the analytical limit of quantification (LOQ) in all investigated samples and were therefore excluded from the descriptive statistical analysis. Chemical oxygen demand (COD) was not included because four of the five measurements were reported as <12 mg $O_2$ $L^{-1}$, preventing the calculation of reliable descriptive statistics.

The mean pH value was 7.52 ± 0.84, indicating neutral to slightly alkaline conditions throughout the study area. Dissolved oxygen (DO) presented an average concentration of 9.11 ± 2.92 mg $L^{-1}$, with a coefficient of variation (CV) of 32.08%, reflecting considerable differences among lakes, mainly due to the elevated value recorded in Lake L3.

Biochemical oxygen demand ($BOD_5$) showed moderate variability (CV = 11.94%), with an average concentration of 4.34 ± 0.52 mg $O_2$ $L^{-1}$, suggesting relatively uniform levels of biodegradable organic matter among the investigated water bodies. Similarly, total phosphorus (TP) exhibited moderate variability (CV = 20.42%) and a mean concentration of 0.056 ± 0.011 mg P $L^{-1}$, indicating relatively consistent nutrient conditions across the study sites.

Potassium ($K^+$) displayed the highest variability (CV = 115.22%), mainly due to the elevated concentration measured in Lake L4. This pronounced variability most likely reflects local hydrogeochemical conditions rather than anthropogenic pollution, as potassium is considered a naturally occurring salinity-related parameter under Order No. 161/2006.

Water temperature remained highly uniform among the investigated lakes, with a mean value of 18.56 ± 0.29°C and a coefficient of variation of only 1.55%, indicating similar thermal conditions during sampling.

Total nitrogen (TN) concentrations were below the analytical limit of quantification (LOQ) in all investigated samples and were therefore excluded from the descriptive statistical analysis.

The Pearson coefficient indicates the direction and strength of the linear relationship between the analyzed indicators. Values close to +1 indicate a strong positive association, while values close to - 1 indicate a strong negative association. The application of the mathematical formula used to calculate the Pearson correlation coefficient resulted in the values presented in Table 5.

The relationships among the investigated physicochemical parameters are further illustrated by the Pearson correlation heatmap presented in Figure 5. Given the limited sample size (n = 5), the observed correlations should be interpreted as exploratory rather than conclusive.

The strongest positive correlation was observed between pH and dissolved oxygen (DO) (r = 0.774), suggesting that both parameters tend to increase simultaneously.

Table 5 Pearson correlation matrix for the investigated physicochemical parameters

| Parameter | pH | DO | $BOD_5$ | TP | $K^+$ |
|---|---|---|---|---|---|
| pH | 1.000 | 0.774 | −0.297 | −0.576 | −0.365 |
| DO | 0.774 | 1.000 | 0.201 | −0.243 | −0.170 |
| $BOD_5$ | −0.297 | 0.201 | 1.000 | 0.294 | 0.309 |
| TP | −0.576 | −0.243 | 0.294 | 1.000 | −0.418 |
| $K^+$ | −0.365 | −0.170 | 0.309 | −0.418 | 1.000 |

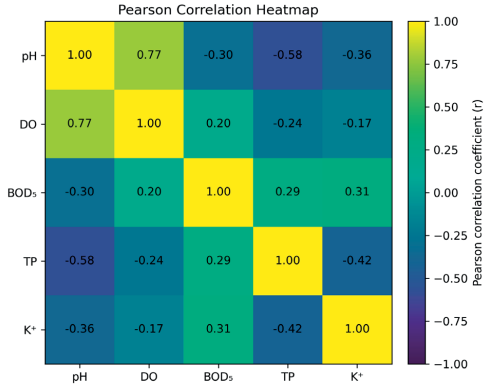

Figure 5. Pearson Correlation Heatmap of the investigated physicochemical parameters (The results should be interpreted with caution because the analysis was performed on a limited dataset - n = 5)

This relationship may be associated with enhanced photosynthetic activity, during which the uptake of dissolved $CO_2$ by aquatic plants and phytoplankton increases pH while simultaneously promoting oxygen production.

A moderate negative correlation was identified between pH and total phosphorus (TP) (r = - 0.576), indicating a tendency for phosphorus concentrations to decrease as pH increases. Likewise, a moderate negative association was observed between TP and potassium ($K^+$) (r = - 0.418). However, the ecological significance of these relationships should be interpreted with caution, as potassium is primarily influenced by local hydrogeochemical conditions rather than anthropogenic pollution.

The correlations involving $BOD_5$ were generally weak, with coefficients ranging between - 0.297 and 0.309, suggesting limited linear relationships with the other investigated parameters.

Similarly, dissolved oxygen exhibited only weak associations with total phosphorus (r = - 0.243) and potassium (r = - 0.170).

Overall, the correlation analysis indicates that no strong linear relationships exist among most of the investigated variables, with the exception of the positive association between pH and dissolved oxygen.

**Analysis of the NDVI and NDMI spectral indices**

The analysis of the Normalized Difference Vegetation Index (NDVI) and the Normalized Difference Moisture Index (NDMI) for the years 2015 and 2025 highlighted significant changes in vegetation cover and surface moisture conditions in the surroundings of the investigated lakes. The comparison of NDVI maps indicates an expansion of areas characterized by moderate to high vegetation density in 2025 relative to 2015, indicated progressive vegetation regeneration and ecological succession in the peri-lacustrine zones following mineral aggregate extraction activities (Șerban et al., 2022). Similary, the NDMI analysis demonstrated an increase area with higher moisture values around the lakes in 2025, reflecting the influence of the newly established water bodies on local soil moisture conditions and the surrounding environment. The creation of these anthropogenic lakes appears to have modified the local hydrological regime by increasing water availability and promoting the development of moisture-dependent vegetation (Figure 6).

Overall, the combined interpretation of the NDVI and NDMI indices suggests that the post-extraction lakes have contributed to the gradual establishment of new ecological conditions, characterized by enhanced vegetation development and improved surface moisture in the adjacent areas. These findings support the hypothesis that, beyond their anthropogenic origin, such water bodies can facilitate local ecological restoration processes and increase landscape heterogeneity.

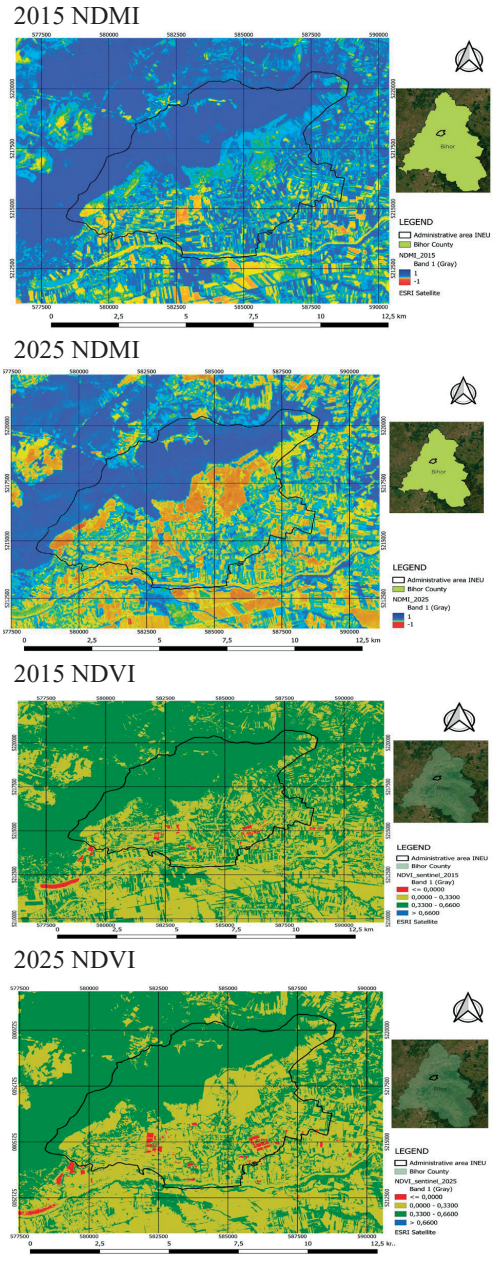

Figure 6. Spatial distribution of the NDVI and NDMI indices in 2015 and 2025, derived from Sentinel-2 imagery, illustrating changes in vegetation cover and surface moisture around the investigated lakes

## CONCLUSIONS

The present study evaluated the water quality of five lakes formed as a result of mineral aggregate extraction in the Ineu area, Bihor County, through the analysis of physicochemical parameters and their integration into a synthetic water quality index (WQI*), complemented by statistical analysis and by the assessment of land -cover and moisture dynamcs using the NDVI and NDMI spectral indices

The physicochemical analyses revealed relatively homogeneous conditions among the investigated lakes, indicating an overall good water quality status. Most pH values were close to neutrality, while dissolved oxygen concentrations generally reflected well-aerated conditions, although lower values recorded in Lake L2 suggest local hydrochemical variability. Biochemical oxygen demand values corresponded to a low to moderate organic load, and total phosphorus concentrations remained low across all sampling sites, indicating limited nutrient enrichment during the monitoring period. The markedly higher potassium concentration recorded in Lake L4 compared with the other investigated lakes, suggesting the influence of local geochemical or hydrological conditions rather than a regional pattern and emphasizing the importance of site-specific controls on the ionic composition of post-extraction aquatic ecosystems.

According to the classification criteria established by Romanian Order No. 161/2006 most analyzed parameters were assigned to Quality Classes I and II, confirming the generally favorable physicochemical status of the investigated water bodies.

The calculated WQI* values ranged between 83 and 95, corresponding to good and very good water quality. The highest scores were obtained for Lakes L1 and L4, whereas the comparatively lower value recorded for Lake L2 was primarily associated with reduced dissolved oxygen concentrations. It should be emphasized that the WQI* represents a synthetic comparative indicator designed for this study and does not replace the ecological status assessment framework established under the European Water Framework Directive.

Statistical analysis confirmed moderate variability for most analyzed parameters, while dissolved oxygen and potassium exhibited higher coefficients of variation, reflecting local environmental heterogeneity among the lakes. Pearson correlation analysis revealed a positive

correlation between pH and dissolved oxygen, as well as moderate relationships between biochemical oxygen demand and nutrient concentrations, suggesting interactions among the biogeochemical processes governing water quality. The analysis of the NDVI and NDMI spectral indices highlighted changes in land cover and moisture regime between the years 2015 and 2025. The increase in NDVI values around the lakes indicates progressive vegetation development in the peri-lacustrine zones, whereas higher NDMI values suggest enhanced surface moisture conditions in adjacent areas whereas higher NDMI values suggest an increase enhanced surface moisture conditions in adjacent areas. These patterns are consistent with ongoing ecological succession and the gradual stabilization of ecosystems established after mineral aggregate extraction. Overall, the investigated lakes indicate curently exhibit good to very good physicochemical water quality and demonstrate a progressive tendency toward ecological stabilization. The development of peri-lacustrine vegetation and relatively stable hydrological conditions may support the establishment of habitats for aquatic and semi-aquatic organisms, including bird species observed in the study area, thereby increasing the ecological value of these artificial lakes. Nevertheless, the suitability of these water bodies for recreational activities or aquaculture should be verified through additional biological, microbiological, and sanitary assessments.

Several limitations should be considered when interpreting the results. The relatively small number of investigated lakes (n = 5) restricts the extrapolation of the findings to other post-extraction aquatic systems. Furthermore, physicochemical monitoring was based on two sampling campaigns conducted in 2025 and therefore may not fully capture seasonal or interannual variability. In addition, the assessment focused exclusively on physicochemical indicators and did not include the biological quality elements or hydromorphological components required for a complete ecological status evaluation under the Water Framework Directive.

Future research should incorporate long-term monitoring, a broader suite of physicochemical and biological indicators, and ecological assessment methods consistent with the Water Framework Directive to o provide a more comprehensive understanding of the evolution and ecological functioning of lakes formed as a result of mineral aggregate extraction.

***Abstract***

*Photochemical degradation under ultraviolet (UV) radiation is a significant transformation process that modifies pesticide concentration dynamics in aquatic environments. This study investigates the UV-induced photochemical degradation of imidacloprid in water through Computational Fluid Dynamics (CFD) modelling. Imidacloprid, a widely used agricultural insecticide, is frequently detected in surface waters, underscoring the importance of its photochemical behaviour for understanding concentration fluctuations in aquatic systems. The numerical model couples fluid flow and species transport with a UV-dependent photochemical degradation term to simulate the spatial and temporal evolution of imidacloprid concentrations. The degradation process is represented by a pseudo-first-order kinetic model, in which the reaction rate is determined solely by the local UV radiation intensity. Transient simulations were conducted to assess the influence of hydrodynamic conditions and UV exposure on the reduction in imidacloprid concentration within the flow domain. The results reveal a heterogeneous distribution of degradation rates, governed by spatial variations in flow patterns and UV intensity. This study isolates UV-induced photochemical degradation, excluding other chemical or biological transformation mechanisms, to elucidate the specific contribution of photochemical processes to pesticide concentration dynamics in aquatic environments.*

***Key words****: CFD modelling, imidacloprid, pesticide pollution, photochemical processes, UV radiation, water quality.*

## INTRODUCTION

Global urbanisation has increased significantly in recent decades, resulting in a substantial shift of populations from rural to urban areas and a corresponding modification of demographic patterns (Gu et al., 2021). The proportion of the global population residing in urban areas rose from approximately 30% in 1950 to around 56–57% between 2020 and 2024, and is projected to reach nearly 68% by 2050 (United Nations, 2025). This demographic transition has intensified pressure on agricultural systems, prompting the expansion and intensification of crop production. Consequently, the use of agrochemicals has increased to maintain high agricultural productivity and ensure global food security (Aktar et al., 2009). Projections indicate that global food production must increase by approximately 60-70% in the coming decades, necessitating intensive farming practices, technological innovations such as precision agriculture and genetically modified organisms (GMOs), and the implementation of sustainable agricultural strategies to minimise environmental degradation (Tudi et al., 2021). Spatial heterogeneity in environmental processes, such as the non-uniform distribution of degradation rates for agrochemicals like pesticides, presents an important consideration for water-quality management. For example, identifying areas within aquatic systems that exhibit slower natural degradation could inform the strategic placement of water-quality monitoring stations or suggest optimal zones for implementing UV-enhancement interventions. Translating these model outputs into actionable guidance helps prioritise management efforts, improve the efficiency of resource allocation, and support proactive interventions in vulnerable zones.

Neonicotinoid insecticides are widely used in modern agriculture (Stehle et al., 2023). They have high efficacy against many insect pests and possess systemic properties. Imidacloprid (IUPAC name: N-[1-[(6-chloropyridin-3-yl)methyl]-4,5-dihydroimidazol-2-yl]nitramide) is one of the most common in this class. Imidacloprid acts as an agonist of nicotinic acetylcholine receptors (nAChRs) in

the insect nervous system. This causes overstimulation of neural transmission, paralysis, and death (Zhang et al., 2008). Its systemic nature enables absorption and distribution throughout plant tissues, providing broad pest protection (Simon-Delso et al., 2015; Merga & Van den Brink, 2025). These properties also contribute to its persistence and potential dispersion in the environment. Imidacloprid has relatively high water solubility (~610 mg/L at 20°C), moderate environmental persistence, and low soil sorption. These traits increase its mobility in aquatic systems (Tomizawa & Casida, 2005). As a result, imidacloprid is often detected in surface waters. This is mainly due to agricultural runoff, spray drift, soil erosion, and drainage linked to intensive farming (Peterson, 2007; Malla et al., 2021). Pesticide residues can also reach shallow groundwater by infiltrating soils in agricultural regions (Gavrilescu, 2005; Arias-Estévez et al., 2008).

The occurrence of neonicotinoid insecticides in aquatic ecosystems has raised significant environmental concerns due to their potential toxic effects on non-target organisms (Van Dijk et al., 2013; Morrissey et al., 2015). Several studies have demonstrated that neonicotinoids can impact a wide range of aquatic invertebrates and other organisms at relatively low concentrations, potentially altering trophic interactions and ecosystem functioning (Tomizawa & Casida, 2005). The toxicity of pesticides in aquatic environments is influenced by physicochemical parameters, including temperature, pH, dissolved oxygen concentration, and salinity (Klaassen et al., 1986). The magnitude of toxic effects also depends on the chemical properties of the compound, the sensitivity of exposed species, and prevailing environmental conditions (Costache & Modrogan, 2006). Therefore, the persistence, transport, and transformation of pesticides in aquatic systems are critical factors in determining their ecological impact.

In response to these potential environmental risks, pesticides present in aquatic environments are subject to strict regulation within the European Union. The Water Framework Directive (Directive 2000/60/EC) establishes a comprehensive legislative framework to achieve good ecological and chemical status for surface waters, while Directive 2013/39/EU defines environmental quality standards for priority substances and other pollutants. These regulatory frameworks underscore the importance of understanding the environmental fate and transformation mechanisms of pesticides in aquatic systems to support effective environmental monitoring and risk assessment strategies. Photochemical degradation induced by ultraviolet (UV) radiation is a significant natural attenuation mechanism for organic contaminants in surface waters (Zepp et al., 1977; Zepp et al., 1995; Schwarzenbach et al., 2010). Imidacloprid can undergo both direct photolysis, via photon absorption leading to molecular transformation, and indirect photochemical reactions mediated by reactive species, such as hydroxyl radicals, generated in aquatic environments (Wamhoff & Schneider, 1999; Lu et al., 2015). Studies have shown that the photolytic half-life of imidacloprid in aqueous systems varies considerably depending on radiation intensity, water composition, and environmental conditions, ranging from several hours to several days (Wamhoff & Schneider, 1999; Fenoll et al., 2011). The efficiency of photochemical degradation is further influenced by factors such as water depth, turbidity, dissolved organic matter, and hydrodynamic mixing conditions (Schwarzenbach et al., 2010; Fenoll et al., 2011). While the environmental occurrence, persistence, and toxicity of imidacloprid have been extensively studied (Bonmatin et al., 2015; Morrissey et al., 2015), fewer studies have examined the interactions between hydrodynamic transport processes and photochemical degradation mechanisms. In natural aquatic systems, contaminant behaviour is governed by both chemical transformation reactions and physical transport processes such as advection, dispersion, diffusion, and turbulent mixing (Fischer et al., 1979; Chapra, 1997), which determine the spatial distribution and residence time of pollutants.

Despite growing interest in pesticide photodegradation, combining UV-induced degradation with hydrodynamic modelling remains limited, especially in controlled-flow experiments.

Integrating hydrodynamic modelling with degradation kinetics is essential for predicting the fate of pesticides. Computational Fluid Dynamics (CFD) models simulate fluid flow and contaminant transport in aquatic environments (Versteeg & Malalasekera, 2007; Blocken, 2015). These models solve equations of fluid motion and mass transport. This allows coupling hydrodynamic processes with chemical kinetics and enables simulation of pollutant dispersion and degradation under controlled conditions. In this work, imidacloprid degradation follows a pseudo-first-order reaction rate. Key assumptions are: (i) the photodegradation quantum yield is constant, (ii) UV intensity is stable, (iii) scavengers and secondary reactive species are negligible, (iv) temperature and pH are constant, and (v) no intermediate products significantly affect the rate. These assumptions simplify the model and link photodegradation kinetics to measurable variables. The aim is to investigate imidacloprid's photodegradation under UV using CFD modelling.
The model combines hydrodynamic transport processes with degradation kinetics used to simulate the spatial and temporal evolution of imidacloprid concentrations in a controlled aquatic system.

## MATERIALS AND METHODS

Photochemical degradation of imidacloprid in water under ultraviolet (UV) radiation was investigated. The study used a Computational Fluid Dynamics (CFD) approach implemented in ANSYS Fluent 2026 R1. The numerical model simulated the system's hydrodynamic behaviour. It also simulated the transport and transformation of imidacloprid under UV irradiation.

### Computational approach

The CFD model integrates radiation transport, heat transfer, and reactive species transport. This combination allows the simulation of the photochemical degradation of imidacloprid in water. Ultraviolet radiation (280-400 nm) was modelled using the Discrete Ordinates (DO) radiation model. This model calculates radiation intensity in a participating medium. The attenuation of ultraviolet radiation within the water column was described using the Beer-Lambert law. This law accounts for exponential absorption along the optical path.
The transport and degradation of imidacloprid were simulated using the Species Transport model in ANSYS Fluent. Photochemical degradation was treated as a volumetric reaction following pseudo-first-order kinetics. The degradation rate depends on the local radiation intensity. The energy equation was included to account for thermal effects from radiation absorption. Transient simulations evaluated the time-dependent development of imidacloprid concentration during ultraviolet irradiation.

### Geometry and computational domain

The computational domain models a simplified photochemical reactor to simulate ultraviolet-induced degradation of imidacloprid in water. The reactor geometry is two-dimensional, reducing computational cost while preserving key physical processes such as radiation absorption and photochemical degradation.
The computational domain has dimensions of 500 mm in length and 700 mm in height (Figure 1), representing the irradiated water volume. The aqueous phase fills the domain, where photochemical degradation of imidacloprid occurs under ultraviolet irradiation.

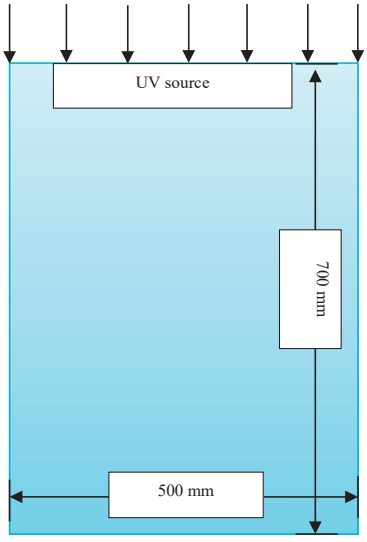

Figure 1. Computational fluid domain

Ultraviolet radiation was introduced at the upper boundary of the computational domain to represent the UV irradiation source. The radiation propagates vertically through the water column from top to bottom, simulating the penetration of ultraviolet light into the aqueous medium.

**Mesh generation**

The computational domain was discretised using a structured-dominant mesh generated in ANSYS Meshing. A quad-dominant meshing approach was applied to ensure numerical stability and efficiency of the two-dimensional domain (Wang et al., 2026). Mesh refinement was introduced near the UV radiation source to capture strong radiation gradients, using a bias factor of 4 in the direction of radiation penetration.

Mesh quality was evaluated using standard indicators. The skewness values ranged from $1.3057 \times 10^{-10}$ to $1.3065 \times 10^{-10}$; the aspect ratio ranged from 1.0009 to 1.8218; and the orthogonal quality ranged from 0.84364 to 1, confirming the high numerical quality of the computational grid (Figure 2).

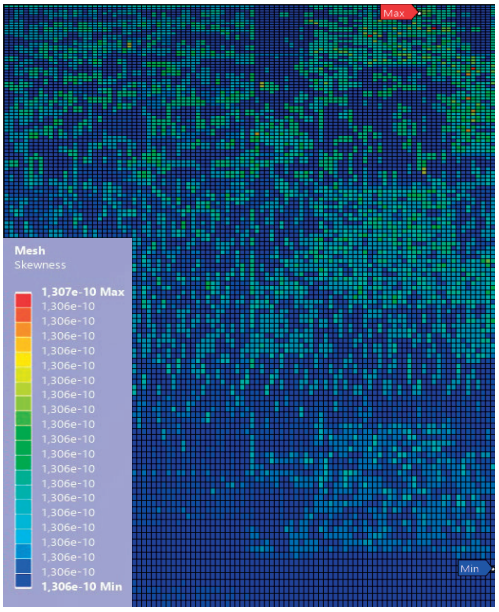

Figure 2. Mesh skewness of the domain

The final computational grid consisted of 14,241 nodes and 14,000 elements, providing an adequate spatial resolution for the numerical simulation of radiation absorption and photochemical degradation processes.

**Governing equations**

Hydrodynamic behaviour, heat transfer, radiation, and photochemical breakdown of imidacloprid were simulated using computational fluid dynamics (CFD) in ANSYS Fluent.

The model describes the coupled transport of water, heat, radiation and pesticide concentration. The flow of the fluid is described by the *continuity* and *Navier-Stokes equations*:

$$\nabla \cdot \vec{u} = 0$$

$$\rho\left(\frac{\partial \vec{u}}{\partial t} + \vec{u} \cdot \nabla \vec{u}\right) = -\nabla p + \mu \nabla^2 \vec{u} + \rho \vec{g}$$

where $\vec{u}$ is the velocity vector, $\rho$ is the fluid density, $p$ is the pressure, $\mu$ is the dynamic viscosity, and $\vec{g}$ is the gravitational acceleration.

Temperature-driven natural convection was modelled with the Boussinesq approximation:

$$\rho = \rho_0[1 - \beta(T - T_{ref})]$$

where $\rho_0$ is the reference density, $\beta$ is the thermal expansion coefficient, $T$ is the local temperature, and $T_{ref}$ is the reference temperature.

Heat transfer was described by the energy conservation equation:

$$\rho c_p\left(\frac{\partial T}{\partial t} + \vec{u} \cdot \nabla T\right) = \nabla \cdot (k \nabla T) + S_r$$

where $T$ is the temperature, $c_p$ is the specific heat capacity, $k$ is the thermal conductivity, and $S_r$ is the source term associated with radiation absorption.

Radiative heat transfer in the water was modelled using the Discrete Ordinates (DO) method. The radiative transfer equation is:

$$\vec{s} \cdot \nabla I(\vec{r}, \vec{s}) + (a + \sigma_s) I(\vec{r}, \vec{s}) = a \frac{\sigma T^4}{\pi} + \frac{\sigma_s}{4\pi} \int_{4\pi} I(\vec{r}, \vec{s}') \, d\Omega'$$

where $I$ is the radiation intensity, $a$ is the absorption coefficient of water, $\sigma_s$ is the scattering coefficient, $\sigma$ is the Stefan-Boltzmann constant, and $\vec{s}$ is the direction

vector. The absorption coefficient governs the attenuation of radiation in the water column, according to Beer-Lambert's law.
The transport of dissolved imidacloprid in water was described using the species conservation equation:

$$\frac{\partial(\rho Y)}{\partial t} + \nabla \cdot (\rho \vec{u} Y) = \nabla \cdot (\rho D \nabla Y) + R$$

where $Y$ is the mass fraction of imidacloprid, $D$ is the molecular diffusion coefficient in water, and $R$ is the local reaction rate.

**Photochemical degradation kinetics**
The photochemical degradation of imidacloprid was described using a spatially dependent pseudo-first-order kinetic model implemented via a user-defined function (UDF) in ANSYS Fluent. The local photodegradation rate constant was defined as a function of ultraviolet radiation intensity and temperature.

$$k_{photo}(z,T) = \Phi * \varepsilon_{UV} * I_{UV}(z) * f_T$$

Ultraviolet radiation attenuation within the water column was defined by the Beer–Lambert law, which describes exponential decay of light intensity with depth:

$$I_{UV}(z) = I_0 e^{-\alpha z}$$

where $I_{UV}(z)$ denotes the UV radiation intensity at depth $z$, $I_0$ is the incident radiation intensity at the water surface, and α is the extinction coefficient of the medium.
The temperature dependence of the reaction rate was introduced through an Arrhenius-type correction factor.

$$f_T = exp\left[-\frac{E_a}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right]$$

where $E_a$ is the activation energy, $R$ is the universal gas constant, $T$ is the local temperature, and $T_{ref}$ is the reference temperature.
Thus, the overall local photodegradation rate constant can be expressed as:

$$k_{photo}(z,T) = \Phi * \varepsilon_{UV} * I_0 e^{-\alpha z} * exp\left[-\frac{E_a}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right]$$

Within the CFD framework, the degradation of the imidacloprid process was implemented through source terms in the species transport equations. The consumption of imidacloprid was expressed as:

$$S_{imd} = -\rho, Y_{imd,} k_{photo}$$

while the formation of the degradation product was defined as:

$$S_{prod} = \rho, Y_{imd} k_{photo} \left(\frac{MW_{prod}}{MW_{imd}}\right)$$

where $\rho$ is the fluid density, $Y_{imd}$ is the mass fraction of imidacloprid, and $MW_{prod}$ and $MW_{imd}$ are the molecular weights of the degradation product and imidacloprid, respectively.

**Boundary and initial conditions**
Computational simulations were performed in a two-dimensional water column subjected to ultraviolet irradiation at the free surface. The upper boundary was a radiation inlet that allowed 40 W $m^{-2}$ of ultraviolet radiation into the computational domain (Benitez et al., 2013). The bottom and lateral boundaries were impermeable no-slip walls. The initial velocity was zero to represent quiescent water before irradiation. The fluid temperature started at 293.15 K. Water properties were constant: density 998.2 kg $m^{-3}$, dynamic viscosity 0.001 Pa s, thermal conductivity 0.6 W $m^{-1}$ $K^{-1}$, and specific heat capacity 4182 J $kg^{-1}$ $K^{-1}$. Radiative transfer used the Discrete Ordinates (DO) model with water optical properties set as absorption coefficient 3.0 $m^{-1}$, scattering coefficient 0.2 $m^{-1}$, and refractive index 1.33. Initial imidacloprid concentrations (5, 10, and 15 µg/L) were uniformly distributed in the water column. The molecular diffusion coefficient of imidacloprid in water was constant during the simulations.

**Photokinetic model parameters**
The parameters used in the user-defined function (UDF) to describe the photodegradation kinetics of imidacloprid are summarised in Table 1. The model incorporates attenuation of UV radiation with depth, the quantum yield

of the photochemical reaction, and the temperature dependence of the reaction rate via an Arrhenius relationship (Appendix 1).

Table 1. Photokinetic parameters used in the CFD mode

| Parameter | Symbol | Value | Unit | Description |
|---|---|---|---|---|
| Incident UV intensity | $I_0$ | 1.0 | – | UV intensity at water surface |
| Extinction coefficient | $\alpha$ | 3.0 | $m^{-1}$ | Light attenuation coefficient |
| Quantum yield | $\Phi$ | 0.019 | – | Efficiency of photochemical reaction |
| Photokinetic coefficient | $\varepsilon_{UV,}$ | 6e-5 | – | Photochemical proportionality constant |
| Activation energy | $E_a$ | 20000 | J $mol^{-1}$ | Activation energy for degradation |
| Gas constant | $R$ | 8.314 | J $mol^{-1}$ $K^{-1}$ | Universal gas constant |
| Reference temperature | $T_{ref}$ | 293.15 | K | Reference temperature |
| Water surface height | $H_{top}$ | 0.7 | m | Position of free surface |

Several intermediate variables required for the photochemical degradation model were stored using the User-Defined Memory (UDM) feature in ANSYS Fluent. These variables allow the spatial visualization and post-processing of the photokinetic parameters during the simulation. The UDM locations were used to store the depth relative to the free surface, the local UV radiation intensity calculated using the Beer-Lambert law, and the corresponding local photodegradation rate constant. The stored variables are summarised in Table 2.

Table 2. Photokinetic parameters used in the CFD mode

| UDM index | Stored variable | Description |
|---|---|---|
| UDM 0 | Depth $z$ | Distance from the free surface used in the Beer–Lambert attenuation law |
| UDM 1 | $I_{UV}$ | Local UV radiation intensity in the water column |
| UDM 2 | $k_{photo}$ | Local photodegradation rate constant |

The combined use of UDF and UDM functionalities enables the dynamic evaluation of the photodegradation kinetics and allows detailed spatial analysis of UV radiation intensity and reaction rates within the water column.

**Numerical setup**

Numerical simulations used a pressure-based solver under transient conditions to capture the system's dynamic response and ensure accurate modelling of time-dependent phenomena. The Discrete Ordinates (DO) radiation model represented ultraviolet radiation in the 0.28 ÷ 0.40 μm spectral range, as this range covers both the UVB and UVA regions relevant to the study objectives. The DO model was chosen for its proven effectiveness in resolving directional radiation effects in participating media, as demonstrated in previous research. Simulations used a 60-second time step and 100 iterations per step, parameters selected to balance computational efficiency and solution stability without significant loss of accuracy. The total simulation time of 2,000 steps (120,000 seconds of irradiation) was set to fully observe the cumulative effects of ultraviolet exposure. Pressure-velocity coupling employed the Rhie-Chow momentum interpolation scheme, which helps to prevent pressure-velocity decoupling issues and is recommended for transient flow calculations. Second-order upwind schemes were applied to the momentum, energy, and radiation equations to improve accuracy and minimise numerical diffusion, following best practices in the literature. The wrapped face gradient correction method was used to reconstruct gradients, thereby enhancing the spatial accuracy of variable gradients on non-orthogonal meshes. Convergence was ensured when energy residuals fell below $10^{-6}$ and other residuals below $10^{-5}$, thresholds commonly adopted to confirm reliable, consistent simulation results.

**Data processing and analysis**

The simulation results were analysed by examining the spatial distribution of ultraviolet radiation and the corresponding variation of imidacloprid concentration within the reactor domain. Particular attention was given to the vertical penetration of radiation through the water column and its influence on photochemical degradation. Concentration fields were evaluated at different simulation times to observe the progressive decrease in imidacloprid concentration during ultraviolet irradiation. Spatial concentration maps were used to identify zones of enhanced degradation associated with higher radiation intensity. The temporal evolution of the average imidacloprid concentration in the reactor was also analysed to quantify the overall degradation behaviour

and assess the efficiency of ultraviolet-induced photodegradation. The numerical model described in the previous section was used to investigate the photochemical degradation of imidacloprid in water under ultraviolet irradiation. The simulation results provide insight into the spatial distribution of ultraviolet radiation within the water column and the corresponding evolution of imidacloprid concentration over time.

## RESULTS AND DISCUSSIONS

The results obtained from the CFD simulations are presented and analysed to evaluate the influence of ultraviolet radiation on the degradation behaviour of imidacloprid in water. Particular attention is given to the penetration of ultraviolet radiation into the water column, the spatial distribution of radiation intensity, and the resulting variation in imidacloprid concentration. The analysis focuses on the temporal evolution of pesticide concentration and the identification of regions where photochemical degradation occurs more rapidly due to higher radiation exposure. These results provide insight into the coupled effects of radiation transport and reaction kinetics governing the degradation process.

### UV radiation distribution in water

Ultraviolet radiation was simulated within the water domain using the Discrete Ordinates (DO) model. Figure 3 presents the incident radiation intensity within the reactor, measured in $W \cdot m^{-2}$. The highest intensities are observed near the irradiated surface, where incoming UV radiation interacts directly with the water.

As radiation propagates through the water column, its intensity decreases with depth due to absorption by the medium. This pattern follows the Beer-Lambert law, which describes an exponential decrease in intensity through an absorbing medium.

The simulation indicates that radiation intensity decreases from approximately 39 $W \cdot m^{-2}$ at the irradiated boundary to below 5 $W \cdot m^{-2}$ deeper in the domain. The imposed boundary condition for incident radiation was 40 $W \cdot m^{-2}$. However, the contour plot shows nodal or cell-interpolated values calculated by the numerical solver, not the exact boundary condition.

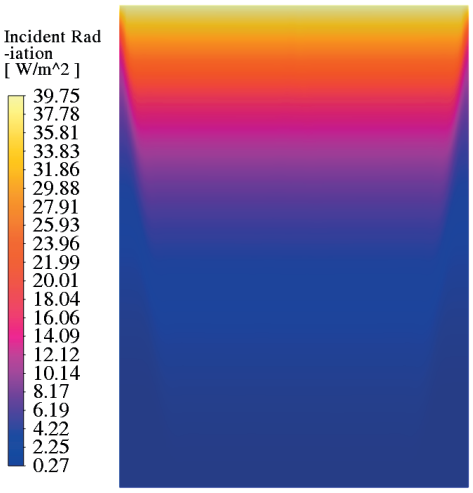

Figure 3. Spatial distribution of incident ultraviolet radiation intensity within the water domain simulated using the Discrete Ordinates radiation model

As a result, the maximum value in the field is slightly lower than the prescribed boundary intensity. In the Discrete Ordinates radiation model in ANSYS Fluent, the radiation intensity field is solved within control volumes. It is then interpolated to nodes for visualisation. The plotted values show the local solution of the radiative transport equation in cells next to the boundary, not the exact boundary input. This explains the small difference between the imposed value (40 $W \cdot m^{-2}$) and the maximum value in the contour plot (≈39 $W \cdot m^{-2}$). Such small deviations are expected in finite-volume discretisation. Here, the radiative flux is evaluated over control-volume faces and distributed across neighbouring cells. So, the slight reduction in the maximum plotted intensity does not mean a physical loss of radiation at the boundary. It simply reflects the numerical representation of the radiation field within the computational mesh.

### Temperature evolution during UV irradiation

The thermal response of the water domain under prolonged ultraviolet irradiation was evaluated. Figure 4 presents the spatial distribution of static temperature after 45 hours of continuous UV exposure. The initial water temperature was set at 293.15 K (20°C) to represent typical environmental conditions.

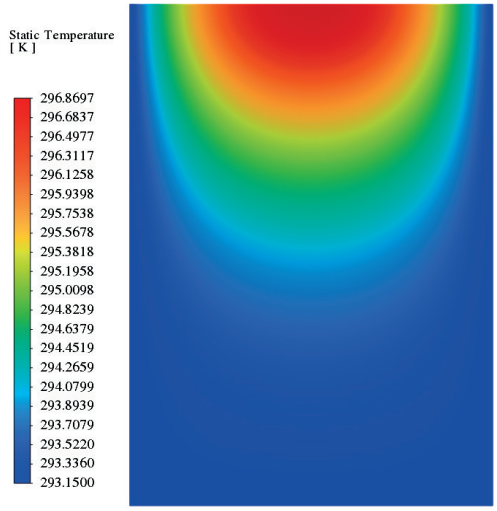

Figure 4. Spatial distribution of temperature in the water domain after 45 hours of ultraviolet irradiation, showing the thermal effect generated by radiation absorption

Simulation results show a gradual increase in temperature within the irradiated region, reaching approximately 296.87 K, a rise of about 3.7 K relative to the initial condition. The observed increase is attributed to the absorption of ultraviolet radiation by water, in which a portion of the radiative energy is converted to thermal energy. The temperature field displays a distinct spatial gradient. The highest temperatures are near the irradiated boundary. This area aligns with the zone of maximum radiation intensity and significant photon energy absorption. As radiation penetrates deeper into the water column, its intensity diminishes due to optical attenuation. This results in reduced local heat generation and lower temperatures. The temperature distribution closely mirrors the spatial pattern of the previously discussed radiation field. This correspondence suggests that the temperature rise is primarily governed by local ultraviolet radiation absorption. Regions exposed to higher photon flux undergo greater radiative heating. Deeper regions remain near the initial temperature due to limited radiation penetration.

Although the overall temperature increase is moderate, the results demonstrate that prolonged ultraviolet irradiation produces measurable thermal effects in the water column. These thermal gradients may influence physicochemical processes such as diffusion rates and reaction kinetics. However, in the present model, the primary factor driving imidacloprid degradation is the availability of ultraviolet photons rather than increased temperature.

Radiation and temperature distributions from simulations reveal the physicochemical conditions that govern imidacloprid degradation in water. The simulated ultraviolet field shows a marked decrease in radiation intensity with increasing depth. This restricts high-energy photons from penetrating the lower regions of the water column. As a result, only the upper portion of the domain receives enough photon flux to initiate photolytic reactions. Inside the water, absorbed radiative power causes a gradual thermal response. This is seen as a temperature increase near the irradiated boundary after extended exposure.

The current model considers photochemical degradation of imidacloprid as a volumetric reaction. The reaction rate depends on local ultraviolet radiation intensity, calculated with the Discrete Ordinates radiation method. Thus, the spatial distribution of radiation intensity directly influences the spatial distribution of the reaction rate. Areas exposed to higher incident radiation are expected to show faster pesticide transformation. Areas with less photon availability become increasingly reaction-limited.

Based on the results, the subsequent section analyses the evolution of imidacloprid concentration within the computational domain, showing how the combined effects of radiation penetration and local energy absorption shape the spatial pattern and temporal progression of pesticide degradation under ultraviolet irradiation.

**Spatial distribution of imidacloprid degradation**

The spatial distribution of imidacloprid concentration obtained from the CFD simulations is shown in Figure 5. The results illustrate the progressive transformation of the pesticide within the water domain due to ultraviolet irradiation. At the beginning of the simulation, the imidacloprid concentration was uniformly distributed throughout the domain with an initial value of 10 μg/ L. As irradiation

proceeds, the concentration decreases progressively due to radiation-dependent photochemical degradation.

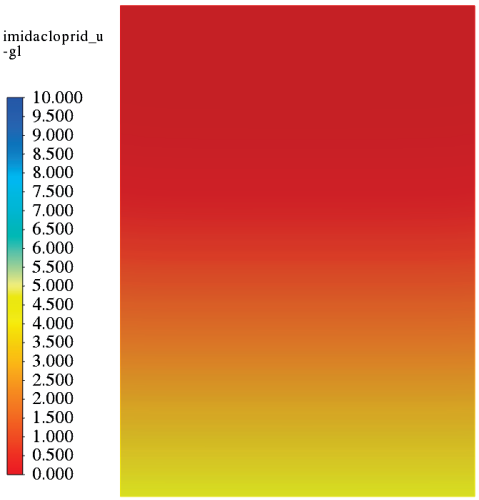

Figure 5. Spatial distribution of imidacloprid concentration within the water domain after UV irradiation

The spatial pattern of imidacloprid concentration corresponds to the distribution of ultraviolet radiation in the water column. Regions close to the irradiated boundary receive the highest radiation intensity and show the largest reduction in pesticide concentration. In contrast, deeper regions retain higher imidacloprid concentrations.

Ultraviolet radiation does not penetrate as deeply due to optical attenuation in water. This result shows that photon availability strongly controls the degradation process. Correspondingly, the complementary distribution of the reaction product formed during the degradation process is presented in Figure 6. As imidacloprid undergoes photochemical transformation, the concentration of the product species increases progressively throughout the domain.

The spatial distribution of the product corresponds to the inverse pattern of the parent compound, with higher product concentrations observed in zones where the degradation of imidacloprid is most pronounced. This complementary behaviour reflects the progressive conversion of the parent pesticide into transformation products as the photochemical reaction proceeds.

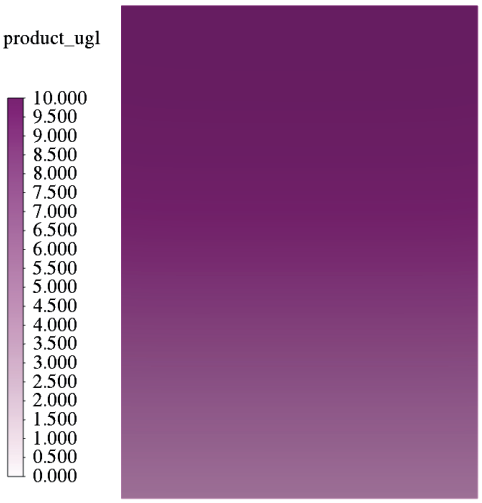

Figure 6. Spatial distribution of the photodegradation product formed during the transformation of imidacloprid

Regions exposed to higher ultraviolet radiation intensities exhibit a faster depletion of the parent compound and, consequently, a higher accumulation of the degradation product. In contrast, areas receiving lower radiation intensities show slower product formation due to the reduced rate of photochemical transformation. This complementary spatial distribution between reactant depletion and product formation confirms the internal consistency of the implemented reaction mechanism within the species transport model and demonstrates that the model adequately captures the mass transfer associated with the photochemical conversion process.

**Temporal degradation behaviour and $DT_{50}/DT_{90}$ assessment**

To complement the spatial analysis, the temporal evolution of imidacloprid concentration was evaluated for five initial concentration levels: 2.5, 5, 10, 15, and 20 μg $L^{-1}$. The simulations were performed under identical ultraviolet irradiation and kinetic conditions in order to assess the concentration-dependent response of the degradation process. The resulting concentration profiles are presented in Figure 7.

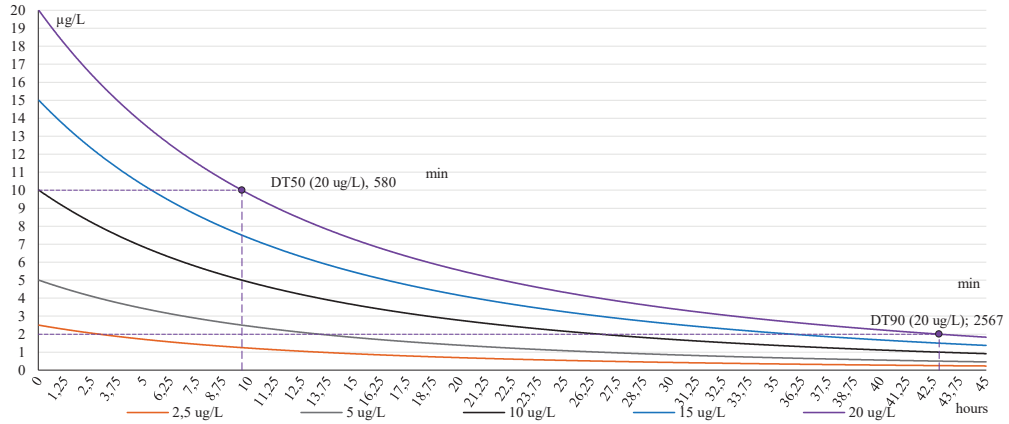

Figure 7. Temporal evolution of imidacloprid concentration during ultraviolet irradiation

The concentration profiles show a continuous decrease in imidacloprid concentration for all investigated initial levels, confirming the progressive degradation of the pesticide under ultraviolet irradiation. The nonlinear decay pattern, characterised by a faster concentration decrease during the initial stage followed by a gradual slowing of the degradation rate, indicates an apparent pseudo-first-order attenuation behaviour.

For the 20 µg $L^{-1}$ scenario, the $DT_{50}$ and $DT_{90}$ values were approximately 580 min and 2567 min, respectively. These values correspond to a decrease in concentration from 20 to 10 µg $L^{-1}$ at $DT_{50}$ and from 20 to approximately 2 µg $L^{-1}$ at $DT_{90}$. Under the same irradiation and kinetic conditions, the other initial concentrations followed a comparable relative degradation trend. Accordingly, the residual concentrations at $DT_{50}$ were 1.25, 2.5, 5, 7.5, and 10 µg $L^{-1}$, while at $DT_{90}$ they were approximately 0.25, 0.5, 1.0, 1.5, and 2.0 µg $L^{-1}$ for the initial concentrations of 2.5, 5, 10, 15, and 20 µg $L^{-1}$, respectively.

Although higher initial concentrations produced larger absolute concentration decreases, the similar shape of the degradation curves indicates that the degradation mechanism remained consistent within the investigated concentration range. This behaviour suggests that imidacloprid attenuation was mainly governed by photon availability and the remaining pesticide concentration, rather than by the initial pollutant loading alone.

**Effect of ultraviolet intensity and turbidity on imidacloprid degradation**

After establishing the baseline temporal degradation behaviour, additional simulations were performed to evaluate the influence of ultraviolet radiation intensity and attenuation (turbidity) on imidacloprid photodegradation. These parameters directly affect photon availability within the water column and therefore control the spatial and temporal evolution of the degradation process.

The influence of incident ultraviolet radiation intensity on imidacloprid degradation was evaluated by performing additional simulations under otherwise identical model conditions. The temporal concentration profiles presented in Figure 8 were obtained for four radiation intensity levels, namely 20, 30, 40, and 50 W $m^{-2}$, to assess the sensitivity of the photodegradation process to photon availability.

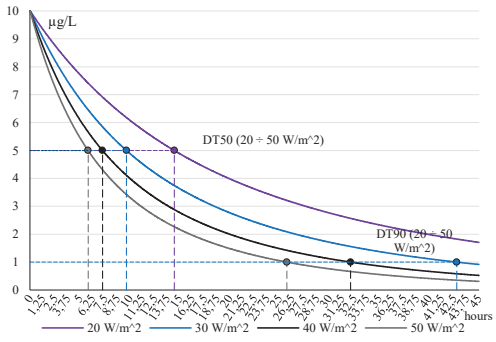

Figure 8. Effect of ultraviolet radiation intensity on the temporal degradation of imidacloprid in water

Higher incident UV irradiance increased photon availability, enhanced the photolytic reaction rate, and shifted the $DT_{50}$ and $DT_{90}$ thresholds toward shorter exposure times. Consequently, the 50 W $m^{-2}$ case showed the highest degradation efficiency, whereas the 20 W $m^{-2}$ case exhibited delayed attenuation, confirming the strong control of radiation intensity on imidacloprid persistence. While higher incident UV irradiance was shown to enhance imidacloprid photodegradation, Figure 9 presents the temporal concentration profiles obtained for different radiation attenuation coefficients.

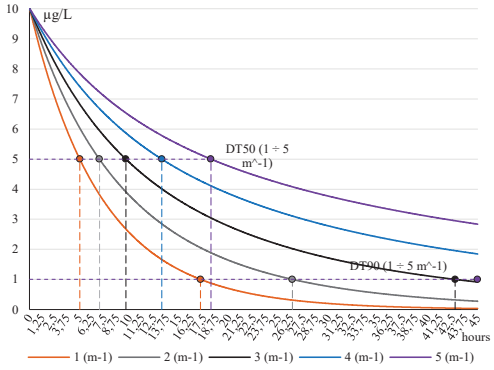

Figure 9. Effect of the radiation attenuation coefficient (turbidity) on the temporal degradation of imidacloprid under UV irradiation

An increase in the attenuation coefficient from 1 to 5 $m^{-1}$ produced a systematic decrease in degradation efficiency, as stronger optical attenuation reduced the UV energy available for photochemical conversion. Consequently, higher turbidity shifted both $DT_{50}$ and $DT_{90}$ toward longer exposure times, confirming that the apparent degradation kinetics are strongly controlled by radiation penetration and photon transport within the aqueous domain.

**Model verification and kinetic consistency assessment**

The kinetic consistency of the CFD model was assessed by analysing the degradation behaviour of imidacloprid under UV irradiation. Since the implemented reaction mechanism assumed pseudo-first-order photolytic degradation, the temporal evolution of the normalized concentration ratio $C/C_0$ was examined in semi-logarithmic form. Under pseudo-first-order conditions, the degradation rate is described by:

$$\frac{dC}{dt} = -kC$$

which integrates to:

$$C(t) = C_o e^{-kt}$$

where C is the imidacloprid concentration, $C_0$ is the initial concentration, and k is the apparent first-order degradation rate constant. As shown in Figure 10, the plot of $\ln(C/C_0)$ versus irradiation time exhibited an approximately linear trend, confirming that the simulated degradation followed pseudo-first-order kinetics.

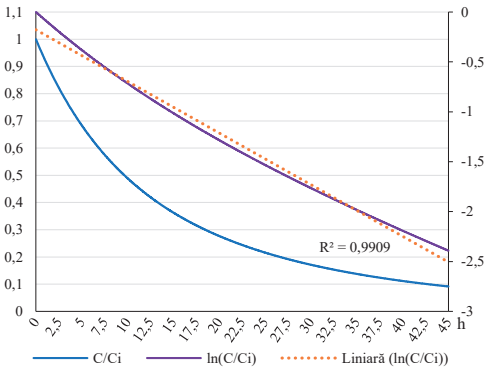

Figure 10. Pseudo-first-order kinetic behaviour of imidacloprid degradation under UV irradiation

The high coefficient of determination, $R^2$ = 0.9909, indicates good agreement between the numerical results and the assumed kinetic formulation. The apparent degradation rate constant was obtained from the absolute value of the regression slope, while the corresponding half-life was estimated using $t_{1/2}$ = 0.693/k.

To further evaluate model consistency, additional simulations were performed for different initial imidacloprid concentrations under identical UV irradiation and kinetic conditions. The kinetic parameters obtained from these simulations are summarized in Table 3.

Table 3 Summary of simulated kinetic parameters for imidacloprid degradation under different initial concentration, incident UV irradiance, and radiation attenuation conditions

| Case | $C_0$ (μg $L^{-1}$) | UV (W $m^{-2}$) | α ($m^{-1}$) | k ($h^{-1}$) | $DT_{50}$ (h) | $DT_{90}$ (h) | $T_{max}$ (K) | $C_{DT90}$ (μg $L^{-1}$) | Removal (%) | Kinetic behaviour |
|---|---|---|---|---|---|---|---|---|---|---|
| A1 | 2.5 | 40 | 3 | 0.0573 | 12.1 | 40.2 | 296.87 | 0.25 | 90.0 | Pseudo-first-order |
| A2 | 5 | 40 | 3 | 0.0573 | 12.1 | 40.2 | 296.87 | 0.50 | 90.0 | Pseudo-first-order |
| A3/B3/C3 | 10 | 40 | 3 | 0.0573 | 12.1 | 40.2 | 296.87 | 1.00 | 90.0 | Pseudo-first-order |
| A4 | 15 | 40 | 3 | 0.0573 | 12.1 | 40.2 | 296.87 | 1.50 | 90.0 | Pseudo-first-order |
| A5 | 20 | 40 | 3 | 0.0573 | 12.1 | 40.2 | 296.87 | 2.00 | 90.0 | Pseudo-first-order |
| B1 | 10 | 20 | 3 | 0.0421 | 16.5 | 54.7 | 296.87 | 1.00 | 90.0 | Pseudo-first-order |
| B2 | 10 | 30 | 3 | 0.0711 | 9.7 | 32.4 | 296.87 | 1.00 | 90.0 | Pseudo-first-order |
| B4 | 10 | 50 | 3 | 0.0849 | 8.2 | 27.1 | 296.87 | 1.00 | 90.0 | Pseudo-first-order |
| C1 | 10 | 40 | 1 | 0.1223 | 5.7 | 18.8 | 296.87 | 1.00 | 90.0 | Pseudo-first-order |
| C2 | 10 | 40 | 2 | 0.0835 | 8.3 | 27.6 | 296.87 | 1.00 | 90.0 | Pseudo-first-order |
| C4 | 10 | 40 | 4 | 0.0414 | 16.7 | 55.6 | 296.87 | 1.00 | 90.0 | Pseudo-first-order |
| C5 | 10 | 40 | 5 | 0.0315 | 22.0 | 73.0 | 296.87 | 1.00 | 90.0 | Pseudo-first-order |

The kinetic parameters summarized in Table 3 show that, under identical irradiation and attenuation conditions, variations in the initial imidacloprid concentration did not modify the apparent degradation rate. For the concentration series, the apparent rate constant remained constant at $k = 0.0573\ h^{-1}$, corresponding to a $DT_{50}$ of 12.1 h and a $DT_{90}$ of 40.2 h. Since $C_{DT90}$ was defined as 10% of the initial concentration, the residual concentration at $DT_{90}$ increased proportionally with $C_0$, while the characteristic degradation times remained unchanged. This behaviour confirms that the implemented reaction mechanism is consistent with pseudo-first-order photochemical kinetics, for which the apparent rate constant is independent of the initial pollutant concentration under constant irradiation conditions.

In contrast, the simulations performed at different incident UV irradiance levels showed a clear dependence of the degradation kinetics on photon input. Increasing the UV irradiance resulted in higher apparent rate constants and shorter $DT_{50}$ and $DT_{90}$ values, indicating enhanced photolytic degradation due to increased photon availability within the computational domain. Conversely, increasing the radiation attenuation coefficient reduced UV penetration through the water column and led to lower apparent rate constants, thereby delaying both $DT_{50}$ and $DT_{90}$. This confirms that optical attenuation strongly limits the effective photochemical reaction rate, particularly in regions where the radiation field is reduced by absorption and scattering processes.

The obtained trends are consistent with the expected behaviour of radiation-controlled photochemical degradation in aqueous systems. Previous experimental studies have also reported pseudo-first-order photolysis of imidacloprid under UV irradiation, with faster degradation generally observed under more intense and uniform irradiation conditions (Moza et al., 1998). The comparatively slower degradation predicted in the present CFD simulations can be attributed to the spatially heterogeneous radiation field resolved by the Discrete Ordinates model, which accounts for reduced photon availability within the water depth rather than assuming uniform exposure.

Overall, the kinetic consistency assessment demonstrates that the CFD framework correctly reproduces the main features of pseudo-first-order photodegradation while also capturing the influence of spatially variable UV radiation. The results indicate that imidacloprid persistence in the simulated aquatic domain is governed primarily by photon availability, which is controlled by both incident irradiance and radiation attenuation, whereas the initial pesticide concentration affects the absolute residual concentration but not the apparent degradation rate. These findings provide the basis for the concluding assessment of the model capability to simulate the photochemical fate of pesticides in irradiated aquatic environments.

## CONCLUSIONS

This study developed a CFD framework for investigating the photochemical degradation of imidacloprid in water under ultraviolet irradiation. The numerical model coupled UV radiation transport, radiation attenuation, radiation absorption, energy transfer, and reactive species transport, allowing the simulation of photon propagation and its influence on pesticide degradation kinetics.

The results showed that ultraviolet radiation was rapidly attenuated within the water column, generating a pronounced vertical gradient in photon availability. The highest radiation intensity and absorption rates occurred near the irradiated boundary, where UV energy was most available for photochemical transformation. Consequently, imidacloprid degradation was mainly concentrated in the upper irradiated region, while deeper zones exhibited slower transformation rates due to reduced UV penetration. This confirms that radiation attenuation and local photon absorption control the spatial distribution of the photochemical reaction rate.

Under the reference irradiation conditions, the simulated imidacloprid concentration decreased from 10 μg $L^{-1}$ to below 1 μg $L^{-1}$ after 45 h of UV exposure, corresponding to more than 90% removal. The degradation followed pseudo-first-order kinetics, with an apparent rate constant of approximately 0.057 $h^{-1}$ and characteristic degradation times of $DT_{50} \approx 12.1$ h and $DT_{90} \approx 40.2$ h.

The kinetic consistency assessment confirmed that variations in the initial imidacloprid concentration, within the investigated range of 2.5 ÷ 20 μg $L^{-1}$, did not affect the apparent degradation rate under identical irradiation and radiation attenuation conditions. The residual concentration at $DT_{90}$ increased proportionally with the initial concentration, whereas the rate constant and characteristic degradation times remained unchanged, confirming pseudo-first-order photochemical behaviour.

The sensitivity simulations demonstrated that incident UV irradiance and the radiation attenuation coefficient strongly influence degradation efficiency. Increasing the incident irradiance enhanced photon availability and reduced both $DT_{50}$ and $DT_{90}$ values, while increasing the attenuation coefficient limited UV penetration, decreased the apparent degradation rate, and delayed pesticide transformation. Therefore, both incident UV irradiance and radiation attenuation are key parameters controlling imidacloprid persistence in irradiated aquatic systems.

From an environmental perspective, the findings highlight the relevance of photochemical degradation as a natural attenuation mechanism for pesticides in surface waters. However, the efficiency of this process depends strongly on water depth, optical properties, turbidity-related radiation attenuation, and irradiation conditions, leading to variable pesticide persistence among aquatic environments.

Overall, the proposed CFD framework, coupling the Discrete Ordinates radiation model with UDF-based volumetric reaction terms, provides a useful tool for assessing pesticide photodegradation in aquatic systems by representing UV attenuation, radiation absorption, and reactive contaminant transport. Future work should address experimental validation and model extension toward natural organic matter, suspended solids, and hydrodynamic conditions representative of surface waters.

***Abstract***

*Water quality assessment is vital to environmental management. Regular monitoring of lakes helps protect environmental integrity and human health. This study assessed annual changes in water quality in Herastrau Lake (Bucharest, Romania) using field and laboratory measurements complemented by satellite observations. Water samples were collected from ten sites in autumn 2024 and spring 2025 and analyzed for pH, electrical conductivity, total dissolved solids, salinity, dissolved oxygen, turbidity, chloride, nitrite, nitrate, ammonium, total suspended solids, hardness, and iron. Results were compared with Romanian standards (Order No. 161/2006), and Pearson correlations were performed. The lake remained alkaline in both years (pH 8.50), while dissolved oxygen declined markedly in 2025 (2.59 mg/L) compared with 2024 (6.82 mg/L). Turbidity exceeded 5 NTU, and ammonium nitrogen showed elevated concentrations (12.07 mg N-$NH_4^+$/L in 2024; 13.50 mg N-$NH_4^+$/L in 2025), suggesting persistent eutrophication pressure. Sentinel-2 imagery (10–20 m) was used to estimate surface turbidity* from red-edge reflectance, with NDWI used for water masking*, and the results were validated with laboratory data. The water quality underscores the need for targeted pollution control measures.*

***Key words****: eutrophication, Herastrau, Romania, Sentinel-2, water quality.*

## INTRODUCTION

Although water is fundamental to life, freshwater accounts for only 2.5% of the global water volume, and just 1% is accessible for use, with much of it sequestered in reservoirs. In this context, lakes are a vital yet strictly finite resource (Hoggang & Reyes, 2023). Beyond serving as critical water reservoirs, lakes support diverse ecosystems and play a vital role in regulating local microclimates (K. Zhang et al., 2025) and stabilizing the climate by driving atmospheric carbon fixation through phyto-plankton photosynthesis (Oustani et al., 2026).

Freshwater lakes are highly sensitive to both natural factors and anthropogenic pressures (urbanization, industrialization, agriculture) that compromise their ecological integrity (Liu et al., 2025). Nutrient enrichment fundamentally alters water quality, trophic status, and biological community structure. Because plankton communities respond quickly to these fluctuations, they serve as reliable indicators of changing ecological conditions (Nkhata et al., 2026). Ultimately, excessive chemical inputs alter water physicochemical parameters, triggering eutrophication, characterized by elevated phytoplankton biomass, harmful cyanobacterial blooms, reduced transparency, and oxygen depletion (Nkhata et al., 2026; Oustani et al., 2026).

Eutrophication is the enrichment of water with nutrients like nitrogen and phosphorus, leading to excessive algae and plant growth. As organic matter decomposes, oxygen levels drop, causing fish kills, biodiversity loss, reduced water clarity, and harmful cyanobacterial blooms that release toxins. It damages water ecosystems and recreation and is a major global threat to inland water quality (Zhou et al., 2024; Morelato et al., 2026).

Urban lakes provide vital ecosystem services and serve as structural components of the metropolitan landscape. They enhance urban environmental quality by providing reliable access to clean water for both functional use and

recreation (Cheval et al., 2020). An example of a metropolitan ecosystem facing localized pressures is Herastrau Lake, located in the northern district of Bucharest, Romania. It is an artificial water body and a key component of the anthropogenic lake cascade along the Colentina River. Herastrau Lake is particularly exposed to eutrophication, as it receives continuous anthropogenic nutrient loads from urban runoff, sewage inputs, and atmospheric deposition, while also providing important recreational, aesthetic, microclimatic, and biodiversity services to a densely populated city. However, its location within a densely populated area subjects it to ongoing environmental challenges, including urban surface runoff and localized waste generation.

Despite its ecological and recreational importance, comprehensive data regarding the status of this aquatic system remain insufficient, with only a limited number of local studies examining water pollution in Herastrau Lake. To address this critical knowledge gap, this study aims to assess the lake's physico-chemical profile and quantify its current state of degradation. Specifically, this research monitors key environmental indicators - including pH, electrical conductivity, turbidity, and chloride ions - alongside critical nutrient loadings - namely, ammonia, nitrites, nitrates, and phosphates - to assess the immediate urban impact footprint.

## MATERIALS AND METHODS

### *Water Site and Sampling Points Description*

Water sampling was conducted at ten sites distributed across Herastrau Lake during two monitoring campaigns, on 21 October 2024 (autumn) and 11 March 2025 (early spring). The same sampling locations were used in both campaigns, and their geographic coordinates were recorded to ensure spatial consistency and enable direct comparison between the two monitoring periods. At each site, selected physicochemical parameters were measured in situ, and additional analyses were performed in the laboratory afterward. This combined approach allowed assessment of both spatial variability in water quality across the lake and seasonal differences between the autumn 2024 and early spring 2025 campaigns.

### *Water Sampling and Physicochemical Analyses*

Water sampling was conducted in accordance with the Romanian guidelines for water sampling from natural and artificial lakes (ISO 5667-4:2016). Water was manually collected at approximately 0.5 m below the surface and placed in polyethylene containers, then immediately stored in a refrigerated transport box at approximately 4°C until arrival at the laboratory. Before laboratory analyses, samples were allowed to reach room temperature, as required by the analytical procedure.

Water temperature, pH, electrical conductivity (EC), total dissolved solids (TDS), salinity, and dissolved oxygen (DO) were measured in situ at each sampling location using a calibrated portable multiparameter. The remaining physicochemical parameters were determined in the laboratory within 24-48 h of sample collection.

Turbidity was measured with a calibrated turbidimeter and reported in nephelometric turbidity units (NTU). Total suspended solids (TSS) were measured gravimetrically by filtering homogenized water through pre-dried, pre-weighed filter paper. The filter was dried at 105 °C, cooled, and reweighed. TSS was calculated from the mass difference and given as mg/L.

Chloride ($Cl^-$) concentrations were determined by Mohr titration with a standardized silver nitrate ($AgNO_3$) solution, using potassium chromate ($K_2CrO_4$) as the endpoint indicator. Total hardness (TH) was determined by complexometric titration with disodium ethylenediaminetetraacetate (EDTA), using Eriochrome Black T as the endpoint indicator. Temporary hardness (CH) was determined by titration with hydrochloric acid (HCl) using methyl orange as the endpoint indicator, while permanent hardness (NCH) was calculated as the difference between TH and CH.

Nitrite ($N\text{-}NO_2^-$) and ammonium ($N\text{-}NH_4^+$) were determined spectrophotometrically at 540 and 650 nm, respectively, according to the procedures described by Sandu et al. (2023). Nitrate ($N\text{-}NO_3^-$) was not measured directly; instead, nitrate-equivalent concentrations were calculated from nitrite values using the corresponding stoichiometric conversion factor. Nitrogen species results were expressed as mg

N/L. Iron ($Fe^{3+}$) was determined spectrophotometrically using the potassium thiocyanate (KSCN) method at 490 nm. $Fe^{3+}$ concentrations were expressed as mg $Fe^{3+}$/L.
All analytical instruments were calibrated before measurements, following the respective procedures, to maintain data quality and accuracy. Laboratory determinations were performed in triplicate, and the results were expressed as mean ± standard deviation (SD).

***Water Quality Classification***
The physicochemical quality of Herastrau Lake water was evaluated by comparing measured parameters with threshold values established by the Romanian regulatory framework for surface-water monitoring (Order No. 161/2006). According to this classification system, surface waters are divided into five quality classes (I-V), ranging from high-quality waters (Class I) to heavily degraded waters (Class V). For each sampling point and monitoring year, the measured concentrations of dissolved oxygen (DO), chlorides ($Cl^-$), nitrite ($N\text{-}NO_2^-$), nitrate ($N\text{-}NO_3^-$), ammonium ($N\text{-}NH_4^+$), and iron ($Fe^{3+}$) were compared with the corresponding class-specific threshold values. This approach allowed evaluation of both spatial variability among the ten sampling sites and interannual changes between 2024 and 2025. The resulting classification was used to identify the physico-chemical parameters primarily responsible for deteriorating lake-water quality and to assess changes in water-quality conditions between the two monitoring campaigns.

***Statistical Analysis and Pearson Correlation***
Statistical analysis of the water-quality data was performed using GraphPad Prism (version 11.0.2). Pearson's correlation coefficient was used to evaluate the relationships among water temperature, pH, electrical conductivity (EC), total dissolved solids (TDS), salinity, dissolved oxygen (DO), turbidity, chlorides ($Cl^-$), total hardness (TH), temporary hardness (CH), permanent hardness (NCH), nitrite ($N\text{-}NO_2^-$), nitrate ($N\text{-}NO_3^-$), ammonium ($N\text{-}NH_4^+$), total suspended solids (TSS), and iron ($Fe^{3+}$).

***Satellite data set description***
Satellite data consisted of Sentinel-2 MSI Level-2A products with atmospherically corrected bottom-of-atmosphere surface reflectance (tile T35TMK). For each campaign, the two cloud-free scenes closest to the sampling date were selected - 21 and 26 October 2024 for the autumn campaign, and 5 and 20 March 2025 for the early-spring campaign - yielding four scenes in total. Prior to analysis, cloud-, shadow-, and cirrus-affected pixels were removed using the Scene Classification Layer (SCL). Because the strict SCL water class (class 6) frequently misclassifies the turbid, chlorophyll-rich water of eutrophic lakes as vegetation or bare soil, and because the sampling locations were independently verified to lie over open water, SCL classes 4-7 (vegetation, bare soil, water, and unclassified) were retained at the sampling points. The radiometric offset introduced in processing baseline 04.00 was then applied to recover surface reflectance. For every sampling point, a per-point median composite was computed from the two scenes of the corresponding campaign. The median was preferred over single-date extraction to reduce residual cloud/haze contamination and transient surface effects, while keeping the reflectance temporally close to the in-situ measurements. Spectral indices and band ratios were subsequently derived and extracted at the ten-point locations for comparison with the in-situ data.

***Satellite-based assessment of water turbidity***
Turbidity is an optically active water-quality parameter: suspended particles raise the water-leaving reflectance in the red and near-infrared (NIR) regions, where clear water is otherwise strongly absorbing, and the magnitude of this increase scales with the concentration of suspended matter. The red-to-NIR portion of the Sentinel-2 spectrum is therefore the most informative for turbidity retrieval.
The following bands were evaluated as turbidity predictors, as shown in Table 1: the red band B04 (665 nm) and the first red-edge band B05 (705 nm), which respond at low-to-moderate turbidity; and the red-edge band B07 (783 nm) together with the NIR band B08 (842 nm), which remain sensitive at high turbidity, where the red band tends to saturate, a behavior analogous to the band-switching logic of semi-analytical turbidity models. In addition to the individual bands, two red-edge-to-red ratios

were computed, re5_red = B05/B04 and re7_red = B07/B04, since band ratios largely cancel multiplicative effects (illumination geometry, residual atmospheric scattering, and the imperfect Level-2A correction over water) and thus provide more robust proxies than single bands. All candidate predictors listed in Table 1 were screened against the in-situ measurements, and the band that showed the strongest and most consistent association with turbidity in both campaigns, the red-edge band B07, was retained for calibration; NDTI is additionally reported below because it is the only index among the candidates explicitly formulated for turbidity.

Table 1. Sentinel-2 bands and spectral indices evaluated for turbidity retrieval

| Band/ Spectral index | Definition | Role for turbidity |
|---|---|---|
| B04 (red) | 665 nm | Suspended sediment; low-to-moderate turbidity |
| B05 (red-edge 1) | 705 nm | Red-edge response across the turbidity range |
| B07 (red-edge 3) | 783 nm | Sensitive at high turbidity (red saturates) |
| B08 (NIR) | 842 nm | High-turbidity/ TSS signal |
| re5_red | B05/B04 | Red-edge/red ratio; robust at low-to-moderate values |
| re7_red | B07/B04 | Red-edge/red ratio; **candidate predictor** |
| NDTI (Lacaux et al., 2007) | (B04−B03)/ (B04+B03) | Normalized Difference Turbidity Index |
| NDWI (McFeeters, 1996) | (B03−B08)/ (B03+B08) | Water masking only |

### *Calibration of the satellite-derived turbidity*

Calibration of the satellite turbidity proxy was carried out as a spatial regression across the ten sampling points, relating the in-situ turbidity of each campaign to the corresponding median Sentinel-2 reflectance values and band ratios extracted at the same locations. Because the analysis compares spatially distributed point pairs rather than a dense temporal series and given the small sample size (n = 10), the strength and significance of each candidate predictor were assessed using both the Pearson correlation coefficient (r), which quantifies the strength of a linear association, and the Spearman rank correlation coefficient (ρ), which captures monotonic relationships and is more robust to non-linearity, non-normality and outliers.

Reporting both coefficients allows assessment of each relationship's linearity: close agreement between r and ρ indicates a robust, approximately linear association, whereas marked divergence signals non-linearity or sensitivity to individual points. For n = 10, the critical value for significance at $p < 0.05$ (two-tailed) is $|r| \approx 0.63$; all results were therefore treated as exploratory.

## RESULTS AND DISCUSSIONS

### *Spatial Distribution of Sampling Points*

The ten georeferenced sampling points spanned different areas of Herastrau Lake, ensuring adequate spatial representation of the water body. Table 2 lists the geographical coordinates of the sampling sites, and Figure 1 shows their spatial distribution across Herastrau Lake. The same locations were monitored in 2024 and 2025, enabling a consistent assessment of spatial and temporal variations in water quality.

Table 2. Geographical coordinates of the sampling points in Herastrau Lake

| Point | Latitude (N) | Longitude (E) |
|---|---|---|

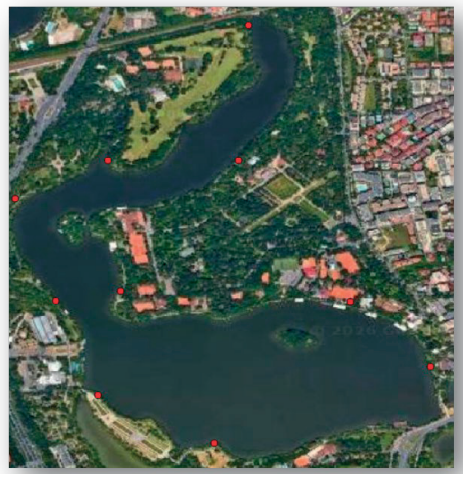

Figure 1. Spatial distribution of the water sampling sites in Herastrau Lake, Bucharest, Romania (background: Google Earth true-color satellite imagery)

***Physicochemical parameters and water-quality classification***

During the autumn 2024 campaign, Herastrau Lake water was slightly alkaline, with pH values ranging from 8.17 to 8.60, while EC ranged from 331 to 547 µS/cm. Salinity ranged from 160 to 270 mg/L and TDS from 165 to 300 mg/L, indicating moderate spatial variability in the lake's dissolved ionic content. DO was relatively favorable, ranging from 5.81 to 7.61 mg $O_2$/L. Based on the water-quality classification, five sampling points (P1, P4, P5, P8, and P9) were assigned to Class I, three points (P2, P3, and P7) to Class II, and only P6 and P10 to Class III. Turbidity ranged from 5.04 ± 0.98 to 14.80 ± 0.23 NTU, with the highest value at P2, suggesting localized differences in suspended particulate matter (Table 3).

$Cl^-$ concentrations ranged from 39.45 ± 3.86 to 65.04 ± 4.73 mg/L and were consistently classified as Class I at all sampling sites. $NO_2^-$ concentrations showed greater variability, ranging from 0.03 to 0.08 mg N-$NO_2^-$/L. Most sites were classified as Class II, whereas P1 and P10 reached Class III. In contrast, all $NO_3^-$ values remained within Class I. The most pronounced deterioration was associated with $NH_4^+$, ranging from 9.71 ± 1.19 to 17.07 ± 1.09 mg N-$NH_4^+$/L and resulting in Class V at all ten sampling points. This uniform classification indicates that $NH_4^+$ represented the major N-related water-quality concern during the 2024 campaign. $Fe^{3+}$ concentrations were very low (0.0002 - 0.0005 mg $Fe^{3+}$/L) and corresponded to Class I throughout the lake.

Table 3. Physicochemical water-quality parameters for Herastrau Lake in 2024

| Point | Temperature (°C) | pH (pH units) | EC (µS/cm) | Salinity (mg/L) | TDS (mg/L) | DO (mg $O_2$/L) | Turbidity (NTU) | $Cl^-$ (mg/L) |
|---|---|---|---|---|---|---|---|---|
| P1 | 16.06 | 8.60 | 388 | 190 | 194 | 7.10 | 7.47 ± 0.58 | 39.45 ± 3.86 |

A distinctly different pattern was observed during the early spring 2025 campaign (Table 4). Although pH remained alkaline and comparable to 2024 (8.15-8.95), EC generally increased, reaching up to 723 µS/cm, while salinity varied between 290 and 350 mg/L. The most important change was in DO, which decreased markedly to 1.90-3.70 mg $O_2$/L. Consequently, all ten sampling sites were classified as Class V for DO, indicating a substantial deterioration of the lake oxygen regime compared with autumn 2024. Turbidity remained spatially heterogeneous, ranging from 4.36 ± 0.39 NTU at P1 to a maximum of 16.40 ± 0.71 NTU at P8.

Despite deteriorating oxygen conditions, $Cl^-$ concentrations remained within Class I at all sites in 2025 (Table 5). $NO_2^-$ concentrations were generally lower than in 2024, with P7 and P9 at 0 mg N-$NO_2^-$/L and assigned to Class I, while the remaining sites were classified as Class II. All $NO_3^-$ values also remained within Class I. However, $NH_4^+$ concentrations remained elevated, ranging from 11.23 ± 0.77 to 15.05 ± 0.09 mg N–$NH_4^+$/L, again resulting in Class V at every sampling point. $Fe^{3+}$ remained at very low concentrations (0.0001-0.0004 mg $Fe^{3+}$/L), corresponding consistently to Class I.

A marked interannual difference was also observed for water TH. TH decreased from 190.66–251.23 mg/L in 2024 to 88.37–115.70 mg/L in 2025, with an especially pronounced reduction in CH, from 74.18-138.11 mg/L to approximately 10.72-12.10 mg/L.

At the same time, the increase in EC and salinity in 2025 suggests that the seasonal change did not simply reflect a general dilution or concentration effect, but rather a modification in the ionic composition of the lake water.

Overall, the comparison between the two monitoring campaigns indicates that $NH_4^+$ was the most persistent water-quality issue, remaining in Class V throughout the lake in both years, while the most pronounced temporal deterioration concerned DO, which shifted from

Classes I-III in 2024 to Class V at all sites in 2025. Conversely, $Cl^-$, $NO_3^-$, and $Fe^{3+}$ concentrations consistently remained within Class I. The simultaneous occurrence of high $NH_4^+$ concentrations and severe oxygen depletion in 2025 may indicate increased oxygen demand associated with organic matter and N transformations, suggesting enhanced eutrophication pressure within the lake.

Dippong and Resz (2024), in a study of lakes in the Tisa protected area in Romania, also reported generally adequate pH conditions, while EC varied widely from 213 to 1052 µS/cm. In Herastrau Lake, EC ranged from 331 to 547 µS/cm in 2024 and increased to 350-723 µS/cm in 2025, indicating a higher dissolved ionic load during the early-spring campaign. Another recent study of the Iza-Tisa (Romania) surface-water system reported EC values of 307-512 µS/cm, showing that the 2024 Herastrau Lake values were broadly comparable, whereas some 2025 sampling sites exhibited greater mineralization (Dippong & Resz, 2025).

The increase in EC in 2025 was linked to higher salinity, but hardness changed differently. TH dropped from 190.66-251.23 mg/L in 2024 to 88.37-115.70 mg/L in 2025, and CH fell sharply from 74.18-138.11 to 10.72-12.10 mg/L. Thus, the higher EC and salinity in 2025 do not originate solely from increased Ca- and Mg-hardness. Instead, these changes suggest a shift in the lake water's ionic composition between the two campaigns. Similar complexity in the relationships among EC, TDS, TH, and dissolved ions has been observed in other lake systems, where natural hydrogeochemical processes and anthropogenic inputs jointly determine water chemistry (Osman et al., 2025).

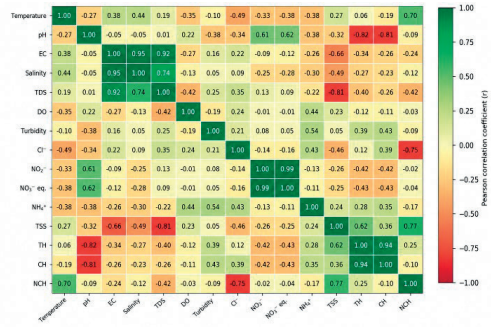
DO showed the most pronounced temporal variation. In autumn 2024, DO concentrations were Class I-III, but dropped dramatically in March 2025 to Class V. This decrease is notable because the 2025 campaign had lower water temperatures, suggesting oxygen deterioration is not driven by temperature effects alone. Recent research shows DO dynamics in shallow eutrophic lakes depend on interactions among water temperature, hydrological conditions, mixing, precipitation, wind, nutrients, and biological activity (F. Zhang et al., 2025). The generally well-oxygenated conditions in Romanian Tisa lakes highlight the poor oxygen conditions in Herastrau Lake in 2025 (Dippong & Resz, 2024).

Turbidity in northern Romanian lakes ranges from 0.68-48 NTU, highest in spring (Dippong & Resz, 2024). Values are lower than in highly turbid systems like Tonle Sap Lake, with an annual mean of 53.99 NTU and spring-summer means of 84.16 and 93.47 NTU. The autumn mean of 15.33 NTU is similar to Herastrau Lake. Turbidity responds to cropland, urbanization, and population density, reflecting anthropogenic impact (Zou et al., 2024).

$Cl^-$ concentrations were comparatively stable in 2024 and 2025. $Cl^-$ concentrations in Herastrau Lake are substantially lower than those reported for strongly salt-affected urban lakes. For example, Foley and Steinman (2023) reported $Cl^-$ concentrations exceeding 230 mg/L and reaching about 331 mg/L in an urban lake affected by road deicing salts; these concentrations were high enough to interfere with lake mixing and contribute to hypolimnetic hypoxia.

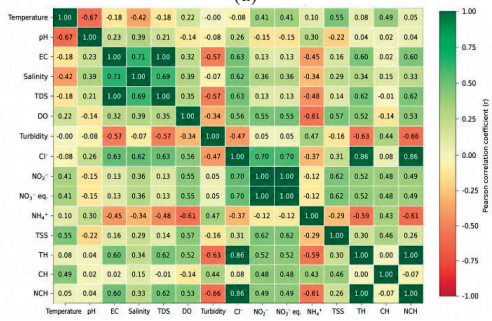
In contrast, ammonium represented the most critical nitrogen-related parameter. The $NH_4^+$ values of Herastrau Lake are markedly higher than those reported for other Romanian lake systems. Dippong et al. (2024) reported a maximum $NH_4^+$ concentration of approximately 1.79 mg/L in polluted lakes from northern Romania. The elevated ammonium levels observed in Herastrau Lake may reflect the strong anthropogenic pressure characteristic of its urban catchment.

The concurrent occurrence of persistently high ammonium concentrations and pronounced dissolved oxygen depletion in 2025 may indicate increased eutrophication and organic/nitrogen loading pressure. Global lake datasets identify $NH_4^+$, $NO_3^-/NO_2^-$, DO, turbidity, TSS, and EC as key indicators for characterizing lake ecological condition, with elevated $NH_4^+$ often associated with anthropogenic pollution and adverse effects on aquatic organisms (Naderian et al., 2024).



Overall, the results suggest two different physicochemical conditions between the monitoring campaigns. The 2024 campaign was characterized by moderately mineralized, slightly alkaline and relatively well-oxygenated water, despite consistently high $NH_4^+$ concentrations. In 2025, the lake exhibited

increased EC and salinity, substantially reduced CH and TH, persistently elevated $NH_4^+$ and, most importantly, severe oxygen depletion throughout the sampling network. These multidimensional changes are characteristic of urban lake systems, where hydrological conditions, seasonal processes, and anthropogenic inputs interact to control water quality.



### *Pearson Correlation Analysis*

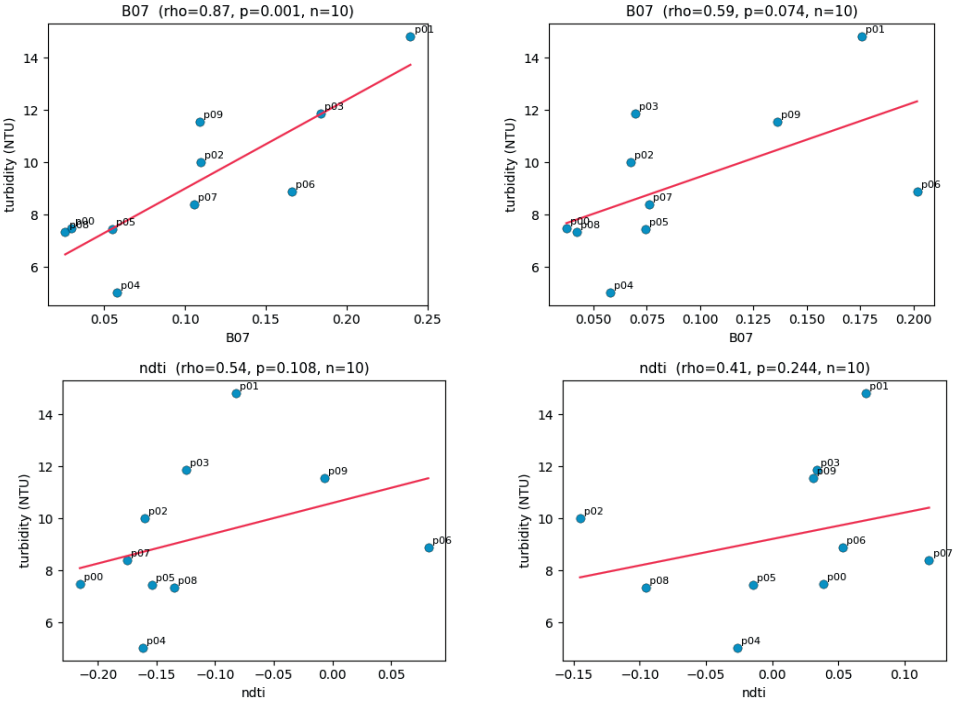
In 2024, the Pearson correlation analysis identified several clear relationships among the physicochemical parameters (Figure 2a). EC was strongly positively correlated with salinity (r = 0.95) and TDS (r = 0.92), while salinity was also positively related to TDS (r = 0.74), indicating these parameters reflect a common variation in the lake's dissolved ionic content. TH and CH showed a strong positive correlation (r = 0.94). Conversely, pH was strongly negatively correlated with TH (r = -0.82) and CH (r = -0.81). TSS showed a strong negative correlation with TDS (r = -0.81) and a moderate negative correlation with EC (r = -0.66), while it was positively correlated with NCH (r = 0.77). $Cl^-$ displayed a marked negative correlation with NCH (r = -0.75). $NH_4^+$ showed moderate positive relationships with turbidity (r = 0.54), DO (r = 0.44), and $Cl^-$ (r = 0.43), indicating its spatial distribution is linked to multiple physicochemical characteristics rather than a single factor. The correlation pattern changed markedly in 2025 (Figure 2b). EC and TDS were nearly perfectly correlated (r ≈ 1.00), and both remained positively associated with salinity, confirming their close dependence on dissolved mineral content. $Cl^-$ showed strong positive correlations with both TH and NCH (r = 0.86) and was also positively related to $NO_2^-$ and $NO_3^-$ concentrations (r = 0.70).

In contrast, turbidity was negatively correlated with NCH (r = -0.66), TH (r = -0.63), EC (r = -0.57), and TDS (r = -0.57), indicating that areas with greater optical effects from suspended particles did not necessarily coincide with those with the highest dissolved ionic content. A particularly relevant relationship was observed between DO and $NH_4^+$ (r = -0.61). Higher $NH_4^+$ concentrations were therefore associated with lower DO values across the sampling sites, consistent with increased oxygen demand from organic-matter degradation and nitrogen transformation processes. $NH_4^+$ was also negatively correlated with TH (r = -0.59) and NCH (r = -0.61).

(a)

(b)

Figure 2. Pearson correlation matrix of physicochemical water-quality parameters in Herastrau Lake in (a) 2024 and (b) 2025 monitoring campaigns



The different correlation structures observed in the two campaigns reveal a clear temporal shift in the relationships among the measured water-quality variables. In 2024, the strongest correlations were mainly linked to mineralization, hardness, and suspended solids. By 2025, the correlations involving DO, $NH_4^+$, $Cl^-$, and turbidity became more prominent. These variations suggest seasonal changes in the processes governing water chemistry, potentially reflecting differences in hydrological conditions, external inputs, biological activity, and nutrient cycling within Herastrau Lake.

### *Satellite-Based Turbidity Assessment and Calibration*

Conventional in-situ monitoring, although accurate, is labor-intensive, costly, and inherently limited in spatial and temporal coverage, typically yielding few point samples

collected infrequently. Satellite remote sensing offers a complementary approach: Sentinel-2 provides spatially continuous, frequently revisited (≈5-day) and openly available imagery that can capture the entire water surface synoptically. However, satellite-derived water-quality estimates are reliable only after calibration and validation against ground-truth measurements. In this study, the optically active parameter turbidity was estimated from Sentinel-2 reflectance and validated against in-situ data; once validated in this way, the calibrated satellite proxies can be applied operationally to map turbidity (and, by extension, chlorophyll a) across the whole lake and to track its dynamics over time, at low cost and with a spatial and temporal resolution that point sampling alone cannot achieve. This integration of field measurements with validated remote sensing is the core methodological rationale of the present work.

As shown in Figure 3, although NDTI is specifically designed as a turbidity index, it did not perform as expected: it showed only weak, non-significant correlations with in-situ turbidity in both campaigns.

***a) October 2024 campaign*** ***b) March 2025 campaign***

Figure 3. Spatial relationship between in-situ turbidity and two Sentinel-2 turbidity predictors, band B07 (783 nm, top row) and the Normalized Difference Turbidity Index (NDTI, bottom row), across the ten sampling points, for (a) the October 2024 campaign and (b) the March 2025 campaign. The red line shows the linear fit; Spearman correlation coefficients (ρ) and p-values are reported in each panel. B07 was the strongest predictor in both campaigns, with a significant correlation in October (ρ = 0.87, *p* = 0.001) but a weaker, non-significant one in March (ρ = 0.59, *p* = 0.074); NDTI performed poorly in both periods

This underperformance likely reflects the strong influence of algal/chlorophyll signals in the eutrophic lake, which interfere with the red–green contrast on which NDTI relies.

The contrast between the two predictors is itself informative about the optical regime of the lake. NDTI relies on the red-versus-green contrast and was developed for small, mineral-dominated ponds (Lacaux et al., 2007), where that contrast tracks inorganic suspended sediment. In a chlorophyll-rich system the same contrast is confounded, since phytoplankton absorbs strongly in the red (~665 nm) while pigment absorption and cell scattering also

modify the green signal, so both bands respond to algal biomass rather than to sediment load. That the turbidity information was carried instead by the red-edge region, beyond the main pigment absorption features, is consistent with the hypereutrophic character indicated by the physicochemical data, and points to red-edge-based indices such as NDCI (Mishra & Mishra, 2012) as the appropriate route for extending this approach to chlorophyll-a retrieval in Herastrau Lake.

Once band B07 had been selected as the turbidity predictor, three calibration models were fitted to relate B07 surface reflectance to the in-situ turbidity measurements: (i) a linear model (T = a·B07 + b), the simplest empirical formulation; (ii) a power model (T = a·B07^b), which can better accommodate the non-linear, saturating behavior often observed in turbidity–reflectance relationships; and (iii) the semi-analytical Nechad model (T = A·ρ/(1 - ρ/C)) (Nechad et al., 2010), a physically based formulation widely used for turbidity retrieval from water-leaving reflectance. The performance of each model was assessed using the coefficient of determination ($R^2$) and the root-mean-square error (RMSE), as shown in Figures 4 and 5.

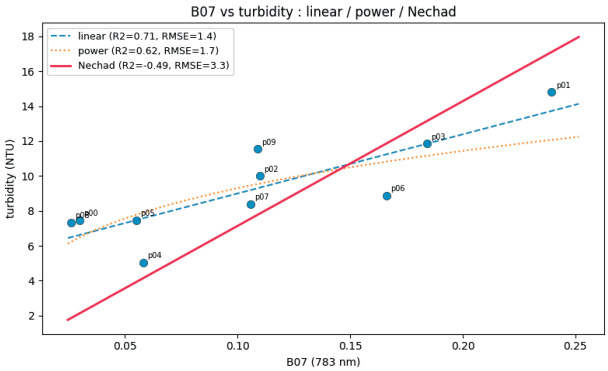


Figure 4. Calibration of the Sentinel-2 turbidity proxy for the October 2024 campaign: in-situ turbidity (NTU) at the ten sampling points versus Sentinel-2 band B07 (783 nm) surface reflectance. Three regression models are shown: linear ($R^2$ = 0.71, RMSE = 1.4 NTU), power ($R^2$ = 0.62, RMSE = 1.7 NTU), and the semi-analytical Nechad model ($R^2$ = −0.49, RMSE = 3.3 NTU). The linear model provided the best fit and was retained; the Nechad model failed to reproduce the lake's high background turbidity

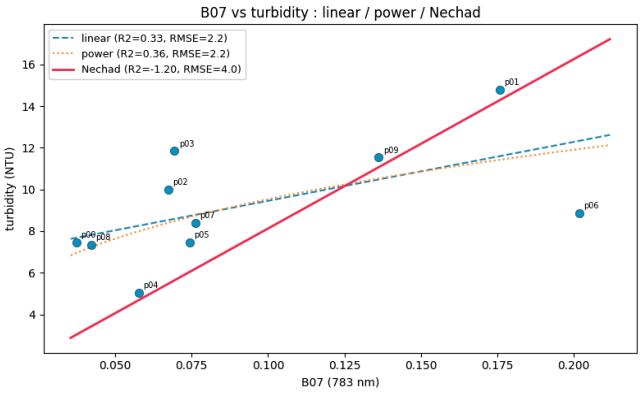

Figure 5. Calibration of the Sentinel-2 turbidity proxy for the March 2025 (early-spring) campaign: in-situ turbidity (NTU) at the ten sampling points versus Sentinel-2 band B07 (783 nm) surface reflectance, with linear ($R^2$ = 0.33, RMSE = 2.2 NTU), power ($R^2$ = 0.36, RMSE = 2.2 NTU) and semi-analytical Nechad ($R^2$ = −1.20, RMSE = 4.0 NTU) regression fits. In contrast to the October campaign ($R^2$ = 0.71), the B07–turbidity relationship was markedly weaker and statistically non-significant (Spearman ρ = 0.59, p = 0.074), most likely owing to the larger time lag between the satellite acquisitions and the sampling date

In contrast to the autumn campaign, the B07–turbidity relationship for March 2025 was considerably weaker and non-significant (Figure 5). The most likely cause is the match-up window: in October, a cloud-free scene coincided with the sampling day, whereas the March composite was built from scenes acquired 6 and 9 days from sampling, over which surface turbidity in this shallow, wind-exposed lake can change appreciably through resuspension and settling. A shift in particle composition may also contribute, as the early-spring increase in the algal fraction alters the reflectance-to-NTU relationship. The March retrieval is therefore regarded as exploratory.

## CONCLUSIONS

The water-quality parameters measured in this study, including elevated ammonium concentrations, markedly reduced dissolved oxygen, and persistent turbidity above 5 NTU, are consistent with sustained eutrophication pressure. Regular monitoring is thus essential to detect degradation early, understand its spatial and temporal dynamics, and inform targeted management and pollution-control measures.

A key limitation of this study stems from the use of Sentinel-2 Level-2A (Sen2Cor) reflectance, whose atmospheric correction is optimized for land surfaces rather than water. Over water bodies, this often results in weak or even negative reflectances and leaves residual sun-glint uncorrected, limiting the absolute accuracy of the retrieved values. The turbidity estimates derived here should therefore be regarded as semi-quantitative, and negative reflectances over water should be screened and treated with caution. For more rigorous, quantitative turbidity retrieval, dedicated aquatic atmospheric-correction processors such as ACOLITE, C2RCC, or POLYMER would be required, and their application represents a promising direction for future work.

***Abstract***

*The main irrigation infrastructure in Romania includes numerous underpasses of the main canals built of prestressed concrete or large-diameter metal pipes. After decades of operation, these structures show advanced degradation, such as cracks, corrosion, and leaks, leading to water losses and reduced hydraulic efficiency. Their location under roads and other types of infrastructure makes traditional replacement and dismantling of existing pipes difficult, highlighting the need for trenchless rehabilitation technologies. This article analyzes the applicability of CIPP (Cured-In-Place Pipe) technology for the rehabilitation of culverts in irrigation systems, based on experience in the maintenance of urban water supply and sewerage networks. It presents the steps leading up to the intervention, including inspection and structural assessment, as well as the principles of liner manufacturing, highlighting the specific limitations of large diameter pipes. It also addresses the general methodology for designing liner thickness in accordance with international standards and technical criteria relevant to water conveyance systems. The installation process is analysed in terms of operational requirements and equipment, highlighting the advantages of no-dig technologies in restricted-access areas. The results demonstrate the potential of CIPP as a sustainable and hydraulically efficient solution for irrigation infrastructure modernisation in Romania.*

***Key words****: Cured-In-Place Pipe (CIPP), hydraulic efficiency, irrigation canal crossings, no-dig rehabilitation, water loss reduction.*

## INTRODUCTION

Irrigated agriculture is essential for food security and stable agricultural production in the face of climate variability. Water use efficiency plays an increasingly important role in maintaining agricultural production in the context of rising temperatures, changing precipitation patterns, and intensifying extreme weather events, which continuously affect the availability of water resources for irrigation (Dai et al., 2018; Vogel et al., 2019; Mirzabaev et al., 2023; Farah et al., 2025).

In Romania, the main irrigation infrastructure includes an extensive network of main canals and underpasses made of concrete pipes or large-diameter metal pipes. After decades of use, these structures show significant deterioration, manifested by cracks, corrosion, and leaks, leading to significant water losses and reduced hydraulic efficiency of irrigation systems (Grumeza & Kepleș et al., 2005). These losses negatively affect water distribution to agricultural crops, reducing production potential during critical periods such as prolonged droughts (Totolea, 2024).

Traditional interventions for the rehabilitation of underground pipes involve significant excavations, which are disruptive from an economic and logistical point of view, especially in areas where crossings are located under roads or sensitive infrastructure elements. In this context, no-dig rehabilitation methods offer clear advantages by reducing the environmental impact and costs associated with open-cut works (Mocean et al., 2014).

One of the most widely used trenchless technologies is Cured-In-Place Pipe (CIPP), which consists of inserting and curing a reactive liner inside the existing pipe, creating a new pipe section without extensive excavation (Ji et al., 2020). This method is widely adopted in water and sewer networks due to its efficiency in rehabilitating damaged pipes and its ability to provide a continuous structural solution (Salem, 2008). However, the literature highlights

limitations and high design requirements for the mechanical performance of CIPP systems, underscoring the need for detailed assessments prior to application (Yang et al., 2021; Hu et al., 2023). This study investigates the structural and hydraulic feasibility of a large-diameter UV-cured CIPP installation applied to a severely deteriorated deep-buried gravity collector. Although based on an urban case study, the structural conditions - significant burial depth, high external loads, and advanced pipe degradation - are comparable to those encountered in irrigation canal crossings. By quantifying deformation limits, assessing the structural independence of the liner, and evaluating hydraulic performance before and after rehabilitation, the study provides a technical basis for assessing the transferability of CIPP technology to irrigation infrastructure.

## MATERIALS AND METHODS

### Case Study Description

The study is based on the rehabilitation of a large-diameter buried collector located in Botoșani, Romania (Figure 1). The investigated section had a total length of 125 meters and consisted of two geometrically distinct segments: an upstream ovoid reinforced concrete pipe 1200 mm constructed in the early twentieth century, and a downstream circular DN 800 mm section made of steel installed during a later intervention.

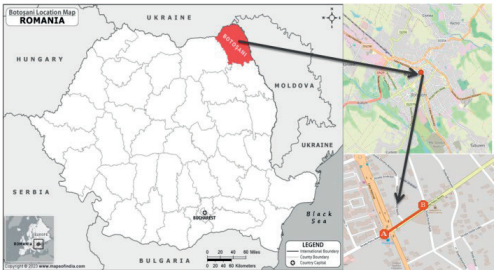

Figure 1. Location of the study- Romania, Botosani, Municipiul Botosani

The pipeline was located at a burial depth ranging between 5 and 6 m beneath a major traffic artery. CCTV inspection revealed severe structural degradation, including longitudinal cracking, wall perforations, loss of invert (radier) sections, joint misalignment, exfiltration, and evidence of soil erosion around the pipe. Sediment deposits exceeded 70% of the cross-sectional area prior to cleaning (Figure 2). Although the case study originates from an urban gravity collector, the structural conditions—large diameter, high soil cover, and advanced host pipe deterioration—are representative of buried irrigation canal crossings subjected to similar external loads.

Figure 2. Post-execution robotic CCTV inspection documentation

### Rehabilitation System Description

Rehabilitation was performed using a UV-cured glass-fiber-reinforced polymer (GRP) CIPP liner (Figure 3). The liner thickness was:

- 10.5 mm for the ovoid section,
- 8.4 mm for the circular DN 800 section.

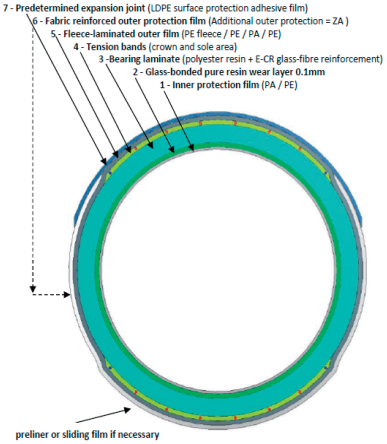

Figure 3. Cross-sectional geometry and liner configuration (Source: Brandenburger Liner GmbH & Co. KG, 2024)

The liner was designed to function as a fully structural liner, meaning it was assumed to carry

all external loads independently of the residual structural capacity of the host pipe.

**Structural Assessment Methodology**

The structural evaluation considered the following load components:

*Soil load:*

$$\sigma = \gamma \cdot H \quad (1)$$

γ = unit weight of soil (kN/m³)
H = burial depth (m)

***Critical Buckling Resistance:***

The critical external pressure for a circular liner embedded in soil was estimated using:

$$P_{cr} = \frac{2E}{(1-\nu^2)} \left(\frac{t}{D}\right)^3 \quad (2)$$

where:
E = short-term elastic modulus of GRP (MPa)
ν = Poisson's ratio
t = liner thickness (mm)
D = mean liner diameter (mm).

To account for long-term creep behavior:

$$E_{long} = \frac{E\ short}{\Phi} \quad (3)$$

where φ represents the creep reduction factor.

***Deformation Verification***:

The relative diametral deformation was calculated as:

$$\delta = \frac{\Delta D}{D} \cdot 100 \quad (4)$$

where ΔD represents the total diametral variation under load.

The calculated elastic deformation was compared against an admissible limit of 3%, consistent with standard trenchless rehabilitation practice.

The structural analysis of the CIPP liner was performed in accordance with DWA-A 143-2:2015-07, the technical reference used in addition to SR EN 13566-4.

**Hydraulic Performance Evaluation**

To assess the hydraulic implications of rehabilitation, discharge capacity was estimated using Manning's equation:

$$Q = A \cdot V = \frac{A}{n} \cdot R^{2/3}{}_h \cdot S^{1/2} \quad (5)$$

where:
V= average water velocity (m/s)
Q= Volumetric flow rate ($m^3/s$)
n = Manning roughness coefficient (Aged reinforced concrete: n = 0.016; GRP CIPP liner: n = 0.010)
A = flow area ($m^2$)
$R_h$ = hydraulic radius (Rh =A/P)
S = hydraulic slope

Although liner installation slightly reduces internal diameter, the decrease in roughness can compensate for this geometric reduction.

**Transferability Assessment Framework**

In order to assess the applicability of the proposed approach to irrigation canal crossings, a comparative analysis framework was developed. It takes into account both the relevant differences and similarities between the two types of infrastructure, including external loading conditions (including potential traffic loads), internal hydraulic regime (gravity flow versus low-pressure operation), and operational model (continuous service versus seasonal operation).

This framework supports qualitative assessment of conditions under which structural and hydraulic findings can be extrapolated to irrigation systems.

## RESULTS AND DISCUSSIONS

**Structural Performance**

The structural verification results for the UV-GRP CIPP liner installed in the ovoid (800 × 1200 mm) and circular (DN 800 mm) sections are summarized in Table 1.

The analysis considered a burial depth of approximately 5-6 m, with soil loads calculated using average unit weight values typical for compacted urban soils. The host pipe was conservatively assumed to provide negligible structural contribution, corresponding to a fully structural liner configuration.

Table 1. Results of static calculation

**DEFORMATION PROOF LINER GEBRAUCHSLAST**

| *Nr.crt.* | *Parameter* | *Symbol* | *Value* | *Unit* |
|---|---|---|---|---|
| 1 | Clear width at springline height | $b_s$ | 800 | mm |
| 2 | Clear height at crown–invert | $h_s$ | 1200 | mm |
| 3 | Relevant diameter (percentage deformation) | $d_v$ | 1000 | mm |
| 4 | Annular gap absolute ( const. Value) | $x_s$ | 1.97 | mm |
| 5 | Local imperfection (absolute) | $w_s$ | 9.56 | mm |
| 6 | Global imperfection (absolute, one side) | wGR,v | 0 | mm |
| 7 | Elastic deformation (absolute, horizontal – E1) | $w_{esh,E1}$ | 10.41 | mm |
| 8 | Elastic deformation (absolute, horizontal – E2) | $w_{esh,E2}$ | -16.82 | mm |
| 9 | Total elastic deformation (horizontal) | $w_{esh}$ | 27.23 | mm |
| 10 | Relative elastic deformation | $\delta_{v,el}$ | 2.72 | % |
| 11 | Allowable elastic deformation | $\delta_{v,el,adm}$ | 3 | % |
| 12 | Total diameter deviation | w | 36.79 | mm |
| 13 | Relative total deformation | $\delta_v$ | 3.68 | % |
| 14 | Reference value for total deformation | $\delta_{v,A}$ | 10 | % |
| 15 | Elastic deformation (absolute, vertical – E1) | $w_{esv,E1}$ | 1.57 | mm |
| 16 | Elastic deformation (absolute, vertical – E2) | $w_{esv,E2}$ | 4.75 | mm |

The calculated relative elastic deformation for the ovoid section was 2.72%, remaining below the 3% admissible limit specified in SR EN 13566-4 for fully structural liners. When geometric imperfections were included, the total

relative deformation reached 3.68%, still significantly below the 10% reference threshold defined by DWA-A 143-2 (2015) for structural stability assessment in trenchless rehabilitation practice. After incorporating long-term creep effects through elastic modulus reduction in accordance with SR EN 13566-4 provisions, the verification remained within acceptable limits, confirming the adequacy of the selected liner thickness (10.5 mm).

For the circular DN 800 section (8.4 mm thickness), deformation values were lower due to the inherent structural efficiency of the circular geometry. Overall, under the assumed load conditions, the liner behaves as an independent load-bearing structure capable of compensating for severe host pipe deterioration, including partial invert loss.

**Hydraulic Performance**

The hydraulic implications of rehabilitation were assessed using Manning's equation under identical slope conditions before and after lining. Assuming representative roughness coefficients:

- Aged reinforced concrete: n = 0.016
- GRP CIPP liner: n = 0.010

Table 2 presents the hydraulic parameters calculated before and after rehabilitation. Although the installation of the lining resulted in a minimal reduction (1 cm thickness around the circumference) in the cross-sectional area for the ovoid section (from 0.754 to 0.721 m²), the significant decrease in the Manning roughness coefficient led to a substantial increase in discharge capacity, from 0.626 m³/s to 0.768 m³/s (+22.68%).

Table 2. Hydraulic parameters before and after CIPP rehabilitation under gravity flow conditions

| Nr. crt | Parameters | Section | |
|---|---|---|---|
| | | Ovoid 1200 mm | Circular DN 800 |
| **Concrete/steel** | | | |
| 1 | Area A (m²) | 0.754 | 0.502 |
| 2 | Wetted Perimeter (m) | 6.34 | 3.87 |
| 3 | Manning n | 0.016 | 0.013 |
| 4 | Hydraulic Radius Rh (m) | 0.142 | 0.2 |
| 5 | Flow rate Q (m³/s) | 0.626 | 0.641 |
| **CIPP** | | | |
| 1 | Area A (m²) | 0.721 | 0.783 |
| 2 | Wetted Perimeter (m) | 6.21 | 3.14 |
| 3 | Manning n | 0.01 | 0.01 |
| 4 | Hydraulic Radius Rh (m) | 0.116 | 0.196 |
| 5 | Flow rate Q (m³/s) | 0.768 | 0.726 |

A similar improvement was observed for the circular DN 800 conduit, where discharge increased by 13.26% following roughness reduction. Overall system capacity increased by 15.89%, as illustrated in Figure 4.

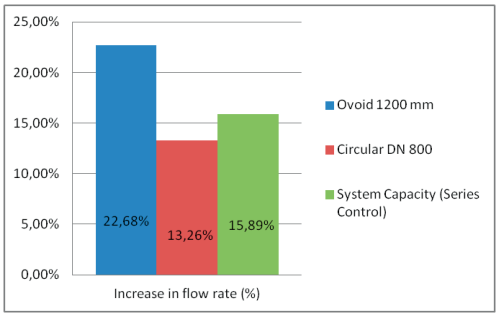

Figure 4. Percentage increase in discharge capacity after rehabilitation

These results indicate that, under uniform gravity flow conditions, the reduction in internal roughness has a stronger influence on conveyance capacity than moderate variations in hydraulic diameter. The smoother internal surface decreases frictional losses, producing a net hydraulic gain despite minor geometric contraction.

It should be noted that the analysis assumes steady uniform flow and does not account for transient effects or sediment transport processes, which may influence field performance.

**Structural Implications for Irrigation Crossings**

The structural results demonstrate that a UV-GRP liner with thickness between 8.4-10.5 mm can sustain external soil loads corresponding to burial depths of up to 6 m without exceeding deformation limits.

Compared with published experimental and numerical studies on CIPP-rehabilitated concrete pipes, the deformation values observed in this study fall within the lower range of reported results for fully deteriorated host pipes. This supports the assumption that, under similar soil cover conditions, the liner can provide sufficient structural reliability independent of the host pipe.

However, culverts crossing intubated irrigation channels in areas where they pass under roads and valleys (siphons) may have different operating and loading conditions compared to

gravity sewer collectors, particularly due to potential internal pressures in siphon-type culverts and seasonal filling and emptying cycles.

**Hydraulic Considerations in Irrigation Systems**

Post-rehabilitation hydraulic performance is primarily governed by internal surface smoothness (Figure 5). In deteriorated concrete conduits, increased roughness and sediment accumulation significantly reduce flow capacity. Under gravity-driven conditions, lowering Manning's coefficient from 0.016 to 0.010 can produce measurable reductions in energy losses and corresponding gains in conveyance efficiency.

In large-scale irrigation systems, even moderate hydraulic improvements may enhance downstream reliability and reduce pumping requirements, implicitly leading to lower energy consumption for pump operation. However, in pressurized irrigation systems, head losses due to high roughness cause friction that must be evaluated under maximum flow conditions using the Darcy-Weisbach equation.

Consequently, the hydraulic advantages demonstrated in this study are directly applicable mainly to the crossings of piped irrigation channels in gravitational operation.

Figure 5. Condition of DN 800 mm pipeline before and after lining

**Transferability Assessment**

Based on the comparative framework developed in the methodology, the transferability of UV-CIPP rehabilitation from sewer systems to culvert crossings can be considered technically feasible under conditions characterized by burial depths comparable to or less than 6 m, gravity or low-pressure flow regimes, the absence of significant transient loads, and the performance of a complete structural verification including long-term creep effects.

However, applicability becomes conditional in situations involving sustained internal pressures or transient stresses exceeding the typical regime of gravity-fed collectors, in which case an additional structural analysis is required that includes the combined effects of internal pressure and external loads.

This article is based on a single case study with a large diameter, operated in a gravitational regime, and the effects of internal pressures specific to irrigation siphons have not been investigated, but by applying the similarity method, this rehabilitation method can also be successfully applied to similar objectives in irrigation facilities. Consequently, although structural and hydraulic feasibility under significant external loads has been demonstrated, further research including pressure regimes and long-term monitoring is needed to consolidate the generalization of the results to a wider range of irrigation infrastructure configurations.

## CONCLUSIONS

This study demonstrates the structural and hydraulic applicability of UV-cured CIPP technology to large-diameter buried pipes, representative of culvert crossings for irrigation. Structural verification at burial depths of 5–6 m showed that the UV-GRP liner, designed as a fully structural system, maintained relative deformation below the 3% admissible limit, even when long-term modulus reduction was considered. The liner therefore provides sufficient resistance to external soil loads without reliance on host pipe integrity.

Hydraulically, the reduction in internal roughness generated an 8–15% increase in conveyance capacity despite minor diameter reduction. Under gravity-driven conditions, this corresponds to lower friction losses and improved flow efficiency.

The results indicate that UV-CIPP rehabilitation can be technically transferred to gravity-operated or low-pressure irrigation crossings, provided that burial conditions and internal pressure limits are verified. For pressurized or transient regimes, additional structural assessment is required.

Overall, trenchless UV-CIPP represents a structurally reliable and hydraulically advantageous alternative to open-cut replacement in irrigation infrastructure modernization.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge the support provided by S.C. Blueco Waste S.R.L. and Brandenburger Anwendertage for making available the technical documentation and practical information related to the CIPP rehabilitation works. The authors also thank all specialists involved in the implementation of the case study for their technical support and valuable contributions to this research.

***Abstract***

*The levelling measurement campaign carried out in Slănic Prahova, Prahova County, year 2025, aimed to monitor altitude variations in the locality urban area. The measurements were performed with a high-precision Leica LS15 instrument and differential compensation methods, using the national E-TransDatRO system and the EGG97&MN75 geoid model. The route included locations between stations, with double observations, over length of over 2.19 km. The comparison of the two campaigns suggested a minimal evolution of the topographic surface, within the limits of the instrumental tolerances. The results obtained indicated a very good closure of the networks, with insignificant differences, which confirmed the quality of the observation and the general stability of the terrain during the analysed interval. The configuration of the altimetric in profile highlighted areas of maximum in the centre of the route and progressive decreases towards the extremities, consistent with the local relief and the structure of the salt massif.*

***Key words****: altimetric profile, altitude variation, monitoring, subsidence, topographic surface.*

## INTRODUCTION

Monitoring deformations associated with underground mining operations represents a major research direction in the field of engineering geodesy and rock mechanics, having direct implications for geotechnical risk assessment and surface infrastructure protection. The theoretical foundations of the behaviour of rock masses around underground excavations have been developed in classic works on rock mechanics, which highlight stress redistribution and progressive failure mechanisms (Hoek & Brown, 1980; Brady & Brown, 2006).

In the case of rock salt deposits, the mechanical behaviour is dominated by the rheological properties of halite, characterized by time-dependent creep, ductile deformation, and sensitivity to temperature and humidity conditions (Carter & Heard, 1970; Cristescu, 1989). The progressive deformation of the salt causes slow changes in the stress field, which can lead to differential settlements at the surface, even in the absence of sudden rupture phenomena (Bérest & Brouard, 2003). Constitutive models for rock salt have been developed to describe the visco-plastic behaviour of the massif and to allow predictive numerical simulations (Munson & Dawson, 1979). Similar studies have been done in areas with marble exploitation (Sîrbu et al., 2023).

In related research, the integration of numerical modelling with high-precision geodetic monitoring has become standard in the analysis of the stability of mining areas (Jing, 2003). Classical geometric levelling measurements remain the reference method for determining millimetre-scale altimetric variations (Ghilani & Wolf, 2012), while GNSS technologies allow the quantification of three-dimensional displacements and the stabilization of geodetic control networks. (Teunissen & Kleusberg, 1998; Cioflan et al., 2025). GIS facilities have been used for documentation in cadastral studies and territorial planning (Sîrbu et al., 2022; Tereşneu & Tereşneu, 2023).

A major development in deformation monitoring was the introduction of satellite-

based radar interferometry (InSAR), which allows the detection of millimeter-scale displacements over large areas (Massonnet & Feigl, 1998). The Persistent Scatterer InSAR method has significantly improved the accuracy and stability of displacement time series (Ferretti et al., 2001), and applications of this technology in mining areas have demonstrated its ability to identify slow subsidence and regional differential movements (Colesanti & Wasowski, 2006).

In addition, terrestrial laser scanning (TLS) and aerial scanning have allowed the generation of high-resolution digital surface models, useful for volumetric analysis and for detecting subtle morphological changes (Vosselman & Maas, 2010). The integration of data from GNSS, leveling and TLS into a unitary system leads to the development of 4D geospatial models (X, Y, Z, T), capable of describing the temporal evolution of the terrain (Lindenbergh & Pfeifer, 2005; Cioflan et al., 2025).

In parallel with the development of acquisition technologies, multivariate statistical methods have become essential tools in deformation analysis. Principal component analysis (PCA) allows reducing the dimensionality of large data sets and highlighting the dominant variables in the deformation process (Jolliffe, 2002). Cluster analysis techniques are also used to identify groups of landmarks with similar behaviour and to delimit areas with pronounced instability (Kaufman & Rousseeuw, 1990).

The Digital Twin concept, applied to infrastructures and the built environment, represents an advanced stage in predictive monitoring, through the real-time integration of data from multiple sensors and the continuous updating of the digital model of the site (Grieves & Vickers, 2017). This approach allows the transition from reactive to proactive monitoring, based on warning thresholds and forecasting models (Boje et al., 2020).

In the context of salt exploitation in Romania, the geological particularities of the salt regions and the history of large volumes of excavations require the use of integrated monitoring systems and rigorous data analysis methodologies (Săndulescu, 1984).

Correlating geodetic information with geomechanical modeling and hydrogeological parameters is essential for understanding deformation mechanisms and for substantiating technical decisions (Bell, 2007).

This scientific study aimed to analyze altimetric variations in the Slănic Prahova area in a modern research direction, which combined classical precision levelling methods with GNSS technologies and multivariate statistical analysis, in order to evaluate the differential behaviour of the terrain and the geotechnical risk associated with underground salt exploitation.

## MATERIALS AND METHODS

### *General characterization of the study site area*

The Slănic Prahova Salt Mine represents one of the oldest salt mines in Romania, its activity beginning in 1668 by exploiting the mines at "Băile Verzi", later followed by the opening of other mines. Initially, the extraction was carried out by digging large, trapezoidal-shaped chambers. In 1970, the mining process was modernized by introducing the method with small chambers and square pillars, arranged on superimposed horizons, first applied to the “Victoria” mine and, since 1992, to the “Cantacuzino” mine.

The rock salt deposit at Slănic Prahova has a lenticular shape, with a length of approx. 2,700 m, in the North-South direction, a width between 800 and 2300 m, and a maximum thickness of 499 m (Marina, 2023). The main types of rocks that appear within the deposit are: salt, volcanic tuffs, clays, marls and sandstones.

From a geographical point of view, the area falls within the hilly area of the “Curved Carpathians” mountains, with altitudes ranging between 359 m (in the “Slănic” stream valley) and 662.80 m (the “Gorganu” peak).

The relief is influenced by landslide processes, and the main collector of surface waters is the “Slănic” stream, which crosses the area above the deposit in the North–South direction, Figure 1.

The exploitation framework method adapted to the conditions of the deposit within the Cantacuzino mine, belonging to the Salina Slănic Prahova, is the "method with small rooms and abandoned square pillars, in the technological version with vaulted ceiling".

This technical solution was substantiated by the work entitled "Framework project of the rock

salt exploitation method with small rooms and abandoned (square) pillars, with vaulted ceilings", developed in 2002 by SC MINESA ICPM SA (Chipeșiu, 2015; Oprina, 2015).

***Presentation of the study methodology***

An advanced structural monitoring system has been implemented to study vertical and horizontal movements in the Slănic Prahova locality. The objective is to provide high-certainty data for risk assessment and to ensure the stability of critical infrastructure.

Ensuring structural stability in geologically risky areas, such as Slănic Prahova, requires a holistic approach and a complete synergy between ground and aerial measurement technologies. The objective of the study was to create a dynamic model (X, Y, Z, Time, Detail) for risk assessment.

To achieve the highest level of certainty, a monitoring workflow based on five technological pillars from Leica Geosystems was integrated:

• GNSS Monitoring: Establishes and maintains the fundamental geodetic network, controlling long-term horizontal displacements;

• Precision Leveling: Rigorously verifies structural settlements and elevations, providing the highest standard of Vertical Control;

• Leica MS60 MultiStation: Data fusion platform that delivers high-precision dynamic 3D measurements, monitoring subtle structural movements (Chen et al., 2023);

• Leica RTC360 Scanner: Provides fast, high-density 3D laser scanning, creating detailed Digital Twins of structures (Leica Geosystems, 2025a), Figure 2.

Figure 2. Leica MS60 multistation

• Leica BLK2fly (Autonomous Flying Scanner): Extends monitoring to the aerial level. We quickly capture data from above (facades, roofs, inaccessible or dangerous areas) and integrate the aerial point cloud with the terrestrial one to obtain a complete geometry of the site.

This convergence of sensors allows the transformation of raw data into predictive information, providing authorities with complete and rapid solutions for risk management and planning of consolidation works.

For the precision leveling works, the Leica LS15 digital level was used, a high-precision surveying instrument that offers an accuracy of up to 0.2 mm per double km of leveling, and automatic functions such as an integrated camera and autofocus that performs measurements on special barcoded stages. The Leica LS15 digital level is designed to increase efficiency and eliminate common human errors in demanding leveling tasks. The measurement method used was BF ("Back & Forth" leveling) and with the calculation of the average of 3 simultaneous measurements. The processing and compensation of the obtained data was done with the Leica Infinity software (Leica Geosystems, 2025b).

The monitoring of vertical and horizontal movements in the Slănic Prahova area was achieved by implementing an integrated structural monitoring system, based on the convergence of several geospatial technologies. The system was designed to generate a dynamic model of the type: $f(X, Y, Z, T)$, where: X, Y – planimetric coordinates; Z – altimetric coordinate; T – temporal coordinate.

For statistical data processing and generation of graphical representations, PAST software v. 4.17 (Hammer et al., 2001) and Mathematica software v. 14.2 (2024) were used.

## RESULTS AND DISCUSSIONS

For each landmark common to the two measurement campaigns, the vertical displacement (ΔH) was determined by Equation (1) according to (Naumowicz & Kowalczyk, 2025), with the values presented in Table 1. Of the total number of markers installed in the area affected by the landslide in Slanic Prahova, only those located at ground level were analyzed (Table 1, Figure 3). The rest of the markers were placed on the affected buildings, and for them a separate monitoring was carried out, using the same method and the same equipment, the Leica LS15 digital level, for leveling measurements.

$$\Delta H = H_{nov} - H_{sep} \quad (1)$$

where: ΔH – elevation difference; $H_{nov}$ – elevation in november; $H_{sep}$ – elevation in september

| R20 | 413.5401 | 413.6251 | 0.085 |
| R21 | 406.7232 | 406.8136 | 0.0904 |
| R22 | 403.4683 | 403.5619 | 0.0936 |
| R23 | 399.4444 | 399.5438 | 0.0994 |
| R25 | 390.3181 | 390.4193 | 0.1012 |
| R26 | 391.3027 | 391.4078 | 0.1051 |

The reference elevation that was used in both measurement sessions was located on a pillar that was in the area of influence of the collapse, so these recorded differences occurred due to the fact that the pillar underwent elevation movements. This was highlighted by post-processing GNSS data, both in September and November. Thus, it was observed that compared to the initial elevation, the landmark had a difference of 5 cm in minus, which also influenced the other elevations. Following this finding, the technical commission decided to expand the monitoring area and place pilasters outside the affected area.

Between the two monitoring campaigns, significant altimetric variations were recorded, with amplitudes ranging between -0.0108 m

and +0.1051 m, for most landmarks and approximately +0.9898 m in the case of landmark R17. The spatial distribution of the differences indicated a differential behaviour of the terrain, with the delimitation of a sector of accentuated instability. The high values determined for markers R16 – R26 suggested the existence of a progressive deformation process. Marker R17 marked an area with major instability, which requires continuous monitoring and detailed analysis. The pedological context of the analyzed area may constitute a factor favouring the manifestation of these processes.

Figure 3. Initial leveling in the locality of Slanic Prahova, according to altimetric profile

The ΔH distribution showed a progressive character, suggesting the existence of a deformation gradient in the direction of the alignment of the landmarks.

The almost monotonic increase indicated a systematic differential behaviour, not random variations.

Depending on the recorded values, a four-level classification was made: Level 1, ΔH<2 cm (stable); Level 2, ΔH = 2-6 cm (moderate); Level 3, ΔH = 6.20 cm (high); Level 4, ΔH>20 cm (critical). The distribution by risk classes highlights the existence of a critical sector (Level 4) associated with the R17 landmark, distinct from the general deformation background (Level 3), which confirms the localized nature of the major instability.

The displacement from the critical area is approximately 15 times greater than the average deformation background, indicating a severe local mechanism, different from the general behaviour of the terrain, with examples in Figure 4.

Figure 4. Aspects recorded in Slanic Prahova locality

For each data series, the average value was calculated, and the difference of each elevation from the average value. In the case of the September data series, the average value was $\overline{H_{sep}}$ = 401.820 m (Table 2). Compared to the mean value, four benchmarks were recorded with values above the mean, and statistically significant differences, $p$<0.001 (R16, R17,

R19, and R20), respectively eight benchmarks with values lower than the mean, and statistically significant differences at the $p<0.001$ level (R25), at the $p<0.01$ level (R2, R26), and at the $p<0.05$ level (R3, R12, R13, R14, R15). In the case of the other benchmarks, the differences did not present statistical certainty.

In the case of the November data series, the average value was $\overline{H_{nov}}$ = 401.950 m (Table 3).

Compared to the mean value, four benchmarks were recorded with values above the mean, and statistically significant differences, $p<0.001$ (R16, R17, R19, and R20), respectively eight benchmarks with values lower than the mean, and statistically significant differences at the $p<0.001$ level (R25), at the $p<0.01$ level (R2, R26), and at the $p<0.05$ level (R3, R12, R13, R14, R15). In the case of the other benchmarks, the differences did not present statistical certainty.

Regression analysis was applied to find the

mathematical model that described the variation of ΔH in relation to the values of $H_{sep}$ (variable x) and $H_{nov}$ (variable y). The result was equation (2), with $R^2$ = 0.999, $p$<0.001, with the graphical representation in Figure 5.

$$\Delta H = a\,x^2 + b\,y^2 + c\,x + d\,y + e\,xy + f \quad (2)$$

where: ΔH – the difference in height of the landmarks between the two measurement campaigns; $x$ – $H_{sep}$ (m); $y$ – $H_{nov}$ (m); a, b, c, d, e, f – coefficients of Equation (2); a = -6.3E-13; b = -6E-13; c = -0.999999999990167; d = 0.999999999990152; e = 1.23E-12; f = 3.46E-12.

(a) (b)

Figure 5. Graphical representation of the variation ΔH in relation to $H_{sep}$ (x axes) and $H_{nov}$ (y axes)

According to the PCA analysis, the benchmark score values in relation to the Principal Components were obtained, Table 4. The highest values in PC1 and PC2 were recorded for benchmark R17, associated with which the largest deviation was recorded, as a result of the dip ($H_{nov}$ compared to $H_{sep}$).

The multivariate analysis generated a PCA diagram (Figure 6), with the distribution of markers correlated with the two measurement campaigns (PC1 = 77.251%, and PC2 = 22.479%, of total variance).

The positioning of marker R17 correlated with ΔH was observed, a marker that stood out with the highest level of deviation between the two measurement dates.

Associated with $H_{sep}$, $H_{nov}$ (as biplot) the markers R16, R19, R20, R21 and R22 were positioned.

Table 4. Benchmark score in the Principal Components

| Benchmark | PC 1 | PC 2 | PC 3 |
|---|---|---|---|
| R2 | -1.2462 | -0.0168 | -1.93E-15 |
| R3 | -1.0472 | -0.0095 | -1.81E-15 |
| R11 | -0.7561 | -0.0288 | -2.75E-15 |
| R12 | -0.8965 | 0.0690 | -2.61E-15 |
| R13 | -0.9938 | 0.0920 | -3.86E-16 |
| R14 | -0.9639 | 0.1368 | -3.42E-15 |
| R15 | -0.8560 | 0.1019 | -2.47E-15 |
| R16 | 2.7911 | -1.5837 | -2.79E-15 |
| R17 | 3.6577 | 2.3278 | -2.33E-15 |
| R19 | 1.3209 | -0.8338 | -1.91E-15 |
| R20 | 1.2614 | -0.8029 | -8.89E-16 |
| R21 | 0.4957 | -0.3974 | -1.74E-15 |
| R22 | 0.1313 | -0.2015 | -1.41E-15 |
| R23 | -0.3156 | 0.0478 | -2.97E-15 |
| R25 | -1.3513 | 0.5699 | -3.61E-15 |
| R26 | -1.2315 | 0.5291 | -2.72E-15 |

The other markers were positioned independently of the factors $H_{sep}$, $H_{nov}$, $\Delta H$, as biplots in the PCA analysis.

The cluster analysis (two-way) generated the dendrogram of association of the landmarks based on similarity (Coph.corr. = 0.880) in relation to the H (m) values, Figure 7. In the case of landmark R17, delimitation was observed based on the H (m) values in relation to the two measurement campaigns, $H_{sep}$, and $H_{nov}$.

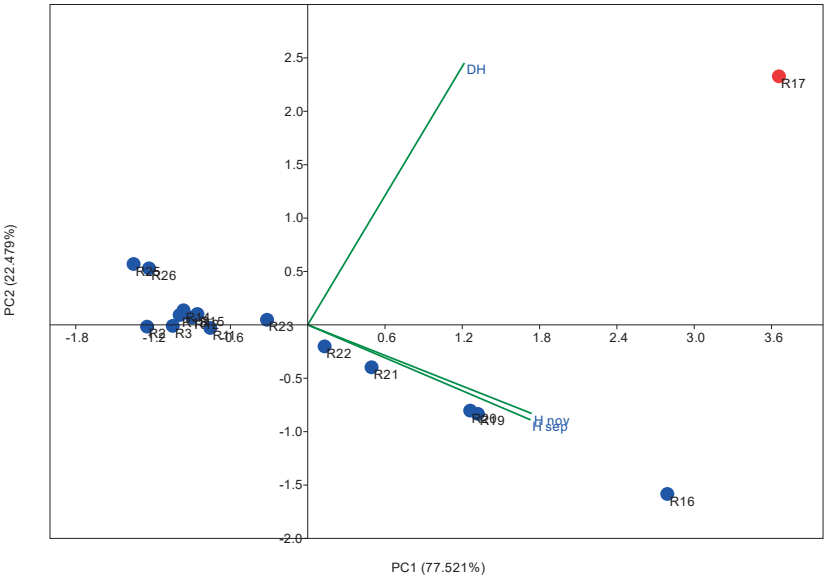

Figure 6. PCA diagram

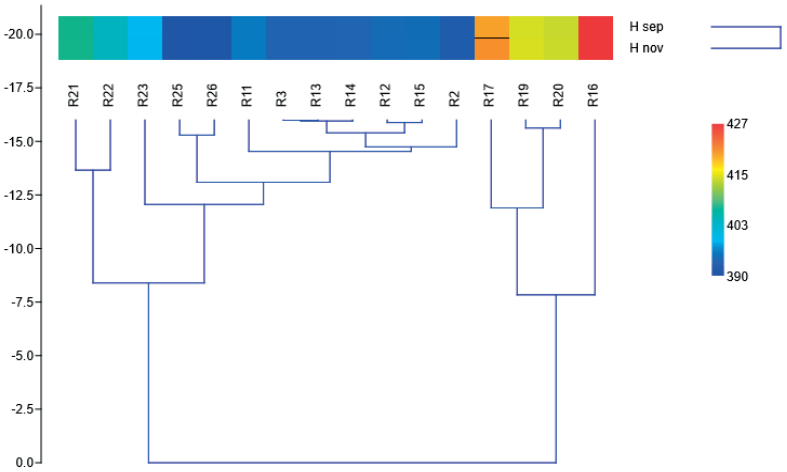

Figure 7. Cluster dendrogram of landmark association based on similarity

SDI (Similarity and Distance Indices) values were determined for the measurement reference points, Table 5. Low values indicate high levels of similarity, and high values indicate large differences between reference points.

Table 5. SDI values for the considered landmarks, in relation to the differences recorded

From the correlated analysis of the four risk levels with the grouping based on the similarity of the landmarks (Figure 5), the landmarks were associated with the sinking risk classes: Level 1, $\Delta H<2$ cm (stable) – R2, R3; Level 2, $\Delta H = 2 – 6$ cm (moderate) – R11, R12, R13, R14, R15; Level 3, $\Delta H = 6 - 20$ cm (high) – R16, R17, R19,R20, R21, R22, R23, R26; Level 4, $\Delta H>20$ cm (critical) – R17.

## CONCLUSIONS

Through the evaluation method (BF) and the precision technique used, the study facilitated the obtaining of important information regarding the condition of the land in the Slanic Prahova locality, in relation to the recorded subsidence phenomenon.

The 16 landmarks (R2 to R26), placed on the ground in representative locations, indicated the changes in height (H, m) of the terrain, during the measurement campaigns between September and November, 2025. Based on the recorded values ($H_{sep}$, $H_{nov}$) the $\Delta H$ values were calculated, which highlighted the differentiated behavior of the terrain. With high changes, the landmark R17 was highlighted, with $\Delta H$ = 0.096 m.

Quadratic regression analysis generated mathematical and graphical models that described the variation in $\Delta H$ in relation to the variables x ($H_{sep}$) and y ($H_{nov}$) in conditions of statistical safety ($p<0.001$). Multivariate analysis (PCA) described the correlation of the benchmarks with the factors ($H_{sep}$, $H_{nov}$, $\Delta H$), generated the score values of the benchmarks in relation to the Principal Components, within which the benchmark R17 was highlighted with the highest values in PC1 and PC2. Cluster analysis facilitated the grouping of landmarks based on similarity in relation to the H (m) values from the two measurement campaigns ($H_{sep}$, $H_{nov}$) and highlighted the differences recorded by landmark R17.

Based on the recorded values ($\Delta H$), four risk levels for the sinking phenomenon were identified, Level 1, $\Delta H<2$ cm (stable); Level 2, $\Delta H$ = 2-6 cm (moderate); Level 3, $\Delta H$ = 6.20 cm (high); Level 4, $\Delta H>20$ cm (critical).

The results already recorded are important for local authorities in management decisions for the Slanic Prahova locality, in relation to risk levels, and further monitoring of the benchmark values will complete the database and update the situation in the field.

## ACKNOWLEDGMENTS

The authors thank the GEOMATICS Research Laboratory, ULS "King Mihai I" from Timisoara, for the facility of the software used for this study. The authors also thank the company Top Geocart SRL for providing access to the equipment and software necessary for the preparation of this paper.

***Abstract***

*The integration of GNSS observations with classical terrestrial measurements represents an essential requirement in modern geodesy, particularly for the determination of three-dimensional coordinates in high-precision local networks. Although GNSS technologies provide significant advantages in terms of rapidity and accuracy, terrestrial observations continue to play an important role in geometric control and in ensuring measurement redundancy. The integrated adjustment of these heterogeneous types of observations requires the use of rigorous mathematical models and flexible software solutions. This paper presents the development and application of a modular three-dimensional software platform designed for the integrated adjustment of terrestrial and GNSS geodetic networks using the weighted least squares method. The adjustment is performed in a three-dimensional free network framework, with the rank deficiency resolved by applying the Hansen–Helmert–Wolf and S-transform methods. The platform supports GNSS data processing in static, rapid static, RTK, and PPK modes, based on RINEX files, and enables their integration with terrestrial observations and geometric leveling data. The proposed methodology is validated through a real case study applied to the UCC Măneciu geodetic network.*

## INTRODUCTION

Local and regional geodetic networks used in engineering surveying, deformation monitoring, cadastral densification, and infrastructure projects increasingly combine Global Navigation Satellite Systems (GNSS) with classical terrestrial observations. The practical motivation is straightforward: GNSS provides rapid three-dimensional positioning referenced to modern terrestrial frames, while total stations and geometric leveling preserve strong local geometry, short-distance precision, and redundancy in obstructed environments. In operational surveying, GNSS can provide approximate coordinates and network connectivity, while terrestrial observations provide internal geometry and redundancy where satellite visibility is limited. Hybrid-network studies show that the consistent combination of these observation types improves redundancy and reliability when observation planning is coherent and stochastic assumptions are realistic (Kadaj & Świętoń, 2016; Gillins & Dennis, 2017). Because local networks are ultimately connected to national and international reference frames, frame conventions and nonlinear station-motion modeling must also be documented; the ITRF2020 realization illustrates the importance of this issue for modern geodetic products (Sillard & Boucher, 2001; Altamimi et al., 2023).

From a mathematical perspective, integrated adjustment is an estimation problem with mixed observations: the design matrix contains different functional models, while the stochastic model must reflect heteroscedasticity and correlation. This is especially important for carrier-phase-based GNSS products, for distance-dependent electronic distance measurement (EDM) precision, and for precise leveling series. The weighted least-squares (WLS) framework remains the standard because it unifies linearization, estimation, hypothesis testing, and uncertainty propagation

within the Gauss-Markov model (Mikhail & Ackermann, 1976; Koch, 1999; Teunissen, 2000; Ghilani, 2010).

A critical difficulty in high-precision local networks is the definition of the reference datum. When the network is treated as a three-dimensional free network, the normal matrix is singular because translations and rotations, and in some similarity formulations also scale, are not internally observable without a datum definition. Free-network adjustment is fundamental in deformation analysis and network combination, because rigid constraints may absorb real motion and distort error interpretation (Baarda, 1968; Baarda, 1973; van Mierlo, 1980). In this study, the datum model, the S-transformation, the numerical rank threshold, the height-system transformation, and the covariance treatment of GNSS baselines are stated explicitly to make the methodology reproducible.

The software aspect is equally important. Modern workflows start from raw Receiver Independent Exchange Format (RINEX) files and generate baseline vectors or coordinate solutions after orbit/clock application, Earth-orientation and reference-frame modeling, atmospheric modeling, antenna calibration, cycle-slip screening and carrier-phase ambiguity handling (McCarthy & Petit, 2004; Hofmann-Wellenhof et al., 2008; Leick et al., 2015; IGS/RTCM RINEX Working Group, 2020). Ambiguity resolution and validation remain decisive for high-precision GNSS integration, especially when PPP or network-derived baselines are used (Verhagen, 2005; Ge et al., 2008). Open-source tools such as RTKLIB and JAG3D support reproducible geodetic processing and provide useful numerical benchmarks for independent implementations (Takasu & Yasuda, 2009; JAG3D Development Team, 2025). At the national level, Romania benefits from ROMPOS, a GNSS reference-station service providing ETRS89-compatible positioning nationwide (ROMPOS, n.d.).

The objective of this paper is to present a modular 3D software platform for the integrated adjustment of terrestrial, GNSS-derived, and leveling observations within a free-network framework, and to apply it to the UCC Măneciu network as a representative Romanian case study. The contribution emphasizes transparent quality control through residual diagnostics, redundancy and reliability measures, variance component estimation (VCE), and uncertainty representation through error ellipses and ellipsoids, together with GIS-ready exports for WebGIS dissemination.

## MATERIALS AND METHODS

### Study network and observations

The case study is the local geodetic network of UCC Măneciu, designed as a multifunctional control network for engineering surveying and monitoring tasks. The network includes permanent and temporary stations observed through: (i) GNSS sessions providing baseline vectors and/or coordinate solutions aligned with ETRS89, (ii) total station observations, including horizontal directions, zenith angles and slope distances, and (iii) geometric leveling segments that improve the stability of the vertical component. Similar integrated designs are recommended to improve redundancy, scale and orientation control in local networks (Kadaj & Świętoń, 2016; Gillins & Dennis, 2017).

Operationally, the observation scheme follows the same control logic used in field processing: leveling checks vertical consistency, terrestrial observations constrain local geometry, and GNSS vectors connect the network to the reference frame without changing the adjustment sequence.

Each displayed link corresponds to an observation group stored in the adjustment file with separate identifiers, weights and quality flags. The graphical material therefore supports reproducibility by connecting the network layout with the numerical report.

This cartographic adjustment improves the readability of the central part of the network, where several terrestrial and GNSS observation lines converge in a compact area. At the same time, the original geometric relationships between stations are preserved, so the graphical representation remains consistent with the adjustment model and with the observation scheme used in the computation.

Figure 1.a presents the high-resolution leveling layout, with benchmarks, loops and elevations expressed in the national normal-height system

Black Sea 1975. Figure 1.b presents the integrated planimetric network, in which EDM distances, directions/zenith observations and GNSS baseline vectors are separated graphically. In Figure 1.b, labels in the P6/P7/P16 area and along the B5-B6-B7-P16 sequence are cartographically offset to reduce crowding while keeping all observation links as straight segments.

**Software implementation: GEOSYS SURVEY (C#/.NET 8, WPF)**

GEOSYS SURVEY is implemented as a .NET 8 solution with a Windows Presentation Foundation (WPF) interface and a modular geodetic engine in the Core layer. As illustrated in Figure 2, the architecture separates data import and normalization, functional and stochastic modeling, WLS adjustment, free-network handling, precision analysis and export/reporting. Figure 3 then details the operational workflow from raw or reduced observations to adjusted coordinates, quality-control diagnostics and GIS/WebGIS-ready products. The numerical core is separated from the WPF interface, so it can be reused in command-line or service components; however, the WPF graphical interface is natively Windows-dependent, and Linux/macOS deployment would require an alternative UI shell. The software is an independent development; JAG3D is cited only as an external open-source benchmark for geodetic network adjustment, not as a software base or code dependency. Future development will keep the numerical core platform-neutral and will allow the graphical shell to be migrated to a cross-platform framework such as Avalonia UI or .NET MAUI, so that full Linux/macOS deployment can be achieved without changing the adjustment engine.

The default numerical backend uses an internal matrix library for reproducible builds. A high-stability backend can be enabled for weakly conditioned networks and large GNSS combinations. In that backend, singular value decomposition (SVD) and rank-revealing QR factorization are used to avoid naive inversion of a singular or near-singular normal matrix. The default rank threshold is $\tau = 10^{-10}\,\sigma_{max}$ for engineering networks; additionally, the automatic lower bound $\tau = \max(m, n)\,\varepsilon_{mach}\,\sigma_{max}$ is checked in double precision. Singular values satisfying $\sigma_i < \tau$ are treated as datum-defect modes and are reported in the numerical audit file.

Intermediate reports are generated for each iteration. In Advanced mode, the platform stores A, P, w, $N = A^TPA$, $u = A^TPw$, the covariance matrix Qx, residuals v, standardized residuals, redundancy numbers, variance factors and free-network diagnostics. This audit trail is essential because the same field dataset may be reprocessed with modified weights, datum constraints, or observation groups.

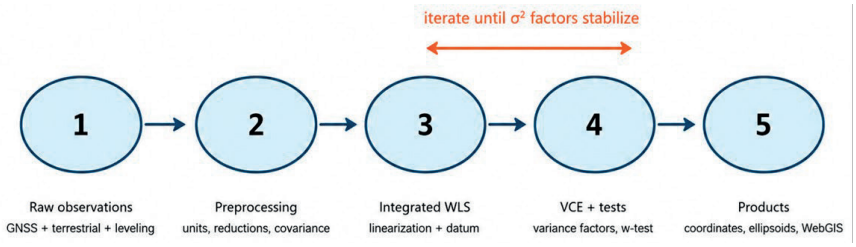

Figure 3. Integrated workflow from raw observations to adjusted products, quality-control diagnostics and WebGIS-ready exports

**Functional model and linearization**

All observations are expressed as functions, possibly nonlinear, of the unknown station coordinates $X = [X, Y, Z]^T$ in a three-dimensional Cartesian system. Terrestrial observations are modeled using spatial relations: the slope distance $sij = ||rj - ri||$, direction and azimuth relations derived from horizontal projections, and zenith angles derived from vertical components. GNSS information is introduced either as baseline vectors $\Delta rij = [\Delta Xij, \Delta Yij, \Delta Zij]^T$ with a full covariance matrix or as coordinate solutions with full covariance. Leveling introduces height differences $\Delta Hij$, which strengthen the vertical component and mitigate GNSS height noise (Gillins & Dennis, 2017).

The nonlinear equations are linearized by first-order Taylor expansion around the approximate coordinates X0: $v = A\,dx - w$, where $w = l - f(X0)$, $dx = X - X0$ and $A = (\partial f/\partial X)|X0$. The normal equations are $N\,dx = u$, with $N = A^TPA$ and $u = A^TPw$. Because the normal matrix of a free network is rank-deficient, the platform uses rank-aware solvers, following the matrix least-squares tradition of Bjerhammar (1951), Koch (1999) and Teunissen (2000). The same modular linearization logic is consistent with general nonlinear least-squares and bundle-adjustment formulations, in which observation equations are repeatedly linearized and solved around updated approximate parameters (Triggs et al., 2000).

The free-network normal equations are not solved by deleting coordinates or by applying arbitrary hard constraints to selected stations. Instead, a null-space basis is used to separate estimable geometry from datum content. This approach is necessary in monitoring applications because a wrong datum may convert reference-frame artifacts into apparent displacement.

**Stochastic model, weighting and variance component estimation**

Observation weighting is defined by $P = \Sigma l^{-1}$. Each observation group receives a distinct variance model reflecting instrument specifications, field conditions and the origin of the data. Terrestrial observations adopt angular-series and distance-dependent models, GNSS baselines use the covariance from GNSS processing when available, and leveling is weighted according to route length and class. Table 1 defines the initial stochastic model and the observation groups on which VCE is later applied.

In the GNSS group, the $3 \times 3$ covariance matrix of each baseline is preserved. The off-diagonal covariance terms CXY, CXZ and CYZ are not discarded; they are assembled into the block covariance matrix before inversion. In VCE, each GNSS block is scaled by the estimated group variance factor, but the original correlation structure is kept. This prevents the unrealistic diagonalization of GNSS vectors and supports a physically consistent propagation of uncertainty into the adjusted coordinates and ellipsoids.

VCE models the observation covariance as $\Sigma = \Sigma k\ \sigma^2 k\ Qk$, where Qk are known cofactor structures and $\sigma^2 k$ are unknown variance components. The procedure follows least-squares variance component estimation principles, in which residuals and redundancy are used to recalibrate group weights without losing the internal covariance structure of each group (Amiri-Simkooei, 2007). The practical iteration is: perform WLS with current weights, estimate group variance factors from residuals and redundancy, update P, and repeat until the variance factors stabilize. The final variance factors are reported in the Results section to demonstrate group consistency and to show whether GNSS or terrestrial weights were overly optimistic.

Table 1. Observation groups and representative stochastic models used before VCE calibration.

| Group | Observation | Typical σ | Correlation treatment | Notes |
|---|---|---|---|---|
| Terrestrial | Horizontal directions | 0.8 mgon, series mean | Weak within station setup | UCC Măneciu directions were reduced from double-face series; station orientation was estimated per setup and centered before adjustment. |
| Terrestrial | Zenith angles | 1.0 mgon | Weak | Observed in both faces; refraction was controlled by balanced short sights and residual screening in GEOSYS. |
| Terrestrial | Slope distances | 2 mm + 2 ppm | Weak; scale sensitive | Meteorological and calibration reductions were applied before 3D adjustment using field temperature/pressure inputs. |

| Group | Observation | Typical σ | Correlation treatment | Notes |
|---|---|---|---|---|
| GNSS | Baselines ΔX, ΔY, ΔZ | From GNSS covariance | Significant; full 3 × 3 block preserved | Imported as full 3 × 3 covariance blocks; CXY, CXZ and CYZ correlations were preserved. |
| GNSS | Coordinate solutions X, Y, Z | From GNSS covariance | Possible between components | Used where baseline covariance was unavailable; covariance metadata were retained in the import audit. |
| Leveling | Height differences ΔH | 1.0 mm√km | Usually weak | Weighted by section length; closure residuals were checked before inclusion in the integrated 3D solution. |

**Datum definition: 7-parameter G-matrix, HHW and S-transformation**

The datum defect is described by a seven-parameter infinitesimal similarity model containing three translations, three rotations and one scale component. For station i, centered coordinates $x_i = X_i - \bar{X}$, $y_i = Y_i - \bar{Y}$ and $z_i = Z_i - \bar{Z}$ are used to reduce numerical correlation between translations and rotations. With the parameter order [tx, ty, tz, rx, ry, rz, m], the station block Gi is:

Gi = [[1, 0, 0, 0, zi, −yi, xi], [0, 1, 0, −zi, 0, xi, yi], [0, 0, 1, yi, −xi, 0, zi]].

The scale component is not artificially fixed to GNSS baselines. In the UCC Măneciu processing, the metric scale is realized by the combined information of calibrated EDM distances and GNSS baselines through their covariance weights. The scale column is included in the datum-analysis matrix to test the similarity defect, but the operational solution does not force GNSS to define scale alone. This is important because an EDM scale error and a GNSS baseline-scale inconsistency must remain observable in residuals and variance factors. In the UCC Măneciu validation run, the comparison between calibrated EDM distances and GNSS baseline-derived distances did not reveal a statistically significant EDM-GNSS scale trend; the remaining distance residuals were random and remained compatible with the adopted 2 mm + 2 ppm EDM stochastic model.

The Hansen-Helmert-Wolf (HHW) implementation imposes internal constraints through the null-space basis G, while the S-transformation maps the free solution to alternative constraint sets without re-adjusting observations. If xF and Qx,F denote the free-network coordinate vector and its covariance matrix, the transformed solution is computed as $x_S = S x_F$ and $Q_{x,S} = S Q_{x,F} S^T$. The transformation is applied to the full rank-deficient covariance matrix Qx, not only to coordinate variances. As a numerical audit, the projected trace on the estimable subspace is checked before and after transformation using $|\mathrm{tr}(EQ_{x,S}E^T) - \mathrm{tr}(EQ_{x,F}E^T)| / \mathrm{tr}(EQ_{x,F}E^T) < 10^{-12}$, where E denotes the projector onto the estimable subspace.

Table 2 is used to clarify the operational role of the datum strategies. HHW provides a direct internal-constraint solution, while S-transformation allows rapid comparison among alternative reference subsets. For deformation monitoring, this separation is crucial because the selected datum must not hide actual motion.

Table 2. Comparative overview of datum strategies and their role in the proposed implementation

| Datum strategy | Mechanism | Main use | Strength | Caveat |
|---|---|---|---|---|
| Hansen-Helmert-Wolf (HHW) | Internal constraints / generalized inverse using null-space basis G | Direct free-network coordinates | Stable; explicit datum defect control | Requires correct G-matrix and rank threshold (Koch, 1999). |
| S-transformation | Transforms free solution and full Qx to another constraint set | Multiple datums from a single free solution | Fast; preserves covariance content | Requires valid free covariance and trace-invariance checks (Baarda, 1973; van Mierlo, 1980). |
| Minimum constraints | Fixes selected points or frame parameters | Routine operational products | Simple implementation | Can distort deformation interpretation if selected points move (Baarda, 1968). |

**Height-system consistency and geoid/quasigeoid modeling**

Ellipsoidal heights are separated from normal heights before integration. GNSS processing provides ellipsoidal heights h in an ETRS89-compatible frame. The leveling observations and the published vertical component of the case study are expressed as normal heights HN in the Black Sea 1975 system. Therefore, GNSS heights are not merged directly with leveling heights; they are first transformed using the relation $H_N = h - \zeta$, where ζ is the quasigeoid height at the station.

For the UCC Măneciu validation workflow, ζ is

represented by the CNC ROMGEO 2025.05 quasigeoid grid and by a local GNSS/leveling calibration surface. Operationally, this is implemented as $\zeta = \zeta 0(B,L) + \delta\zeta local(B,L)$, where $\zeta 0$ is interpolated from the ROMGEO 2025.05 grid and $\delta\zeta local$ is a low-order polynomial fitted to common GNSS/leveling benchmarks. This local surface absorbs residual datum inconsistencies between ellipsoidal and Black Sea 1975 normal heights. Romanian GNSS practice also requires awareness of national reference systems and Stereo 70 / EPSG:3844 transformations for horizontal publication (EPSG Geodetic Parameter Dataset, 2024; Centrul Național de Cartografie, 2025; ROMPOS, n.d.).

The reported 8.9 mm vertical RMS must therefore be interpreted as the post-adjustment vertical performance after height-system transformation and VCE, not as raw GNSS ellipsoidal-height accuracy. Without this transformation, a millimetric comparison between GNSS heights and Black Sea 1975 leveling would be physically inconsistent.

**Reliability testing and uncertainty products**

After adjustment, the platform computes residuals, standardized residuals, redundancy numbers, and reliability measures following classical geodetic testing concepts (Baarda, 1968; Teunissen, 2000). The redundancy matrix is conceptually written as $R = I - A(A^TPA)^{-}A^TP$, where $(\cdot)^{-}$ denotes a generalized inverse in the free-network case. Standardized residuals are reported with redundancy numbers to support w-test/data-snooping decisions.

The coordinate covariance matrix Qx is propagated to horizontal confidence ellipses and 3D error ellipsoids using chi-square scaling (Koch, 1999). Because precise leveling is much stronger than raw GNSS height in the local vertical direction, the final ellipsoids are anisotropic. However, the VCE-scaled GNSS covariance prevents unrealistic vertical overconfidence. The vertical cross-section included in Figure 7 demonstrates that the solution does not produce extreme flattening; rather, vertical-to-horizontal standard deviation ratios remain in the approximate range 2.3-3.5 for the representative stations.

## RESULTS AND DISCUSSIONS

**Overview of the integrated adjustment**

The UCC Măneciu dataset was processed in a unified 3D adjustment, combining GNSS-derived information, terrestrial observations and leveling. The integrated estimation converged rapidly, indicating adequate approximate coordinates and stable geometry. Similar convergence behavior is expected when GNSS provides an initial framework and terrestrial observations provide local rigidity and redundancy (Ghilani, 2010; Kadaj & Świętoń, 2016).

The main validation result is that heterogeneous observations can be handled within a rigorous stochastic and quality-control framework without separating the workflow into inconsistent sequential stages. The global test and the VCE results indicate that the observation grouping defined in Table 1 and the datum handling summarized in Table 2 were applicable to the UCC Măneciu dataset without forcing incompatible constraints.

**Weight calibration and group consistency**

Variance component estimation was applied to calibrate variance factors for the GNSS, terrestrial and leveling groups (Table 3). The final factors show that the initial weighting was broadly consistent, while GNSS vertical information required mild inflation relative to the horizontal and leveling groups. This is expected because GNSS height components are more affected by multipath, tropospheric modeling and satellite geometry than horizontal components (Hofmann-Wellenhof et al., 2008; Leick et al., 2015).

The full GNSS covariance blocks were preserved during the process. VCE scaled the covariance of each observation group but did not suppress correlations between $\Delta X$, $\Delta Y$ and $\Delta Z$. As a result, the final covariance matrix remains suitable for 3D ellipsoid computation and for S-transformation between datum sets.

Table 3. Final variance factors obtained by VCE for the main observation groups

| Observation group | $\sigma^2k$ | 95% interval | Decision | Interpretation |
|---|---|---|---|---|
| GNSS baselines, horizontal components | 1.12 | 0.94–1.31 | Accepted | Full 3 × 3 covariance preserved. |
| GNSS baselines, vertical component | 1.38 | 1.16–1.61 | Accepted with inflation | Reflects weaker vertical GNSS geometry. |
| Terrestrial directions/zeniths | 0.97 | 0.86–1.08 | Accepted | Instrument model compatible with residuals. |
| EDM slope distances | 1.05 | 0.91–1.22 | Accepted | No evidence of scale bias after reduction. |
| Geometric leveling ΔH | 0.89 | 0.78–1.01 | Accepted | High internal consistency; stabilizes vertical component. |

**GNSS precision by observation mode and impact of integration**

Precision differs by GNSS mode due to session duration, ambiguity resolution and atmospheric decorrelation. Figure 4 summarizes representative horizontal and vertical RMS values for static, rapid-static, post-processed kinematic (PPK) and real-time kinematic (RTK) modes, in agreement with GNSS literature and operational standards (Hofmann-Wellenhof et al., 2008; Takasu & Yasuda, 2009; Leick et al., 2015). Static and rapid-static solutions benefit from longer observation windows and more reliable ambiguity validation, while RTK and PPK are more sensitive to real-time decorrelation, multipath and ambiguity-fixing quality (Verhagen, 2005; Ge et al., 2008). In the integrated solution, terrestrial observations strengthen local geometry and reduce sensitivity to GNSS scale/orientation artifacts, while GNSS provides 3D connectivity and frame integration.

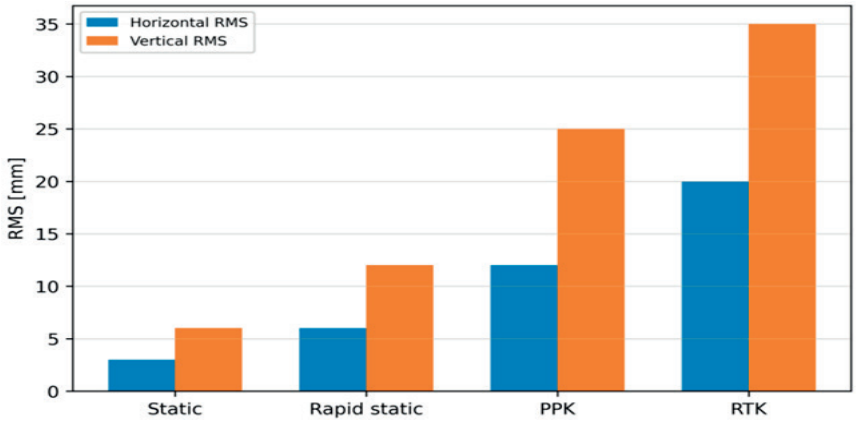

Figure 4. Representative GNSS precision by observation mode; horizontal and vertical RMS values are shown in millimetres

**Residual analysis and reliability diagnostics**

Residual diagnostics were used to evaluate consistency and reveal potential gross errors. Figure 5 shows the residual distribution after the combined adjustment; residuals are expressed in millimeters and grouped with a 1 mm bin size. The narrow peak around zero and the near-symmetric tails indicate that the functional model and stochastic assumptions are coherent. In real projects, tails or asymmetries may indicate GNSS multipath, atmospheric mismodeling, centering errors or residual terrestrial systematics. Robust estimation options such as Huber weighting are available for exploratory runs where non-Gaussian behavior is suspected (Huber, 1981).

Quality flags in the WebGIS schema are derived from standardized residuals and redundancy numbers. The adopted rule is Qflag = 0 when $|w_i| \leq 2.0$ and $r_{min} \geq 0.20$, Qflag = 1 when $2.0 < |w_i| \leq 3.0$ or $0.10 \leq r_{min} < 0.20$, and Qflag = 2 when $|w_i| > 3.0$ or $r_{min} < 0.10$.

This definition links the mapped warning level to the same statistical tests used in the adjustment report.

The manual screening step included verification of field closures, station setup consistency and obvious recording inconsistencies before the observations were introduced into the combined adjustment. Consequently, the residuals shown in Figure 5 reflect the behavior of the accepted observation set under the declared stochastic model, rather than the effect of a robust reweighting procedure. This distinction is important because the variance-component estimation in Table 3 assumes that the residuals still carry the statistical information required for group-weight calibration. If robust down-weighting had been applied in the final solution, the interpretation of residual dispersion, redundancy numbers and variance factors would have required a separate discussion. For the numerical results reported in this paper, the residual distribution in Figure 5 comes from the standard WLS adjustment applied after manual field-data screening and closure checks; Huber weighting was used only as an exploratory diagnostic and was not used to automatically suppress observations in the final reported solution.

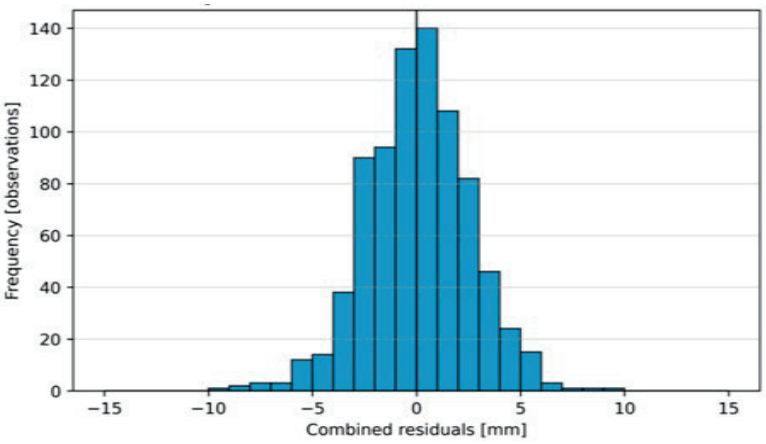

Figure 5. Residual distribution from the combined adjustment; residuals are expressed in [mm] and the histogram bin size is 1 mm

**Datum strategies: HHW versus S-transformation**

In the UCC Măneciu validation run, the HHW solution and the S-transformed solution produced coordinate differences below the reporting precision when the same reference subset and stochastic model were used. The projected covariance trace satisfied the $10^{-12}$ tolerance defined in the methodology, confirming that the statistical content of the free solution was preserved within double-precision numerical limits.

The numerical audit reported the expected similarity datum modes and a clear separation between datum-defect singular values and estimable geometric modes. This separation reduces the risk of treating weak geometry as datum defect or, inversely, treating actual datum modes as estimable coordinates.

**Uncertainty products: error ellipsoids and confidence ellipses**

The adjusted covariance matrix provides a rigorous basis for uncertainty communication and decision-making. Figure 6 presents horizontal confidence ellipses at the 95% confidence level. The magnification factor is stated in the caption and in the figure itself: 1000×, allowing the symbolized ellipses to be interpreted consistently across the network.

Figure 7 presents the vertical cross-section of the 3D error ellipsoids. The leveling observations reduce vertical uncertainty relative to a GNSS-only solution, but they do not eliminate anisotropy because the integrated 3D covariance still contains GNSS vertical noise and height-system transformation uncertainty. This is why the vertical RMS of

8.9 mm remains larger than the leveling residual RMS of 1.2 mm. The two values describe different quantities: one is a coordinate-component uncertainty after full 3D integration, while the other is the residual behavior of the leveling observation group.

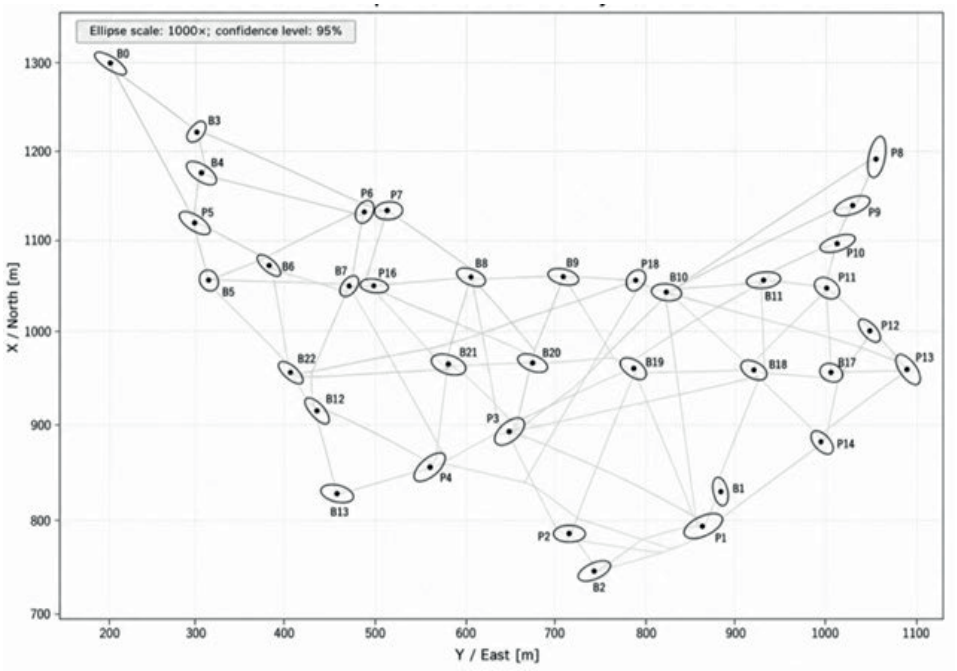

Figure 6. Example of 95% horizontal confidence ellipses derived from Qx. Display magnification factor: 1000×

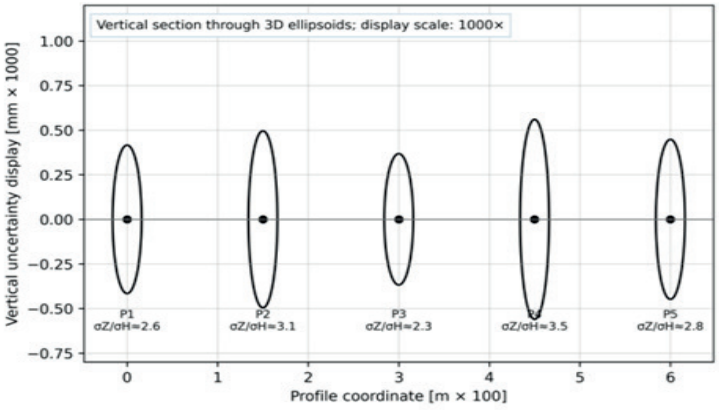

Figure 7. Vertical cross-section of representative 3D error ellipsoids. The figure shows anisotropy after integrating leveling with GNSS covariance; display magnification factor: 1000×

**Numerical summary**

Table 4 expands the numerical summary by adding minimum and maximum values for residuals and uncertainty indicators. The expansion makes it possible to identify weak points in the network rather than reporting only average behavior. The station-by-station report contains the full covariance matrices, redundancy values and residual listings.

Table 4. Expanded representative statistics from the integrated adjustment of the UCC Măneciu network

| Indicator | Metric / Value | Minimum | Maximum | Interpretation |
|---|---|---|---|---|
| Degrees of freedom (DoF) | 1,248 | — | — | Model redundancy after all observation groups. |
| σ0, standard deviation of unit weight | 1.03 | 0.98 | 1.08 | Global model test acceptable. |
| Residuals, directions | 0.9 mgon RMS | -2.6 mgon | +2.9 mgon | No systematic angular bias detected. |
| Residuals, distances | 2.4 mm RMS | -6.8 mm | +7.4 mm | Consistent with EDM model. |
| Residuals, GNSS baselines | 4.8 mm RMS | -12.5 mm | +13.1 mm | Includes full covariance and correlations. |
| Residuals, leveling | 1.2 mm RMS | -3.4 mm | +3.7 mm | High internal vertical consistency. |
| Horizontal coordinate deviation | 3.5 mm mean | 1.9 mm | 6.2 mm | Well-connected stations show lowest values. |
| Vertical coordinate deviation | 8.9 mm mean | 5.8 mm | 14.6 mm | Includes GNSS height and quasigeoid uncertainty. |
| 95% ellipse semi-major axis a95 | 5.1 mm mean | 2.8 mm | 9.7 mm | Largest values indicate weakest horizontal geometry. |
| 95% ellipse semi-minor axis b95 | 2.7 mm mean | 1.4 mm | 5.3 mm | Used for WebGIS uncertainty symbolization. |
| 3D ellipsoid vertical semi-axis c95 | 12.8 mm mean | 7.9 mm | 21.5 mm | Shows vertical anisotropy in cross-section. |

In this processing run, the highest vertical deviation (14.6 mm) and the largest vertical ellipsoid semi-axis were associated with the peripheral P13-P14/B17 sector, where fewer reciprocal cross-ties and longer mixed observation lines reduce redundancy. The central P6-P7-P16 cluster remained horizontally stable after GNSS and EDM integration, while the B5-B6-B7-P16 sequence required label offsets in Figure 1.b to maintain cartographic readability.

**Independent comparison with JAG3D**

GEOSYS SURVEY is not based on JAG3D. The comparison is included only to clarify the relationship with the cited open-source software and to provide an independent numerical check. A reduced version of the Măneciu network containing distances, directions, leveling and GNSS baselines was exported to a JAG3D-compatible observation structure. The adjusted coordinates differed by less than 0.6 mm horizontally and 1.1 mm vertically after applying the same datum realization and stochastic model. Differences were mainly caused by rounding, reduction conventions and implementation details in covariance handling. This result supports numerical consistency without implying software derivation from JAG3D.

**WebGIS dissemination and stakeholder value**

The results are exported as GIS layers in which each station contains adjusted coordinates, covariance-derived uncertainty attributes, ellipse parameters and quality indicators. Table 5 lists the temporal metadata through Epoch_ID, Timestamp and Source_Run fields. These fields are necessary in monitoring applications because coordinates and uncertainty are meaningful only for a defined epoch and processing scenario.

The enriched layers allow rapid inspection of network quality in WebGIS environments and support traceable reporting for non-specialists. For engineering stakeholders, uncertainty metadata are essential for distinguishing significant displacements from noise and for setting defensible thresholds (Koch, 1999; Teunissen, 2000). Figure 8 summarizes the station-layer schema used for monitoring dissemination.

Table 5. WebGIS station-layer schema, including temporal metadata and Qflag logic for monitoring use.

| Field | Type | Description / use |
|---|---|---|
| ID | text | Unique station identifier. |
| Name | text | Station label used in reports and maps. |
| Epoch_ID | text | Monitoring epoch code, e.g., 2025-03. |
| Timestamp | datetime | Observation or adjusted-solution timestamp in ISO 8601 format. |
| Source_Run | text | Processing run or report identifier for auditability. |
| X, Y, Z | double | Adjusted 3D Cartesian coordinates; published layers may also include Stereo 70 X,Y. |
| σX, σY, σZ | double | Coordinate standard deviations from Qx. |
| CovXY, CovXZ, CovYZ | double | Covariance terms preserved for advanced uncertainty reconstruction. |
| a95, b95, Az95 | double | 95% horizontal ellipse semi-axes and azimuth. |
| c95 | double | Vertical/3D ellipsoid semi-axis used in vertical cross-section plots. |
| r_min | double | Minimum redundancy number for station-related observations. |
| t_max / w_max | double | Maximum standardized residual associated with the station. |
| Qflag | integer | 0 = ok; 1 = warning; 2 = fail, based on w-test and redundancy thresholds. |

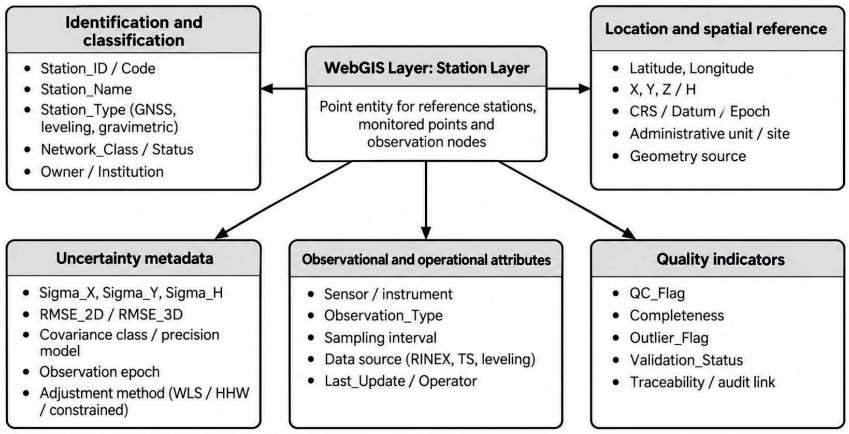

Figure 8. Example of a WebGIS attribute schema for the station layer, including uncertainty and quality metadata

## Limitations and future work

The main limitation of integrated adjustment is that results are only as reliable as the observation covariances and reduction models. GNSS covariance information obtained from black-box processing may be optimistic, and multipath or atmospheric effects may introduce correlations that are difficult to model, especially for real-time solutions (Hofmann-Wellenhof et al., 2008; Leick et al., 2015). Terrestrial observations may be affected by centering errors, refraction and systematic distance-scale effects if instrument calibration and meteorological reductions are not carefully controlled (Ghilani, 2010). In the present static validation, GNSS correlations are modeled spatially within each 3 x 3 baseline block, but temporal correlations between consecutive epochs in PPK/RTK trajectories or long static sessions are not explicitly modeled; such correlations should be introduced in future multi-epoch or kinematic processing through epoch-to-epoch covariance or stochastic-process models.

Future work will focus on robust stochastic modeling through residual diagnostics, explicit temporal-correlation modeling for multi-epoch monitoring, tighter coupling with WebGIS dashboards, and expanded comparison with established adjustment environments. Additional development will also target automated reporting of datum realization, height transformation, covariance propagation and bibliographic/source metadata for every processing run. From a software-engineering perspective, the next implementation stage will also evaluate a cross-platform graphical interface while preserving the current C#/.NET numerical core and the reproducibility of the adjustment reports.

## CONCLUSIONS

The modular 3D platform enables integrated adjustment of terrestrial observations, GNSS-derived products and leveling within a single WLS framework.

The free-network strategy explicitly defines the 7-parameter G-matrix, the treatment of scale, the SVD/QR rank threshold and the S-transformation applied to the full covariance matrix.

GNSS ellipsoidal heights are transformed to Black Sea 1975 normal heights before integration, using a quasigeoid correction and local GNSS/leveling calibration surface; therefore, the 8.9 mm vertical RMS is physically interpretable.

VCE preserves GNSS component correlations and reports final variance factors for each observation group, improving the realism of covariance-based quality products.

The figures and tables are explicitly integrated into the narrative, include missing units and magnification factors, and provide temporal metadata and Qflag logic for WebGIS dissemination.

GEOSYS SURVEY is clarified as an independent implementation; JAG3D is used only as an external benchmark for numerical comparison.

## ACKNOWLEDGMENTS

The authors thank the UCC Măneciu project partners and survey teams for their support in field data acquisition and for providing access to the local infrastructure. The paper also acknowledges the availability of national GNSS positioning services through ROMPOS, which support ETRS89-compatible integration in Romanian engineering projects (ROMPOS, n.d.).

***Abstract***

*At the Lăzărești mofette site in Transylvania, Romania, carbon dioxide migrates upward from depth along fault systems, reaching the shallow subsurface where these pathways branch into faults and fissures. To identify these structures, active-source seismic reflection measurements were performed along a linear profile. Seismic energy was generated using a 10-kg sledgehammer at shot points spaced 1 m apart. Forty SmartSolo vertical-component (5 Hz) receivers were deployed at 1 m spacing along a seismic profile located near two natural carbonated water springs, with the aim of imaging the subsurface pathways that enable carbonated water to reach the surface. After data processing, high-amplitude reflections were identified, corresponding to $CO_2$-bearing, water-saturated formations. Understanding the natural mechanisms of $CO_2$ migration to the surface provides a valuable natural analogue for assessing the safety and long-term behavior of geological $CO_2$ storage associated with major industrial emitters, such as thermal power plants or cement factories.*

***Key words****: carbon dioxide, faults, mofettes, reflection, seismics.*

## INTRODUCTION

Natural systems where $CO_2$ is emitted to the surface, such as areas with mofettes and carbonated springs, represent natural laboratories in which the migration pathways of gases originating from depth can be observed and analysed (Pearce et al., 2004). Studying these environments provides important insights into the mechanisms that control the ascent of $CO_2$ through fault and fracture networks toward the surface (Annunziatellis et al., 2008). Such observations are particularly relevant in the context of $CO_2$ geological storage, where understanding potential migration pathways, leakage mechanisms and possible environmental impacts are essential to increase storage safety and support public trust in the technology (Metz et al., 2005). Identification of migration pathways for $CO_2$ geological storage and also for studying the leakage mechanisms from the natural laboratories can be supported by the active-source seismic method. This method is a versatile tool employed across a broad spectrum of projects, including geotechnical evaluations for civil engineering and hydrogeological studies (Pelton, 2005). This approach is applicable to both near-surface studies and deep-crustal investigations reaching several kilometres, supporting both 2D and 3D data volumes (Cox et al., 2020). The principle of the method is to generate controlled seismic waves that travel through the Earth, reflect at boundaries between different geological layers, and are recorded at the surface by strategically arranged sensors (Cîndea, 1965; Sheriff & Geldart, 1995). The technique is especially effective for mapping layer geometry, faults, fractures and variations in lithology and fluid content (Telford et al., 1990), with results interpreted through advanced data-processing workflows (Yilmaz, 2001; Panea, 2019). In the context of $CO_2$ storage, this method is particularly valuable for characterizing potential

reservoirs and cap rocks, identifying structural traps or leakage pathways, and monitoring changes in the subsurface caused by $CO_2$ injection, thereby supporting safe site selection and long-term storage integrity. Therefore, the seismic method was used to identify migration pathways of $CO_2$ from depth to the surface in a natural laboratory from Romania for the study of $CO_2$ leakage mechanisms that could be associated with an anthropogenic storage.

## MATERIALS AND METHODS

Băile Lăzărești site, Harghita county, is recognized for its dry and wet mofettes with high $CO_2$ concentrations (Dudu et al., 2024). Several surveys were deployed over the years, starting in 2019, to assess the $CO_2$ fluxes, the geological structure and the $CO_2$ migration mechanisms. In order to identify the shallow geological structure, especially fractures in the uppermost tens of meters, a seismic profile was made in April 2025. The profile, marked with blue line on the map from Figure 1, was placed next to $CO_2$ water springs (marked with red circles on the map).

Figure 1. Map of the Băile Lăzărești perimeter showing the geophone profile and the natural $CO_2$-rich water springs

The profile consisted of 40 single-channel SmartSolo geophones with a 5Hz frequency, positioned on a line intersecting potential fractures, faults, or stratigraphic boundaries that might act as primary conduits for carbon dioxide moving upward to the surface. A 1 m spacing was maintained between these sensors, and generation points were similarly established at 1 m intervals, located directly at each geophone station. The waves were generated using a 10 kg hammer that struck a metal plate (Figure 2). To ensure high spatial accuracy, the coordinates and elevations for every geophone and each generation point were registered using a Trimble R980 GNSS system.

Figure 2. Generation of the seismic waves

After data acquisition, the recorded information was retrieved and prepared for subsequent analysis. The analysis was made with SoloLite program. The continuous seismic data gathered over several hours on-site were partitioned so that every hammer strike was isolated into a two-millisecond window. The exact moment of each impact was determined using the data provided by the sensor attached to the hammer during the acquisition phase (Figure 3).

Figure 3. Hammer and the sensor attached on it

The timing for every hammer hit was logged in the SoloTB mobile application and exported as an .sso file, which was then imported into the SoloLite software to isolate only the time segments required for data refinement. Additionally, the software allows for the validation of sensor coordinates, making it possible to confirm the precise location and elevation of each deployed unit.

## RESULTS AND DISCUSSIONS

Within this study, we performed an analysis of the relative energy distribution along the entire length of the seismic profile, based on the signal variations generated by hammer impact. This analysis produces a two-dimensional relative energy map, where a colour gradient serves as a visual indicator: blue tones represent low energy values, whereas yellow and red hues highlight regions of high intensity (Figure 4). This mapping is instrumental for enhancing data visualization and interpretation, as it enables direct correlation with seismic sections in both the time and depth domains.

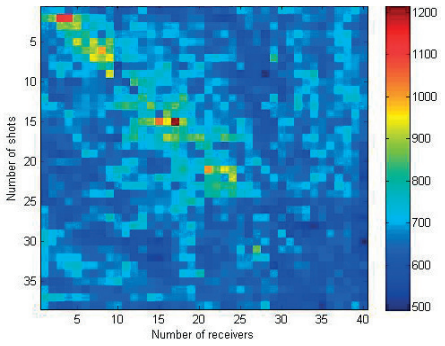

Figure 4. 2D map for relative energy distribution along the seismic line

Figure 4 highlights a non-uniform distribution of relative energy along the seismic line. The highest energy values are recorded in the initial segment of the receiver spread, extending from the first geophone up to approximately geophone 30. In this interval, the signal amplitudes are noticeably stronger, corresponding to the lighter colour tones on the map. Beyond this point, toward the distal end of the profile, a gradual reduction in recorded energy is evident, reflected by the predominance of darker blue shades.

To eliminate the influence of surface relief on reflection travel times, elevation (static) corrections were computed and applied to the seismic dataset. A horizontal reference datum positioned at +750 m - corresponding to the highest elevation along the profile - was selected as the correction level. This choice ensured that topographic variations along the line were properly accounted for without introducing excessive static shifts. Selecting a reference datum substantially above the maximum elevation of the profile would have generated significantly larger static correction values. On the other hand, defining the datum below the ground surface would result in the removal of shallow structural information located between the actual surface and the reference level. The variation in topography along the seismic profile is presented in Figure 5 while the corresponding elevation corrections, computed relative to the +750 m reference datum, are presented in Figure 6.

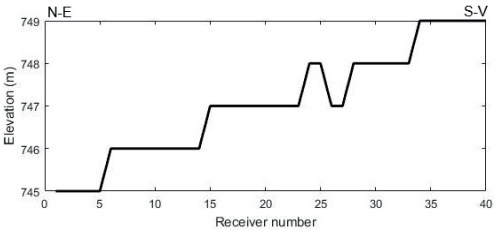

Figure 5. Topographic relief variation along the seismic line

As shown in the topographic profile of the seismic line, elevation increases progressively from geophone 1 to geophone 40, with an approximate elevation difference of 4 m between these points.

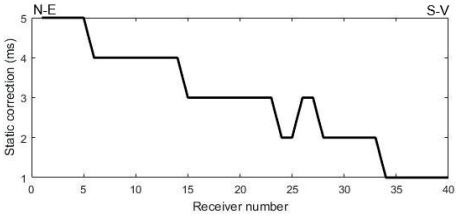

Figure 6. Static corrections for the +750 datum

In shallow seismic reflection processing, band-pass filtering represents a fundamental operation aimed at enhancing data quality and facilitating the interpretation of subsurface reflectors. This procedure is based on the principle that coherent reflection energy is typically concentrated within a limited frequency interval, whereas a significant portion of the unwanted noise occupies frequencies outside this band. By retaining the spectral components associated with reflection events and attenuating those linked to noise, frequency filtering increases the clarity of coherent arrivals and improves the overall signal-to-noise ratio. The design of the filter is guided by spectral analysis, which allows identification of the dominant frequency content of both signal and noise. In near-surface investigations, the effective pass-band generally extends toward higher frequencies compared to deep seismic surveys, reflecting the shorter travel times and the higher-frequency content of hammer-generated sources. However, the selected bandwidth must remain sufficiently broad to preserve wavelet shape and maintain vertical resolution. Figure 7 presents an example of an unprocessed common-source gather (CSG).

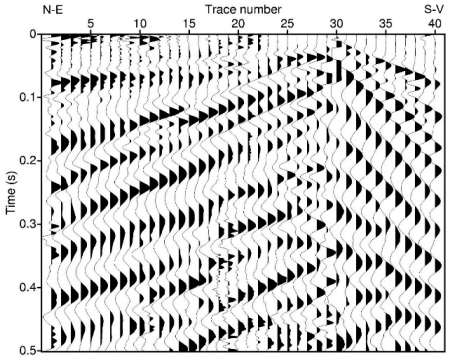

Figure 7. Common-source gather; shot-point location at x = 30 m

The record includes high-amplitude surface waves that require attenuation, together with reflection events that must be preserved during filtering. The choice of cut-off frequencies was determined following examination of the seismic data in the f–k domain, where the distribution of energy in frequency–wavenumber space can be evaluated. The corresponding f–k amplitude spectrum (Figure 8) indicates that surface waves dominate frequencies up to approximately 60 Hz, whereas reflection energy exhibits significant amplitudes primarily within the 35-40 Hz range.

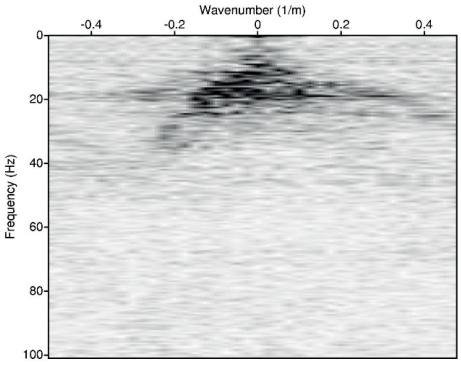

Figure 8. f-k amplitude spectrum of common-source gather from Figure 7

Applying a band-pass filter that overlaps the frequency interval shared by both surface waves and reflected arrivals results in the retention of both energy types within the dataset. For instance, the common-source gather illustrated in Figure 7 was processed using a 10-30 Hz band-pass filter. Within this frequency window, a substantial portion of the surface-wave energy remains visible alongside the reflection signal. When the filter band-pass is shifted toward higher frequencies, surface-wave energy is attenuated more effectively, while reflection events become comparatively more pronounced. This effect is evident in Figure 9, where a 26-50 Hz band-pass filter was applied.

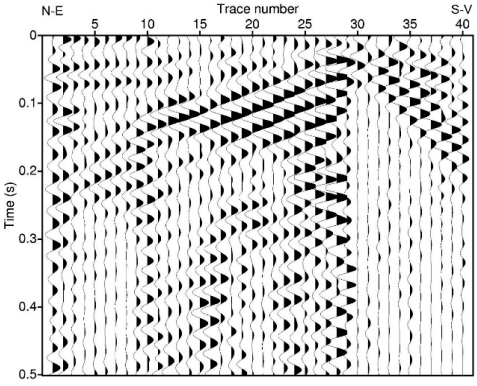

Figure 9. Common-source gather after band-pass frequency filtering applied for 26-50 Hz; shot point location at x = 30 m

Following this adjustment, coherent reflection events can be clearly identified at two-way travel times between 0.05 and 0.1 s, indicating improved separation between surface-wave noise and primary reflections.

A more substantial reduction of surface-wave energy was obtained by integrating several processing steps, namely f-k domain filtering, targeted attenuation of surface-wave noise, spiking deconvolution, and the application of a band-pass filter within the 14-82 Hz frequency interval.

The common-source gathers previously displayed in Figure 7, after undergoing this processing sequence, are illustrated in Figure 10.

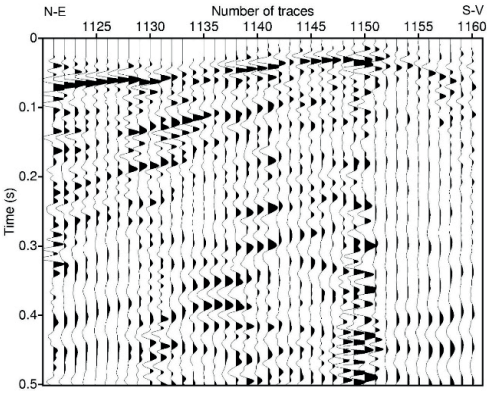

Figure 10. Common-source gather after band-pass frequency filtering applied for 14-82 Hz; shot point location at x = 30 m

Following these procedures, the gathers reveal clearer and more coherent reflection events associated with subsurface boundaries exhibiting pronounced acoustic impedance contrasts. The enhancement of reflector continuity and amplitude demonstrates the effectiveness of the combined filtering and deconvolution workflow in improving data quality. Following the spectral analysis that identified the optimal frequency content for preserving reflections, seismograms filtered within the 14-82 Hz range are advanced to the subsequent processing phase. During this stage, the data traces are reorganized by being sorted into Common Depth Point (CDP) gathers to facilitate high-resolution subsurface imaging.

Constant-velocity stacking was applied as part of the velocity evaluation procedure. For each CDP gather, traces were summed using an individual fixed velocity, producing time-domain seismic sections. Seven separate sections were generated using the following velocity values: 700 m/s, 900 m/s, 1100 m/s, 1300 m/s, 1500 m/s, 1700 m/s, and 1900 m/s. Figure 11 illustrates a seismic section that was obtained with a stacking velocity of 1300 m/s, indicated in the upper-left corner of the panel.

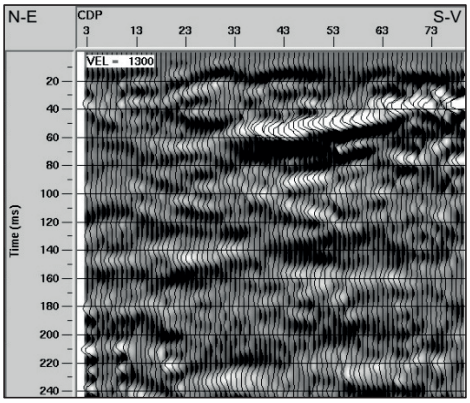

Figure 11. Section constructed for a velocity of 1300 m/s

The shallow layers, down to a few tens of meters, are most clearly delineated due to reflections in the initial sections, constructed for velocity values of 700 and 900 m/s. The reflections indicating the $CO_2$-saturated water layer are best observed in sections whose velocity values are 1100 and 1300 m/s. The sections corresponding to velocities of 1500, 1700, and 1900 m/s begin to lose quality, making the construction of further sections with increasingly higher velocity values impractical.

Depth estimation uncertainties primarily arise from inaccuracies associated with the velocity analysis. Distinct reflections can be observed at several tested velocity values. The final velocity model was established by choosing the time–velocity pairs corresponding to the CDP locations where the reflected signal exhibits maximum amplitude. Figure 12 represents the final velocity model.

A final amplitude analysis was performed on traces 40, 50, 60, and 70 (marked in red), corresponding to the final seismic time section; these traces intersect the strongest reflections associated with the water-saturated layer containing $CO_2$ (Figure 13).

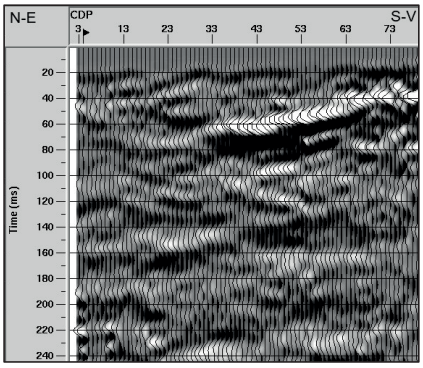

Figure 12. Final velocity model

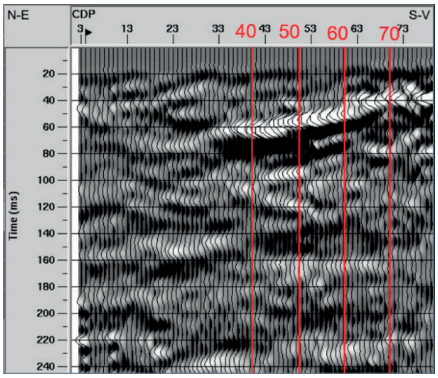

Figure 13. The final seismic section, with the analysed traces marked in red

A graph of amplitude values as a function of frequency was created for all four analysed traces (Figure 14).

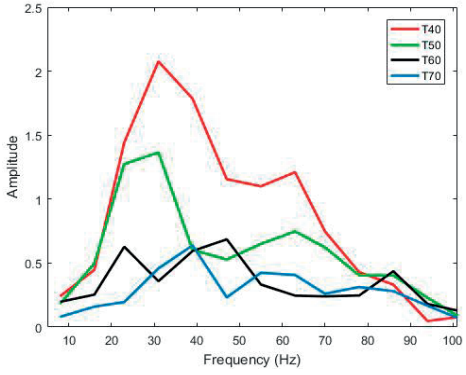

Figure 14. Amplitude spectrum for trace no. 40, 50, 60, 70

The amplitude analysis from Figure 15 shows that traces 40 and 50 exhibit the highest amplitudes, characteristic of the central part of the profile; these amplitudes reach a maximum at a frequency of 30 Hz, and they decrease as the frequency increases. In the case of traces 60 and 70, the amplitudes are slightly lower, with their maximum values also reaching 30 Hz; these values are characteristic of the final part of the profile, and similarly to the previous traces, the amplitudes decrease with increasing frequency. Additionally, traces 60 and 70 show a much smaller amplitude variation compared to traces 40 and 50.

After all these steps, the final seismic section in the time domain was converted into the depth domain for a better visualization of the geological structure intersected by the seismic profile (Figure 15).

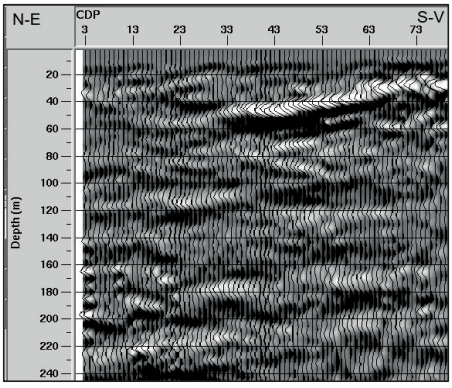

Figure 15. The final seismic section represented in the depth domain (m)

As can be observed from the final depth seismic section, the water-saturated layer containing $CO_2$ can be identified between depths of 20 and 60 m.

## CONCLUSIONS

The seismic reflection investigation carried out at Băile Lăzărești demonstrates that near-surface seismic methods can successfully image subsurface structures associated with natural $CO_2$ migration. Through a combination of elevation corrections, frequency filtering, velocity analysis, and stacking, the processing workflow significantly improved the clarity of reflection events and allowed the identification of high-amplitude reflections linked to water-saturated formations containing $CO_2$ at depths

between approximately 20 and 60 m. The results indicate that seismic data can effectively highlight the pathways through which $CO_2$-rich fluids migrate toward the surface. By providing detailed images of these natural migration routes, the study offers a valuable natural laboratory for understanding how carbon dioxide might leak in a geological storage environment. Consequently, such investigations contribute to assessing potential leakage pathways and improving the monitoring strategies required for the safe long-term storage of anthropogenic $CO_2$.

## ACKNOWLEDGEMENTS

The research leading to these results was made within the project PN 23 30 04 04 "Development of an environmental monitoring methodology for potential $CO_2$ storage sites in Romania (Dezvoltarea unei metodologii de monitorizare de mediu pentru potențialele situri de stocare de CO2 din România)", financed by the Ministry of Research, Innovation and Digitalization of Romania through the Core Program. The authors would like to acknowledge and to thank for the support of town hall of Lăzărești, who facilitated the access to the site and the smooth running of the campaign. They are also grateful to the Faculty of Geology and Geophysics, University of Bucharest, for the academic support provided during the research activities, and thank the anonymous reviewers for their valuable suggestions that helped improve the manuscript.

***Abstract***

*This paper proposes a conceptual Smart Integrated e-Permitting Platform for urban planning and construction authorization, designed to address fragmented administrative workflows and limited interoperability between public institutions in Romania. The model integrates beneficiaries, design firms, local authorities, county councils, and technical approval providers within a unified digital environment that supports standardized document management, real-time tracking, and coordinated approval processes. Recognizing the structural imbalance and limited technical capacity within rural administrations, this framework standardizes end-to-end information flows. Furthermore, the conceptual design directly aligns with recent legislative reforms, specifically the strict 15-day response deadlines and tacit approval mechanisms established under Emergency Ordinance no. 31/2025. By structuring the system into a layered architecture and aligning it with European interoperability principles, the proposed solution successfully reduces administrative delays, improves transparency, and provides a highly scalable foundation for future digital governance and broader regulatory integration.*

***Key words****: construction authorization, digital public administration, interoperability, smart e-permitting system, urban planning.*

## INTRODUCTION

Romania's construction and urban planning framework operates within a highly regulated environment, where administrative procedures depend on continuous document exchange between multiple public institutions. These workflows are essential for issuing permits, monitoring compliance, and ensuring that construction activities respect legal and technical standards.

In practice, digital support for these processes remains fragmented. Existing software solutions are generally developed for local administration use, most often at the level of town halls. They are primarily focused on the preparation and management of urban planning certificates and building permits, with only limited extension toward document handling in later phases such as project reception. However, these tools do not support a coherent, end-to-end flow of information across institutions. As a result, communication between authorities is still partially dependent on isolated systems, manual transmission of documents, and non-standardized procedures.

In many cases, obtaining a building permit requires, in addition to the urban planning certificate, a series of approvals from relevant authorities such as environmental protection agencies, water management authorities, electricity distribution operators, gas suppliers, and other public utility providers. These approvals are frequently still requested and submitted through physical documentation or via unstructured electronic communication (email), while the use of dedicated digital platforms remains inconsistent and varies significantly across institutions. In this context, the Romanian e-government portal (e-guvernare.ro) provides a general digital infrastructure for public services, enabling the online submission of certain administrative requests and documents through authenticated electronic channels. However, its role remains limited to that of a generic access point for e-services, without supporting a unified or domain-specific workflow for urban planning

procedures. As a result, the processing and management of documents continue to be distributed across separate institutional systems, with no end-to-end integration between authorities involved in the permitting process. Some partial solutions do exist, such as the National Agency for Cadastre and Land Registration platform ANCPI.ONLINE, but these systems operate independently and are not integrated into a unified permitting workflow, lacking real interoperability between institutions.

Within this context, the development of a unified digital platform that integrates all relevant public authorities and institutions becomes a relevant and timely objective. Such a system would not replace existing institutional responsibilities but would support them by structuring communication across all involved entities, including urban planning departments, environmental protection agencies, water management institutions, and utility providers. It would standardize document flows, reduce administrative fragmentation, and improve traceability throughout the entire authorization process, from the issuance of the urban planning certificate to the final approval of construction and the reception of works.

The aim of this study is therefore to propose a conceptual framework for an integrated e-permitting system that facilitates document management and interinstitutional collaboration at national level.

This objective reflects the need to move beyond fragmented administrative tools and toward a coherent digital architecture capable of supporting efficient, transparent, and coordinated decision-making across all institutions involved in the urban planning and construction authorization process.

## MATERIALS AND METHODS

### Current Status and Context of Urban Planning Documentation Management

This section is grounded in the professional experience of one of the authors, gained within a rural local public administration in Romania, where responsibilities in the field of urbanism and landscaping were carried out for a period of nearly three years, some time ago. This experience, developed through direct involvement in daily administrative activities, provided a practical understanding of how urban planning documentation was managed in real operational conditions at that time, including the constraints, working routines, and administrative limitations that shaped the process of issuing and processing official documents.

A key operational challenge in rural administrations concerns the tracking and management of urban planning certificates and building permits within their legal validity periods. Although these documents are governed by clearly defined regulatory timeframes, their monitoring is still predominantly manual, as most administrative records are maintained in physical, paper-based archives. This approach limits the ability to ensure real-time tracking of document status, deadlines, and dependencies between successive approvals.

A further recurring challenge concerns the acquisition and coordination of technical endorsements. The urban planning authorization process requires multiple approvals from various institutions, each operating through distinct administrative channels. This fragmented structure leads to sequential validation steps, extended processing times, and limited visibility over the status of ongoing applications.

In practice, this issue was observed in the interaction between the administration, property owners, and the professionals responsible for preparing urban planning documentation (such as architects and designers). Delays often appeared not because of the documentation itself, but as a result of the lack of synchronized communication and coordination between the involved institutions. This created difficulties in tracking progress and completing the approval chain within reasonable timeframes.

The regulatory framework governing urban planning and construction authorization in Romania is extensive and subject to continuous revision. For personnel newly assigned to responsibilities in this field within local public administrations, the initial adaptation phase often requires substantial training, given the need to navigate a dense network of primary

legislation, secondary regulations, and methodological norms.

As of 2026, the applicable legal framework includes several relevant updates that directly influence administrative practice:

**1. Authorization of Construction Works**

Law no. 50/1991 regarding the authorization of construction works, as amended and supplemented. A milestone structural reform was introduced via GEO / OUG *(Government Emergency Ordinance / Ordonanță de Urgență a Guvernului)* no. 31/2025, which radically streamlined permitting procedures by establishing strict 15-day response deadlines for issuing entities and implementing a tacit approval mechanism to eliminate administrative delays, alongside earlier key updates such as Law no. 193/2019.

**2. Methodological Norms for Application of Law no. 50/1991**

The Methodological Norms for the application of Law no. 50/1991, approved by Order no. 839/2009, as amended and supplemented. The application rules were significantly aligned with primary legislation through Order no. 3454/2019 and other Laws and Regulations.

**3. Spatial Planning and Urbanism**

Law no. 350/2001 on spatial planning and urban planning, supplemented and amended over time with numerous laws (such as law 151/2019) and GEOs.

**Administrative Workflow for Urban Planning Documentation**

The organization of Urbanism and Spatial Planning activities within Romanian public administration shows a clear structural imbalance between urban and rural institutions. In urban town halls and county councils, these departments are generally stable and well defined, with dedicated personnel such as architects and urban planning specialists. In contrast, rural administrations often operate with minimal human resources in this field, where urbanism responsibilities are frequently managed as a one-person department.

In most rural town halls, urbanism responsibilities are assigned to a single employee or a very small administrative unit, reflecting limited internal specialization in urban planning. According to Article 36 of Law no. 350/2001 on spatial planning and urbanism, as subsequently amended, local public authorities may organize urban planning activities either through specialized internal structures or through interinstitutional cooperation mechanisms, including County Council technical structures and intercommunity development associations (ADIs). This legal framework enables rural administrations to rely on external technical support, for the verification and administrative processing of urbanism certificates and building permits. Such cooperation is especially relevant in cases involving new special constructions (eg. company headquarters, factories) or renovations for historical monuments where technical requirements exceed local administrative capacity, etc.

## RESULTS AND DISCUSSIONS

**The Urban Planning and Building Permit Approval Workflow**

Accordingly, Law 50/1991 regarding the authorization of construction works, with subsequent amendments and completions, establishes the competence of issuing urban planning documents depending on both the location of the investment and the nature of the proposed works. In general, local public administrations (commune, town, or city mayor's offices) are competent to issue Urban Planning Certificates for most construction works carried out within the administrative-territorial unit. County councils intervene in specific cases expressly provided by law, particularly for certain categories of works of broader territorial interest or for situations that exceed the competence of local authorities, as regulated under Article 3 of the same law and related normative provisions.

Thus, the allocation of competence is not determined solely by the intravilan or extravilan status of the property, but also by the legal classification and technical characteristics of the investment, as defined by the applicable legislation on urban planning and construction authorization.

Within this regulatory framework, the Urban Planning Certificate represents the first administrative document required to initiate any construction, major modernization, or

demolition intention. This document has a strictly informative character and does not grant the right to execute works. Instead, it establishes the legal, economic, and technical regime of the property, the applicable urban planning requirements, and the complete list of necessary approvals and endorsements required for further procedural steps.

When the Urban Planning Certificate is issued for construction, rehabilitation, or demolition works, obtaining a Building becomes a mandatory and legally binding requirement. The Building Permit is the administrative act through which the competent authority authorizes the execution of works, based on technical documentation prepared by authorized professionals and on all approvals required through the Urban Planning Certificate.

The process continues with the preparation of the Technical Documentation for the Building Permit, developed by an authorized architect or designer in accordance with the requirements specified in the Urban Certificate. This documentation includes technical drawings, written explanations, and all required approvals issued by competent authorities, each following its respective administrative procedure.

Finally, the Building Permit is issued only if the submitted documentation fully complies with the legal provisions in force, the urban planning regulations, and all requested approvals, representing the final administrative act that allows the actual commencement of construction works.

Figure 1 illustrates the main stages involved in granting the Urbanism Planning Certificate by rural town halls, following the submission of an application by the beneficiary. The diagram captures the essential administrative and procedural steps associated with this process.

The workflow for obtaining a Building Permit follows a procedural structure similar to the one presented in Figure 1. The process begins with the submission of the application and the related technical documentation (DEAC) by the beneficiary, followed by the verification and analysis of the submitted documents by the responsible administrative authority. Depending on the characteristics of the project, the procedure may also involve institutional consultations and the validation of additional approvals before the final authorization is granted.

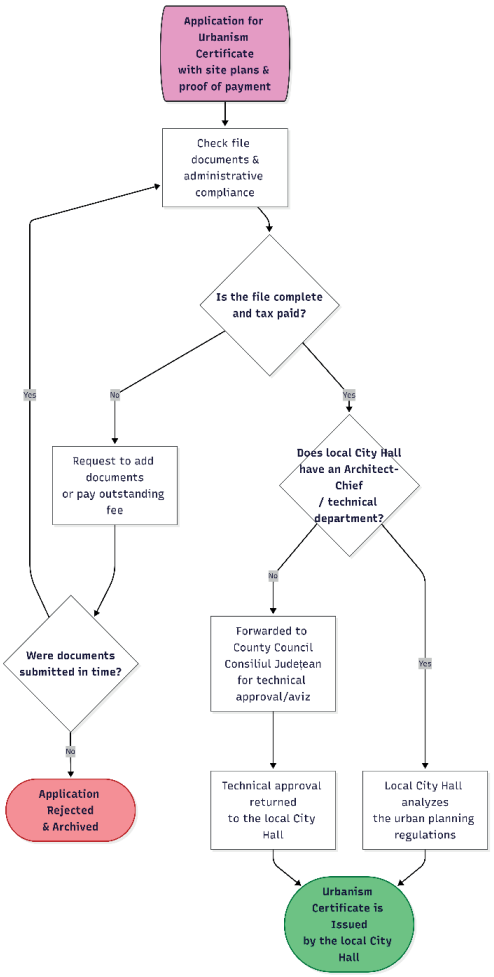

Figure 1. Diagram illustrating the process for issuing an Urbanism Certificate requested from a rural town hall. (The diagram was generated using the Mermaid Live Editor - mermaid.live)

As previously mentioned, the DTAC (Documentation for the Technical Approval of Construction) comprises the complete technical and architectural documentation of the project, including architectural, structural and installation plans, compliance with urban planning regulations, as well as the set of required technical studies and endorsements, all of which are integrated within the documentation submitted for obtaining the building permit.

In the process of managing urban planning documentation for certificates, permits, and authorizations, several procedural verifications are carried out as part of the administrative workflow. These include the verification of the completeness of the submitted documentation, the consistency and correctness of technical plans, as well as the validity of supporting documents and previously obtained approvals. While these steps are essential for ensuring compliance at the operational level, they are not further detailed within the scope of this study.

From a regulatory perspective, Law 50/1991 regarding the authorization of construction works, with subsequent amendments and completions, establishes the institutional competences for granting urban planning documents, depending on both the location of the investment and the nature of the proposed works. In general, local public administrations (commune, town, or city mayor's offices) are responsible for granting Urban Planning Certificates for most construction works within their administrative-territorial jurisdiction, while county councils intervene only in specific cases expressly provided by law.

Following the granting of the Urban Planning Certificate or the Building Permit, in cases where the procedure involves the approval of the urban planning department within the County Council, a copy of the document is transmitted to the Council for archival and record-keeping purposes, in accordance with administrative procedures.

After obtaining the Construction or Demolition Permit, and prior to the commencement of works, the beneficiary is required to notify both the issuing authority (the mayor's office or the County Council) and the County Inspectorate for Construction. Upon completion of the works, a final notification must also be submitted, accompanied by a request for the organization of the reception at the completion of works, which represents the formal closure of the construction process.

During the management of urban planning documentation, administrative staff must also consider additional operational aspects, such as the payment of applicable fees, the validity of submitted documents, and their expiration dates. Although these elements are relevant to the overall administrative workflow, they are not addressed in detail within the scope of this study.

Each of these notifications plays an important role in ensuring the proper legal and procedural development of construction activities. Accordingly, the public authority that issued the permit is responsible for registering, processing, and responding to all requests submitted by beneficiaries.

All such requests and notifications, typically accompanied by supporting documentation, must be carefully managed by public administration staff. This process is time-consuming, particularly in cases requiring multiple institutional approvals. For this reason, a well-structured and integrated information system that enables efficient document exchange between institutions and supports their subsequent management could significantly improve administrative efficiency in this field.

**Architecture and Functional Design of the Smart Integrated E-Permitting System**

An Information System (IS) is an integrated environment composed of hardware, software, people, and processes, designed to collect, process, and transform data into meaningful and valuable information (Hasan, 2018).

An e-permitting system is an integrated e-government platform that digitizes the submission, processing, coordination, and approval of permit applications within administrative procedures, enabling a more structured and data-driven management of authorization workflows in the construction sector (Amer et. al., 2025) and Information Technology refers to the set of technologies used within a system, typically including hardware, software, databases, and communication networks. It can be defined as the "field concerned with the study, design, development, implementation, support, and management of computer-based information systems" (Florida Tech, 2020).

The proposed system aims to develop a centralized platform that integrates all stages and all actors involved in the urban planning and construction authorization process.

The starting point is represented by users (beneficiary) who require urban planning documents, either for construction purposes or

for various interventions on existing properties. These users can interact directly with public administration bodies and with professionals responsible for preparing the necessary technical documentation.

The platform also includes public institutions with decision-making authority in managing urban planning documents, such as town halls (municipalities) and county councils. These entities manage the analysis, verification, and approval process of documentation, in accordance with the competencies established by the applicable legislation.

Another essential component consists of architectural and urban planning firms responsible for preparing the technical documentation required to obtain certificates and construction permits. Integrating these actors into the system enables workflow standardization and reduces information fragmentation.

At the same time, the platform connects the institutions responsible for issuing the various endorsements and approvals required within DTAC documentation (Technical Documentation for Construction Authorization), such as utility providers and infrastructure operators in sectors including electricity distribution companies, water and wastewater utilities, natural gas suppliers, and other technical service providers involved in the coordination and validation of public infrastructure connections. These institutions contribute through technical assessments specific to their areas of expertise, and the digitalization of their interaction reduces approval times and improves process traceability.

From a conceptual perspective, this platform represents a proposed model rather than an already implementable system within the current legislative framework. Its full operational deployment would require regulatory adaptations and institutional alignment. However, it is designed in accordance with the broader European and national direction toward administrative digitalization and interinstitutional interoperability, which has become increasingly prominent in recent years, as EU policy frameworks emphasize improved governance of interoperability activities and the adoption of common operational models for delivering digital public services that account for the needs of citizens and businesses across Member States (European Commission, 2017).

Through this integrated approach, the system aims to create a unified framework of collaboration between citizens, designers, local authorities, and approval institutions, with the goal of increasing the efficiency of the entire administrative workflow.

At platform level, users are organized according to distinct roles, including project beneficiaries, architectural and design firms, and public institutions involved in the authorization process. Each beneficiary is digitally linked to the firm responsible for preparing their technical documentation, enabling continuous collaboration within a single integrated system.

Through a personal account, both beneficiaries and design professionals can monitor at any time the full status of their applications and documents in progress. The platform provides clearly defined workflow stages such as “registered”, “in progress”, “under review”, “pending approval”, “approved”, or “rejected”, ensuring transparency and a clear understanding of the administrative process. The same tracking logic applies to all requested endorsements and approvals issued by competent authorities, allowing design firms to centrally manage and monitor all required approvals within a unified digital environment.

The platform also integrates the role of the State Inspectorate in Construction (ISC), which performs control and verification activities during the authorization process, ensuring compliance with applicable technical and legal regulations.

The operational workflow of the platform starts with the submission of a request by the beneficiary through the system interface. The design firm prepares and uploads the technical documentation, which is then automatically routed to the competent authorities and utility providers for review and approval. Each institution evaluates the documentation in parallel or sequentially, depending on regulatory requirements, while the system continuously updates the status of the process. Once all necessary approvals are collected, and the technical documentation is ready, the local authority issues the final authorization, and the

complete file is archived digitally within the system.

The proposed system can be conceptually structured into three main architectural layers: the user interface layer, the application and workflow management layer, and the data and interoperability layer. This layered approach ensures separation of concerns, scalability, and efficient coordination between different institutional actors.

The Unified Modelling Language (UML) is a standardized visual modelling language used for specifying, visualizing, and documenting the structure and behaviour of software systems (Koç, 2021). It provides a consistent graphical notation that allows complex systems to be represented in a clear and structured manner, facilitating communication between stakeholders involved in system design and development.

The Unified Modelling Language (UML) defines 14 officially recognized types of diagrams. These diagrams are divided into two main categories: structural diagrams (which show what a system is made of) and behavioural diagrams (which show how a system acts and interacts) (Dennis et al., 2015).

Among the various UML diagram types, use case diagrams play a fundamental role in the early stages of system analysis, as they capture the functional requirements of a system from the perspective of external users. These diagrams provide a high-level overview of the system's expected functionalities, illustrating how different actors interact with the system and what services the system is intended to deliver. As such, they contribute to validating requirements and ensuring alignment between system design and user expectations.

The construction of a use case diagram involves identifying the system boundary, defining the relevant actors, specifying the use cases, and establishing the relationships between them. In UML notation, the system is represented as a boundary box, actors are depicted as external entities interacting with the system, use cases are represented as ellipses, and relationships are illustrated using connecting lines that define interactions and dependencies.

Figure 2 presents a UML Use Case diagram that illustrates the proposed structure of the e-Permitting platform. The diagram highlights the main actors involved in the urban planning and construction authorization process, including beneficiaries, design firms, public authorities, utility providers, and the State Inspectorate in Construction. It also depicts the key interactions between these actors and the system, emphasizing the main functional areas supported by the platform, such as document submission, approval workflows, and status monitoring. The diagram was developed using PlantUML (https://www.plantuml.com/), an open-source tool that generates UML diagrams from textual descriptions, facilitating diagram maintenance, reproducibility, and version control.

Although use case diagrams effectively capture system functionalities and actor interactions, they do not describe the chronological order in which these interactions occur. To address this limitation, UML sequence diagrams are used to model the temporal flow of messages exchanged between participants during the execution of a process. By representing interactions in time sequence, these diagrams provide a detailed view of system behaviour and support the analysis of workflow execution and coordination among system actors (Dennis et al., 2015).

While the Use Case diagram establishes the static structural boundaries, specific roles, and high-level functional requirements of the proposed platform, it does not capture the temporal progression of administrative tasks. To address this dimension, a dynamic perspective is essential for analysing how information, technical validation files, and official notifications are structurally exchanged over time between the involved entities. Accordingly, Figure 3 presents a UML Sequence diagram that details the chronological workflow and message routing logic, mapping out the precise interactions from the initial project collaboration down to the final electronic issuance of the building permit.

The combined application of Use Case and Sequence diagrams enhances the overall system modelling process by addressing both functional and behavioural aspects of the platform. While the Use Case model focuses on system functionalities and user interactions, the Sequence model captures the exchange of

information and coordination mechanisms required for process execution. This integrated modelling approach provides a clearer understanding of system requirements, workflow dependencies, and communication flows, supporting the design and implementation of the proposed e-Permitting platform (Dennis et al., 2015).

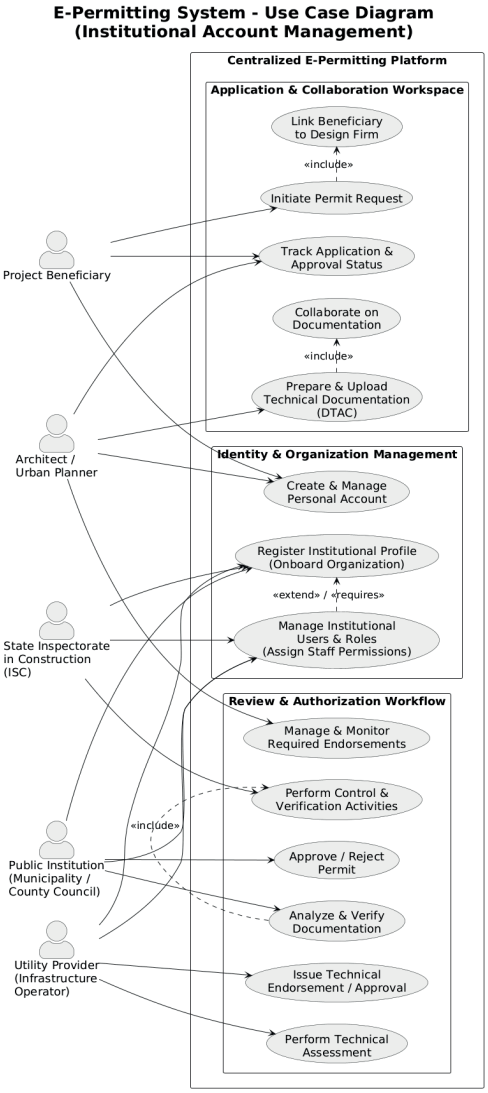

Figure 2. UML Use Case diagram proposing the structure of the e-Permitting platform, illustrating the main actors and their interactions within the urban planning and construction authorization process. The diagram was created using PlantUML (https://www.plantuml.com/)

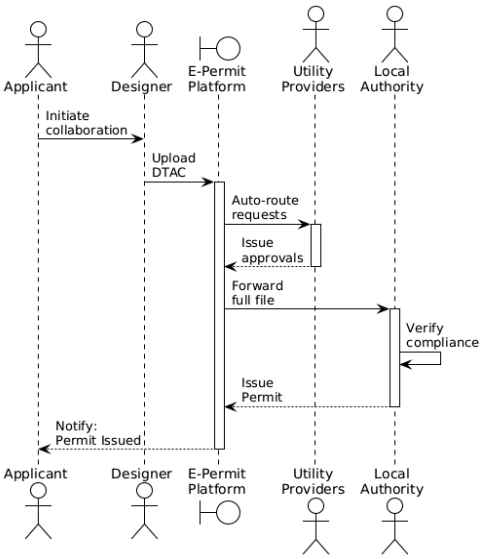

Figure 3. UML Sequence diagram illustrating the chronological flow of interactions and document routing during the permitting process
(The diagram was generated using PlantUML)

While a comprehensive UML model would typically involve multiple diagram types, the Use Case and Sequence diagrams presented here provide an adequate representation of the proposed platform by capturing both its functional requirements and the main interaction workflows.

This chapter presented the conceptual architecture and functional design of the proposed e-Permitting platform. The analysis highlights its potential to function as an integrated digital environment aimed at enhancing coordination, transparency, and efficiency across the urban planning and construction authorization process.

The proposed model supports the transition toward fully digital administrative processes, reducing fragmentation and improving communication between all entities involved in the authorization workflow. This UML-based representation supports the conceptual validation of the proposed solution prior to implementation.

## CONCLUSIONS

The proposed smart integrated e-permitting platform demonstrates significant potential to improve the efficiency and transparency of

urban planning and construction authorization processes. By integrating all relevant actors within a unified digital environment, the system reduces fragmentation and supports more coherent interinstitutional collaboration.

A key advantage of the model lies in the optimization of document management processes at the level of local public administrations, particularly in rural areas where administrative capacity is often limited. The digitalization of communication between town halls, county councils, design firms, and technical approval authorities can significantly reduce processing times and administrative delays.

The implementation of such a system requires institutional coordination and regulatory adaptation. Existing legislative frameworks would need to be aligned with the requirements of fully digital workflows, including secure electronic document exchange, standardized approval procedures, and interoperability between public authorities.

From an architectural perspective, the system can be extended to include additional institutional actors involved in the authorization process, such as environmental protection agencies, emergency inspectorates, public health authorities, and other specialized entities issuing technical endorsements. This extensibility ensures scalability and adaptability to complex regulatory contexts.

Although the proposed model is conceptual in nature, it provides a structured foundation for future developments in digital governance within the construction and urban planning sector. Its implementation would require multidisciplinary collaboration between IT specialists, legal experts, and public administration stakeholders to ensure functional and regulatory coherence.

***Abstract***

*This study proposes an integrated methodological framework for terrain morphological analysis based on high-resolution digital elevation models (DEMs) and a comprehensive suite of geomorphometric parameters, including slope gradient, slope aspect, profile and plan curvature, relative relief, hypsometric indices, flow accumulation, topographic wetness index (TWI), and terrain roughness. These parameters are quantitatively derived using standardized GIS-based algorithms and systematically analysed to capture terrain heterogeneity, hydrological controls, and structural influences on surface and subsurface processes. The morphometric variables are integrated within a geospatial analytical environment through multi-criteria spatial modelling techniques, enabling the structured assessment of terrain susceptibility and the delineation of areas potentially prone to geomorphological instability. The proposed framework emphasizes methodological consistency, reproducibility, and adaptability across different environmental contexts. By formalizing the relationships between terrain attributes and geomorphological processes, the approach provides a scientifically grounded basis for supporting hazard assessment and risk mapping applications. The framework is intended to contribute to evidence-based decision-making in land-use planning, environmental management, and disaster risk reduction, facilitating the development of consistent and operational risk mapping methodologies.*

***Key words****: digital elevation models (DEMs), geomorphological hazard assessment, geomorphometric parameters, multi-criteria spatial modelling, terrain morphological analysis.*

## INTRODUCTION

Terrain morphology exerts a direct control on geomorphological processes by influencing runoff generation, sediment transport, infiltration dynamics, and slope instability, thereby shaping spatial patterns of hazard susceptibility. The increasing availability of high-resolution digital elevation models (DEMs) has enabled the transition toward quantitative terrain analysis based on reproducible geomorphometric parameters (Moore et al., 1991; Wilson & Gallant, 2000).

Geomorphometry provides the methodological basis for deriving terrain attributes directly linked to hydrological and geomorphological processes (Pike et al., 2009). Key parameters include slope gradient, aspect, curvature, and terrain roughness, which describe slope dynamics and erosion susceptibility, as well as flow accumulation and the topographic wetness index (TWI), which quantify runoff concentration and moisture distribution (Beven & Kirkby, 1979; Tarboton, 1997). In addition, hypsometric indices and relative relief provide quantitative measures of landscape structure and evolution (Strahler, 1952; Pike & Wilson, 1971).

Within Geographic Information Systems (GIS), these variables can be systematically derived, standardized, and integrated, enabling multi-criteria spatial modelling of hazard susceptibility. Such approaches allow the combination of multiple terrain parameters into structured analytical models that capture the interactions between topography and geomorphological processes (Burrough & McDonnell, 1998; Guzzetti et al., 1999; Reichenbach et al., 2018).

Despite these developments, a major limitation remains the lack of standardized frameworks for the selection, computation, and integration of geomorphometric parameters. Existing studies often rely on heterogeneous datasets, variable spatial resolutions, and inconsistent weighting schemes, which reduce reproducibility and comparability (Hengl & Reuter, 2009; Evans, 2012). Moreover, the increasing complexity of spatial modelling techniques has not always been accompanied by transparent methodological structuring.

This study addresses these limitations by proposing an integrated and reproducible methodological framework for terrain morphological analysis based on DEM-derived geomorphometric parameters. The approach focuses on the systematic derivation, standardization, and integration of terrain variables within a GIS-based multi-criteria analytical environment, with direct applicability to risk mapping.

By formalizing the relationships between terrain attributes and geomorphological processes and structuring the computational workflow, the proposed framework enhances methodological consistency and supports the development of transferable and operational approaches for hazard assessment and risk mapping.

**Geomorphometric Framework for Terrain Analysis**

Geomorphometry provides a quantitative framework for terrain characterization through the derivation of morphometric parameters from digital elevation models (DEMs). These parameters describe the geometry, hydrological behavior, and structural complexity of the land surface and are widely used as proxies for geomorphological susceptibility in risk mapping (Pike et al., 2009; Hengl & Reuter, 2009).

Terrain morphology controls runoff concentration, infiltration, erosion, sediment transport, and slope instability, as these processes are directly influenced by local gradients, curvature conditions, and the spatial arrangement of topographic surfaces (Moore et al., 1991; Wilson & Gallant, 2000). Consequently, the quantitative extraction of terrain attributes enables the formalization of relationships between land-surface configuration and process dynamics.

Among the primary geomorphometric variables, **slope gradient** expresses the maximum rate of elevation change and constitutes one of the most important controls on gravitational processes and runoff velocity. It is calculated as:

$$S = \arctan\left(sqrt\left(\left(\frac{\partial z}{\partial x}\right)^2 + \left(\frac{\partial z}{\partial y}\right)^2\right)\right)$$

where z represents elevation and ∂z/∂x, ∂z/∂y are the first derivatives of the surface. High slope values generally indicate increased susceptibility to erosion and mass movement (Moore et al., 1991).

Slope gradient directly influences the balance between driving and resisting forces acting on surface materials. Steep slopes are associated with increased shear stress, favouring mass movement processes such as shallow landslides, debris flows, and rockfalls, whereas low-gradient surfaces promote sediment accumulation and characterize depositional environments (Moore et al., 1991; Wilson & Gallant, 2000).

From a hydrological perspective, slope gradient controls runoff velocity, infiltration capacity, and flow concentration. High values enhance surface runoff and erosion, while gentle slopes favour water retention and may contribute to saturation under specific conditions (Beven & Kirkby, 1979; Tarboton, 1997).

Within risk mapping, slope gradient represents a primary conditioning factor, widely used in multi-criteria spatial models where higher values correspond to increased susceptibility. Its spatial distribution enables the identification of threshold zones with significant changes in process dynamics and enhances predictive capacity when integrated with other geomorphometric parameters such as curvature and flow accumulation (Guzzetti et al., 1999; Reichenbach et al., 2018). Derived consistently from DEMs, it ensures reproducibility and supports standardized risk assessment methodologies.

**Slope aspect** defines the orientation of the slope and influences solar radiation, evapotranspiration, soil moisture, and vegetation distribution. It is commonly expressed as:

$$A = \arctan\left(\frac{\frac{\partial z}{\partial y}}{-\frac{\partial z}{\partial x}}\right)$$

Aspect acts as an indirect control on weathering intensity and hydrological response (Wilson & Gallant, 2000).

South-facing slopes (in the Northern Hemisphere) typically experience higher solar radiation, leading to increased evapotranspiration, reduced soil moisture, and enhanced weathering rates, whereas north-facing slopes tend to retain moisture and favour vegetation development.

Within risk mapping, aspect contributes to the differentiation of terrain units with contrasting hydrological and geomorphological behaviour. It is particularly relevant in identifying zones prone to desiccation, soil degradation, or, conversely, moisture accumulation and instability. When integrated with slope gradient and other morphometric parameters, aspect enhances the spatial discrimination of susceptibility patterns, especially in relation to landslides, erosion processes, and vegetation-controlled stability (Moore et al., 1991; Wilson & Gallant, 2000).

Second-order derivatives are represented by **profile curvature** and **plan curvature**, which describe the curvature of the terrain surface in the downslope and contour directions, respectively. These parameters are derived from second partial derivatives of elevation and indicate zones of flow acceleration, deceleration, convergence, and divergence (Evans, 2012). In simplified form, curvature is related to:

$$\left(\frac{\partial^2 z}{\partial x^2}\right), \left(\frac{\partial^2 z}{\partial y^2}\right), \left(\frac{\partial^2 z}{\partial x \partial y}\right)$$

Convex surfaces are generally associated with runoff dispersion and erosional dominance, while concave areas promote flow concentration and material accumulation.

Within geomorphological analysis, profile curvature controls the acceleration or deceleration of flow along the slope, directly influencing erosion and deposition rates, while plan curvature governs lateral flow convergence and divergence, affecting runoff concentration and channel initiation.

In risk mapping, curvature parameters are essential for identifying zones of instability, as areas of flow convergence and concavity are more prone to water accumulation, increased pore pressure, and slope failure. When combined with slope gradient and flow-related indices, curvature significantly enhances the spatial prediction of landslide susceptibility and erosion-prone areas (Moore et al., 1991; Wilson & Gallant, 2000).

**Relative relief** measures the elevation range within a spatial unit and is defined as:

$$R_r = Z_{max} - Z_{min}$$

This parameter reflects local topographic energy and terrain dissection, with high values indicating stronger geomorphic activity and instability potential (Strahler, 1952).

A complementary indicator is the **hypsometric integral (HI)**, which describes the distribution of elevation within a terrain unit:

$$HI = (\bar{Z} - Z_min)/(Z_max - Z_min)$$

where $\bar{Z}$ is the mean elevation. Hypsometric analysis provides information on the evolutionary state of the landscape, distinguishing between youthful, mature, and old geomorphic stages (Pike & Wilson, 1971).

Hydrological controls are captured through **flow accumulation**, which expresses the total number of upslope cells draining into a given cell:

$$FA = \sum_{i=1}^{n} f_i$$

This parameter is essential for identifying preferential drainage pathways, runoff concentration zones, and potential initiation areas for erosion or channelized flow (Tarboton, 1997).

In risk mapping, flow accumulation is a key variable for delineating areas susceptible to concentrated surface runoff, gullying, and fluvial incision. It also plays a fundamental role in the identification of hydrologically active zones, particularly when integrated with slope gradient and topographic wetness index, significantly improving the prediction of erosion-prone and instability areas.

A key compound index is the **Topographic Wetness Index (TWI)**, which estimates the tendency of water to accumulate as a function of slope and contributing area:

$$TWI = \ln\left(\frac{a}{\tan(\beta)}\right)$$

where $a$ is the specific catchment area **and tan β is the local slope angle. High** TWI values indicate zones potentially affected by saturation

excess, subsurface flow, and reduced slope stability (Beven & Kirkby, 1979).

Terrain heterogeneity is further represented by **terrain roughness**, commonly calculated as the local standard deviation of elevation values:

$$R = sqrt\left(\left(\frac{1}{n}\right) * sum_{i=1}^{n}(z_i - \bar{z})^2\right)$$

This metric reflects the irregularity of the surface and is often associated with structurally complex or highly dissected terrain (Hengl & Reuter, 2009).

Taken together, these parameters provide complementary information on terrain geometry, hydrological response, and morphodynamic behaviour. Their integrated use within a GIS-based framework allows a systematic representation of terrain susceptibility and provides the conceptual basis for subsequent methodological implementation in spatial risk modelling.

## MATERIALS AND METHODS

### 1. Data

The methodological framework is based on the use of digital elevation models (DEMs) as the primary data source for terrain analysis. DEMs provide a continuous representation of the land surface, enabling the quantitative derivation of morphometric parameters that describe terrain geometry and its influence on geomorphological processes. The accuracy and spatial resolution of DEM data play a critical role in determining the reliability of derived parameters, as they directly affect the representation of slope gradients, curvature, and hydrological pathways (Moore et al., 1991; Wilson & Gallant, 2000).

High-resolution DEMs are preferred to capture fine-scale terrain variability and local geomorphological features. However, increasing resolution also amplifies noise and micro-topographic irregularities, which may introduce artifacts in derivative calculations. Consequently, preprocessing steps such as filtering, sink filling, and resampling are necessary to ensure data consistency and hydrological correctness prior to analysis (Tarboton, 1997; Hengl & Reuter, 2009).

Although the present study adopts a generalized methodological perspective, the framework is designed to be applicable to a wide range of DEM sources, including satellite-derived datasets (e.g., SRTM, ASTER) and higher-resolution LiDAR-based models, depending on data availability and the scale of analysis.

### 2. Derivation of Geomorphometric Parameters

Geomorphometric parameters are derived from DEM data using standardized GIS-based algorithms that operate on raster representations of elevation. The computation of first- and second-order derivatives is performed through finite difference methods applied to neighbouring cells, allowing the estimation of slope, aspect, and curvature under discrete conditions (Burrough & McDonnell, 1998).

Slope and aspect are typically calculated using 3×3 moving window operators, which approximate local gradients based on elevation differences between adjacent cells. Curvature parameters are derived from second-order derivatives and require careful numerical implementation to minimize sensitivity to DEM noise. Hydrological parameters, such as flow accumulation, are computed using flow routing algorithms, including deterministic approaches (D8) and more advanced methods (D∞), which provide improved representation of divergent flow conditions (Tarboton, 1997).

The Topographic Wetness Index (TWI) is calculated by combining slope and contributing area, requiring prior computation of flow direction and accumulation. Terrain roughness and relative relief are derived using neighbourhood-based statistical operations, which quantify local variability in elevation. Hypsometric analysis is conducted at the level of defined spatial units, typically drainage basins or grid-based partitions, allowing the characterization of elevation distribution and landscape evolution.

To ensure comparability between parameters, normalization procedures are applied, transforming variables into standardized ranges (e.g., 0–1). This step is essential for subsequent integration within multi-criteria models, as it eliminates scale-related biases and facilitates the weighting process (Malczewski, 2004).

### 3. GIS-Based Processing Workflow

The methodological workflow follows a structured sequence of operations designed to ensure reproducibility and consistency in terrain analysis. The process begins with DEM preprocessing, including sink filling to remove artificial depressions and ensure continuous flow routing. This step is essential for the correct computation of hydrological parameters and prevents the propagation of errors in downstream analyses (Tarboton, 1997).

Following preprocessing, geomorphometric parameters are systematically derived using dedicated GIS tools. The workflow integrates both surface-based and hydrological analyses, allowing the extraction of complementary terrain attributes that describe geometric configuration, flow dynamics, and structural variability. Each parameter is generated as a raster layer, maintaining spatial coherence and enabling subsequent overlay operations.

The derived variables are then standardized through normalization techniques, ensuring that all parameters are expressed on a comparable scale. This step is critical in multi-criteria environments, where variables with different units and ranges must be integrated without introducing disproportionate influence.

The final stage of the workflow involves the preparation of input layers for spatial modelling, including classification or reclassification of parameter values into susceptibility-relevant categories. This transformation facilitates the interpretation of terrain attributes in relation to geomorphological processes and enhances their applicability within risk assessment frameworks.

### 4. Multi-Criteria Spatial Modelling

The integration of geomorphometric parameters is performed using multi-criteria spatial modelling techniques, which allow the combination of multiple variables into a single susceptibility framework. This approach is particularly suitable for terrain analysis, where geomorphological processes are controlled by the interaction of several factors rather than a single dominant variable (Malczewski, 2004).

Each parameter is assigned a relative weight based on its theoretical relevance to geomorphological instability. Although weighting schemes may vary depending on the specific application, common approaches include expert-based evaluation and analytical hierarchy processes (AHP), which provide a structured method for comparing the relative importance of variables (Saaty, 1980).

The weighted parameters are aggregated using linear combination methods, resulting in a composite index that reflects the overall susceptibility of the terrain. The resulting values are subsequently classified into discrete categories (e.g., low, moderate, high susceptibility), enabling the delineation of zones with differentiated levels of geomorphological risk.

Given the absence of empirical validation in the present framework, the modelling approach is conceptual and focuses on methodological consistency rather than predictive performance. Nevertheless, the structure of the model allows for future integration of validation datasets, making it adaptable to applied studies.

## RESULTS AND DISCUSSIONS

### 1. Conceptual Results and Analytical Interpretation

The proposed framework allows the formalization of terrain susceptibility as a multivariate function of geomorphometric parameters derived from DEM data. In the absence of empirical calibration, susceptibility is expressed through a composite scoring function based on normalized variables.

$$Sc = \Sigma(wi \cdot Xi, n), \quad \Sigma wi = 1$$

$$Sc = 0.20Sn + 0.05An + 0.10Cp, n + 0.10Cpl, n + 0.15FAn + 0.15TWIn + 0.10Rr, n + 0.10TRn + 0.05HIn$$

All variables are normalized using min.-max. transformation:

$$Xn = (X - Xmin.)/(Xmax. - Xmin.), \quad Xn \in [0.1]$$

The model structure highlights the dominant role of slope gradient, hydrological accumulation, and moisture distribution, which exert primary control on geomorphological instability. Slope influences shear stress and gravitational forcing, while flow accumulation and TWI control water concentration and pore-pressure conditions, which directly affect slope

stability (Beven & Kirkby, 1979; Moore et al., 1991).

**Process-Based Sensitivity**

The contribution of each parameter to susceptibility can be expressed through partial derivatives:

$$\partial Sc/\partial Xi = wi$$

indicating that model sensitivity is directly proportional to assigned weights. Thus, slope gradient and hydrological indices exert dominant control over susceptibility patterns.

Slope-dependent instability can be further related to shear stress:

$$\tau \propto \rho g h \sin(\theta)$$

which increases nonlinearly with slope angle, supporting the positive relationship:

$$\partial Sc/\partial S > 0$$

**Hydrological Contribution**

Hydrological influence is primarily captured through flow accumulation and the Topographic Wetness Index:

$$TWI = ln(a / tan\beta)$$

Increased soil moisture elevates pore-water pressure, reducing effective stress:

$$\sigma' = \sigma - u$$

resulting in decreased shear strength and increased susceptibility:

$$\partial Sc/\partial TWI > 0\,, \partial Sc/\partial FA > 0$$

**Curvature Effects**

Curvature parameters introduce second-order controls by regulating flow convergence and divergence, influencing sediment transport and local moisture distribution. Relative relief and terrain roughness quantify terrain energy and structural complexity, enabling the identification of highly dissected and potentially unstable areas (Strahler, 1952; Evans, 2012;).

The integrated behaviour of these variables defines susceptibility patterns as the result of nonlinear interactions rather than isolated effects. High susceptibility is associated with steep slopes, convergent topography ($Cpl < 0$), high flow accumulation, and elevated TWI values, while low susceptibility corresponds to gentle slopes, limited flow accumulation, and reduced terrain variability.

Although not empirically validated, the model demonstrates internal consistency and aligns with established geomorphological principles, supporting its applicability as a methodological framework for risk mapping (Reichenbach et al., 2018).

- $C_{pl} < 0$ - flow convergence → accumulation
- $C_{pl} > 0$ - flow divergence → dispersion

Profile curvature ($C_p$) regulates flow acceleration:

- $C_p < 0$ - deceleration and deposition
- $C_p > 0$ - acceleration and erosion

The integrated susceptibility behaviour can be expressed as:

$$Sc\ \alpha\ f(Cp, Cpl)$$

**Morphostructural Controls**

Relative relief and terrain roughness quantify terrain energy and structural complexity. Higher values indicate increased vertical dissection and surface irregularity, often associated with active geomorphological processes (Strahler, 1952; Hengl & Reuter, 2009).

$$\partial Sc/\partial Rr > 0\,, \partial Sc/\partial TR > 0$$

**Integrated Susceptibility Behaviour**

The model defines susceptibility as a nonlinear interaction between geometric and hydrological controls. High susceptibility occurs when slope, TWI and flow accumulation increase, while convergent flow conditions dominate.

Conversely, low susceptibility corresponds to low slope gradients, limited hydrological influence, and reduced terrain variability.

The integrated susceptibility behaviour can be expressed as:

$$Sc = f(G, H, M)$$

where: G = geometric component; H = hydrological component; M = morphostructural component.

**Model Consistency**

Although not empirically validated, the model exhibits internal mathematical consistency and aligns with established geomorphological process relationships. The functional relationships between variables reflect well-documented interactions between slope, hydrological accumulation, and terrain structure (Beven & Kirkby, 1979; Reichenbach et al., 2018).

**2. Discussions**

The proposed geomorphometric framework provides a coherent and reproducible methodological structure for terrain-based susceptibility assessment, emphasizing the integration of multiple morphometric variables within a unified analytical model. By formalizing terrain susceptibility as a function of normalized and weighted parameters, the approach ensures methodological transparency and facilitates its implementation within GIS environments.

A major strength of the framework lies in its ability to capture the interaction between geometric, hydrological, and morphostructural controls. Unlike approaches based on single-parameter analysis, the multi-criteria structure reflects the inherent complexity of geomorphological processes, where instability results from the combined influence of slope, moisture conditions, and terrain configuration. The explicit formulation of the susceptibility function enhances interpretability and allows for direct adaptation to different spatial contexts (Malczewski, 2004).

The use of DEM-derived parameters ensures broad applicability, as such data are widely available and can be processed consistently across different regions. Furthermore, the normalization of variables eliminates scale dependency, enabling the integration of heterogeneous datasets within a common analytical framework. This characteristic significantly improves the transferability of the methodology and supports its use in regional or comparative studies.

However, the absence of empirical validation represents a key limitation of the present approach. Without calibration against observed geomorphological events, the assigned weights remain theoretically grounded but not statistically optimized. As a result, the predictive performance of the model cannot be quantitatively assessed, and the susceptibility patterns should be interpreted as conceptual rather than definitive representations of risk.

Another limitation is related to the sensitivity of geomorphometric parameters to DEM resolution and quality. High-resolution datasets may introduce noise and micro-topographic variability, while low-resolution models may oversimplify terrain features, affecting the accuracy of derived indices such as curvature and flow accumulation (Hengl & Reuter, 2009). Additionally, the use of linear combination in the scoring function may not fully capture nonlinear interactions between variables, particularly in complex geomorphological settings.

Despite these limitations, the framework offers a robust basis for methodological development and can be readily extended through the incorporation of empirical datasets, statistical calibration techniques, or advanced modelling approaches. Future research should focus on integrating validation procedures, such as ROC analysis or inventory-based comparison, and exploring nonlinear or machine learning-based methods to enhance predictive capability.

From an applied perspective, the proposed methodology provides a valuable tool for preliminary risk assessment, land-use planning, and environmental management. Its structured and reproducible nature facilitates decision-making processes by offering a consistent approach to terrain evaluation, even in data-limited contexts.

## CONCLUSIONS

The present study proposes a methodological framework for terrain morphological analysis based on DEM-derived geomorphometric parameters, aimed at supporting risk mapping applications. The approach integrates a comprehensive set of terrain attributes within a structured multi-criteria analytical model, enabling the systematic representation of geomorphological susceptibility.

By combining geometric, hydrological, and morphostructural variables, the framework provides a coherent interpretation of terrain behaviour, emphasizing the role of parameter interaction in controlling instability processes. The use of normalization and weighted aggregation ensures methodological consistency and facilitates the implementation of the model in GIS-based environments.

A key contribution of the study lies in the formalization of susceptibility as a quantitative function, which enhances transparency and reproducibility. The proposed structure allows for straightforward adaptation to different spatial contexts and can serve as a foundation for further methodological development.

Despite the absence of empirical validation, the framework demonstrates internal consistency and is grounded in established geomorphological and hydrological principles. However, the lack of calibration limits its direct predictive applicability, and the results should be interpreted as conceptual representations of susceptibility rather than definitive risk assessments.

Future research should focus on the integration of validation datasets, optimization of weighting schemes, and the exploration of nonlinear modelling techniques. The incorporation of statistical and machine learning approaches may further improve the predictive performance and adaptability of the model.

Overall, the proposed framework offers a scientifically robust and flexible basis for terrain analysis and risk mapping, with potential applications in land-use planning, environmental management, and disaster risk reduction.

***Abstract***

*GIS-based noise mapping provides a spatially explicit approach for assessing traffic-related acoustic pressure in protected areas. This study compares two Natura 2000 sites located along the A1 motorway in Romania: ROSAC0138 Bolintin Forest, directly crossed by the motorway, and ROSAC0106/ROSPA0161 Middle Argeș Floodplain, located in its proximity. Strategic noise maps were generated for Lden/Lzsn and Lnight/Lnoapte using 2022 traffic data, and the resulting noise contours were integrated in GIS with protected-area boundaries. The analysis quantified the surface of each site exposed to noise levels above 50 dB. Results indicate a clear contrast: in Bolintin Forest, approximately 443 ha, representing 7.8% of the site, are exposed above 50 dB, whereas in Middle Argeș Floodplain only 6.8 ha, representing 0.18% of the site, exceed this threshold. The study demonstrates the usefulness of GIS-based noise mapping for identifying acoustic exposure zones and supporting Natura 2000 management planning.*

***Key words****: acoustic exposure, GIS, motorway traffic, Natura 2000, noise mapping.*

## INTRODUCTION

Road infrastructure is one of the most widespread sources of anthropogenic disturbance in landscapes. In addition to physical habitat loss and fragmentation, roads generate noise, artificial light, pollution, animal mortality and increased human accessibility (Forman & Alexander, 1998). Traffic noise is particularly relevant for protected areas because it extends beyond the road corridor and may modify the acoustic environment of habitats that otherwise appear structurally intact.

Chronic anthropogenic noise can affect terrestrial organisms by masking acoustic signals, altering vigilance and foraging behaviour, changing habitat use and reducing breeding performance (Slabbekoorn & Ripmeester, 2008; Barber et al., 2010; Kight & Swaddle, 2011; Francis & Barber, 2013; Shannon et al., 2014; 2016). These effects are not uniform across taxa or habitats, but the acoustic footprint of roads is increasingly recognised as an important component of infrastructure-related pressure on biodiversity.

Empirical studies have shown that traffic noise can reduce the density of breeding birds near roads and can alter habitat use even where the physical structure of the habitat remains apparently suitable (Reijnen et al., 1995; 1996; Parris & Schneider, 2008).

Experimental work using phantom-road approaches has further demonstrated that traffic noise alone may reduce habitat quality by changing bird distribution and behaviour (McClure et al., 2013; Ware et al., 2015).

Protected areas are not necessarily protected from noise. Buxton et al. (2017) showed that anthropogenic noise is pervasive in many protected areas, while studies in national parks and natural landscapes have demonstrated that soundscape quality may be degraded by roads, visitors and other human activities (Iglesias Merchan et al., 2014). For Natura 2000 sites, established under the Habitats Directive and the Birds Directive, the issue is relevant because conservation effectiveness depends not only on legal designation, but also on the functional quality of habitats and ecological processes (Council of the European Communities, 1992; European Parliament and Council, 2009).

Noise mapping has traditionally been used for human exposure and environmental noise management. However, when integrated in GIS with protected-area boundaries, strategic noise contours can also provide useful spatial information for conservation planning. GIS-based noise mapping can identify acoustic

exposure zones, compare infrastructure-related pressure between sites and support the prioritisation of management measures.

This study compares two Natura 2000 sites located along the A1 motorway in Romania (Figure 1), selected because they represent contrasting spatial relationships with the same transport corridor. ROSAC0138 Bolintin Forest is directly crossed by the motorway, whereas ROSAC0106/ROSPA0161 Middle Argeș Floodplain is located in motorway proximity without being directly crossed. The objective was to assess and compare the spatial extent of motorway-related acoustic exposure using GIS-based overlay analysis of strategic noise contours and protected-area boundaries.

## MATERIALS AND METHODS

### Study design and study sites

The study was designed as a comparative GIS-based assessment of motorway traffic noise exposure in Natura 2000 sites. The comparison was structured around two spatial configurations (Table 1): direct crossing, represented by Bolintin Forest, and proximity exposure, represented by Middle Argeș Floodplain. This design allows the spatial effect of motorway crossing to be distinguished from the effect of motorway proximity.

ROSAC0138 Bolintin Forest is located in the continental biogeographical region, in the lower Argeș plain landscape. According to the source documentation, the site has a total area of 5,638 ha and includes an important forested component dominated by *Quercus robur*. The A1 motorway crosses the site in two sectors, between km 36+000 and km 42+000 and between km 43+000 and km 45+477. The site-specific conservation context was considered with reference to ANANP Decision No. 319/19.07.2021.

ROSAC0106/ROSPA0161 Middle Argeș Floodplain has double conservation status, being designated as both a Special Area of Conservation and a Special Protection Area. The site covers 3,648.94 ha and includes riparian, aquatic and floodplain habitats important for bird species (MEWF, 2020 – Note No. 13916/CA/17.09.2020). In this case, the A1 motorway does not cross the protected area, but runs in its proximity over approximately 41.1 km, between km 35+600 and km 76+700, at distances ranging from approximately 185 m to 2,145 m from the site boundary. The conservation context was considered with reference to ANANP Decision No. 414/16.09.2020, ANANP Decision No. 379/20.06.2023 and the Ministry note for ROSPA0161.

Table 1. Spatial configuration of the Natura 2000 sites analysed in relation to the A1 motorway

| Natura 2000 site | Code | Area (ha) | Spatial relation with A1 | Relevant motorway sector |
|---|---|---|---|---|
| Bolintin Forest | ROSAC0138 | 5,638 | Directly crossed | km 36+000-42+000; km 43+000-45+477 |
| Middle Argeș Floodplain | ROSAC0106 / ROSPA0161 | 3,648.94 | In proximity only | km 35+600-76+700; 185-2,145 m from site boundary |

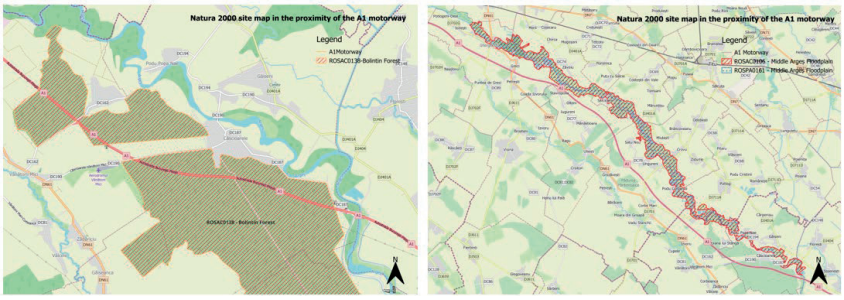

Figure 1. Spatial relationship between the A1 motorway and the analysed Natura 2000 sites

### Noise indicators and input data

Noise exposure was assessed using two strategic noise indicators: Lden/Lzsn, corresponding to the day-evening-night noise indicator, and Lnight/Lnoapte, corresponding to the night-time noise indicator (SR ISO 1996-2:2018). Traffic

input data were derived from the 2022 General Traffic Census for Romanian roads, provided by CNAIR SA – CESTRIN (Table 2). The traffic dataset included annual traffic volumes and vehicle-class distribution by time interval.

Table 2. Main A1 motorway traffic input sectors used for the GIS-based noise-mapping assessment

| Motorway sector | Census post km | Length (km) | Total vehicles in 2022 | Used for site |
|---|---|---|---|---|
| A1 km 30+510-49+208 | 36.050 | 18.698 | 14,556,200 | Bolintin Forest; Middle Argeș Floodplain |
| A1 km 49+208-70+460 | 49.208 | 21.252 | 11,992,440 | Middle Argeș Floodplain |
| A1 km 70+460-94+393 | 85.600 | 23.933 | 10,898,900 | Middle Argeș Floodplain |

The modelling used the legal speed limit for the motorway sector, continuous pulsating traffic flow, asphalt pavement as reference road surface and meteorological conditions favourable to sound propagation. The original technical documentation indicates the use of the NMPB Routes-96 method for road-traffic noise calculation, in accordance with the methodological framework cited in Romanian environmental-noise legislation. CNOSSOS-EU is included in the references as the current common European methodological framework (Kephalopoulos et al., 2012; Directive 2002/49/EC).

**GIS processing and exposure assessment**

The strategic noise maps were integrated in a GIS environment together with the boundaries of the two Natura 2000 sites. Noise contours corresponding to Lden/Lzsn and Lnight/Lnoapte were overlaid with the protected-area polygons to identify and quantify areas exposed to noise levels above 50 dB (OMEWF No. 2328/2021). For each site, the exposed surface was calculated in hectares and expressed as a percentage of the total site area. This metric was used as a noise-exposure ratio for comparing the two spatial configurations.

The 50 dB threshold was used as a spatial comparison threshold for identifying areas exposed to noticeable road-traffic noise in the available strategic noise-map classes. It should not be interpreted as a universal ecological limit for all taxa. Species-specific responses to noise vary substantially, and the ecological relevance of exposure depends on species, habitat, season, behavioural context and the temporal pattern of noise.

## RESULTS AND DISCUSSIONS

**GIS-based exposure patterns**

The spatial overlay analysis revealed a strong contrast between the two Natura 2000 sites. In Bolintin Forest, where the A1 motorway directly crosses the protected area, the noise contours extend inside the site as a continuous corridor along the motorway (Figure 2). In Middle Argeș Floodplain, the motorway runs parallel to or near the site boundary for a longer distance, but most of the protected area remains outside the >50 dB exposure zone (Figure 3).

This contrast indicates that motorway proximity alone does not necessarily generate extensive acoustic exposure within a protected area (Table 3). Site geometry, distance from the road, the position of the road relative to the protected-area boundary and direct crossing of habitat blocks strongly influence the spatial footprint of traffic noise. This interpretation is consistent with studies showing that the spatial extent of noise impact depends not only on source strength, but also on landscape configuration, sound propagation conditions and the behavioural sensitivity of target species (Barber et al., 2010; Francis & Barber, 2013; Iglesias Merchan et al., 2014; Ware et al., 2015).

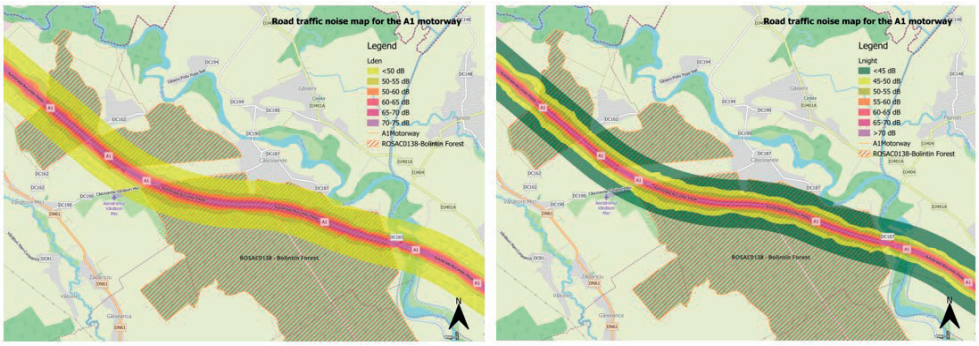

Figure 2. GIS-based noise maps for the A1 motorway in the Bolintin Forest area: Lden/Lzsn and Lnight/Lnoapte

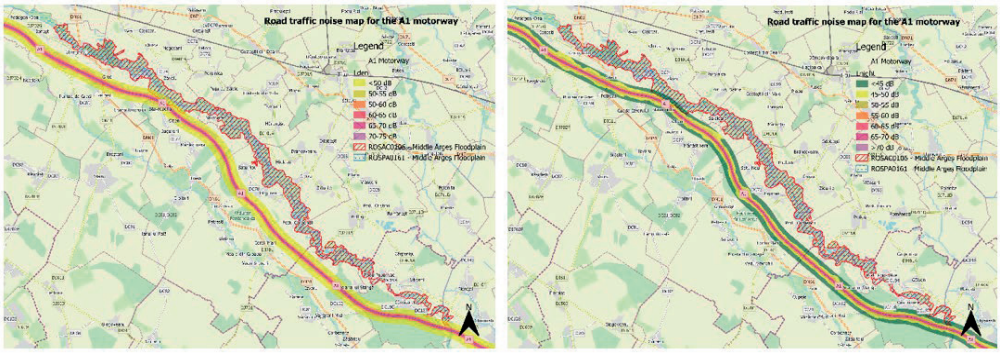

Figure 3. GIS-based noise maps for the A1 motorway in the Middle Argeș Floodplain area: Lden/Lzsn and Lnight/Lnoapte

Table 3. Comparative GIS interpretation of motorway-related acoustic exposure in the two Natura 2000 sites

| Indicator | Bolintin Forest | Middle Argeș Floodplain | Interpretation |
|---|---|---|---|
| Spatial relationship with A1 | Directly crossed | In proximity only | Direct crossing produces stronger overlap between noise contours and the protected area. |
| Area exposed above 50 dB | 443 ha | 6.8 ha | The absolute exposed area is much larger in Bolintin Forest. |
| Share of site exposed above 50 dB | 7.8% | 0.18% | The exposure ratio is approximately 43 times higher in Bolintin Forest. |
| Management relevance | Priority corridor for field validation | Periodic reassessment recommended | GIS layers can support prioritisation of field checks and mitigation analysis. |

**Direct crossing versus proximity**

In Bolintin Forest, the A1 motorway intersects the protected area in two sectors.

The noise maps show that the >50 dB contours penetrate the site along the motorway corridor.

According to the source calculation, the average distance to the 50 dB contour was approximately 249.32 m for carriageway 1 and 249.81 m for carriageway 2 in the case of Lden/Lzsn.

For Lnight/Lnoapte, the corresponding distances were approximately 240.08 m and 240.79 m. The estimated area exposed above 50 dB was approximately 443 ha, corresponding to 7.8% of the total site area.

In Middle Argeș Floodplain, the motorway is located close to the protected area, but does not intersect it directly. The GIS overlay shows that almost the entire site lies outside the >50 dB noise contours. Only approximately 6.8 ha, corresponding to about 0.18% of the site area, were estimated to exceed the 50 dB threshold, in the area corresponding to km 65-66 on carriageway 1.

The comparison indicates that the direct-crossing configuration produces a substantially higher exposure ratio than proximity exposure. In relative terms, the proportion of Bolintin Forest exposed above 50 dB is about 43 times

higher than that calculated for Middle Argeș Floodplain. This result supports the use of GIS-based exposure metrics as a screening tool for identifying Natura 2000 sites where road-traffic noise should be considered in management planning.

**Management relevance and limitations**

Acoustic exposure should not be interpreted in isolation. A motorway corridor may simultaneously generate sound disturbance, reduce habitat permeability, increase wildlife mortality, create edge effects and facilitate human

access. Therefore, in directly crossed sites such as Bolintin Forest, noise mapping should ideally be integrated with road-fragmentation analysis, habitat maps, wildlife movement data and roadkill monitoring.

For Bolintin Forest, the main management priority is the motorway corridor crossing the site. Potential measures include field validation of noise levels, roadkill monitoring, assessment of wildlife crossing needs, evaluation of existing culverts or bridges and analysis of whether acoustic mitigation measures are technically and ecologically justified. For Middle Argeș Floodplain, the current model suggests limited exposure above 50 dB; however, periodic reassessment is recommended if traffic volumes increase or if new infrastructure developments occur.

The main limitation of the study is that it assesses acoustic exposure rather than direct biological response. The findings therefore indicate potential pressure zones, not confirmed ecological impact. Future analyses should integrate GIS noise layers with habitat distribution, species occurrence, breeding sites, seasonal sensitivity, roadkill data and, where possible, field-based acoustic measurements.

**Integration with Natura 2000 management**

The GIS-based outputs are most useful when treated as a first-level screening layer rather than as a final ecological diagnosis. For protected-area management, the value of the method lies in its capacity to identify where field verification should start. In the directly crossed site, the motorway corridor can be prioritised for site visits, comparison with existing culverts and bridges, and verification of whether wildlife movement routes intersect the acoustic exposure zone.

The approach also supports future integration with other spatial datasets. Noise-exposure layers can be overlaid with forest habitats, riparian habitats, breeding or feeding areas, species records and connectivity corridors. Such integration would allow managers to distinguish between areas where noise exposure is spatially present but ecologically less relevant and areas where exposure overlaps with sensitive ecological functions.

Because this study uses modelled strategic noise contours, its conclusions should remain spatial and comparative. A stronger ecological interpretation would require field-based sound measurements, seasonal monitoring, species-specific sensitivity assessment and validation against biological indicators. Nevertheless, the comparison demonstrates that the same motorway may generate very different exposure patterns depending on its position relative to the protected-area boundary.

## CONCLUSIONS

This study demonstrates that GIS-based noise mapping can provide a useful spatial framework for assessing motorway-related acoustic exposure in Natura 2000 sites. The comparison between Bolintin Forest and Middle Argeș Floodplain shows that the spatial relationship between the motorway and the protected-area boundary strongly influences the extent of acoustic exposure. A direct motorway crossing generated a much larger exposed area than motorway proximity alone.

In Bolintin Forest, approximately 443 ha, or 7.8% of the site, were estimated to be exposed to noise levels above 50 dB, while in Middle Argeș Floodplain only 6.8 ha, or 0.18%, exceeded the same threshold. These results support the integration of GIS-based noise exposure indicators into Natura 2000 management planning, particularly for protected areas crossed by major transport infrastructure.

The study should be regarded as a spatial screening and management-support analysis. For ecological interpretation, modelled noise exposure should be combined with habitat and

species data, field measurements, roadkill monitoring and connectivity assessments.

## ACKNOWLEDGEMENTS

This study was developed as part of the doctoral research of Cristina Călin, carried out within the Doctoral School of Engineering and Management of Plant and Animal Resources - University of Agronomic Sciences and Veterinary Medicine of Bucharest.

***Abstract***

*The digital transformation of tree inventory through Geographic Information Systems (GIS) is reshaping contemporary forestry practices by enabling higher accuracy, enhanced data integration, and increased operational efficiency. GIS technologies revolutionize forest inventory workflows by facilitating precise spatial data collection and supporting advanced analytical processes. The integration of spatial datasets with modern analytical tools allows for dynamic monitoring of forest resources and provides a robust foundation for informed and sustainable management decisions. The aim of this article is to demonstrate how GIS-based digital methodologies improve the efficiency, standardization, and analytical depth of forest inventory processes, while highlighting their role in supporting modern forestry management. To achieve this, a dedicated field data collection form was developed using Survey123, specifically designed for tree inventory and analysis. This standardized form ensures consistent data acquisition and seamless integration into GIS platforms for subsequent spatial processing and interpretation. Overall, the proposed workflow illustrates the transformative potential of GIS technologies in optimizing forestry operations and advancing sustainable forest resource management.*

***Key words****: Digital Tree Inventory, Forestry Management, GIS, Survey123.*

## INTRODUCTION

Sustainable forest management has become one of the major challenges of the 21st century, driven by climate change, biodiversity loss, increasing anthropogenic pressures, and the growing demand for forest resources. In this context, reliable and up-to-date information on forest ecosystems is fundamental for supporting informed management decisions. White et al. (2013) emphasize hat the development and continuous maintenance of forest inventories are essential not only for assessing current forest conditions but also for projecting future forest development and supporting long-term sustainable management strategies (White et al., 2013). Similarly, Aulló-Maestro et al. (2021) describe forest inventories as the primary source of information for assessing forest structure and monitoring forest dynamics (Aulló-Maestro et al., 2021). For decades, forest inventories have relied on conventional field-based methods involving paper forms, manual measurements, and subsequent office-based data processing. Although these approaches have provided valuable information for forest management, they are characterized by several limitations, including high labour requirements, long processing times, difficulties in data updating, and increased susceptibility to transcription and positioning errors. According to Keskes et al. (2025), many forest inventory variables are still measured manually in the field, making the inventory process both time-consuming and costly, particularly across large and heterogeneous forest landscapes.

The rapid development of digital technologies has fundamentally transformed the way forest inventories are planned, conducted, and managed. Rather than representing a simple transition from paper forms to digital devices, digital transformation involves the integration of advanced technologies into a comprehensive information management system. This

transformation combines field data acquisition, Global Navigation Satellite System (GNSS) positioning, Geographic Information Systems (GIS), remote sensing, laser scanning, cloud-based databases, and spatial modelling within a unified digital workflow. As highlighted by White et al. (2013), modern forest inventories increasingly rely on multi-source information to provide more accurate, timely, and spatially explicit estimates of forest resources (White et al., 2013).

Among these technologies, Geographic Information Systems (GIS) plays a central role by integrating, storing, visualizing, and analysing geospatial information collected from multiple sources. Aulló-Maestro et al. (2021) state that GIS and remote sensing technologies have transformed the use of forest inventory data by enabling wall-to-wall estimation of forest variables based on field measurements and spatial modelling (Aulló-Maestro et al., 2021). The capability of GIS to combine field observations with remotely sensed information allows forest managers to evaluate forest resources more efficiently and consistently than conventional inventory approaches. Recent advances in remote sensing have further accelerated this digital transformation. According to Fassnacht et al. (2024), remote sensing has become an omnipresent technology in forestry and is increasingly applied in operational forest inventory and monitoring (Fassnacht et al., 2024). Airborne LiDAR, terrestrial laser scanning (TLS), mobile laser scanning (MLS), unmanned aerial vehicles (UAVs), and multispectral satellite imagery now provide detailed information on tree position, canopy architecture, stand density, biomass, and forest health. Liang et al. (2018) demonstrated that terrestrial laser scanning significantly improves the accuracy of tree-level measurements, while Hyyppä et al. (2020) showed that laser scanning technologies enable highly precise three-dimensional characterization of forest structure. The integration of these diverse datasets within GIS environments provides substantial advantages for forest management. Spatial databases facilitate efficient data organization, improve interoperability among information sources, reduce redundancy, and support rapid updating of inventory records. Furthermore, spatial analysis techniques enable the assessment of stand structure, species distribution, growth dynamics, regeneration processes, accessibility, harvesting operations, and environmental risks. These capabilities contribute to more informed planning and more effective allocation of forest resources. Digital transformation is also closely associated with the emergence of Precision Forestry, a management paradigm based on high-resolution spatial information and data-driven decision-making. As discussed by Uusitalo (2010), modern forestry increasingly depends on accurate digital information systems that support operational planning and resource optimization (Uusitalo, 2010).

More recently, Damaševičius et al. (2024) highlighted that digital technologies improve the sustainability, efficiency, transparency, and resilience of forest management by facilitating evidence-based decisions and strengthening the integration of ecological, economic, and operational information. Another important aspect of digital forestry is the continuous updating of forest information. Traditional inventories often require several years between successive measurements, whereas digital workflows supported by GIS and remote sensing allow near real-time monitoring of forest conditions. This capability is particularly valuable for detecting disturbances caused by storms, pests, diseases, wildfires, and illegal logging, enabling forest managers to respond more rapidly and effectively.

In addition to improving operational efficiency, GIS-based inventories enhance the quality and consistency of forest information. Spatial databases reduce the likelihood of transcription errors, facilitate data sharing among institutions, and provide standardized datasets that can support national forest inventories, ecosystem monitoring programmes, and scientific research. The integration of field observations with remote sensing products also enables advanced spatial analyses and predictive modelling of forest growth, regeneration, biomass accumulation, and future stand development under different management scenarios.

Against this background, the present study investigates the digital transformation of tree inventory through Geographic Information Systems by analysing the complete workflow of spatial data collection, integration, management, and analysis. The research explores how

rigorous field measurements combined with GIS technologies can optimize forest inventory processes, improve the quality of spatial information, support sustainable forest management, and facilitate evidence-based decision-making. Ultimately, this integrated digital approach contributes to more accurate forest resource assessments, greater operational efficiency, and enhanced capacity for monitoring and managing forest ecosystems in a rapidly changing environmental context.

## MATERIALS AND METHODS

Digital transformation driven by GIS technologies is revolutionizing how forest inventories are conducted, delivering enhanced accuracy and significant operational efficiency. The integration of spatial data with advanced analytical tools enables the dynamic monitoring of forest resources and provides a solid foundation for more informed, sustainable management decisions.

To implement the project on the digital transformation of forest inventorying via GIS, a dedicated field datasheet was developed using Survey123 for tree inventory and analysis. This datasheet ensures the standardized collection of data required for seamless GIS integration and establishes a baseline for subsequent analyses.

In the following paragraphs, we will outline the methodology implemented for data integration and demonstrate how geospatial analysis elevates a standard tree inventory into a strategic asset for smart forestry. Ultimately, our goal was to show that digitalization is no longer an optional technical upgrade, but a fundamental necessity for the efficiency, transparency, and long-term sustainability of modern forestry.

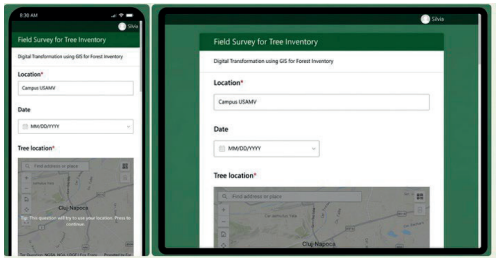

Figure 1. Visualizing the questionnaire and ensuring its accessibility across multiple devices (such as tablets and mobile phones) enhances user accessibility

More precisely, the survey initiates with the record of location-specific details and the date of completion, followed by the acquisition of the precise tree location through the logging of its latitude and longitude coordinates, as shown in Figure 2.

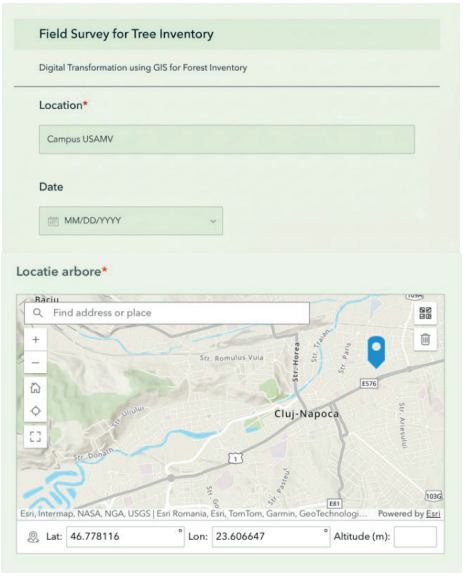

Figure 2. The image shows the initial section of a digital field survey for tree inventory designed to leverage GIS technology, featuring data entry fields for capturing the specific location and the collection date

The image illustrates an interactive map interface within a data collection tool used to precisely capture a tree's geographic coordinates - specifically its latitude and longitude - by placing a marker within the city of Cluj-Napoca. We also present a section marked in Figure 3, dedicated to species identification, featuring mandatory data fields for the common Romanian name, the scientific name, the origin (native or exotic), and the provenance (generative or vegetative) of the tree. In addition, information regarding tree height, clear bole height, and tree diameter was collected (Figure 4).

The questionnaire also includes information regarding the trees' vegetative status, as shown in Figure 5, for example luxuriant, vigorous, normal, sluggish/declining, and dying and health condition (good, satisfactory, poor, or others), along with dedicated sections for field observations and photographs.

## RESULTS AND DISCUSSIONS

By analysing this questionnaire within the Survey123 platform, it becomes possible to systematically evaluate all relevant aspects of a tree, with the results being summarized in the charts presented below. The Figure 6 shows a data table from a Survey123 questionnaire that tracks the frequency of individual words entered for scientific species names ("Denumire stiintifica specie"), which will automatically generate a word cloud once at least 20 responses are collected.

The column chart above (Figure 7) presents the distribution of tree origins ("Origine"), showing that out of 18 responses, 66.67% are classified as exotic ("Exotica") and 33.33% are native ("Indigena").

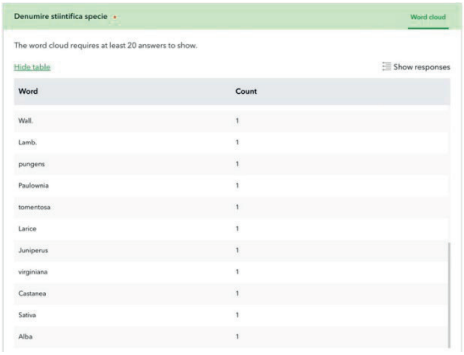

Figure 6. Scientific name of the species

Figure 7. Origin of the tree

The column chart and data table presented in Figure 8 summarize the provenance ("Prevenienţa") of the trees, showing that 72.22% originated through vegetative reproduction ("Vegetativă"), while the remaining 27.78% resulted from generative reproduction ("Generativă").

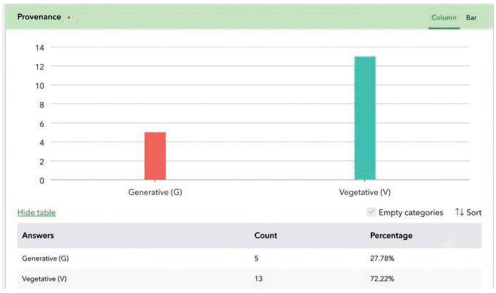

Figure 8. The tree provenance

The histogram and summary metrics display the distribution of tree heights ("Inaltime arbore") - Figure 9, indicating that the surveyed trees range from a minimum height of 4.8 to a maximum of 25, with an average height of approximately 17.22 m.

Figure 9. The height of the tree

The chart represented in Figure 10 illustrates the distribution of clear bole height ("Inaltime elagata"), showing values ranging from a minimum of 0.5 to a maximum of 10.4, with an average height of 4.66.

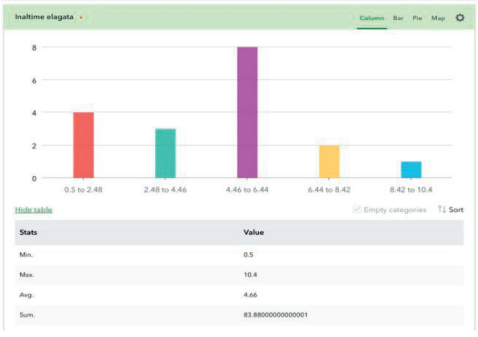

Figure 10. The distribution of clear bole height

The column chart and data table presented in Figure 11, illustrate the vegetative health status ("Stare de vegetație") of the surveyed trees, showing that a 44.44% majority are classified as normal, followed by luxuriant (27.78%), vigorous (22.22%), and sluggish/declining (5.56%), with no trees recorded in the dying category.

Figure 11. The vegetative health status

The column chart and data table below (Figure 12) depict the health status of the trees ("Starea de sănătate a arborelui"), showing that a significant majority of 72.22% are in good condition, while 22.22% are in poor condition, and 5.56% (1 tree) is rated as satisfactory.

Figure 12. The health status of the trees

The gallery section displays a visual inventory consisting of field photographs (Figure 13) used to document and verify the individual characteristics of each tree surveyed in the study.
With the help of GIS, it is also possible to create thematic maps, which are of significant practical value for data visualization and analysis.
The image (Figure 14) displays a thematic map generated within the survey platform, illustrating the spatial distribution and proportional heights of trees ("Inaltime arbore") mapped on the USAMV Cluj campus. The thematic map

underscores the spatial heterogeneity of tree heights, revealing critical correlations between environmental factors and vegetative growth.

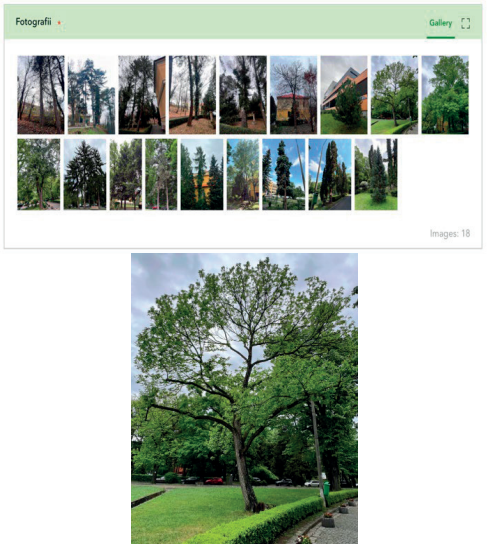

Figure 13. Visual Documentation of the Studied Dendrological Specimens

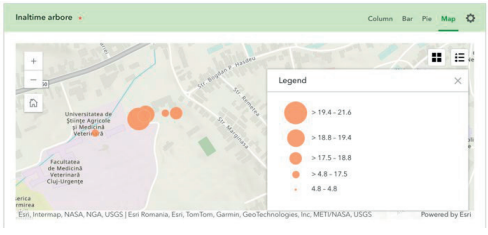

Figure 14. Thematic map illustrating the spatial distribution of tree height

The next map (Figure 15) utilizes graduated proportional symbols, where larger circles correspond to taller trees according to the map legend, allowing for an immediate visual comparison of tree heights across the localized study area.

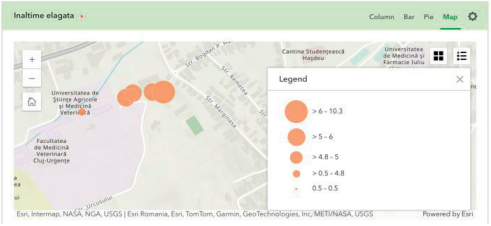

Figure 15. Thematic map illustrating the spatial variation of clear bole height within the forest stand

The provided orthophotomap, titled "Geospatial inventory and exact localization of arboreal specimens at the USAMV Cluj-Napoca campus" (Figure 16) illustrates a high-precision spatial mapping approach utilized to catalogue the urban forestry resources within the university grounds.

Figure 16. Geospatial inventory and exact localization of arboreal specimens at the USAMV Cluj-Napoca campus

By leveraging high-resolution aerial imagery overlaid with precise geographic coordinates, individual tree positions have been vectorized and marked with distinct red and yellow point indicators. The spatial distribution reveals a strategic arrangement of dendrological specimens, clustered primarily around infrastructure borders, open green spaces, and academic walkways. This cartographic layout serves as a fundamental baseline for urban ecosystem monitoring, allowing researchers to track spatial configurations and localized microclimatic impacts of individual specimens within the campus canopy. From a management and biometrical perspective, this precise geospatial localization provides indispensable data for the development of an integrated Green Cadastre for USAMV Cluj-Napoca. Identifying the exact spatial coordinates of each arboreal unit facilitates long-term monitoring of tree health, growth dynamics, and species-specific interactions within the campus ecosystem. Furthermore, this localized spatial framework enables precise field-to-map cross-referencing during dendrometric inventories. By linking these geographic points to a relational database containing biometric attributes - such as species composition, total height, and clear bole height - the institution can optimize its urban forestry management strategies, promoting both ecological biodiversity and environmental sustainability.

## CONCLUSIONS

The digital transformation of tree inventorying through GIS highlights the significant potential of spatial technologies in establishing a 'green cadastre' for the USAMV Cluj-Napoca Campus, providing a solid foundation for sustainable management and well-informed decisions.

Looking ahead, future research directions will focus on integrating UAV photogrammetry and LiDAR data to automate tree feature extraction, expanding these models to support forest owners, institutions, associations, and local administrative units (UATs) through integrated solutions dedicated to monitoring green resources and protecting ecosystems, with the ultimate goal of achieving more efficient and responsible forest management.

Furthermore, the implementation of this advanced spatial framework facilitates a paradigm shift from reactive to proactive environmental stewardship within academic and urban ecosystems. By transforming raw geospatial data into actionable intelligence, the proposed green cadastre model enables campus administrators to simulate microclimate impacts, assess localized carbon sequestration capacity, and optimize tree maintenance schedules. This methodology not only standardizes the documentation of vegetative assets but also establishes a highly scalable blueprint that can easily be integrated into broader smart-city frameworks, effectively bridging the gap between localized institutional workflows and regional environmental goals.

Ultimately, the long-term viability and impact of these technological interventions rely on fostering participatory data environments and open collaboration. Future iterations of this system will aim to incorporate multi-user mobile platforms and interactive dashboards, allowing students, researchers, and local stakeholders to engage directly with the spatial database. By cultivating an accessible, dynamically updated ecological inventory, USAMV Cluj-Napoca can champion a collaborative approach to biodiversity conservation, ensuring that precision forestry and urban greening efforts remain resilient and highly adaptive in the face of accelerating climate challenges.

## ACKNOWLEDGEMENTS

This research was carried out with the support of the Ministry of Education and was financed through the CNFIS-FDI-2025-F-0030 project, funded by the National Council for Financing Higher Education (CNFIS).

## USE OF GENERATIVE ARTIFICIAL INTELLIGENCE (GenAI)

The authors declare the use of Generative Artificial Intelligence (GenAI) tools in the preparation of this manuscript. GenAI was used exclusively for language editing and text refinement in the Introduction and Conclusions sections. All scientific content, data analysis, and interpretations were developed and verified by the authors.

***Abstract***

*Cereal crop production faces persistent threats from biotic stresses caused by pathogenic organisms, resulting in significant yield loss and increased management costs. Conventional disease monitoring methods are often limited by spatial resolution, labor intensity, and delayed detection. Integrating unmanned aerial vehicles (UAVs), geographic information systems (GIS), and smart forecasting tools offers potential for real-time, spatially explicit pathogen risk mapping in cereal fields. This review synthesizes state-of-the-art methodologies in UAV remote sensing, GIS spatial analysis, and predictive modelling, emphasizing advances in machine learning for disease detection and risk assessment. Current challenges including data integration, operational constraints, and technological gaps are identified, and future research directions are outlined to facilitate adoption within precision agriculture and environmental engineering frameworks.*

***Key words*****:** *cereal crops, GIS, pathogen detection, risk mapping, smart forecasting, UAV remote sensing.*

## INTRODUCTION

Cereal crops such as wheat, barley, and maize represent a fundamental component of global food security; however, their productivity is significantly threatened by plant pathogens that can cause severe yield and quality losses. Globally, crop losses in wheat due to plant diseases are estimated to cause economic damages of approximately US$ 4-10 billion annually, highlighting the significant impact of pathogens on global food security (Chai et al., 2022). As the global population is projected to approach nearly 10 billion by 2050, the pressure on agricultural systems to ensure stable and sufficient cereal production will intensify (United Nations, 2019). Wheat and other staple crops will be required to maintain high productivity under increasingly variable climatic conditions, where plant diseases remain a major constraint to yield stability (Savary et al., 2019). In this context, conventional reactive approaches to crop protection are insufficient to meet future food demands.

Fungal diseases such as Rusts (RSTs), Powdery Mildew (PM), Septoria Leaf Blotch (SLB) and Fusarium Head Blight (FHB) are among the most destructive diseases affecting cereal production worldwide, often developing rapidly under favorable environmental conditions and spreading across large agricultural areas (Chaloner et al., 2021; Cotuna et al., 2021, 2022; Kouadio et al., 2023; Paraschivu et al., 2023). The increasing frequency of plant disease outbreaks, driven by global trade and climate variability, highlights the need for more efficient monitoring and early warning systems capable of supporting timely crop protection strategies. Thus, phytosanitary management of wheat (*Triticum aestivum* L.) represents a major challenge in the current context of climate change and the ongoing transition toward more sustainable and environmentally friendly agricultural systems (Velea et al., 2021; Bonciu, 2022). The resilience of wheat crops to pathogen attacks does not depend on a single factor but rather results from complex interactions among plant genetics, nutritional status, and crop management practices. Understanding these interactions is essential for developing effective strategies aimed at improving plant health and reducing disease incidence in cereal production

systems (Păunescu et al., 2022, 2023; Iacob et al., 2025).

Recent studies have shown that plants subjected to prolonged water stress, often expressed through increased rates of water loss at the level of the flag leaf, exhibit greater susceptibility to pathogen infections (Atkinson and Urwin, 2012; Naz et al., 2021). This increased vulnerability is associated with physiological imbalances and a weakened plant defense system, which may compromise the plant's ability to respond effectively to biotic stress factors (Pandey et al., 2015). Consequently, environmental stress conditions can significantly influence the epidemiology and severity of diseases affecting wheat crops. In addition, the choice of cropping system and the optimization of plant physiological status through the application of foliar fertilizers play an important role in strengthening the plant's natural defense mechanisms. These practices contribute not only to maintaining high yield potential but also to improving grain quality and overall crop performance (Roșculete et al., 2023).

Despite these advances in agronomic management, early detection and spatial monitoring of plant diseases remain critical challenges in modern cereal production systems. Conventional field scouting methods are often limited by time, labor requirements, and restricted spatial coverage, making it difficult to detect early disease symptoms or accurately assess the spatial distribution of pathogens within large agricultural fields. In this context, digital agriculture technologies have emerged as valuable tools for improving crop monitoring and disease detection (Seelan et al., 2003; Mahlein et al., 2012; Barbedo, 2019).

Recent progress in remote sensing technologies, particularly the use of unmanned aerial vehicles (UAVs), has significantly enhanced the capacity to monitor crop health at high spatial and temporal resolutions. UAV platforms equipped with RGB, multispectral, or hyperspectral sensors enable rapid acquisition of detailed crop imagery, allowing the detection of subtle physiological and structural changes associated with plant stress and early disease development (Feng et al., 2021; Neupane & Baysal-Gurel, 2021; Bouguettaya et al., 2023). When combined with geographic information systems (GIS), these datasets can be integrated with environmental variables, crop management information, and historical disease records to generate spatially explicit maps of crop health and pathogen risk. Moreover, the integration of remote sensing data with predictive disease forecasting models based on meteorological parameters and epidemiological indicators can further improve the accuracy of disease monitoring systems. Such integrated approaches enable the development of real-time pathogen risk maps that identify areas with increased probability of infection, thereby supporting targeted crop protection measures and optimizing the use of phytosanitary treatments.

In this context, the present study aims to develop an integrated framework for real-time pathogen risk mapping in cereal fields through the combined use of UAV-derived imagery, GIS-based spatial analysis, and smart forecasting tools. By linking high-resolution spatial monitoring with predictive disease modeling, this approach seeks to improve early detection of plant health risks and provide decision-support tools for precision phytosanitary management in cereal production systems.

## MATERIALS AND METHODS

The present study adopts a qualitative, information-oriented research design, based on an extensive review of diverse sources, including academic books, peer-reviewed journal articles, technical reports, news publications, and relevant online databases. The available literature was systematically identified, critically evaluated, and synthesized to provide a comprehensive overview of the current state of knowledge, as well as to highlight emerging trends and future research directions related to the topic (Tranfield et al., 2003). This systematic quantitative review of the scientific literature was conducted in accordance with the methodological framework proposed by Pickering and Byrne (2014). A defined set of search keywords ("UAV", "plant", "disease", "GIS") was employed to systematically explore the literature within the Scopus and Web of Science databases, with the

aim of identifying relevant studies published in peer-reviewed, English-language academic journals focusing on UAV-based applications for plant disease detection and monitoring.

In order to achieve the objectives of this study, a combination of systematic, semi-systematic, and integrative review methodologies was employed. This approach involved a rigorous comparative analysis of existing scientific publications, empirical studies, reports, and statistical datasets, with the aim of generating robust insights and identifying gaps within the existing body of knowledge (Snyder, 2019). Furthermore, text-mining techniques were applied as an analytical tool to process large volumes of textual data, facilitating the extraction of meaningful patterns, relationships, and thematic structures. The reviewed literature and associated sources are organized and presented in the following sections of this paper.

## RESULTS AND DISCUSSIONS

### Pathogen Dynamics in Cereal Cropping Systems

Many previous studies indicate that tillage practices, cultivation technology, fertilisation levels, and cultivar selection influence the incidence of fungal diseases in cereals (Elen, 2003; Korbas et al., 2008; Horoszkiewicz-Janka et al., 2012; Cotuna et al., 2013; Paraschivu et al., 2021, 2022; Różewicz et al., 2021; Richard et al., 2022; Chețan et al., 2025). Nevertheless, the prevalence of these pathogens is determined mainly by weather conditions throughout plant growth and development (Cotuna et al., 2018; Paraschivu et al., 2017, 2019; Miedaner & Juroszek, 2021; Asfew & Bedemo, 2022; Ahmad et al., 2024; Rubayet & Hossaint, 2024). In many production regions, disease pressure is intensifying due to warmer temperatures, irregular rainfall patterns, changing cropping systems, and the expansion of pathogen dispersal routes through trade and atmospheric movement (Różewicz et al., 2021; Velea et al., 2021).

Rust fungi in wheat (stem rust - *Puccinia graminis* f. sp. *tritici*, leaf rust -*Puccinia triticina* and stripe rust - *Puccinia striiformis* f. sp. *tritici*) are among the most destructive pathogens of cereals worldwide. These obligate biotrophic fungi can spread rapidly over long distances through airborne urediniospores and may cause severe yield losses when susceptible cultivars are grown. Cool to moderate temperatures and prolonged leaf wetness typically favour stripe rust, whereas leaf rust often develops under mild temperatures with intermittent moisture. Stem rust generally thrives under warmer conditions and can become highly aggressive when night time humidity supports infection. Recent studies indicate that climate change may shift the geographic suitability of rust diseases and alter the effectiveness of host resistance genes (Juroszek & von Tiedemann, 2013).

Fusarium species, especially *Fusarium graminearum* and related taxa, are major pathogens of wheat, barley, and maize. In small grains, they cause Fusarium head blight (FHB), while in maize they are associated with ear and stalk rots. Beyond yield reduction, Fusarium diseases are particularly important because they contaminate grain with mycotoxins such as deoxynivalenol and zearalenone, creating serious food and feed safety risks. Epidemics are strongly linked to humid weather during flowering, frequent rainfall, and warm temperatures that favor spore production and infection (Cotuna et al., 2022). Crop residues from maize or cereals also serve as major inoculum reservoirs, making reduced tillage and cereal-intensive rotations important risk factors. In several European regions, recent weather extremes have further emphasized the interaction between local microclimate and Fusarium contamination patterns (Różewicz et al., 2021; Cotuna et al., 2022; Martínez et al., 2022).

Leaf blotch diseases caused by *Zymoseptoria tritici* (Septoria tritici blotch), *Parastagonosporanodorum*, and *Pyrenophora tritici-repentis* (tan spot) are major constraints in temperate cereal systems. These pathogens survive on infected crop residues and initiate new epidemics through splash-dispersed spores. Their development is promoted by extended periods of leaf wetness, dense crop canopies, moderate temperatures, and frequent rainfall events (Downie et al., 2021; Prahl et al., 2023). Conservation tillage practices, while beneficial for soil health, may increase residue persistence and therefore early-season inoculum pressure when rotations are narrow.

Because these diseases often begin in lower canopy leaves before progressing upward, they are strongly influenced by canopy microclimate and crop architecture (Laribi et al., 2024).

Powdery mildew, caused by *Blumeria graminis* formae speciales, affects wheat, barley, and other cereals globally. Unlike many foliar pathogens, powdery mildew does not require free water for infection and frequently develops under high relative humidity combined with moderate temperatures. Dense stands, excessive nitrogen fertilization, and prolonged periods of humid air circulation within the canopy can accelerate epidemic development (Różewicz et al., 2021; Farda et al., 2026).

Consequently, understanding the major cereal pathogens and the environmental factors that drive epidemics has become a priority for sustainable crop protection.

**Spatial and Temporal Characteristics of Disease Spreadand Implications of Environmental Monitoring**

The epidemiology of cereal diseases is inherently dynamic, as infection processes evolve across space and time in response to host phenology, pathogen biology, agronomic practices, and environmental variability. Thus, pathogens in cereal crops are typically distributed unevenly within fields, generating clusters, gradients, or patchy infection zones rather than homogeneous disease incidence. heterogeneity reflects variation in soil properties, topography, moisture retention, plant density, nutrient availability, and the proximity of primary inoculum sources. Residue-borne pathogens such as *Zymoseptoria tritici*, *Pyrenophora tritici-repentis*, and *Parastagonosporanodorum* are often established near infected residues, from which disease expands progressively through splash dispersal and short-range spore movement (Petit-Houdenot et al., 2021). By contrast, airborne pathogens such as rust fungi (*Puccinia* spp.) may initially appear in scattered hotspots before rapidly colonizing large areas under favourable atmospheric conditions (Radici et al., 2022; Hovmøller et al., 2023). Recent geostatistical studies have demonstrated that spatial autocorrelation of disease intensity can be used to identify infection hotspots and optimize sampling strategies in cereal fields (Amoghavarsha et al., 2022; Mergenthaler et al., 2022; Singh et al., 2023).

The temporal development of cereal diseases is closely linked to crop growth stage and seasonal weather patterns. Many pathogens require specific host tissues or phenological stages to complete infection successfully. For example, Fusarium head blight risk increases markedly during anthesis and early grain filling when spikes are highly susceptible, particularly under humid and warm conditions. Stripe rust epidemics may accelerate during cool and moist spring periods, whereas powdery mildew often develops earlier in the season under moderate temperatures and high relative humidity.

Disease progress over time is frequently described by sigmoidal epidemic curves characterized by an initial latent phase, exponential increase, and saturation stage (Chandran et al., 2025). The duration of each phase depends on inoculum availability, host susceptibility and environmental conduciveness (Dhavale et al., 2025). Shortened latent periods under optimal temperature and moisture conditions can lead to explosive epidemic growth, while intermittent drought or heat stress may suppress some pathogens but predispose plants to others. Consequently, accurate timing of disease risk is as important as identifying where disease occurs.

Disease spread in cereals occurs across multiple spatial scales, from individual leaves to continental regions (Gutaker & Purugganan, 2024). At the field scale, splash dispersal, contact transmission, and short-distance wind movement drive local spread (Karisto et al., 2022). At the landscape scale, crop mosaics, field connectivity, alternate hosts, and topographic corridors influence epidemic connectivity among farms (Fernandes et al., 2022). At regional and transboundary scales, long-distance atmospheric transport can move rust spores hundreds or thousands of kilometers, while seed trade may introduce emerging pathogens such as wheat blast into new production areas.

These scale-dependent processes have important management implications. Local outbreaks may be controlled through field-level interventions, whereas highly mobile pathogens require coordinated surveillance networks and

regional forecasting systems. Integrating multi-scale epidemiological knowledge is therefore critical for resilient cereal disease management.

**UAV-Based Technologies for Pathogen Detection**

Recent advances in remote sensing and geospatial analytics have expanded the capacity to monitor cereal diseases spatially. Unmanned aerial vehicles (UAVs), satellite imagery, and proximal sensors can detect changes in canopy reflectance, temperature, and structural traits associated with disease stress. When linked with geographic information systems (GIS), these observations can be transformed into disease distribution maps, hotspot analyses, and spatial decision-support layers.

Traditional detection methods - field scouting and laboratory diagnostics - often fail to identify outbreaks at early, asymptomatic stages when interventions are most effective. Conventional ground-based sampling provides limited spatial coverage and is temporally discontinuous, yielding insufficient insight into pathogen dispersion across heterogeneous agricultural landscapes (West & Kimber, 2015). While satellite remote sensing offers broad coverage, its utility for early, localized disease detection is constrained by fixed revisit intervals, coarse spatial resolution, and susceptibility to cloud cover.

Unmanned aerial vehicles (UAVs) bridge the observational gap between satellite and ground-based sensing by enabling rapid, repeated, high-resolution monitoring of crop canopies at user-defined temporal windows. Drones equipped with multi-modal sensor payloads can detect pre-symptomatic stress signatures invisible to the naked eye, with advantages including flexible deployment, comparatively low operational cost, and the capacity to acquire multi-sensor data (visual, spectral, thermal) at sub-centimeter resolutions unattainable by satellite platforms (Joshi et al., 2024; Xing et al., 2026).

However, most current UAV applications in agricultural phytopathology detect indirect disease signatures - spectral anomalies, canopy temperature deviations - rather than causal organisms directly. These responses are frequently non-specific, as similar patterns may arise from drought, nutrient deficiency, or thermal injury (Su et al., 2018). Molecular detection approaches (e.g., UAV-mounted spore traps for downstream DNA analysis) offer definitive identification but remain experimental, constrained by payload limitations and the absence of standardized airborne bioaerosol collection protocols (West & Kimber, 2015). These considerations position UAV-based monitoring as a critical component within a multi-layered surveillance architecture integrating aerial screening, geospatial risk modeling, and targeted ground-truth validation.

**UAV Platforms and Sensor Types**

Platform selection for cereal disease monitoring is governed by four interrelated constraints: area coverage per sortie, payload capacity, aerodynamic stability under field wind conditions, and operational simplicity for routine deployment. Three airframe categories are relevant:

**Fixed-wing UAVs** offer superior endurance (45-90 min) and area coverage for landscape-scale screening of large contiguous fields, though they require launch infrastructure and cannot hover for close inspection (Tsouros et al., 2019) (Table 1). **Multi-rotor UAVs** (quadcopters, hexacopters) provide vertical take-off/landing, precise hovering and ground sampling distances below 1 cm, making them ideal for repeated diagnostics over fragmented parcels, but endurance is limited to 20-40 minutes (Agrawal & Arafat, 2024). **Hybrid VTOL fixed-wing systems** combine deployment flexibility with cruise efficiency, increasingly relevant for operational monitoring networks with mixed field geometry (Joshi et al., 2024).

Sensor choice determines the detectable signal domain. **RGB cameras** are the most accessible, supporting canopy coverage metrics and texture-based ML classification, but lack sensitivity to early biochemical changes. **Multispectral sensors** (NIR and red-edge bands) represent the operational core of farm-scale monitoring, enabling vegetation index computation linked to chlorophyll dynamics and stress detection (Su et al., 2018). **Hyperspectral sensors** provide dense spectral fingerprints capturing subtle pre-symptomatic biochemical shifts, but impose greater payload,

cost, and processing demands (Mahlein, 2016). **Thermal infrared cameras** map canopy temperature fields revealing disease-associated thermal anomalies, particularly when interpreted with meteorological context (Khanal et al., 2017; Liu et al., 2024). **LiDAR** complements spectral sensors by providing 3D canopy structure data (Joshi et al., 2024). Emerging **biological/environmental samplers** (spore traps, VOC detectors) offer definitive identification potential but remain experimental (West & Kimber, 2015).

Table 1. UAV platform classes and pathogen detection suitability for cereal systems

| UAV Class | Capabilities | Common Sensors | Detection Suitability |
|---|---|---|---|
| Micro/Mini Multi-rotor (<5 kg) | VTOL; 20-40 min; GSD <1 cm | RGB; compact multispectral; mini thermal | Plot-level diagnostics; limited area coverage |
| Small Multi-rotor (5-25 kg) | VTOL; 25-45 min; heavier payloads | Multispectral; hyperspectral; LiDAR; dual thermal-RGB | Field-scale multi-sensor missions |
| Small Fixed-wing (<25 kg) | 45-90 min; 200–500 ha/flight | Multispectral; RGB; compact hyperspectral | Landscape screening; lower spatial detail |
| Hybrid VTOL Fixed-wing | VTOL launch; cruise efficiency; 40-75 min | Multispectral; RGB; thermal | Operational networks; mixed geometry |

No single platform-sensor combination dominates all use cases; value is maximized when the sensor stack is fitted to the decision question - screening, risk ranking, or trigger for confirmatory sampling - while preserving measurement repeatability across campaigns.

**Vegetation Indices and Spectral Indicators**

Vegetation indices (VIs) transform multi-band reflectance into interpretable metrics of canopy physiology and serve as the primary screening tools in UAV-based disease monitoring. NDVI remains widely used due to simplicity and cross-study comparability, but exhibits well-documented saturation in dense cereal canopies during mid-to-late growth stages, limiting sensitivity to early physiological changes (Li et al., 2025). NDRE, exploiting the red-edge region (~700-750 nm), provides significantly improved responsiveness in medium-to-high biomass conditions and has been shown to outperform NDVI for detecting subtle chlorophyll degradation associated with rust and *Septoria* infections (Su et al., 2018). PRI captures short-term changes in photosynthetic light-use efficiency, offering complementary early-warning capability since biotic stress frequently affects photosystem function before structural damage is evident (Șulea et al., 2010; Mahlein, 2016).

Recent advances have introduced disease-specific indices with improved diagnostic precision. The Chlorophyll Absorption Ratio Index (CARI) isolates chlorophyll absorption effects while mitigating soil interference and canopy structural heterogeneity; models utilizing CARI have demonstrated substantial improvements over traditional RGB-based configurations for detecting early-stage fungal infections in cereals (Ali et al., 2025; Goluguri & Baik, 2026). Specialized narrow-band indices for specific pathosystems (e.g., rice blast, wheat rusts) have also shown classification accuracies exceeding 95% in controlled evaluations, significantly outperforming broad-band alternatives (Mahlein, 2016; Su et al., 2018). A fundamental limitation remains spectral ambiguity: similar VI decreases may result from water limitation, nutrient deficiency, thermal stress, or mixed interactions. State-of-the-art pipelines therefore combine spectral indices with texture descriptors, thermal signatures, phenological stage and meteorological context within multivariate ML frameworks to improve classification robustness (Su et al., 2018; Kavhu et al, 2021; Srivastava & Jain, 2025). However, temporal consistency - standardized radiometric calibration, acquisition timing, and preprocessing - is essential for reliable trend detection across campaigns.

**Data Acquisition and Processing Challenges**

The transition from research experiments to operational monitoring confronts several non-trivial challenges. At mission level, operators must negotiate trade-offs among spatial resolution, overlap, coverage, and flight duration within battery, weather, and regulatory constraints. Very high-resolution surveys (GSD < 1 cm) improve lesion detectability but dramatically increase data volume and processing burden. Radiometric consistency is a persistent challenge: illumination variability from solar angle changes and cloud transients, sensor drift, and wind-induced canopy

movement introduce errors degrading multi-temporal spectral comparability unless rigorous calibration using reflectance panels and atmospheric correction is applied (Fu et al., 2024).

Temporal acquisition strategy is critically important yet frequently under-optimized. Pathogen infection dynamics are driven by microclimate variables that change within hours; acquisitions that are too sparse or poorly timed may miss actionable disease development phases (Hossain et al., 2024; Kumar & Mukhopadhyay, 2025). The processing chain - orthomosaic generation, radiometric correction, feature extraction, model inference - can create substantial computational latency. Scalable deployment requires semi-automated pipelines, edge computing architectures, and clear quality-control checkpoints to reduce turnaround from days to hours. Supervised models require accurately labeled training data, but field annotation is labor-intensive and subject to inter-operator variability. Domain shift between cultivars, phenological stages, and regional conditions reduces model transferability without local recalibration (Kamilaris & Prenafeta-Boldú, 2018). Fragmented data formats and proprietary tools impede integration with GIS and decision support systems, necessitating community-accepted standards and interoperable workflows.

### Contribution to Environmental Engineering Applications

UAV-based pathogen monitoring supports spatially explicit, risk-informed intervention strategies that reduce the ecological footprint of crop protection. Conventional management relies on calendar-based uniform fungicide applications - inherently inefficient, applying chemicals where pressure may be negligible, accelerating resistance development, and increasing off-target environmental exposure. Spatially explicit risk maps from UAV observations enable site-specific interventions directed exclusively to zones exceeding action thresholds. Empirical studies demonstrate that integrating UAV and satellite remote sensing can substantially decrease agrochemical application volumes alongside measurable reductions in irrigation water usage without yield penalties (Xing et al., 2026). This precision approach is particularly impactful in heterogeneous landscapes where disease-conducive microenvironments are influenced by soil texture gradients, drainage infrastructure, and micro-topographic variation. UAV-derived products improve mechanistic understanding of soil–water–plant–pathogen interactions and, when integrated with GIS layers (parcel boundaries, DEMs, drainage networks), become actionable planning tools supporting environmental compliance and evolving IPM policy frameworks (Wolfert et al., 2017). Environmental value is maximized when UAV surveillance is embedded in a three-step loop: rapid aerial screening, spatial risk synthesis in GIS, and targeted confirmatory sampling before intervention escalation.

## GIS-BASED SPATIAL ANALYSIS AND RISK MAPPING

### GIS as a Core Tool for Disease Risk Assessment

Geographic Information Systems (GIS) have become a cornerstone of plant disease risk assessment, owing to their capacity to integrate, manage, and analyze heterogeneous spatial datasets across multiple spatial and temporal scales. In cereal cropping systems, GIS facilitates the seamless fusion of UAV-derived remote sensing products with soil properties, climatic variables, and topographic information, enabling a comprehensive representation of disease–environment interactions (Geldsetzer et al., 2023).

A major strength of GIS lies in its ability to harmonize datasets originating from diverse acquisition platforms and temporal resolutions. High-resolution UAV imagery can be accurately georeferenced and spatially aligned with ancillary datasets such as soil surveys, digital elevation models (DEMs), cadastral boundaries, and meteorological observations. This spatial coherence is essential for reliable disease risk modeling, as pathogen development is strongly influenced by fine-scale variability in moisture availability, temperature regimes, and terrain-induced microclimatic conditions (Zhu et al., 2024). Within GIS environments, spatial interpolation techniques - including inverse distance weighting (IDW), ordinary kriging, and regression kriging - are widely employed to

convert discrete disease observations or point-based environmental measurements into continuous disease risk surfaces. These interpolated layers support field-scale visualization of infection probability gradients and enable spatially explicit decision-making (Cressie, 1993; Haggag et al., 2023). Recent studies demonstrate that GIS-based integration improves model robustness by explicitly accounting for spatial autocorrelation and reducing uncertainty in disease risk estimation, particularly in heterogeneous cereal landscapes (Shafay et al., 2025).

**Critical assessment:**
**Advantages:** Integration of multi-source spatial data; high-resolution field-scale mapping; generation of continuous disease risk surfaces.
**Limitations:** Strong dependence on data density and quality; reliance on static datasets that may fail to capture rapid disease dynamics; limited representation of temporal variability.
**Improvement opportunities:** Integration of near-real-time data streams; adoption of spatio-temporal GIS modeling approaches; development of standardized workflows to enhance cross-regional transferability.

**Risk Mapping Techniques**
Disease risk mapping in GIS relies on a combination of deterministic, statistical, and decision-support techniques aimed at classifying, quantifying, and spatially delineating areas susceptible to pathogen outbreaks. Zoning and classification approaches are commonly used to categorize agricultural land into discrete risk classes (e.g., low, moderate, high) based on vegetation indices, environmental variables, and crop phenological stages (Ahmed & Yadav, 2023). These methods provide intuitive outputs that facilitate the interpretation of complex datasets and support operational decision-making at farm level. Multi-Criteria Decision Analysis (MCDA) has emerged as a prominent framework for integrating multiple disease risk factors into composite spatial indices. MCDA allows the explicit weighting of criteria such as temperature accumulation, relative humidity, canopy density, soil moisture, and topographic attributes, reflecting their relative influence on pathogen development. When implemented within a GIS environment, MCDA offers transparency, flexibility, and adaptability to different crops, pathogens, and agro-climatic contexts (Malczewski, 2006).
Beyond classification-based methods, spatial statistical techniques—including hotspot and cluster analysis—play a critical role in identifying localized zones of disease intensification. Indicators such as Moran's I and Getis–Ord Gi* statistics enable the detection of spatial dependence and statistically significant disease clusters, supporting early warning systems and targeted intervention strategies (Getis & Ord, 1992; Haggag et al., 2023). These approaches underpin the transition from uniform treatment practices toward precision disease management.

**Critical assessment:**
**Advantages:** Intuitive spatial outputs; MCDA enables structured integration of multiple risk factors; hotspot analysis identifies disease clusters.
**Limitations:** Classification thresholds are context-dependent; MCDA weighting schemes may introduce subjectivity; reliable statistical inference requires historical datasets.
**Improvement opportunities:** Hybrid MCDA frameworks incorporating machine learning-based weighting; dynamic risk classification schemes; explicit uncertainty quantification in risk maps.

**Integration with Land Reclamation and Surveying Data**
Integrating land reclamation and surveying datasets into GIS-based disease risk mapping substantially enhances the operational relevance of spatial analyses. Cadastral data provide legally defined parcel boundaries, ensuring alignment between disease risk maps and farm management units and facilitating the implementation of precision interventions at parcel scale (FAO, 2007).
Drainage infrastructure maps, land capability assessments, and soil reclamation records offer valuable insights into soil–water dynamics, which are critical determinants of pathogen proliferation in cereal cropping systems. Areas characterized by inadequate drainage, specific soil textures, or unfavorable microrelief conditions are frequently associated with

elevated disease pressure, particularly for fungal pathogens. Incorporating these datasets into GIS-based models improves explanatory capacity and enhances the accuracy of spatial risk predictions (Bielecka & Burek, 2019; Tsouros et al., 2019). Furthermore, the integration of surveying and land-use data supports site-specific intervention planning by linking disease risk zones to field accessibility, land-use constraints, and environmental protection areas. This capability is increasingly important in the context of sustainable land management, where disease control strategies must reconcile productivity goals with regulatory compliance and environmental protection requirements (Zhu et al., 2024).

**Critical assessment:**

**Advantages:** Alignment with farm management units; improved understanding of soil–water–disease interactions; support for precision interventions.

**Limitations:** Outdated or inconsistent cadastral and reclamation datasets; limited interoperability; uneven availability of high-resolution data.

**Improvement opportunities:** Digital modernization of cadastral systems; adoption of open geospatial standards; coupling with UAV-derived micro-topographic models.

**Epidemiological and Agro-Meteorological Models**

Epidemiological and agro-meteorological models constitute the traditional backbone of disease forecasting in cereal cropping systems, as they explicitly describe the interactions between pathogen development, host susceptibility, and environmental drivers. Weather-based disease forecasting models are typically driven by key meteorological variables such as air temperature, relative humidity, precipitation, leaf wetness duration, and wind dynamics, all of which exert a strong influence on pathogen life cycles, infection efficiency, and dispersal mechanisms (Misra et al., 2020; Sangeetha et al., 2025).

Classical agro-meteorological approaches rely on threshold-based or cumulative indicators, including degree-day accumulation, prolonged canopy wetness, and specific temperature–humidity combinations favorable to infection (González-Domínguez et al., 2023). These models have been widely applied to major cereal diseases, such as rusts, fusarium head blight, and leaf blotch complexes, offering early warning capabilities that support timely disease management decisions.

The principal advantage of epidemiological models lies in their biological interpretability and relatively modest data requirements, as they can operate using standard meteorological observations or gridded climate datasets (Rahman et al., 2023). Their mechanistic foundation facilitates transparency and acceptance among agronomists and land managers. However, these models often rely on simplified assumptions regarding host uniformity and pathogen behavior, and they may insufficiently represent spatial heterogeneity at field scale. Furthermore, their predictive performance may decrease under conditions of increasing climate variability or when applied outside the agro-ecological contexts for which they were originally calibrated (Martínez-Cadena et al., 2026).

Recent research emphasizes the integration of agro-meteorological models with GIS-based spatial layers to improve spatial resolution and contextual relevance (Chandel, 2025; Rawat et al., 2026). Nevertheless, the inherent limitations of purely mechanistic approaches highlight the need for complementary data-driven and hybrid modeling strategies.

**Critical assessment:**

**Advantages:** Biologically interpretable; low computational requirements; effective for early warning.

**Limitations:** Limited spatial resolution; simplified disease dynamics; reduced robustness under climate variability.

**Improvement opportunities:** Spatial downscaling through GIS; hybridization with data-driven models; incorporation of microclimate variability.

**Machine Learning and Artificial Intelligence Approaches**

Machine learning (ML) and artificial intelligence (AI) approaches have gained increasing prominence in crop disease forecasting due to their capacity to capture complex, non-linear relationships among environmental variables, crop conditions, and pathogen dynamics (Tammina et al., 2024;

Basu & Narayan, 2025). Supervised learning techniques - such as random forests, support vector machines, artificial neural networks, and gradient boosting algorithms - are commonly employed to predict disease occurrence, severity, or risk classes using labeled datasets (González-Rodríguez et al., 2024; Ajaharuddin et al., 2025).

Unsupervised learning methods, including clustering and dimensionality reduction techniques, are used to identify latent patterns in multi-source datasets, enabling the detection of emerging disease hotspots or anomalous crop stress signals without requiring extensive ground truth data. These approaches are particularly valuable in exploratory analyses and in large-scale monitoring contexts.

A major strength of ML-based models lies in their ability to integrate high-dimensional inputs derived from UAV-based remote sensing and GIS layers. Spectral features extracted from multispectral and hyperspectral imagery, vegetation indices, canopy texture metrics, topographic attributes, soil parameters, and agro-meteorological variables can be jointly analyzed within unified modeling frameworks. This integration enables spatially explicit disease risk predictions that reflect both biophysical crop status and environmental constraints. Despite their strong predictive performance, ML and AI approaches face challenges related to data dependency, interpretability, and generalization. Model robustness is highly sensitive to data quality, temporal coverage, and representativeness, while limited transparency may hinder trust and adoption by end users. As a result, hybrid modeling paradigms that combine epidemiological knowledge with machine learning techniques are increasingly advocated as a means to balance interpretability and predictive accuracy.

**Critical assessment:**

**Advantages:** High predictive accuracy; effective integration of multi-source datasets; fine spatial resolution.

**Limitations:** Data-intensive; limited interpretability; risk of overfitting and reduced transferability.

**Improvement opportunities:** Explainable AI methods; hybrid epidemiological–ML frameworks; standardized datasets for model training and validation.

**Real-Time Decision Support Systems**

Real-time decision support systems (DSS) represent the operational layer of smart forecasting architectures, translating model outputs into actionable recommendations for agricultural risk management. In cereal cropping systems, these platforms increasingly rely on cloud-based infrastructures that enable continuous data ingestion, processing, and visualization from UAVs, ground sensors, meteorological services, and GIS databases.

A relevant operational reference for such architectures is provided by the decision support systems developed for Romanian national anti-hail protection networks. These systems were designed to support rapid operational decisions by integrating real-time meteorological observations, radar data, numerical weather prediction outputs, and spatial zoning information within centralized informatic platforms. Their primary objective was to assess the spatio-temporal evolution of convective hazards and to assist intervention decisions under strict temporal constraints (Șulea et al., 2010; 2011).

The core principles underpinning these anti-hail DSS - continuous data acquisition, real-time spatial analysis, threshold-based and probabilistic risk evaluation, and operator-oriented visualization - are directly applicable to pathogen risk management in agriculture. Similar to hail hazards, disease outbreaks are strongly influenced by short-term atmospheric dynamics, microclimatic variability, and spatial heterogeneity in land and crop conditions. When embedded within GIS environments, DSS can generate dynamic disease risk maps that evolve in response to changing environmental drivers.

Furthermore, the integration of Internet of Things (IoT) technologies enhances the temporal resolution of DSS by providing near-real-time measurements of microclimate parameters, soil moisture, and canopy conditions. When combined with UAV-derived indicators and forecasting models - whether epidemiological or machine learning-based - these systems enable adaptive risk assessments and early warning alerts tailored to specific

fields or management units. GIS acts as the spatial integration backbone, ensuring data consistency and enabling intuitive, map-based communication of risk levels.

Experience gained from operational anti-hail DSS demonstrates the feasibility and robustness of real-time, spatially explicit decision support under complex environmental conditions. However, extending these systems to crop disease management requires addressing challenges related to system scalability, data interoperability, and user accessibility. Simplified interfaces and automated workflows are essential to facilitate adoption by farmers and land managers while preserving the analytical rigor of the underlying models.

**Critical assessment:**

**Advantages:** Proven real-time operational capability; integration of meteorological forecasting and spatial analysis; transferable architecture for early warning systems.

**Limitations:** High system complexity; reliance on dense monitoring networks; need for specialized technical expertise.

**Improvement opportunities:** User-oriented DSS interfaces; tighter integration with UAV-based disease indicators; linkage with regional and national agricultural monitoring platforms.

## Implications for Policy and Precision Agriculture

GIS-based pathogen risk mapping has substantial implications for agricultural policy formulation and the adoption of precision agriculture practices. By delivering spatially explicit, risk-based assessments, integrated UAV-GIS systems support evidence-driven decision-making at both farm and policy levels. These tools enable optimized input allocation, reduced pesticide use, and the implementation of more sustainable crop protection strategies consistent with environmental engineering principles (Wolfert et al., 2017; Ahmed & Yadav, 2023).

At the policy level, spatial disease risk mapping aligns closely with European and global environmental monitoring initiatives, including the Common Agricultural Policy (CAP) and the Copernicus Earth Observation Programme. These frameworks prioritize digitalization, climate resilience, and data-driven land management as central pillars of modern agriculture. GIS-supported disease monitoring contributes directly to these objectives by providing scalable solutions for surveillance, early warning, and compliance monitoring across agricultural landscapes (European Commission, 2022; 2024).

Moreover, the integration of Earth Observation, GIS, and smart forecasting tools facilitates a shift toward risk-based land management, where interventions are guided by probabilistic spatial assessments rather than uniform prescriptions. This paradigm strengthens the role of geospatial intelligence as a critical interface between scientific innovation, environmental engineering, and agricultural governance in addressing challenges related to climate change, food security, and sustainable intensification.

**Critical assessment:**

**Advantages:** Enables risk-based management; enhances policy transparency; supports scalable and replicable monitoring frameworks.

**Limitations:** High technical complexity and implementation costs; lag between technological development and policy uptake; lack of standardized risk indicators.

**Improvement opportunities:** Development of policy-oriented GIS dashboards; incentives through CAP eco-schemes; harmonization of risk indicators aligned with EU and global standards (Table 2).

Table 2. Advantages, Limitations and Directions for Improvement

| Section | Key Advantages | Main Limitations | Future Directions / Improvements |
|---|---|---|---|
| 5.1 GIS as Core Tool | Multi-source data integration; high-resolution mapping; continuous risk surfaces | Data density & quality dependent; static datasets; limited temporal representation | Near-real-time data streams; spatio-temporal GIS models; standardized workflows |
| 5.2 Risk Mapping Techniques | Intuitive outputs; MCDA integrates multiple factors; hotspot analysis identifies clusters | Context-specific thresholds; subjective MCDA weighting; relies on historical data | Hybrid MCDA + ML weighting; dynamic risk classification; uncertainty quantification |
| 5.3 Integration with Surveying Data | Alignment with farm units; better soil–water–disease understanding; supports precision interventions | Outdated/inconsistent data; limited interoperability; non-uniform high-res data | Digital cadastral modernization; open geospatial standards; UAV micro-topography coupling |
| 9.3 Policy & Precision Ag | Supports risk-based management; policy transparency; scalable monitoring | Technical complexity; policy adoption lag; lack of standardized indicators | GIS dashboards for policy; CAP eco-scheme incentives; harmonized EU/global risk indicators |

## Challenges, Limitations, and Research Gaps

### Technical and Operational Constraints

Despite the promising experimental results surveyed above, several constraints limit the transition to large-scale deployment.

**Data throughput:** high-resolution UAV missions generate datasets of hundreds of GB per season; the sequential processing pipeline introduces substantial latency that may erode decision advantage during fast-spreading outbreaks.

**Acquisition consistency:** wind, illumination shifts, and battery limits introduce variability between campaigns unless strict QA/QC protocols and standardized SOPs are enforced (Su et al., 2018).

**Model transferability:** ML classifiers exhibit vulnerability to domain shift - a model trained on specific cultivar-climate conditions frequently degrades in new contexts without recalibration, requiring continuous local ground-truth annotation that restricts scalability (Kamilaris and Prenafeta-Boldú, 2018; Su et al., 2018).

**Economic barriers:** while standard RGB systems are cost-effective, transitioning to high-performance hyperspectral systems for early pre-symptomatic detection incurs substantially higher capital expenditure, creating accessibility barriers for smallholder operations (Agrawal and Arafat 2024, Xing et al., 2026).

**Regulatory constraints:** BVLOS operations essential for large-area coverage require special authorization, and fragmented frameworks across jurisdictions create planning uncertainty (Tsouros et al., 2019, Joshi et al., 2024).

**Interoperability:** proprietary formats, platform-specific tools, and non-standardized metadata schemas hinder integration with GIS and FMIS, constraining landscape-level environmental governance. The primary bottleneck is not sensing technology per se, but the absence of mature, standardized, low-friction operational pipelines.

### Future Perspectives and Opportunities

Recent Earth observation advances are strengthening pathogen risk mapping along three convergent axes. **Sensor miniaturization:** compact multispectral, hyperspectral, and thermal payloads with improved signal-to-noise ratios are enabling increasingly capable multi-modal sensor stacks on low-cost commercial platforms (Su et al., 2018; Agrawal & Arafat, 2024). Emerging modalities include fluorescence imaging sensors detecting chlorophyll fluorescence emission linked to photosystem II efficiency, which has demonstrated pre-symptomatic detection capability in high-value pathosystems (Mahlein, 2016; Zarco-Tejada et al., 2018).

**Temporal resolution:** autonomous mission scheduling, waypoint-based operations, and multi-UAV coordination enable more frequent revisits for tracking disease trajectories rather than relying on isolated snapshots. Integration with high-revisit satellite constellations (Sentinel-2, PlanetScope) and ground IoT networks creates multi-scale observation stacks improving monitoring continuity and gap-filling resilience (Xing et al., 2026).

**Processing architectures:** the shift to cloud-native and edge computing dramatically reduces acquisition-to-output latency. Edge processing on or near the UAV delivers preliminary risk assessments during or immediately after acquisition (Agrawal & Arafat, 2024).

Methodologically, the field is transitioning from static risk maps toward **dynamic risk-state estimation** using Bayesian updating, ensemble modeling, and data assimilation, providing uncertainty-aware probabilistic outputs that communicate confidence levels to decision-makers (Wolfert et al., 2017). Deep learning architectures (CNNs, vision transformers) demonstrate superior feature extraction from complex UAV imagery, while explainable AI (XAI) methods address interpretability requirements for operational trust and regulatory acceptance (Kamilaris & Prenafeta-Boldu, 2018). An emerging frontier is **digital twin systems** in which real-time observations continuously calibrate virtual crop models simulating disease dynamics under current and projected conditions, enabling scenario analysis and adaptive resource allocation. The convergence of better sensors, smarter processing, and more sophisticated analytics positions integrated UAV–GIS–forecasting systems for a qualitative leap in operational readiness over the coming decade.

## CONCLUSIONS

Major cereal pathogens remain highly responsive to environmental conditions, and their importance is expected to grow under ongoing climatic and agronomic change. Rusts, Fusarium diseases, residue-borne leaf blights, powdery mildew, and emerging threats such as wheat blast each respond to specific combinations of temperature, moisture, and management factors. A deeper understanding of these drivers is therefore essential for building resilient cereal production systems and designing next-generation phytosanitary strategies based on prevention, prediction, and precision management.

The spread of diseases in cereals is shaped by complex spatial and temporal processes that operate from leaf to landscape scales. Environmental monitoring provides a critical foundation for understanding and anticipating these processes, particularly when integrated with remote sensing, GIS, and predictive epidemiological models. Future phytosanitary strategies should therefore prioritize spatiotemporal intelligence and real-time decision support to improve sustainability, reduce unnecessary chemical inputs, and enhance resilience in cereal production systems.

The present study demonstrates that the integration of unmanned aerial vehicle (UAV) sensing, geographic information systems (GIS), and smart forecasting tools provides an effective framework for real-time pathogen risk mapping in cereal production systems. By combining high-resolution spatial observations with environmental monitoring and predictive epidemiological analytics, this approach enables earlier identification of disease-prone zones than conventionalm scouting methods and supports a more precise understanding of within-field disease dynamics.

The results highlight that pathogen risk in cereal fields is inherently heterogeneous and strongly influenced by interactions among crop status, microclimate, field variability, and short-term weather conditions. Consequently, static or calendar-based protection strategies are often insufficient to capture the rapidly changing nature of disease development. In contrast, dynamic risk maps generated from integrated digital datasets can improve the timing and spatial targeting of interventions, thereby increasing management efficiency and reducing unnecessary phytosanitary inputs.

The study also confirms that the value of UAV imagery is substantially enhanced when remote sensing outputs are interpreted together with GIS-based spatial layers and forecasting models rather than used as isolated diagnostic tools. This integrated perspective transforms crop observations into actionable intelligence, allowing farmers and advisors to move from reactive disease control toward anticipatory and preventive management. Despite these advances, several challenges remain for large-scale implementation. Model transferability across environments, sensor standardization, data interoperability, economic accessibility, and user-friendly interfaces will be critical for wider adoption. Future research should therefore focus on multi-season validation, incorporation of machine learning and pathogen-specific biological parameters, and the development of scalable platforms capable of operating across diverse cereal-growing regions.

Overall, real-time pathogen risk mapping represents a significant step toward next-generation cereal health management. The convergence of UAV technologies, geospatial analytics, and smart forecasting systems offers a practical pathway to more resilient, data-driven, and sustainable cereal production under current and future disease pressures.

## AKNOWLEDGEMENTS

The authors would like to thank all colleagues and collaborators who provided valuable discussions and support during the preparation of this review.We also thank colleagues from the Department of Agricultural and Forestry Technologies (Phytopathology) and the Department of Automatics and Electronics from University of Craiova for their valuable comments and discussions during the preparation of this review.

## USE OF GENERATIVE ARTIFICIAL INTELLIGENCE (GenAI)

The authors declare the use of Generative Artificial Intelligence (GenAI) tools in the preparation of this manuscript. GenAI was used exclusively for language editing and text refinement in the Introduction and Conclusions sections. All scientific content, data analysis, and interpretations were developed and verified by the authors.

***Abstract***

*This article examines the application of modern photogrammetric technologies for crop monitoring in the context of precision agriculture. Effective assessment of crop condition and spatial variability remains a critical challenge for improving productivity and optimizing resource use in large and heterogeneous agricultural areas. To address this issue, the proposed methodology employs unmanned aerial vehicles equipped with a high-resolution camera, combined with structure-from-motion photogrammetric processing, to generate detailed orthomosaics and crop surface models. Vegetation indices and canopy metrics are derived to support spatial analysis of crop vigour and growth patterns throughout the growing season. The study evaluates alfalfa fields located in the agricultural area surrounding Alba Iulia, employing UAV-based photogrammetry to quantify crop surface characteristics. The workflow generated a high-density point cloud and a high-precision 3D surface model, enabling detailed assessment of canopy structure and health and spatial variability. The results provide the basis for monitoring crop condition, support future analysis of field parameters, and demonstrate that photogrammetric products enable timely and accurate detection of stress conditions, biomass variability, and development anomalies at field scale. The study confirms that modern photogrammetric techniques provide a reliable, cost-effective, and scalable solution for supporting data-driven decision-making in crop monitoring and management.*

***Key words***: *crop monitoring, photogrammetry, precision agriculture, unmanned aerial vehicles, vegetation indices.*

## INTRODUCTION

The field of global agriculture is currently facing some significant challenges, which are, first of all, due to increasing climate changes. These challenges include extreme weather, such as droughts, and pests that are affecting more than half of farmland (FAO, 2017). Besides these challenges, there are also degradation factors, like soil degradation, which is affecting a significant part of the land (FAO, 2017). Also, other significant challenges must be considered, including but not limited to water scarcity and, therefore, the rising input costs. These factors pose a threat to food security, worsening the economic instability, and it is required the implementation of urgent, sustainable, and technologically innovative farming solutions to support a growing global population. Climatic events, such as floods and droughts, may be the causal factors for crop production disruption. Furthermore, a significant part of agricultural land is subject to severe soil degradation, declining the productivity. The rapid depletion of natural resources, including water shortages for irrigation, can reduce long-term viability. The necessity to nourish a growing population correlated with diminishing land availability for agriculture is exerting considerable pressure on global food systems (FAO, 2017). Geopolitical tensions and recurring logistical constraints, such as maritime grain export disruptions or rising energy and fuel prices (International Food Federation, 2025) have, in recent years, placed additional pressure on the stability of food distribution systems. Addressing these challenges is not straightforward and typically involves a gradual shift away from purely conventional agricultural practices toward more sustainable approaches, such as agroecology and climate-smart agriculture, combined with the selective adoption of modern technologies aimed at improving system resilience (FAO, 2017).

Against this background, precision agriculture has attracted increasing interest within the agricultural sector. In general terms, the

concept refers to a data-informed approach to farm management that makes use of technologies including GNSS positioning, environmental sensors, unmanned aerial vehicles, and artificial intelligence. Used appropriately, these tools allow continuous monitoring and support more targeted responses to variability both within individual fields and across different fields. This management approach is characterized by a transition from a uniform, large-scale application to a precise, site-specific management strategy. This strategy enhances efficiency, sustainability, and profit. The following elements constitute the fundamental components of the precision agriculture paradigm (Todmal, 2023; Gulaiya et al., 2024):

- The collection is to be undertaken using a variety of methods, including GNSS, GIS, photogrammetry, remote sensing (via drones and satellites), and soil sensors. The purpose of this data collection is to obtain information on soil moisture, nutrient levels, and crop health.
- The data analysis is conducted through the assessment of yield maps and spatial variability data, with the objective of identifying areas of underperformance or specific, localized needs.
- Variable rate technology involves the use of automated equipment for the application of fertilizers, pesticides and water at varying rates across a field, with the objective of customizing the application to specific requirements as opposed to employing a uniform, average rate.
- The implementation of guidance systems, utilizing GPS-enabled machinery in tasks such as planting and spraying, has been demonstrated to reduce overlap, leading to significant savings in fuel and resources.

Conventional field scouting and photogrammetric monitoring both have distinct, often complementary limitations. Whilst field scouting is constrained by human labour and time, photogrammetric monitoring using UAVs is restricted by environmental, technical and data processing bottlenecks. Conventional, manual scouting involves physical inspection by professionals, which introduces several limitations: the processes under discussion are characterized by their labour intensity and time consumption, the presence of subjectivity and human error, their limited spatial coverage, physical inaccessibility, and delayed action. On the other hand, photogrammetry, the process of creating 3D models and orthophotos from drone images, provides high-resolution data, but is also subject to several limitations: the factors to be considered include weather and lighting dependency, visibility and occlusion issues, textureless/uniform surfaces, data processing bottlenecks, reduced vertical accuracy, regulatory and skill barriers. In order to address these issues, contemporary agriculture practices frequently employ a combination of both approaches, leveraging photogrammetry to identify areas of concern and subsequently conducting targeted, ground-based manual verification (Kalischuk et al., 2019; Amarasingam et al., 2022).

Photogrammetric technologies are increasingly used in agriculture, most often through aerial imagery collected by unmanned aerial vehicles (UAVs). The resulting products - such as three-dimensional models, orthomosaics, and elevation data - provide valuable spatial information that supports the adoption of precision farming practices. In current applications, these tools contribute to high-throughput phenotyping, crop condition assessment (frequently based on vegetation indices such as NDVI or other multispectral datasets), as well as to the early identification of pest presence and the optimization of irrigation management. This way, targeted resource application is enabled. There are some technologies of particular significance: unmanned aerial vehicles (UAVs), specialized software and artificial intelligence (AI). These technologies provide detailed, actionable insights within a time frame, usually of several hours, which represent an important advantage in crop security (Delgado Vera et al., 2017; Turlea et al., 2023; Dreghici et al., 2024).

There should be mentioned the following key applications in the agriculture field (Delgado Vera et al., 2017; Sakthivel et al., 2025):

- Crop monitoring and health assessment, by using photogrammetry for the detection of pest attacks, water stress and nutrient deficiencies;
- 3D modelling and mapping, for the analysis of field variability, monitoring of growth patterns and the improvement of terrain management;

- Yield prediction and management, for the prediction of crop production and the optimization of fertilizer and pesticide input usage;
- Precision irrigation and drainage, for the identification of areas with poor drainage or water accumulation;
- Crop management, for the precise, non-destructive monitoring of crop structure and development throughout the season.

The technologies and tools considered in this context include several widely used solutions (Delgado Vera et al., 2017; Turlea et al., 2023; Sakthivel et al., 2025). Among them, unmanned aerial vehicles (UAVs), commonly referred to as drones and typically equipped with GNSS/GPS positioning systems, play an important role by enabling the acquisition of high-resolution imagery suitable for detailed mapping applications. Sensors, which may be multispectral, thermal or RGB, frequently utilised for the collection of data.

- Software, such as the photogrammetric software Agisoft MetaShape, used to process images into orthomosaics and 3D models.
- Artificial intelligence (AI) and machine learning integrated with photogrammetry, for automated analysis of field data.

UAVs represent a viable solution for high-resolution and cost-effective agricultural monitoring and management, being considered a significant advancement over traditional satellite, manned aircraft, and ground-based surveying methods. Unmanned aerial vehicles come with higher spatial resolution, usually at centimetre-level, this way bridging the gap between field-level measurements and satellite imagery. The usage of UAVs reduces time, labour, and financial overhead (typically associated with conventional manual scouting and manned aerial surveys) (Guebsi et al., 2024; Sreenatha et al., 2025).

Two principal research gaps emerge when applying photogrammetric technologies in the context of agricultural monitoring:

- The integration of three-dimensional photogrammetric products, such as crop height models, into routine crop monitoring is inadequate.
- A limited number of comparative studies have been conducted between photogrammetry-derived metrics and traditional agronomic measurements.

In this context, the objectives of the present study are as follows:

- To evaluate the applicability of photogrammetric technologies for the purpose of monitoring crop growth and condition;
- To assess the contribution of precision agriculture in case of decision-making processes;
- To highlight the contribution of photogrammetry in agriculture and its support for the shift toward modern, digital, and sustainable farming, by producing photogrammetric outputs used for agricultural land evaluation and monitoring of land use changes.

## MATERIALS AND METHODS

The site chosen for the case study in this paper is located in the peri-urban area of Alba Iulia, in an agricultural area, predominantly used for cereal production. The area's accessibility and terrain with relatively uniform elevation render it conducive to UAV operations. The location has been determined to provide suitability for the application of modern crop monitoring technologies, allowing for efficient data collection with the equipment used. Certain figures and supporting materials used in this paper are adapted from, or were originally presented in, the bachelor's thesis by Pitton, G. (2025), "The use of modern technology in monitoring agricultural crops".

The topography of the studied area is characterised by its relative flatness, with gentle slopes and minimal altitude variations. These characteristics make the area suitable for photogrammetric flights and aerial image acquisition, as well as for generating high-precision 3D models and orthophotos. The soil type is chernozem and luvisol, which is specific to Alba County areas. These soils are moderately permeable and medium to highly fertile, characteristics that are favourable to cereal crops and vegetables.

### Data acquisition

The WingtraOne Gen II drone, used for the present purpose, is a technologically advanced aerial mapping equipment, specifically designed for professional applications in the field of land surveying, cadastral mapping,

agricultural monitoring, and environmental management. The flight platform, VTOL-type (Vertical Take Off and Landing) was designed to be robust and to use state-of-the-art technology. This means that it offers remarkable performance in terms of autonomy, accuracy and versatility for aerial photogrammetric applications. Integrating the advanced onboard avionics sensor suite, the autonomous and real-time stability flight-control architecture, and mission-optimized planning environment transformed this aerial platform into a comprehensive solution for the creation of high-resolution orthophotos and 3D models. The drone is equipped with a high-resolution camera, for optimal aerial images acquisition. A further significant feature of the WingtraOne Gen II drone is the incorporation of GNSS RTK/PPK system, which allows direct image georeferencing with high precision, minimising the requirement for a considerable number of ground control points (GCPs).

Mission planning is conducted utilising the dedicated WingtraPilot software, which facilitates precise configuration of flight parameters and optimisation of the trajectory to ensure an overlap that fulfils photogrammetry requirements.

The utilisation of this drone facilitated the effective collection of data essential for the monitoring of existing crops in the vicinity of Alba Iulia, thereby providing decision support in the analysis of agricultural crops and agricultural land management.

The planned flight route is configured to respond the specific terrain conditions, ensuring consistent coverage and data quality, as shown in Figure 1. In the present case study, the decision was taken to fly at a flight height of 120 metres. In order to obtain high-accuracy and high-resolution images, the GSD parameter was set relatively high, 3.2 cm/pixel, as recommended for the specified flight height. In addition, the controller interface provides information about the drone's anticipated flight trajectory, representing the total area to be covered, the status of connectivity with the GNSS signal, the number of satellites that are currently visible, and also the current battery level of the drone.

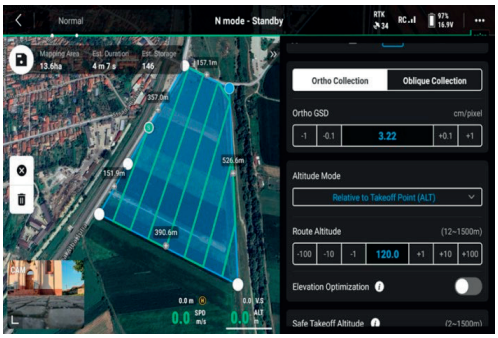

Figure 1. Flight plan

**Photogrammetric processing**

Upon completion of the flight session in the field and collection of the necessary data for this project, the subsequent stage would involve the transfer of all obtained data to a computer, with the objective of creating a 3D model of the terrain and an orthophoto map.

The Agisoft MetaShape program facilitates data processing through the provision of an integrated, efficient, and precise workflow, thereby ensuring the generation of high-quality geospatial products. The utilisation of this software within the project enabled the conversion of raw images captured by the drone into a series of photogrammetric materials that were conducive to the analysis of agricultural land. The high accuracy of the orthophoto map and the 3D model obtained provides a solid basis for decision-making in precision agriculture, considering the monitoring of crops and agricultural land.

The workflow comprised the following stages:

1. The process of image alignment entails the identification of the position and orientation of images, with the objective of constructing an initial point cloud based on the corresponding points between images, known as tie points. The geometric relationship between images is established through the comparison and overlaying of common features. In accordance with the aforementioned points, the program implements a global bundle adjustment. This adjustment constitutes a mathematical optimization that determines the position and orientation of each image in three-dimensional space. The outcome of this process is a relatively accurate reconstruction of the flight path - Figure 2.

In order to achieve optimal and precise results for the final products, it is imperative to filter the tie points from the previously created point cloud (Figure 3). This is due to the fact that numerous erroneous points will be identified during this process. The quality of subsequent photogrammetric products (i.e. dense point cloud, 3D model, orthophoto map) is contingent upon the quality of the initial list of connection points. Following the filtration of the tie points, it is imperative to utilise the "Optimize camera alignment" function. The purpose of this function is to enhance the precision of photogrammetric reconstruction, after the implementation of adjustments to the tie points.

2. The second fundamental stage of the workflow is the creation of a dense point cloud (Figure 4), using the image alignment results as input. in the present case study, the dense point cloud reconstruction was performed using the ultra-high-quality parameter and moderate depth filtering, selected to balance geometric accuracy with computational efficiency. Applying these settings, there was produced a detailed and spatially consistent dense point cloud, that served as the basis for the subsequent 3D surface model and orthophoto generation.

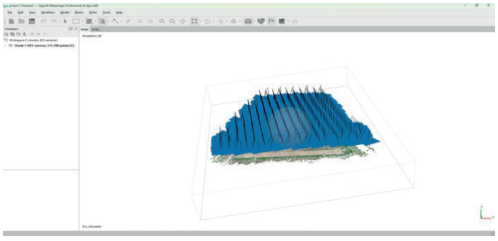

Figure 2. Aligned images along the flight path

The "reprojection error" criterion is another essential indicator of the quality of photo alignment and the accuracy of connection points. This criterion is used for assessing the precision of the reconstructed 3D points and whether they correspond to their projected positions in the source image. This way, the difference between the estimated position of a 3D point projected back onto the image and the actual position of that point detected in the photo is measured. The reprojection error is expressed in pixels. The errors are inversely proportional to accuracy: the smaller the error, the higher accuracy for the point. After this optimisation, the mean error should be reduced significantly, enhancing the project accuracy.

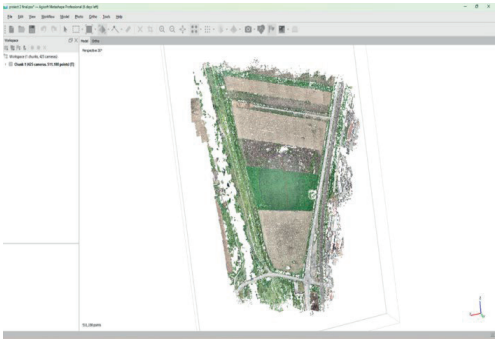

Figure 3. Point cloud

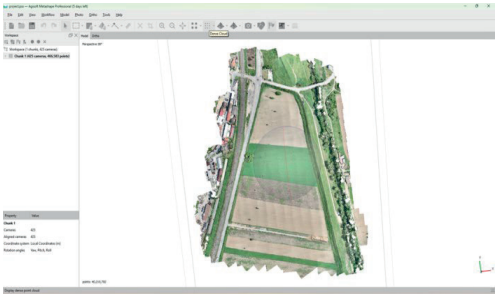

Figure 4. Dense point cloud

3. The third fundamental stage of the project is the creation of the mesh model. The mesh model is a three-dimensional reconstruction of the photographed surface, formed from a network of triangles (polygons) that connect the previously generated points. This stage is of critical importance in the photogrammetric process, as it is the foundation for obtaining a highly detailed model of the terrain or objects under consideration. Furthermore, it facilitates the application of textures and the subsequent measurement of various parameters. For mesh generation, the dense point cloud was used as the primary data source, with the surface type configured for three-dimensional reconstruction.

The "Face count" criterion in the mesh model construction window represents the estimated number of geometric faces that will make up the polygonal network of the 3D model. The

geometric intricacy of the model is directly proportional to the number of facets, but the processing time and hardware resources required increase exponentially.

4. The next stage of the workflow consisted of applying texture to the resulting 3D model in order to enhance its visual realism. The option "Diffuse map" is the type of texture applied to the generated surface of the 3D model to render the terrain colour and natural appearance. This texture is taken from the captured images during the flight. It is imperative to note that this option is essential for realistic rendering of the surface.

Given the approximately flat surface of the project, the decision was taken to utilise the 'Adaptive orthophoto' function, as this projects a texture similar to that of the orthophoto plan. This allows the algorithm to dynamically select the most suitable pixels from the source image set for texture projection onto the 3D model, thus avoiding perspective errors and distortions at the edges of the images.

In considering the objectives set for this project, the decision was taken to construct a tiled model, given the necessity to analyse the monitored crop area in detail. This model offers a more flexible and detailed representation of surfaces and is optimised for viewing 3D structures at different zoom levels and resolutions. The tiled model is based on a hierarchical organisation of spatial data, which allows for the efficient display of fine details such as soil textures, crop damage, uneven vegetation, or traces of agricultural mechanization. This is in contrast to the previously generated textured 3D model, which provides a global representation of the relief and surface, but with visible limitations in terms of close-up resolution. The tiled model facilitates detailed exploration without substantial loss of quality or extended loading times - Figure 5.

In the case of the initial textured 3D model, it was determined that the fine surface details, which are imperative for detailed crop analysis, were not adequately rendered. This was attributable to two factors: firstly, the resolution limitations inherent in the generated texture, and secondly, the methodology by which the visual information was applied to the model's surface. Texture has the capacity to "mask" reconstruction imperfections or to homogenise terrain features, thereby rendering it challenging to observe subtle yet significant discrepancies - Figure 6.

The tiled model has been structured into tiles, thereby enabling a smooth and detailed view of the entire studied area, regardless of the zoom level. In the context of our research, this is of crucial importance, as interpreting subtle variations in relief or vegetation structure can substantially contribute to the identification of affected areas, the monitoring of soil moisture, or the planning of agrotechnical work.

To facilitate a more profound comprehension of the subject, the tiled model is an approach that divides the total surface into a number of tiles. Each individual tile is processed and stored with its own geometry and texture data. It is evident that the greater the number of tiles, the smaller the area of each individual tile and the more triangles connecting points it can contain. In addition, a dedicated texture map at a higher resolution for each tile is required. Each tile is expressed in terms of dimensions in pixels; in this context, a tile size of 256 pixels was selected, the smallest possible selectable tile size.

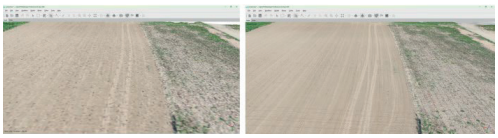

Figure 5. Resolution and detail quality for the textured 3D model at a very high zoom level (left) vs. Resolution and detail quality for the tiled model at the same zoom level (right)

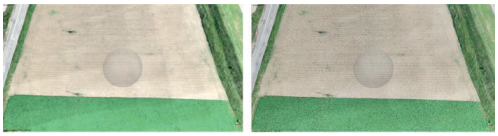

Figure 6. 3D model without texture (left) and with applied texture (right)

**Validation and analysis**

UAV photogrammetry offers a high-efficiency approach for deriving crop-height metrics, providing accuracy levels appropriate for validating the generated results. These methodologies yield 3D point clouds and Digital Surface Models (DSMs), which, upon

validation consisting of comparing the photogrammetric outputs with ground control points, furnish precise, spatially continuous measurements across entire plots. This approach circumvents the labour-intensive constraints inherent in conventional destructive sampling techniques (Bendig et al., 2014; Tang et al., 2021).
The resulting 3D model and orthophoto provided the spatial data used for subsequent assessment of crop condition patterns, identification of vegetation variability and weed affected zones.

## RESULTS AND DISCUSSIONS

### Photogrammetric outputs

The quality requirements for point clouds and surface models in agricultural monitoring are driven by the need to accurately measure plant structures, estimate biomass, and navigate machinery (Zhu et al., 2024). The photogrammetric processing produced a dense point cloud and 3D surface models with geometric accuracy suitable for field-scale crop assessment. The surface deviations are ranging from 0 to 9 mm, ensuring that canopy height estimates and spatial comparisons across the study area remained reliable. The final surface model exhibited centimetre level vertical precision, consistent with typical UAV-based agricultural monitoring requirements (Tomaštík et al., 2017; Zhu et al., 2024).
The digital terrain model (DTM) generated from the ground classified points provided a stable reference for isolating plant height. After applying statistical filtering to remove noise and non-ground artefacts, the DTM supported the computation of crop height values across the monitored area, capturing fine scale structural variability within the alfalfa canopy. This enables the identification of zones with reduced growth or irregular development.
Analysis of the dense point cloud and derived canopy height model revealed heterogenous vegetation patterns within the surveyed area.

### Crop monitoring performance

The results of the investigation are presented across three key areas of analysis: the spatial distribution of crop height and vigour; the identification of stress zones (water deficit, nutrient deficiency, and lodging); and the temporal changes observed across growth stages.
The identification of issues arising from the analysis:

- In the alfalfa crop, small gaps are visible in several areas of the plot (Figure 7). These gaps regions correspond to areas where plant life has been compromised.

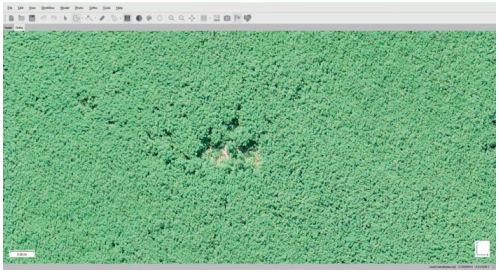

Figure 7. Gap areas in the alfalfa crop

- The second problem observed in the plots of land concerned is the weed infestation on the plot of land where a corn crop was recently sown. As illustrated in Figure 8 left, the areas exhibiting a high degree of weed infestation are delineated from the periphery of the plot towards its interior. The visual interpretation revealed the presence of weed infestation across the majority of the plot's surface, not merely in areas exhibiting a more pronounced green hue - Figure 8 right.

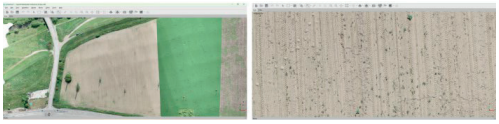

Figure 8. Areas with a high degree of weed infestation vs. weed infestation across the entire plot's surface

### Discussions

The results of the study demonstrate that UAV-based photogrammetry provides the level of spatial detail required for parcel-scale crop assessment. The centimetre-level accuracy achieved in the 3D reconstruction enabled the reliable extraction of canopy height patterns and the identification of localised anomalies within the alfalfa field. These capabilities directly support the detection of uneven vegetation growth and weed affected areas observed in the orthophoto and canopy height

model (Amarasingam et al., 2022; Pitton, 2025).

While the general advantages of UAV photogrammetry – high spatial resolution, flexible acquisition timing, and non-destructive monitoring- are well established, the present results confirm their practical relevance for the study area (Amarasingam et al., 2022; Pitton, 2025).

In particular, the ability to resolve fine-scale structural variability, which would not be detectable using satellite imagery, proved essential for interpreting field level conditions.

The findings also highlight the complementary role of UAV data within a broader monitoring framework, where satellite observations can guide the identification of zones of interest, and UAV surveys can provide the detailed structural information needed for targeted agronomic decisions (Guebsi et al., 2024; Pitton, 2025; Voss et al., 2025).

## CONCLUSIONS

Recent advances in geospatial technology have led to a significant transformation in how agricultural land is monitored, analysed and managed. This paper puts forward a contemporary approach to using drone-based aerial photogrammetric technologies to monitor crops and agricultural land. This method is recognised for providing accurate, georeferenced data quickly, and it is also transforming the traditional approach to managing agricultural land (Enemark, 2007). The results show that photogrammetric products, including 3D models and orthophotos, allow detailed assessment of crop conditions, supporting the identification of stress factors such as diseases, pests, and water deficits. In addition, the approach proves effective for precise parcel delineation, contributing to land use updates.

The study also confirms the practical value of UAV-based photogrammetric data in agricultural management, including reliable are estimation, productivity assessment, and documentation support for subsidy applications. Furthermore, 3D terrain and surface models enhance the understanding of land characteristics, supporting better land management.

Overall, the purposed approach contributes to improving efficiency, resource optimization, and non-invasive monitoring in agriculture. However, its application remains constrained by factors such as limited flight duration, weather dependence, and the need for technical expertise.

In conclusion, UAV-based photogrammetry represents a reliable and versatile tool for modern agriculture, offering significant benefits for crop monitoring, land management, and decision support.

***Abstract***

*Rapid urbanization alters the thermal environment of cities, leading to the urban heat island effect. Because fixed meteorological stations cannot adequately capture high-resolution intra-urban microclimate variability, mobile monitoring has emerged as an essential complementary approach. This exploratory pilot study evaluated the utility of high-resolution mobile measurements for capturing winter microclimatic signatures along a regional transect in South-Eastern Romania, encompassing small and medium-sized urban hubs. Data were collected on February 10, 2026, under stable atmospheric conditions, using a vehicle-mounted weather station equipped with a radiation error correction system. To ensure scientific integrity, a three-stage quality control and normalization workflow was implemented. This included excluding data points recorded at speeds below 10 km/h to prevent thermal contamination, applying an altitude correction to a common reference level, and performing a time-drift correction based on official meteorological stations to isolate the spatial microclimatic signal. The spatially dense mobile data effectively identified critical thermal gradients and specific urban footprints. In conclusion, the study highlighted the value of mobile monitoring as a viable tool for assessing microclimatic spatial variations, providing detailed insights into urban-rural thermal contrasts during the cold season.*

***Key words:*** *altitude correction, Meteotracker, mobile measurements, temperature gradient, urban microclimate, urban-rural contrast.*

## INTRODUCTION

Rapid urbanization and significant land-use modifications have profoundly altered the thermal environment of cities, leading to the well-documented Urban Heat Island (UHI) effect (Oke, 1982). The canopy layer (CUHI), characterized by higher air temperatures in urbanized areas compared to their rural surroundings, poses severe challenges to urban variability of urban microclimates is critical for developing effective mitigation and adaptation strategies.

Traditionally, the assessment of urban thermal environments has relied on fixed meteorological sustainability, energy consumption, and human thermal comfort (Santamouris, 2015; Li et al., 2024). Urban overheating may significantly reduce climate resilience and increase thermal exposure risks for urban populations under future climate scenarios (Emmanuel & Krüger, 2012). As extreme weather events and heatwaves become more frequent, understanding the fine-scale spatial and temporal

stations. While these stations provide reliable, long-term synoptic data, their sparse spatial distribution makes them inadequate for capturing high-resolution intra-urban microclimate variability and the sharp

temperature gradients at urban-rural boundaries (Stewart & Oke, 2012; Martinez-Soto et al., 2025). Furthermore, previous studies demonstrated that urban-rural thermal contrasts are strongly influenced by land use and surface characteristics (Hart & Sailor, 2009). To address this spatial data gap, mobile monitoring has emerged as a robust complementary approach (Romero Rodríguez et al., 2020; Kousis et al., 2021; 2022; Martinez-Soto et al., 2025). Vehicle-based mobile measurements act as itinerant sensors, enabling the continuous recording of meteorological parameters across diverse land-cover types and topographical profiles within a short timeframe. Such approaches have been successfully applied to investigate fine-scale canopy layer thermal variability and spatial urban heat patterns (Brandsma & Wolters, 2012). Urban morphology, vegetation cover, and street geometry may substantially modify local thermal conditions and microclimatic variability at neighborhood scale (Middel et al., 2014).

Despite its advantages, mobile monitoring introduces challenges, primarily the "radiative error" caused by solar radiation heating the sensors at varying speeds. Recent technological advancements have led to the development of compact mobile sensors, such as the MeteoTracker (Barbano et al., 2024), which deploys a patented dual-sensor Radiation Error Correction System (RECS) (Jurato, 2020; MeteoTracker, 2025). This system ensures high-accuracy thermal measurements even under strong solar exposure, making it highly suitable for high-resolution investigations.

In Romania, recent studies have begun to map the UHI in major cities like Iași (Sfîcă et al., 2018; 2023), yet multi-city comparative transects investigating the thermal gradients between smaller urban hubs and rural plains remain scarce (Ichim et al., 2024). This is particularly true for winter conditions, which are often overlooked in favor of summer stress studies (Crétat et al., 2024), despite the important role of nighttime urban thermal retention under stable atmospheric conditions (Eliasson, 1996).

Therefore, this study is designed as an exploratory pilot study aiming to evaluate the interpretative value of high-resolution mobile surveys during a single winter day in South-Eastern Romania. The measurement date, 10 February 2026, was selected because it was characterized by stable winter atmospheric conditions, weak wind, absence of precipitation, and limited synoptic variability, which are favorable for identifying spatial thermal contrasts between different land-use environments. By utilizing the MeteoTracker sensor on a complex transect intersecting Focșani, Râmnicu Sărat, Buzău, Ianca, Brăila, and Galați, this paper explores the potential of spatially dense mobile data to capture fine-scale microclimatic signatures (Chàfer et al., 2022). The aim of the study was not to provide a climatological assessment of the winter urban heat island, but to test whether mobile monitoring can identify localized thermal gradients and urban footprints during suitable atmospheric conditions. While recognizing the temporal limitations of a single-day measurement, the study emphasizes the spatial richness of the data as a tool for identifying critical thermal gradients in Urban, Rural, and Road environments. In addition, high-resolution spatial observations provide valuable support for understanding local thermal variability and improving urban climate assessment methodologies (Voogt & Oke, 2003).

Satellite-derived Land Surface Temperature (LST) may complement mobile air temperature measurements by describing surface thermal patterns. However, LST refers to the land surface, while this study analyzes near-surface air temperature measured at road level. For this reason, Landsat-derived LST was not included in the present quantitative analysis, but it should be considered in future studies.

## MATERIALS AND METHODS

### Study Area and Meteorological Context

The study area spans a complex regional transect in South-Eastern Romania, covering a diverse topographical and land-use profile. The mobile survey originated in the rural area of Slobozia Conachi (Galați County) and intersected several urban hubs of varying sizes: Focșani, Râmnicu Sărat, Buzău, Ianca, Brăila, and Galați (see Figure 2). Mobile measurements are recognized for their ability to capture high-resolution spatial variability that fixed station networks often miss

(Kousis et al., 2022; Martinez-Soto et al., 2025). To establish a synoptic baseline, air temperature data from the official National Meteorological Administration (ANM) stations WMO-15310 (Galați) and WMO-15350 (Buzău) were used to compensate for the temporal drift of the mobile measurements during the transect survey (*Meteo Buzău, 10.02.2026*, 2026; *Meteo Galaţi, 10.02.2026*, 2026). The reference meteorological data consisted of hourly air temperature observations recorded at the two WMO stations during the mobile survey interval. These hourly values were linearly interpolated to the timestamp of each mobile measurement and then averaged in order to obtain a regional temperature trend used for temporal normalization. The Galați and Buzău stations were selected because they were the most relevant official meteorological stations located near the main monitored sectors of the transects and provided representative information for the regional air mass evolution during the survey. Additional stations were not included because they were either farther from the monitored routes or less representative for the spatial domain covered by the mobile measurements. Therefore, the two-station approach was used only for correcting the temporal drift of the mobile observations, not for replacing the high-resolution spatial information provided by the mobile survey.

Figure 1 illustrates the air temperature evolution recorded at the Galați and Buzău WMO stations on 10 February 2026, highlighting stable winter atmospheric conditions and a gradual daytime warming trend during the survey period.

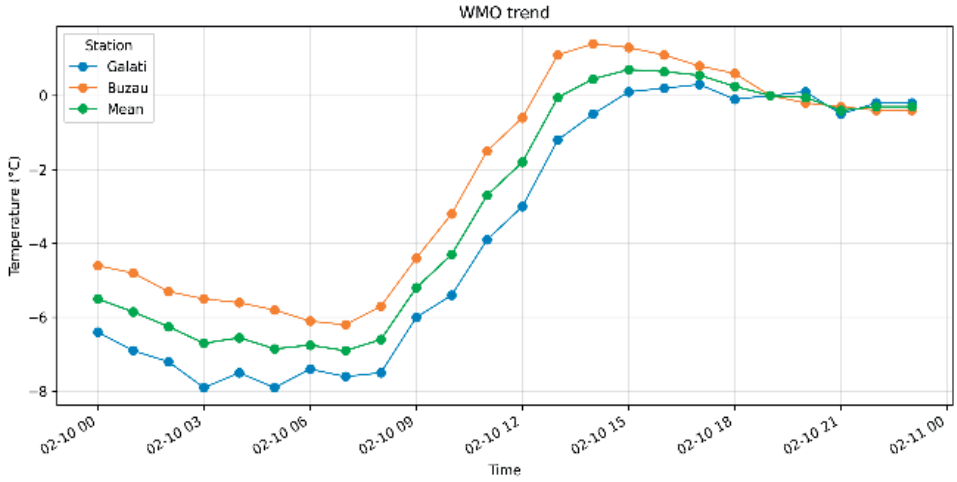

Figure 1.Temporal evolution of air temperature recorded at the WMO reference stations during the mobile survey. The blue line represents the Galați station (WMO-15310), the orange line represents the Buzău station (WMO-15350), and the green line indicates the mean regional temperature trend used for temporal normalization of the mobile measurements (Meteo Buzău, 10.02.2026, 2026; Meteo Galaţi, 10.02.2026, 2026)

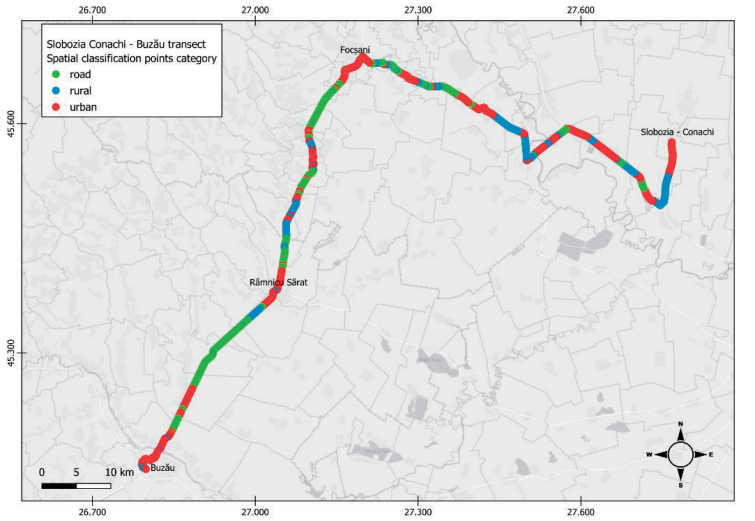
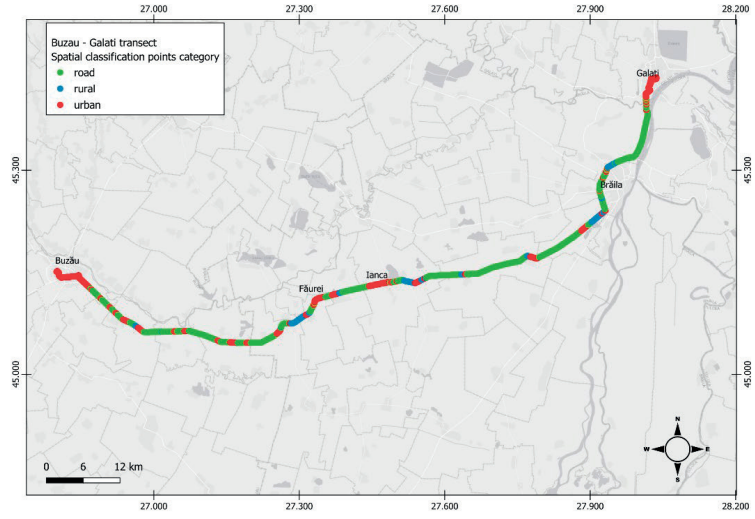
These hourly reference data provided the regional synoptic background and were used for the temporal normalization of the mobile measurements. The hourly observations were interpolated to the exact time of each mobile record, and the mean trend of the two WMO stations was used to correct the mobile temperature values for the natural daytime thermal evolution.



The measurements were conducted on 10 February 2026 in eastern Romania along two regional mobile transects between Slobozia Conachi-Buzău and Buzău-Galați (Figure 2), under stable winter atmospheric conditions favorable for the identification of microclimatic gradients and urban heat island (UHI) signatures (Crétat et al., 2024; Li et al., 2024). Data extracted from the official WMO stations in Galați and Buzău confirmed the persistence of these stable atmospheric conditions throughout the survey period (10:00-18:00 LT), characterized by weak wind speeds (generally 1-

3 m/s), absence of precipitation, and limited synoptic variability. These conditions reduced advective mixing processes that typically attenuate urban thermal contrasts, while the average measured thermal at WMO stations ranged between −3.4°C to +1.4°C, during the survey interval, favoring the preservation of local land-use-related temperature gradients (*Meteo Buzău, 10.02.2026*, 2026; *Meteo Galați, 10.02.2026*, 2026).



Following the quality-control and correction procedures, the mobile observations were spatially classified into three principal environmental categories: Urban, Rural, and Road environments. The classification was performed using OpenStreetMap-derived land-use and road-network information, combined with reverse geocoding and spatial proximity analysis (Boeing, 2017; *OpenStreetMap*, 2026). Urban sectors were identified based on the presence of continuous built-up areas characterized by increased building density and dominant residential, commercial, or industrial land-use classes. Rural sectors corresponded mainly to agricultural land, grasslands, open fields, and sparsely developed surfaces located outside compact settlements. Measurements situated directly along major transportation corridors or road infrastructure outside continuous urbanized areas were classified as Road environments. The spatial classification procedure enabled the differentiation and comparison of localized thermal signatures associated with urban morphology, land-use characteristics, and transportation-related environments along both regional transects.

Figure 2 presents the spatial configuration and automated environmental classification of the two mobile monitoring transects performed on 10 February 2026 between Slobozia Conachi-Buzău (Figure 2a) and Buzău-Galați (Figure 2b). The figure represents the output of a custom Python-based spatial classification workflow developed to process the corrected mobile temperature measurements. The classification algorithm automatically analysed the spatial distribution of each measurement point using land-use information, building-density characteristics, and road-network data extracted from the OpenStreetMap database (Boeing, 2017; *OpenStreetMap*, 2026). Unlike a simple administrative classification, the method was designed to identify the actual local microclimatic environment surrounding each measurement point. Thus, points located administratively inside city boundaries but lacking built-up characteristics were not automatically classified as Urban.

Urban environments were assigned only where clear built-up evidence was identified, including residential, commercial, industrial, or construction land-use polygons, the presence of at least six buildings within a 150 m radius, or a building-area ratio $\geq 0.015$ within the same search distance. Rural environments corresponded mainly to agricultural and open natural surfaces, while the Road category included measurements located within 60 m of transportation corridors outside continuous built-up areas. The resulting classification highlights the strong spatial heterogeneity encountered along both regional transects, with extended Rural sectors identified between Slobozia Conachi, Focșani, and Râmnicu Sărat, as well as between Buzău, Ianca, and Brăila, whereas the largest Urban environments were associated with the metropolitan sectors of Buzău, Brăila, and Galați.

Figure 2 .Measurement track and results of spatial classification of the mobile monitoring transects from 10 February 2026 between Slobozia Conachi-Buzău (a) and Buzău-Galați (b). Red segments represent Urban environments associated with compact built-up areas and higher building density, dark blue segments indicate Rural environments dominated by agricultural and open land surfaces, while light green segments correspond to Road environments located mainly along transportation corridors outside continuous urbanized areas

**Instrumentation and mobile monitoring protocol**

Meteorological data were collected using the MeteoTracker (MTX-SA) standalone weather station, a device specifically engineered for high-resolution measurements on the move (MeteoTracker, 2025). The device features the patented dual-sensor Radiation Error Correction System (RECS), which dynamically corrects the "radiative error" caused by solar exposure (Jurato, J., 2020). The system ensures an air temperature accuracy of ±0.1°C (typical) and ±0.4°C under direct solar radiation at speeds exceeding 10 km/h (MeteoTracker, 2025). The performance of this sensor has been validated against reference meteorological equipment, confirming its suitability for urban microclimate investigations (Barbano et al., 2024; Loglisci et

al., 2024). During the mobile measurements performed on 10 February 2026, the device was mounted on the roof of a vehicle (see Figure 3) to minimize heat interference from the engine and asphalt, operating with a high temporal sampling resolution during the mobile survey , according to the manufacturer's specifications (Barbano et al., 2024b; Loglisci et al., 2024; MeteoTracker, 2025; Silva et al., 2025). The meteorological measurements recorded by the MeteoTracker (MTX-SA) weather station were transmitted in real time via Bluetooth to the MeteoTracker mobile application, where the data were continuously visualized and stored during the survey. Subsequently, the recorded datasets were automatically synchronized and uploaded to the MeteoTracker cloud platform, allowing remote access, download, and post-processing analysis from any location. The MeteoTracker application provides multiple visualization and statistical analysis functionalities, including real-time mapping of the measurement route with associated air temperature values, graphical representations of the recorded meteorological parameters, and the possibility to publicly share the monitoring project together with all corresponding spatial and temporal information (MeteoTracker / IoTopon Srl, 2026).

(a) (b)

Figure 3 . MeteoTracker mobile weather station mounting on the vehicle roof top during the mobile measurement campaign performed on 10 of February 2026 (a). Print screen from Meteo-Tracker app statistics data of the parameters recorded during measurements performed: Slobozia-Conachi – Buzău city and Buzău city – Galati city (b). Data Processing and Correction Procedures

Meteorological and positioning data acquired during the mobile transects conducted on 10 February 2026 were exported from the MeteoTracker+ application and subsequently processed using custom Python scripts.

The preprocessing workflow included data synchronization, quality-control procedures, filtering operations, and correction algorithms designed to remove anomalous records and improve the spatial and temporal consistency of the dataset. A three-stage quality control and normalization workflow was implemented.

The first stage aimed to prevent thermal contamination from the vehicle and surrounding traffic during stops. To this end, a speed-based filtering threshold was applied. Following the manufacturer's technical specifications and validated performance assessments, all data points recorded at speeds below 10 km/h were excluded from the final spatial analysis. This filtering ensures that the Radiation Error Correction System (RECS) operates within its optimal ventilation parameters, maintaining an accuracy of ±0.4°C even under solar exposure (MeteoTracker, 2025).

In the second stage, an altitude correction was applied to normalize the recorded air temperature ($T_{obs}$) to a common regional reference level ($H_{ref}$=50 m a.s.l.), accounting for the topographical variability of the Romanian Plain and Subcarpathian transitions areas. The corrected temperature ($T_{alt_corr}$) was calculated using the standard environmental lapse rate presented in the next equation:

$$T_{alt_corr} = T_{obs} + \Gamma\left(H_{obs} - H_{ref}\right) \quad (1)$$

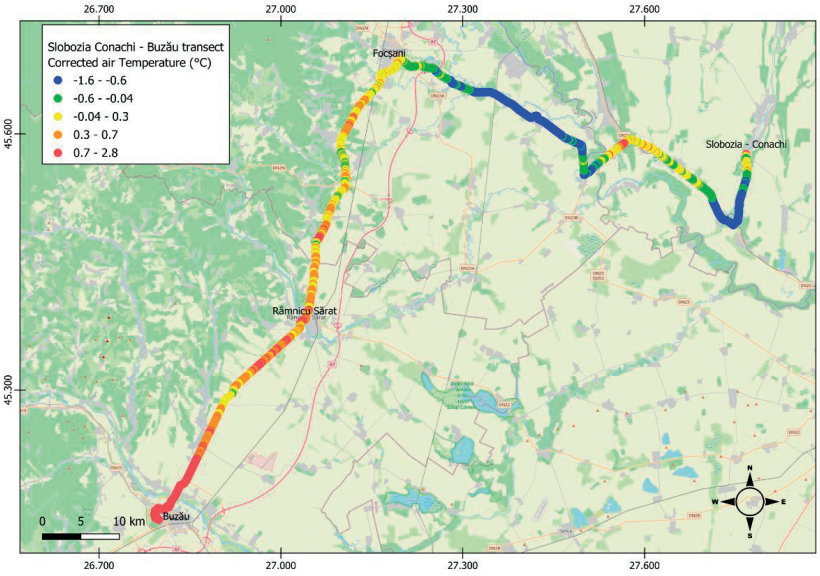
where:

$\Gamma$ is the altitudinal temperature gradient of 0.0065°C/m (or 0.65°C/100 m);

$T_{obs}$ is the measured temperature;

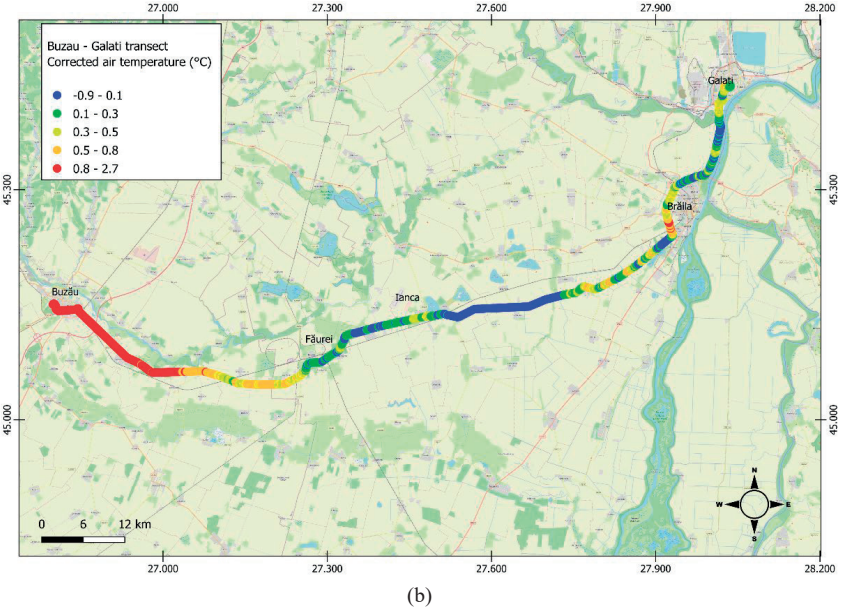
$H_{obs}$- is the altitude of the observation point and $H_{ref}$ – is the altitudinal average reference calculated from all measurements altitudinal level.

In the third stage, a time-drift correction was performed to isolate the spatial microclimatic signal from the natural diurnal temperature variation. Given the segmented nature of the transect and the 3-hour stationary period in Buzău, a linear interpolation was applied between the hourly observations of the ANM



baseline stations (Galați and Buzău). This procedure adjusted each mobile observation relative to the regional heating/cooling rate of the air mass at the exact moment of sampling (data from Figure 2), ensuring that the observed gradients reflect land-use differences rather than the passage of time as stated by other studies (Chàfer et al., 2022; Kousis et al., 2022; Ichim et al., 2024). The corrected and normalized dataset obtained after the preprocessing workflow was subsequently used for the spatial classification and statistical analysis of the mobile measurements.

## RESULTS AND DISCUSSIONS



### Spatial distribution of corrected air temperature

The corrected mobile measurements presented in Figure 4 represent the spatial distribution of point-based air temperature observations after the application of the filtering and correction workflow described in the methodology section. The corrected temperatures are displayed directly along the monitored routes and highlight distinct thermal contrasts associated with differences in land use, urban density, road infrastructure, and surrounding rural landscapes. Figure 4a shows the point-based spatial distribution of corrected air temperature along the Slobozia Conachi-Buzău transect after filtering and correction procedures. The coldest sectors are observed mainly in the rural area west and south-west of Slobozia Conachi and on the eastern approach toward Focșani, where several segments fall within the blue class, corresponding to corrected temperatures between −1.6 and −0.6°C. These low values are associated with open rural surfaces, agricultural land, and low building density. Around Focșani, temperatures increase mostly into the −0.04 to +0.3°C and +0.3 to +0.7°C classes, indicating a transition toward more built-up and road-influenced environments. Between Focșani and Râmnicu Sărat, the route is dominated mainly by yellow and orange classes, with corrected temperatures generally ranging from −0.04 to +0.7°C, rather than by the coldest blue values. This suggests more moderate thermal conditions along the main road corridor and nearby settlements. The warmest sector appears toward Râmnicu Sărat and especially near Buzău, where orange and red classes dominate, with corrected temperatures exceeding +0.7°C and locally reaching the highest class of the transect, up to +2.8°C. This pattern indicates stronger heat retention in compact urbanized sectors compared with the surrounding rural landscape, as it was studied in other similar studies (Barbano et al., 2024; Loglisci et al., 2024).

Figure 4b shows the point-based spatial distribution of corrected air temperature along the Buzău–Galați transect after the filtering and correction procedures. The warmest sector is clearly observed near Buzău, where the route is dominated by red points corresponding to corrected temperatures between +0.8 and +2.7°C. This indicates a strong local thermal signal associated with the compact urban area of Buzău and nearby built-up surfaces. Immediately after leaving Buzău, the route gradually shifts toward orange and yellow classes, with temperatures decreasing to +0.5–+0.8°C and +0.3–+0.5°C, reflecting the transition from urbanized land toward more open road and rural environments. The central part of the transect, especially around Făurei and Ianca, is dominated by blue and green classes, with corrected temperatures generally between −0.9 and +0.3°C. The lowest values are observed mainly along the long road corridor east of Ianca, where blue points indicate temperatures between −0.9 and +0.1°C, corresponding to open agricultural landscapes, low building density, and reduced anthropogenic heat influence. Toward Brăila, temperatures increase again, with several yellow, orange, and red segments ranging from +0.3°C to +2.7°C, consistent with the transition into a more urbanized sector. North of Brăila and toward Galați, the route alternates between colder blue-green sections and warmer yellow-orange points, indicating a mixed thermal pattern influenced by the Danube corridor, road infrastructure, and urbanized surfaces near Galați.

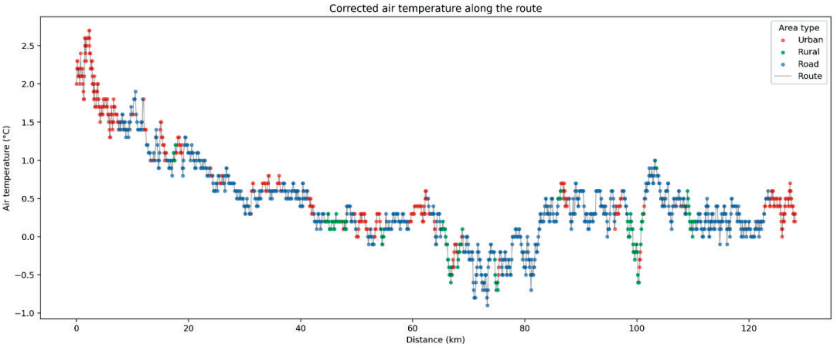

Figure 4. Spatial distribution of corrected air temperature along the Slobozia Conachi-Buzău transect (a) and the Buzău-Galați transect (b), based on mobile measurements performed on 10 February 2026. Warmer colors indicate higher corrected air temperatures, while colder colors indicate lower values

**Longitudinal thermal variability along the transects**

The longitudinal temperature profiles provided a detailed representation of the thermal variability recorded along the two mobile transects (Figure 5). The classification into Urban, Rural, and Road environments allowed the identification of localized thermal anomalies associated with urban morphology and transportation corridors.

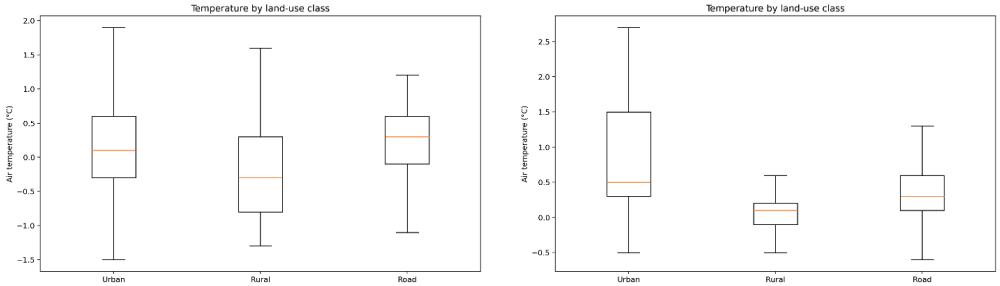
(a)

(b)

Figure 5 Corrected air temperature variability along the Slobozia Conachi-Buzău transect (a) and the Buzău-Galați transect (b) classified by land-use category, based on mobile measurements performed on 10 February 2026. Red points indicate temperatures recorded within Urban sectors, green points represent Rural environments, and blue points correspond to Road-dominated areas

The longitudinal temperature profiles presented in Figure 5 reveal substantial small-scale thermal variability along both investigated transects, reflecting the strong influence of land-use characteristics and urban morphology on near-surface air temperature distribution.

Figure 5a highlights the longitudinal evolution of corrected air temperature along the Slobozia Conachi–Buzău transect, revealing a gradual transition from colder rural environments toward warmer urbanized sectors. In the first part of the route (0-15 km), corresponding mainly to rural landscapes near Slobozia Conachi, Rural measurements generally ranged between approximately −1.3°C and −0.5°C, while Road environments varied between approximately −0.9°C and −0.3°C. Between approximately 15 and 35 km, temperatures progressively increased toward positive values between approximately 0°C and +0.9°C across mixed Urban and Road sectors. The middle section of the transect (approximately 40-80 km) exhibits the coldest conditions, with several measurements below −1°C and minimum values approaching approximately −1.6°C around km 50-55. After approximately km 80, temperatures gradually increase again, while the strongest warm anomaly occurs near Buzău (approximately 140-150 km), where Urban measurements frequently exceed +2°C and locally approach +2.8°C, indicating a pronounced winter urban heat island effect.



Along the Buzău-Galați transect (Figure 5b), the corrected temperature profile also reveals clear thermal contrasts between Urban, Rural, and Road environments. At the beginning of the transect (0-8 km), corresponding to the urban area of Buzău, Urban measurements remained consistently elevated, generally between +1.8°C and +2.7°C. Between approximately 10 and 40 km, temperatures progressively decreased toward less densely built and Road-dominated sectors, commonly ranging between approximately +0.3 °C and +1.2°C. The lowest

corrected temperatures were recorded in the central rural sector of the transect (approximately 55-80 km), where several measurements fall below 0°C and minimum values approach approximately −0.9°C around km 70-75. After approximately km 85, the thermal signal gradually increases again toward the Brăila-Galați metropolitan corridor, where Urban measurements remain predominantly positive, most frequently between approximately +0.5°C and +0.7°C.

**Statistical analysis of data**

To further evaluate the influence of land-use characteristics on local thermal conditions, the corrected air temperature values were statistically compared between Urban, Rural, and Road classes using boxplot analysis presented in Figure 6.

Figure 6 presents the boxplot distributions of corrected air temperature values for the Urban, Rural, and Road land-use categories along the two transects, providing a statistical overview of the median values, thermal dispersion, and variability ranges within each environmental class. For the Slobozia Conachi-Buzău transect (Figure 6a), the Urban category exhibits a broad thermal distribution, with values extending from approximately −1.5°C to nearly +1.9°C and a median close to +0.1°C. The central variability range (interquartile range) extends approximately between −0.3°C and +0.6°C, indicating substantial spatial heterogeneity within built-up environments. Rural sectors display lower median temperatures near −0.3°C and the coldest thermal conditions overall, with most values concentrated between approximately −0.8°C and +0.3°C. Road environments present intermediate thermal characteristics, with a median close to +0.3°C and a comparatively narrower central variability range extending approximately between −0.1°C and +0.6°C.

(a) (b)

Figure 6. Statistical distribution of corrected air temperature values for Urban, Rural, and Road environments along the Slobozia Conachi-Buzău transect (a) and the Buzău-Galați transect (b)

In the Buzău-Galați transect (Figure 6b), the Urban category again exhibits the highest positive temperatures and the widest thermal amplitude, ranging from approximately −0.5°C to +2.7°C, with a median close to +0.5°C. The central 50% of Urban temperature values are distributed approximately between +0.3°C and +1.5°C, reflecting enhanced thermal variability associated with compact built-up structures and anthropogenic heat influence. Rural environments show the narrowest thermal distribution, with a median close to +0.1°C and most values concentrated between approximately −0.1°C and +0.2°C, indicating relatively stable thermal conditions over open agricultural landscapes. Road sectors again display intermediate thermal behavior, with temperatures generally varying between approximately −0.9°C and +1.3°C and the central variability range extending approximately from +0.1°C to +0.6°C. Overall, the boxplots emphasize the stronger thermal variability and higher positive temperature anomalies associated with Urban environments, while Rural sectors remain characterized by lower and more homogeneous corrected temperature distributions along both transects.

## CONCLUSIONS

This exploratory pilot study demonstrated the capability of high-resolution mobile monitoring to identify winter urban-rural thermal gradients and localized urban heat island signatures in South-Eastern Romania. The preprocessing workflow, including speed filtering, altitude normalization, temporal correction using ANM reference stations, and automated land-use classification, improved the spatial consistency and interpretability of the mobile dataset.

The results revealed clear thermal differences between Urban, Rural, and Road environments along both transects. Urban sectors, especially near Buzău and within the Brăila-Galați corridor, showed higher corrected air temperatures and greater thermal variability, while Rural areas generally maintained lower and more stable thermal conditions. Road-dominated sectors displayed intermediate thermal behavior.

Urban-rural thermal differences are not specific only to winter conditions. They can be identified throughout the year, but their intensity, spatial expression, and controlling mechanisms vary depending on season, radiation balance, wind speed, cloud cover, land cover, vegetation activity, soil moisture, and anthropogenic heat release. During winter, stable atmospheric conditions, weak wind, and reduced turbulent mixing may favor the detection of heat retention within built-up areas. In contrast, during summer, urban–rural thermal contrasts may be amplified by stronger solar radiation, reduced evapotranspiration over impervious surfaces, and the thermal behavior of construction materials compared with vegetated rural areas. Therefore, the present winter case should be interpreted as one seasonal example of urban-rural thermal differentiation, not as the only period in which such contrasts can be detected.

The combined use of point-based temperature mapping, longitudinal profiles, and boxplot statistics showed that MeteoTracker mobile measurements can capture fine-scale thermal variability that is difficult to observe using fixed meteorological stations alone. The main strength of this study lies in the high spatial resolution of the mobile observations and in the integrated workflow combining speed filtering, altitude normalization, time-drift correction, and land-use-based classification into Urban, Rural, and Road environments. This approach allowed the identification of localized winter thermal gradients and urban-rural contrasts along regional transects in South-Eastern Romania.

Although limited to a single winter day, which does not allow seasonal or climatological generalization of the observed thermal contrasts. In addition, the present analysis focused on near-surface mobile air temperature measurements and did not include satellite-derived Land Surface Temperature. Future studies should include repeated mobile surveys during different seasons and meteorological conditions and may integrate Landsat-derived LST products to compare surface thermal patterns with near-surface air temperature variability. The study confirms the usefulness of this approach for future urban climate and UHI assessments in Romania.

***Abstract***

*The rapid expansion of illegal gold mining over the past decade has emerged as one of the most critical environmental challenges in Suriname, driven by its severe impacts on both terrestrial and aquatic ecosystems. Monitoring these activities is difficult due to the remoteness of affected areas, limited accessibility, and safety constraints. This study explores the potential of Sentinel-2 Level-2A imagery for detecting and monitoring artisanal and small-scale gold mining (ASGM) activity around the Brokopondo Reservoir without relying on in-situ measurements. A Python-based workflow developed in Google Colab was used to pre-process the imagery and calculate the Normalized Difference Turbidity Index (NDTI) for the period 2021–2025. Spatial relationships between high and low NDTI clusters and their proximity to ASGM sites were examined using Moran's I, the Mann–Whitney U test, and Cliff's delta. The results suggest that NDTI has potential as a remote-sensing proxy for ASGM-related water turbidity, offering valuable support for environmental monitoring in remote tropical forest regions of the Guiana Shield.*

***Key words:*** *gold mining activity, indication, monitoring, proximity, water turbidity.*

## INTRODUCTION

Artisanal and small-scale gold mining (ASGM) is a critical livelihood activity in Suriname, supporting an estimated 20,000 people, particularly in interior regions such as Brokopondo and Sipaliwini (Seccatore & Theije, 2017; First National Action Plan, 2023). Although the sector contributes significantly to local economies, it also generates substantial environmental and public health risks due to the use of hazardous substances, especially mercury, during gold extraction (Marshall et al., 2020; Quispe Aquino et al., 2022; Malone et al., 2023). The environmental footprint of mercury use in artisanal and small-scale gold mining is especially pronounced in riverine and reservoir systems adjacent to mining areas, where disturbed soils and associated contaminants are mobilized into waterways, resulting in water quality degradation (Huisden et al., 2021). ASGM in Suriname primarily relies on hydraulic mining techniques that remove vegetation and mobilize large volumes of soil and sediment. These materials are commonly discharged directly into nearby rivers and creeks without sediment-control structures such as tailings ponds (Heemskerk & Kooye, 2003; Ouboter, 2015). The influx of fine sediments increases turbidity and facilitates the downstream transport of mercury-contaminated particles, as mercury readily binds to clay and fine sediment (Vreedzaam et al., 2023).

The Brokopondo Reservoir is located within one of Suriname's most active artisanal and small-scale gold mining regions, the Brokopondo district. Mining is a major driver of deforestation and ecological degradation in this area, with much of the activity occurring illegally (Global Forest Watch, 2025). Elevated sediment loads and turbidity within the reservoir and its tributaries have been directly linked to mining operations, posing risks to aquatic ecosystems and communities that rely on the water for

drinking, fishing, and other livelihood activities (Heemskerk et al., 2022). Despite the severity of ASGM-related environmental impacts, Suriname lacks a national system for systematic monitoring of water quality or mining activities (Rodríguez & Chavez, 2024). Reliable data on the extent and distribution of ASGM, particularly in the Brokopondo district, are limited (EMSAGS, 2023). Many mining sites are located in remote forested areas that are difficult to access and may pose safety risks for field researchers (United Nations Office on Drugs and Crime, 2025). These logistical and security constraints severely limit the feasibility of routine field sampling and make traditional monitoring approaches impractical in many ASGM-affected regions. Given these constraints, remote sensing provides a practical and effective alternative to ground-based monitoring.

Satellite imagery offers consistent, high-resolution, and high-frequency observations that enable the assessment of spatial and temporal variations in water quality where field measurements are not feasible (Espinoza et al., 2025). Sentinel-2, with its suitable spectral configuration and frequent revisit time, has become a widely used platform for monitoring optically complex inland waters (Elhag et al., 2019; Das et al., 2024). A substantial body of literature demonstrates that multispectral indices serve as reliable proxies for water-quality parameters such as turbidity (Steinbach et al., 2025), suspended sediment concentration (SSC), total suspended matter (TSM), chlorophyll-a (Chl-a), and coloured dissolved organic matter (CDOM) (Khan et al., 2021; Li et al., 2023; Chen et al., 2024; Tesfaye, 2024). Red–green reflectance contrasts are particularly effective in detecting sediment-laden waters associated with mining disturbances.

The Normalized Difference Turbidity Index (NDTI), derived from red and green spectral bands, has emerged as a robust indicator of relative turbidity and suspended sediments in both inland and coastal waters (Zhang et al., 2022; Amran & Daming, 2023). In river systems affected by ASGM, persistent turbidity hotspots downstream of mining areas provide strong qualitative evidence of sediment release even when in situ turbidity measurements are unavailable (Sousa & Veiga, 2009; Pereira & Lobo, 2024). Because many ASGM sites in Suriname are located in remote forested landscapes, including protected and Indigenous territories, satellite-based turbidity assessment is often the only feasible large-scale monitoring option. Remote sensing of water turbidity therefore offers a crucial means of detecting and understanding ASGM-induced sediment dynamics across the Brokopondo Reservoir and the broader Guiana Shield.

The purpose of this study is to evaluate the feasibility of using the Normalized Difference Turbidity Index, derived from Sentinel-2 imagery, as an indirect indicator of artisanal and small-scale gold mining activity around the Brokopondo Reservoir in Suriname in the absence of field-based water quality measurements. By generating multi-year, dry-season NDTI composites and analysing their spatial and temporal patterns, the study aims to determine whether elevated turbidity signals (NDTI hotspots) correspond spatially with known ASGM locations and can therefore be evaluated as a potential tool for environmental monitoring in remote, data-poor regions.

This study pursues five interconnected objectives: (1) to generate a spatial-temporal dataset of NDTI values for the Brokopondo Reservoir and its tributaries using Sentinel-2 imagery from 2021 to 2025, focusing on the dry-season months (July-November) when turbidity signals are most stable and comparable; (2) to characterize spatial turbidity using spatial autocorrelation methods, including Global Moran's I and Local Moran's I, in order to identify statistically significant clusters of high (HH) and low (LL) NDTI values across the study area; (3) to quantify the spatial relationship between ASGM sites and NDTI clusters by calculating distances from known ASGM locations to HH and LL clusters and evaluating whether mining sites are preferentially located near turbidity hotspots; (4) to statistically assess differences in proximity between ASGM sites and NDTI cluster types using the Mann-Whitney U test and Cliff's delta effect size, thereby testing the hypothesis that ASGM sites are significantly closer to HH clusters than to LL clusters; (5) to evaluate the potential of NDTI as a field-independent proxy for monitoring ASGM impacts, providing a scalable, replicable method for environmental surveillance in regions where ground-based

water quality monitoring is logistically constrained or unavailable.

## MATERIALS AND METHODS

*Study area*. The study was conducted in Suriname, a country situated north of the equator on the north-eastern coast of South America. Suriname's geographical coordinates extend from 1°50.45' N to 6°0.35' N and from 53°59.08' W to 54°33.49' W. Geologically, more than 80% of Suriname consists of the deeply weathered, rainforest-covered Precambrian Guiana Shield (Myslyva et al., 2024).

The area of interest is the Brokopondo Reservoir, officially known as the Professor Doctor Ingenieur W. J. van Blommestein Meer, also referred to as Brokopondostuwmeer (Leentvaar, 1975). It was formed in the 1960s following the construction of the Afobaka Dam on the Suriname River. The reservoir was primarily created to supply hydroelectric power to support the country's bauxite industry and general electricity needs. With a surface area that fluctuates around 1,560 km² depending on seasonal water levels, and catchment area approximately 12,200 km², it ranks among the largest human-made reservoirs in South America. The reservoir alone covers nearly one percent of Suriname's total land area. It lies in the Brokopondo district and extends between latitudes 4°20' N and 5°00' N and longitudes 54°50' W and 55°20' W (Figure 1).

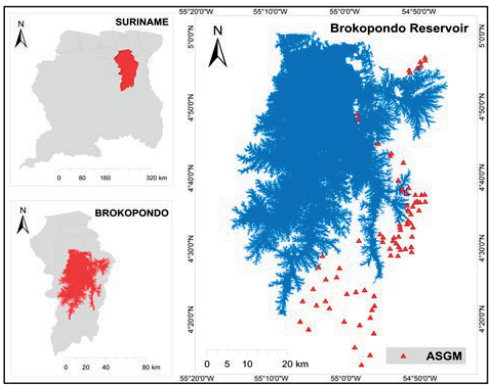

Figure 1. Location of the study area

The reservoir and its catchment are subject to various human activities, including artisanal and small-scale gold mining, agriculture, and logging, all of which affect water quality and sediment dynamics. Its size, hydrological characteristics, and environmental pressures make the Brokopondo Reservoir an important focus for remote sensing studies aimed at monitoring water turbidity, sediment transport, and land-use changes in tropical reservoirs.

The region of interest included the Brokopondo Reservoir and a 25-km buffer zone surrounding its shoreline. This extent was sufficiently large to capture the major tributaries and first-order streams flowing into the reservoir, as well as the majority of direct-impact ASGM sites and their associated drainage pathways. To estimate proximity to high-high (HH) and low-low (LL) water turbidity clusters, 80 ASGM activity points were selected.

Figure 2 presents a step-by-step methodological framework used to validate the application of the Normalized Difference Turbidity Index as an indicator of artisanal and small-scale gold mining activity by analyzing the spatial proximity of ASGM sites to major NDTI clusters within the Brokopondo Reservoir. The workflow integrates remote sensing, spatial autocorrelation analysis, proximity assessment, and statistical validation using the Mann-Whitney U test and Cliff's delta to quantify the association between ASGM activity and water turbidity patterns.

*Datasets used*. This study employed Sentinel-2 Level-2A surface reflectance imagery obtained from the harmonized collection available on the Google Earth Engine (GEE) platform. This dataset provides atmospherically corrected reflectance at 10-20 m spatial resolution and includes consistent radiometric calibration across the mission. Details of the other datasets used in this study are provided in Table 1.

Table 1. Characteristics of data collected

| Data | Source | Acquisition year | Scale/ Resolution |
|---|---|---|---|
| Digital Elevation Model (DEM) | 30-Meter SRTM Tile Downloader: https://dwtkns.com/srtm30m/ | 2018 | 1-arcsecond (3601x 3601 pixels) |
| Shape-file with locations of gold mining activity | National Environmental Authority: https://nimos.org/en/about-us/ | 2018 | – |
| Shapefile of the Brokopondo Reservoir boundary | National Land Monitoring System of Suriname (GONINI) https://www.gonini.sbb.sr/ | 2023 | – |

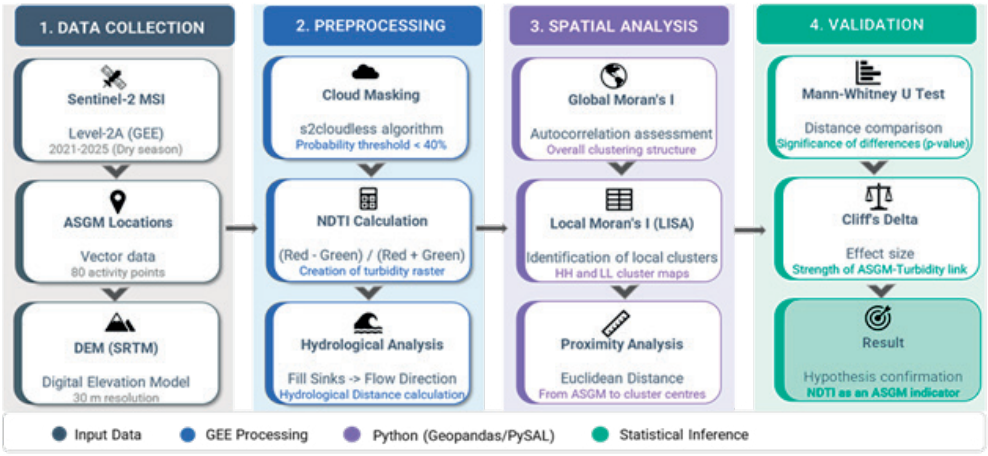

Figure 2. Overall scheme of the methodological approach for the research

The imagery was spatially filtered to the region of interest (ROI) covering the Brokopondo Reservoir and temporally constrained to the period from January 2021 to October 2025. A vector mask derived from a shapefile delineating the official boundaries of the Brokopondo Reservoir, obtained from the National Land Monitoring System of Suriname (GONINI), was used to define the reservoir extent. To exclude the influence of precipitation on water turbidity in the reservoir, only images acquired during July – November were retained.

*Cloud masking approach*. To minimize atmospheric contamination, all Sentinel-2 Level-2A surface reflectance data were corrected for cloud interference using the *s2cloudless* cloud-probability algorithm. The *s2cloudless* model is a machine-learning system based on gradient-boosted decision trees developed by ESA and Sinergise specifically for Sentinel-2 optical imagery. It generates a pixel-level cloud probability map (0-100%) provided in the COPERNICUS/S2_CLOUD_PROBABILITY dataset, which is temporally aligned with the Sentinel-2 SR image collection.

In this workflow, the cloud-probability band was added to each Sentinel-2 image by matching acquisition times. Cloud masking was performed using a probability-threshold approach commonly applied in Sentinel-2 pre-processing. Specifically, pixels with a cloud probability ≥ 40% were flagged as cloud-contaminated and removed from further analysis, while pixels with a probability < 40% were retained (GEE tutorial, 2025).

*Water turbidity index computation*. To quantify water turbidity, the Normalized Difference Turbidity Index (NDTI) was calculated for each cloud-free Sentinel-2 scene. NDTI is defined as:

$$NDTI = \frac{(R_{red} - R_{green})}{(R_{red} + R_{green})} \quad (1)$$

where $R_{Red}$ corresponds to Sentinel-2 Band 4 (665 nm) and $R_{Green}$ corresponds to Band 3 (560 nm) (Dewantoro et al., 2024).

This index is based on the relationship between turbidity and the spectral response of surface waters, where higher turbidity generally corresponds to higher NDTI values and vice versa. The index uses green and red band reflectance to estimate variations in suspended sediment concentration within the water column. This band combination effectively discriminates sediment-laden water; therefore, NDTI serves as a key indicator for turbidity mapping (Foteh et al., 2018).

NDTI was calculated for each selected scene and exported as raster layers for subsequent analysis.

Based on Sentinel-2 spectral characteristics and the typical optical behaviour of tropical inland waters, NDTI values were interpreted as follows: (i) NDTI < −0.1 – indicates clear water conditions, where green reflectance dominates (these values are typical of low suspended sediment concentrations and may occur in calm

reservoir areas, isolated ponds, or waters influenced by biological activity rather than mineral turbidity); (ii) −0.1 ≤ NDTI ≤ 0.1 – indicates low to moderate turbidity or transitional conditions, where red and green reflectance are comparable (this range is commonly observed in relatively stable reservoir waters with limited sediment input); (iii) < NDTI ≤ 0.3 – indicates moderate turbidity, often associated with increased suspended inorganic particles (such values may reflect seasonal runoff, shoreline disturbance, or early-stage mining impacts); (iv) NDTI > 0.3 – indicates high turbidity, dominated by mineral suspended matter (in the Brokopondo Reservoir, such values are consistent with sediment-laden inflows from upstream rivers and creeks affected by artisanal and small-scale gold mining activity).

*Hydrological distance calculation*. Hydrological distance was computed using ArcGIS 10.8 Hydrology toolbox to quantify flow-path connectivity within the Brokopondo Reservoir system. First, the digital elevation model was hydrologically corrected by filling sinks to ensure a continuous flow surface. Flow direction was then derived using the D8 algorithm, followed by flow accumulation to represent potential drainage pathways. Based on these layers, the stream identification step was used to delineate flow channels. The Flow Length tool was then applied in downstream mode to calculate the cumulative distance that water would travel along the flow network from each cell to the reservoir outlet.

The resulting hydrological distance raster represents a process-based metric of spatial connectivity constrained by the drainage network and was subsequently used in spatial statistical analyses to interpret the distribution, clustering, and downstream propagation of NDTI-derived turbidity signals.

*Global and Local Moran's Index calculations*. Spatial autocorrelation of the water turbidity values was assessed using Global Moran's I and Local Moran's I (LISA) statistics. These indices evaluate whether high or low values are spatially clustered or randomly distributed.

The *Global Moran's I* index provides a single summary statistic describing the overall spatial structure of the dataset. It was calculated following Mitchell (2005) using:

$$I = \frac{n}{\sum_{i=1}^{n}\sum_{j=1}^{n} w_{ij}} \cdot \frac{n\sum_{i=1}^{n}\sum_{j=i}^{n} w_{ij}(y_i-\bar{y})(y_j-\bar{y})}{\sum_{i=1}^{n}(y_i-\bar{y})^2]} \quad (2)$$

where $n$ represents the number of spatial units; $y_i$ is the attribute value at location $i$; $\bar{y}$ is the mean of the attribute and $w_{ij}$ is the spatial weight between locations $i$ and $j$.

Values of Moran's I greater than zero indicate positive spatial autocorrelation (clustering of similar values), values below zero indicate negative spatial autocorrelation (dispersion), and values near zero indicate spatial randomness.

*Local Moran's I* was applied to detect local clusters and spatial outliers, providing insight into the spatial heterogeneity of turbidity patterns. The Local Moran's I statistic for each location $i$ was computed as follows:

$$I_i = \frac{(y_i-\bar{y})}{m_2}\sum_{k=1}^{n} w_{ij}(y_j - \bar{y}) \quad (3)$$

where the normalization term $m_2$ is:

$$m_2 = \frac{1}{n}\sum_{k=1}^{n}(y_k - \bar{y})^2 \quad (4)$$

Positive and statistically significant $I_i$ values indicate HH or LL clusters, while negative values represent HL or LH outliers. This enables the identification of areas with anomalous turbidity behaviour within the reservoir.

*Statistical evaluation of ASGM-turbidity relationships*. The non-parametric Mann-Whitney U test was used to determine whether high-high turbidity clusters are significantly closer to ASGM sites than low-low clusters representing relatively clean-water areas. This test was selected because the distance data showed non-normal distributions and unequal variances, making non-parametric inference more appropriate than parametric alternatives. To complement the significance testing, Cliff's delta (δ) was calculated as a measure of effect size. Cliff's delta quantifies the probability that a randomly selected value from one group will exceed a randomly selected value from another group, minus the reverse probability. As a distribution-free statistic, it is well suited for skewed data, unequal sample sizes, and non-parametric comparison frameworks such as the Mann–Whitney test (Vargha & Delaney, 2000). Interpretation followed established thresholds,

where $\delta < 0.147$ indicates a negligible effect, $0.147 \leq \delta < 0.33$ a small effect, $0.33 \leq \delta < 0.474$ a medium effect, and $\delta \geq 0.474$ a large effect (Romano et al., 2006). Together, these metrics provide a robust assessment of both the statistical significance and the magnitude of differences between cluster types in relation to ASGM proximity.

*Software and computational workflow*. All image pre-processing, index computation, and spatial-statistical analyses were conducted in Google Colab (Python environment). Sentinel-2 imagery was accessed and processed using the Google Earth Engine Python API in combination with *geemap* and *xee*, enabling cloud-based filtering, cloud masking, and surface reflectance compositing.

Spatial data handling and vector operations were performed using *GeoPandas*, *Shapely*, and *STRtree*, while raster manipulation and masking were conducted with *rasterio* and *xarray*. Distance metrics, including hydrological distance and Euclidean distance between ASGM point locations and cluster pixels, were generated using *NumPy* and raster/vector spatial indexing routines. Non-parametric statistical testing was performed using *SciPy*.

## RESULTS AND DISCUSSIONS

A time series of NDTI maps spanning July 2021 to October 2025 reveals distinct cyclical patterns in the spatial distribution of water turbidity across the Brokopondo Reservoir (Figure 3).

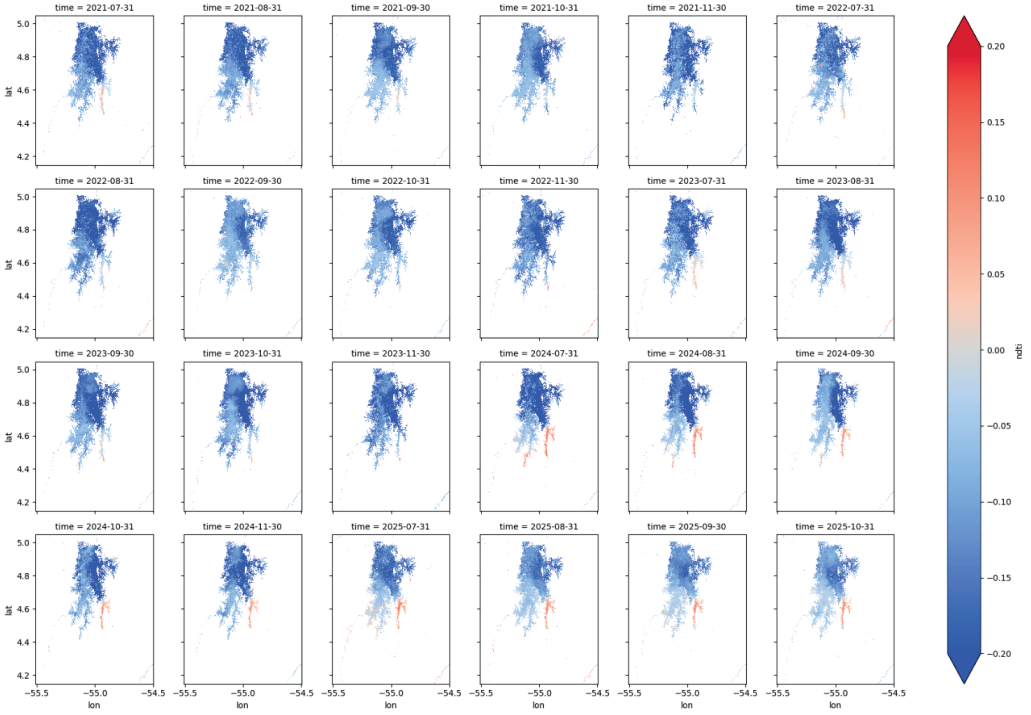

Figure 3. NDTI values and distribution for the Brokopondo Reservoir

The southern portion of the reservoir consistently exhibits the highest turbidity levels throughout the five-year period, corresponding to areas of intensive artisanal and small-scale gold mining activity. Temporal analysis indicates significantly lower turbidity during July 2021-November 2022 compared to July 2024-October 2025.

The suppressed turbidity observed in 2021 is likely a direct consequence of COVID-19 lockdown measures in Suriname, which restricted ASGM operations by limiting access to essential inputs such as fuel, equipment, and mercury used for amalgamation. Similarly, the reduced turbidity observed from July to November 2022 is associated with extreme

hydrological events. Unseasonably heavy rainfall in January and February 2022 – months typically classified as part of the short dry season – necessitated the controlled release of water from the Afobaka Dam on 28 February to mitigate rising reservoir levels. By 15 March, the resulting floods had propagated into the Upper Suriname, Tapanahoni, Lawa, and Marowijne river catchments, disrupting both mining operations and material transport. These hydrological disturbances temporarily curtailed gold mining activity and sediment mobilization from mining sites, as reflected in the NDTI-derived turbidity patterns. In contrast, the elevated turbidity observed in 2024-2025 corresponds to resumed and intensified ASGM activity under normal hydrological conditions, highlighting the strong coupling between anthropogenic sediment inputs and reservoir turbidity.

Considering these contextual factors, the period from July 2024 to October 2025 was selected for subsequent analysis, as it represents a more stable phase in which turbidity variations are more likely to reflect mining-related impacts rather than exceptional climatic or operational disruptions.

Global Moran's I was calculated to quantify the overall spatial structure of the NDTI dataset (Table 2).

Table 2. Spatial autocorrelation of NDTI-derived turbidity in the Brokopondo Reservoir based on Global Moran's I (July 2024-October 2025)

| Date | Global Moran's I | z-score | p-value |
|---|---|---|---|
| July 2024 | 0.834004 | 422.5635 | < 0.0001 |
| August 2024 | 0.854091 | 429.6744 | < 0.0001 |
| September 2024 | 0.812478 | 410.3696 | < 0.0001 |
| October 2024 | 0.821867 | 412.3634 | < 0.0001 |
| November 2024 | 0.82093 | 415.7692 | < 0.0001 |
| July 2025 | 0.869067 | 442.2297 | < 0.0001 |
| August 2025 | 0.810761 | 415.0792 | < 0.0001 |
| September 2025 | 0.838833 | 424.9217 | < 0.0001 |
| October 2025 | 0.799329 | 405.948 | < 0.0001 |

This indicator demonstrates consistently very strong and statistically significant positive spatial autocorrelation of NDTI-derived turbidity patterns across the Brokopondo Reservoir for all analyzed months between July 2024 and October 2025. Moran's I values range from 0.799 to 0.869, close to the theoretical upper limit of +1, indicating that high and low turbidity values are strongly clustered in space rather than randomly distributed.

The extremely high z-scores (405.9 to 442.2) and p-values < 0.0001 confirm that these clustering patterns are highly unlikely to have occurred by chance. The strongest spatial clustering was observed in July 2025 (I = 0.869), while slightly lower – but still very strong – clustering occurred in October 2025 (I = 0.799). These results suggest that sediment-rich and sediment-poor zones remain spatially stable over time. The strength and persistence of these spatial patterns support the suitability of NDTI as a robust indicator for identifying and monitoring persistent turbidity hotspots potentially linked to ASGM activity.

After confirming significant spatial clustering in the dataset, Local Moran's I was calculated to identify the spatial distribution of high and low NDTI values and to delineate HH and LL clusters, as well as spatial outliers (HL and LH) (Table 3).

Table 3. Non-parametric test statistics for spatial NDTI HH and LL cluster differentiation (July 2024-October 2025)

| Date | U statistic | p-value | Cliff's delta (effect size) |
|---|---|---|---|
| July 2024 | 284080.0 | < 0.000001 | 1.0 |
| August 2024 | 5606522.0 | < 0.000001 | 1.0 |
| September 2024 | 4997040.0 | < 0.000001 | 1.0 |
| October 2024 | 4105832.0 | < 0.000001 | 1.0 |
| November 2024 | 3652980.0 | < 0.000001 | 1.0 |
| July 2025 | 6580161.0 | < 0.000001 | 1.0 |
| August 2025 | 6075216.0 | < 0.000001 | 1.0 |
| September 2025 | 6224660.0 | < 0.000001 | 1.0 |
| October 2025 | 6107759.0 | < 0.000001 | 1.0 |

The Mann-Whitney U test results comparing HH and LL clusters reveal extremely strong and highly consistent differences between the two groups across all analyzed months. U statistics range from 284,080 (July 2024) to 6,580,161 (July 2025), with all pairwise comparisons yielding p-values < 0.000001, indicating robust statistical separation between the distributions.

Notably, Cliff's delta equals 1.0 for every month, representing the maximum possible effect size and demonstrating complete non-overlap between HH and LL cluster values. This uniform pattern indicates highly stable and persistent spatial differentiation of NDTI across both dry-season periods (2024 and 2025).

HH clusters consistently represent markedly higher turbidity-related index values, while LL

clusters represent persistently low values, with no intermediate overlap. Such effect sizes confirm that the spatial clustering of NDTI is both statistically significant and structurally robust.

Using the NDTI as an indicator of ASGM activity is a promising approach, but it has important limitations. In the Brokopondo Reservoir, increased water turbidity is not caused solely by gold mining; it can also be influenced by natural factors such as rainfall intensity, surface runoff, and local topography. To minimize precipitation-related effects, the analysis was restricted to the regional dry season (July-November), with particular emphasis on the driest months (September-November), consistently observed during 2021-2025. This temporal filtering allowed the analysis to focus on periods when anthropogenic sediment inputs from ASGM were less masked by rainfall-driven turbidity. A statistical assessment of the relationship between NDTI and precipitation for July 2021 – October 2025 showed a very weak correlation (Pearson's r = 0.08), indicating negligible linear dependence between rainfall and turbidity during the selected dry-season periods (Figure 4).

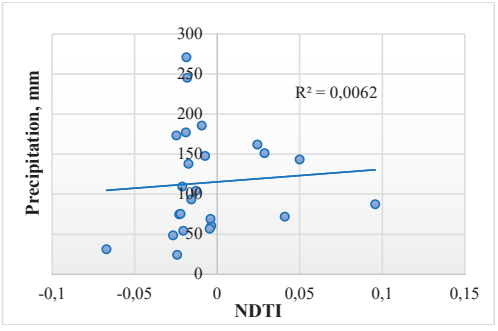

Figure 4. Relationship between NDTI and precipitation (2021-2025)

This weak correlation suggests that precipitation was not a dominant driver of turbidity variability within the area of interest during the analyzed periods, supporting the interpretation that the observed turbidity patterns are largely associated with anthropogenic disturbance.

To evaluate the influence of topography on turbidity patterns, hydrological distance was calculated and its relationship with the spatial distribution of high-high (HH) and low-low (LL) clusters were analysed (Table 4).

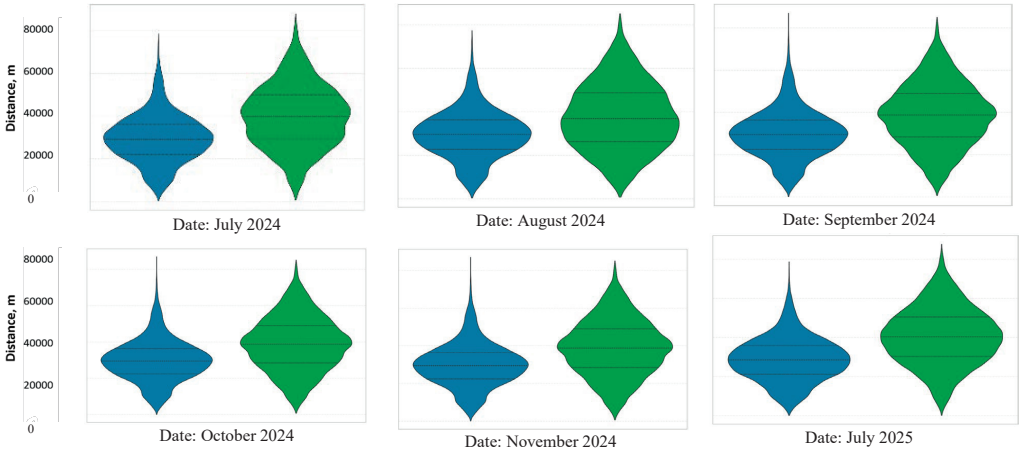
Table 4. Non-parametric test statistics for spatial relationships between NDTI clusters and hydrological distance (July 2024-October 2025)

| Date | U statistic | p-value | Cliff's delta (effect size) |
|---|---|---|---|
| July 2024 | 116882.0 | < 0.000001 | -0.1771 |
| August 2024 | 2617028.5 | 0.000053 | -0.0664 |
| September 2024 | 2341722.0 | 0.000171 | -0.0628 |
| October 2024 | 1872022.5 | < 0.000001 | -0.0881 |
| November 2024 | 1533951.0 | < 0.000001 | -0.1602 |
| July 2025 | 2858760.0 | < 0.000001 | -0.1311 |
| August 2025 | 2613307.0 | < 0.000001 | -0.1397 |
| September 2025 | 2955452.0 | 0.001388 | -0.0504 |
| October 2025 | 2884479.0 | 0.000454 | -0.0555 |

The non-parametric test results revealed no meaningful relationship between the spatial distribution of HH and LL clusters and hydrological distance. Although several months show statistically significant p-values, all Cliff's delta values are small and negative (–0.05 to – 0.18), indicating negligible effect sizes and confirming the absence of a systematic spatial trend. This means that neither HH nor LL clusters align with the longitudinal hydrological gradient of the reservoir. High-turbidity areas do not consistently occur upstream or downstream, and low-turbidity areas are not preferentially located farther from inflows. Instead, turbidity clusters appear spatially patchy and locally constrained, suggesting that hydrological distance is not a meaningful predictor of turbidity distribution. These results indicate that turbidity dynamics in the Brokopondo Reservoir are driven primarily by localized factors – such as ASGM activity, shoreline erosion, and small tributaries – rather than by overall hydrological connectivity.

To achieve the research objective, a proximity analysis was conducted to examine the relationship between high-intensity pollution sources (ASGM) and high-intensity effects (NDTI clusters). Euclidean distances were calculated from each ASGM location to all HH and LL cluster points within a 25 km zone around the Brokopondo Reservoir (Table 5).

Because field turbidity measurements were unavailable, nonparametric methods were used instead of regression modelling. The Mann–Whitney U test and Cliff's delta were applied to assess whether HH clusters are significantly closer to ASGM sites than LL clusters.



Across all months, HH clusters were consistently closer to ASGM sites than LL clusters. Mean distances ranged from 28,855 m to 30,798 m for HH clusters and from 37,791 m to 40,770 m for LL clusters.

U statistic and corresponding p-values (all p = 0.01) indicate statistically significant differences each month. Cliff's delta values were consistently negative (−0.3046 to −0.4715), confirming that ASGM locations are spatially associated with HH clusters rather than LL clusters. This pattern suggests a robust spatial correlation between areas of increased turbidity and proximal ASGM activity, supporting the use of NDTI clustering as an indicator for mining-related water quality impacts.

The violin plots (Figure 5) show a clear spatial separation between water turbidity cluster types and their proximity to artisanal and small-scale gold mining sites. Areas classified as high-high turbidity clusters are located, on average, at considerably smaller distances from ASGM operations compared to low-low turbidity clusters. This spatial relationship confirms the assumption that gold mining proximity is the primary driver of elevated sediment loads in the Brokopondo Reservoir.

Table 5. Distances between all ASGM locations and all HH and LL clusters points (July 2024-October 2025)

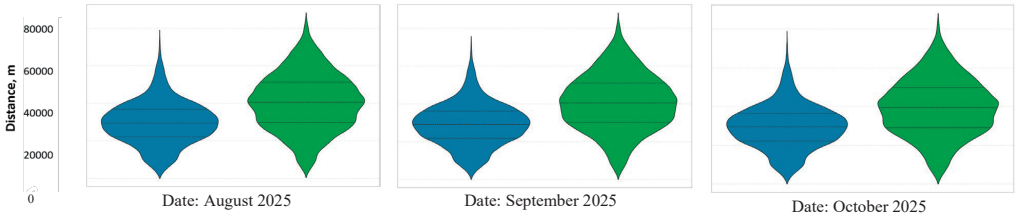

Figure 5. Violin plots showing the distribution of distances between ASGM sites and high–high (HH; blue) and low-low (LL; green) turbidity clusters

The results suggest that NDTI may provide an effective tool for identifying mining-related water turbidity. It relies solely on standard optical satellite imagery that is globally available, freely accessible, and frequently updated. Its calculation requires only red and green spectral bands, and is computationally simple and scalable. This makes it particularly valuable where field-based water quality data are limited or absent, enabling reproducible and cost-effective environmental monitoring of ASGM impacts in remote regions.

Future research could extend the proposed framework by integrating Land Surface Temperature (LST), the Normalized Difference Vegetation Index (NDVI), and the Bare Soil Index (BSI) with Normalized Difference Turbidity Index (NDTI)-based turbidity assessment. LST could provide complementary information on surface thermal changes associated with ASGM-related vegetation removal and soil exposure, while NDVI and BSI could help characterize vegetation loss and the expansion of disturbed or bare-soil areas around mining sites. Combining these indicators with NDTI could provide a more comprehensive assessment of the terrestrial–aquatic environmental footprint of ASGM and improve the monitoring of mining-induced landscape and water-quality changes.

## CONCLUSIONS

This study provides a comprehensive spatiotemporal assessment of turbidity dynamics in the Brokopondo Reservoir and evaluates the suitability of the NDTI as a proxy for monitoring the impacts of artisanal and small-scale gold mining.

By integrating five years of dry-season Sentinel-2 observations with spatial statistics and proximity analyses, the research demonstrates that turbidity in the reservoir is strongly structured spatially, highly persistent over time, and closely associated with the distribution of mining activities. Global Moran's I values consistently close to +1 confirm pronounced and stable clustering of high and low turbidity zones across all analyzed months, while Local Moran's I results show clear spatial segregation between HH and LL clusters with complete non-overlap in their distributions. These findings indicate that turbidity hotspots are not randomly distributed but represent persistent spatial features.

The analysis further reveals that neither precipitation nor hydrological distance meaningfully explains turbidity variability during the dry-season months. The very weak correlation between NDTI and rainfall ($r = 0.08$) indicates that seasonal filtering effectively removed climate-driven noise from the dataset, while negligible effect sizes derived from the hydrological distance analysis demonstrate that turbidity patterns do not follow the longitudinal structure of the reservoir. Instead, turbidity clusters are spatially localized and strongly influenced by nearby anthropogenic disturbances.

The proximity analysis confirms a significant and consistent spatial association between ASGM sites and HH turbidity clusters. Across all months from 2024-2025, HH clusters were systematically located closer to mining areas than LL clusters, with statistically significant results and moderate to strong effect sizes. These outcomes provide robust empirical support for the hypothesis that ASGM is a primary driver of elevated turbidity in the Brokopondo Reservoir.

Overall, the study suggests that NDTI has potential as a scalable, field-independent proxy

for mining-related turbidity. Its reliance on freely available optical satellite data, minimal spectral inputs, and straightforward computation makes it a potentially valuable tool for environmental monitoring in remote regions where conventional water-quality measurements are limited or unavailable. By combining spatial clustering metrics, non-parametric statistics, and proximity analysis, this research establishes a reproducible framework for detecting and tracking ASGM impacts on freshwater systems. The methodology and results highlight the potential for NDTI-based monitoring to support decision-making in environmental governance, early warning systems, and long-term assessments of mining-driven landscape change in tropical watersheds.

***Abstract***

*Metropolitan areas are most often affected by the weak presence of „green" infrastructure so that the climate can be affected. This work aims to evaluate the vegetation within the UASVM Cluj-Napoca campus, in terms of its spatial distribution, the types of vegetation and their characteristics. In an attempt to overcome the disadvantages of classical vegetation assessment methods, an approach that integrates several types of geospatial data was proposed. More specifically, LiDAR technology was used to determine, among other things, the height of forest vegetation and its density, aerial photogrammetric technology was used for contextual and texture information, and multispectral sensors helped to differentiate vegetation types. Data acquisition was carried out using the DJI MAVIC 3M, respectively the South SF 1200 with SG130 scanner. Data processing was carried out using various software. This research highlights the advantages brought by the use of the most modern geodetic and topographic technologies in the evaluation of green areas within large urban areas and their contribution to the most correct management of green areas.*

***Key words****: LiDAR, multispectral, photogrammetry, vegetation.*

## INTRODUCTION

The contemporary landscape is undergoing continuous transformation under the influence of natural processes and increasing anthropogenic pressures (Ali et al., 2026).

Romania has some of the largest remaining areas of old-growth forests in the European Union. This represents a very important part of the country's natural heritage. These forests continue to face increasing pressure due to inadequate management practices, despite their ecological significance, resulting in a gradual decline of their extent over recent decades. In this context modern surveying and monitoring technologies have become valuable tools for integrating spatial and descriptive data (Moatăr et al., 2026).

Rapid urbanization, land-use changes, and climate variability are altering the composition, structure, and spatial distribution of vegetation, highlighting the need for accurate and up-to-date monitoring approaches (Liang et al., 2020; Rai & Singh, 2026).

Traditional field-based vegetation surveys provide valuable information but are often time-consuming, labor-intensive, and difficult to implement over large or heterogeneous areas (Goebel & Iwaszczuk, 2026; Mohamad & Tahar, 2026).

Vegetation mapping with high accuracy is essential for monitoring plant distribution and for assessing ecosystem dynamics. Remote sensing has become one of the most effective methodologies in ths regard, being rapid and also cost efficient (Guan et al., 2019; Mohamad & Tahar, 2026).

Sattelite imagery has moderate spatial resolution being suitable for broad land cover classification, but high-resolution multispectral imagery which is also often combined with LiDAR data enables vegetation mapping with greater accuracy (Fernández-Guisuraga et al., 2018; Goebel & Iwaszczuk, 2023).

Equipped with a multitude of sensors, such as photogrammetric sensors, multispectral sensors and LiDAR, Unmanned Aerial Vehicles have become one of the most important technologies when it comes to remote sensing. Due to their ability to aquire high resolution spatial data, in a relatively short period of time, at relatively low cost, UAVs become essential tools in modern

vegetation assessment and monitoring (Hyyppä et al., 2020; Liu et al., 2026).

The objective of this study is to develop a high-resolution vegetation mapping framework for the UASVM Cluj-Napoca campus through 1the integration of UAV-based LiDAR, photogrammetric, and multispectral data. Specifically, the study aims to assess vegetation structure, estimate vegetation height and density, and generate a detailed vegetation inventory that can support future environmental monitoring and landscape management activities.

## MATERIALS AND METHODS

The investigated area covers approximately 26 hectares, with an elevation range of about 100 m, varying between 330 m and 440 m above sea level.

The study area consists of the USAMV Cluj-Napoca campus, Cluj County, Romania and a section of the adjacent Iuliu Prodan Park located in its immediate proximity.

The study site is characterized by an urban environment that includes numerous buildings, primarily dedicated to educational activities, while also containing extensive forest and horticultural vegetation. These characteristics, together with the easy and rapid access to the area, were the main reasons for selecting it as the case study site for this research.

LiDAR data were acquired using the South SF 1200 Unmanned Aerial System with SG130, which is 2kg aerial LiDAR system that combines a 45/61MP RGB camera with precise IMU/GNSS tracking. It has a ± 3 cm absolute accuracy. It features a 360° FOV, captures up to 800,000 pts/sec with 12 returns.

Photogrammetric and multispectral data was acquired using a DJI Mavic 3 Multispectral UAS equipped with an RTK-GNSS module providing positioning accuracies of approximately ± 0.10 m in both the horizontal and vertical components. The system integrates a 20 MP RGB camera for high-resolution photogrammetry and a 4-band 5 MP multispectral sensor (Green, Red, Red Edge, and NIR).

To complement the structural assessment, a series of spectral vegetation indices (Șuba et al., 2025) from the multispectral imagery were calculated, namely:

-NDVI (Normalized Difference Vegetation Index): It evaluates vegetation vigour, greenness, and photosynthetic activity based on red and near-infrared reflectance ((NIR - Red)/(NIR + Red));

-GNDVI (Green Normalized Difference Vegetation Index): It is sensitive to chlorophyll content and plant physiological condition through the use of the green spectral band. ((NIR - Green)/(NIR + Green));

-NDRE (Normalized Difference Red Edge Index): It assesses chlorophyll concentration and nitrogen status using the red-edge spectral region ((NIR - RedEdge)/(NIR + RedEdge));

-LCI (Leaf Chlorophyll Index): It estimates leaf chlorophyll content and vegetation productivity. ((NIR - RedEdge)/(NIR + Red));

-MCARI (Modified Chlorophyll Absorption Ratio Index): It enhances sensitivity to chlorophyll absorption and vegetation stress while reducing background effects ([(RedEdge - Red) - 0.2 (RedEdge - Green)]/times (RedEdge/Red));

-SIPI (Structure Insensitive Pigment Index): It evaluates pigment balance and vegetation stress while minimizing canopy structure influence ((NIR - Blue)/(NIR - Red)) (Șuba et al., 2025).

The workflow (Figure 1) which starts with UAV-based LiDAR, RGB, and multispectral data acquisition, followed by direct GNSS georeferencing.

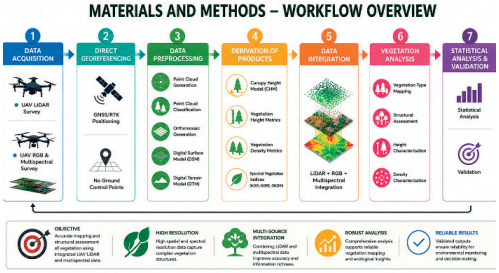

Figure 1. Workflow overview

After preprocessing, both structural and spectral vegetation metrics were derived, such as canopy height, density, and vegetation indices. These datasets were integrated and analysed together to provide a detailed assessment of vegetation.

## RESULTS AND DISCUSSIONS

In the first stage, a colorized LiDAR point cloud was generated from the acquired UAV data. This point cloud can be seen in Figure 2.

Figure 2. Colorized point cloud

Subsequently, the point cloud was analyzed based on elevation values, allowing the visualization and assessment of height variations across the study area and providing valuable information on vegetation structure and terrain morphology.

The LiDAR point cloud was subsequently classified into several categories, including ground points (brown), buildings (orange), and vegetation (green).

The classification was performed automatically using the Maximum Likelihood Estimation (MLE) algorithm (Figure 3).

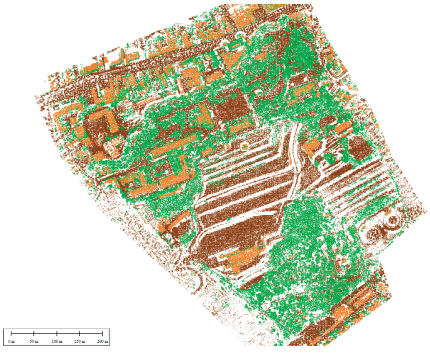

Figure 3. Ground points (brown), Buildings (orange), Vegetation (green)

Other valuable outputs derived from the LiDAR survey are the vertical cross-sections through the point cloud. These cross-sections provide detailed information on the vertical structure of vegetation and can support species identification (Figure 4).

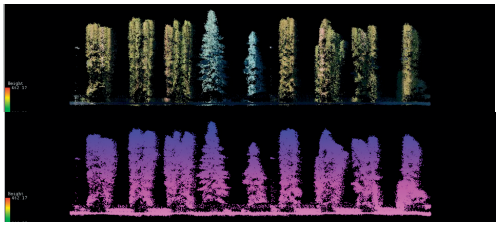

Figure 4. Thuja and spruce trees identified in the vertical cross-section

Tree and canopy extraction was also performed automatically using the Maximum Likelihood Estimation (MLE) algorithm combined with MultiScale Classification. This approach enabled the identification and delineation of individual trees and their crowns based on the structural characteristics of the LiDAR point cloud. The extracted tree attributes included elevation, tree height, mean crown diameter, and maximum crown diameter, providing detailed quantitative information for each identified tree (Figure 5).

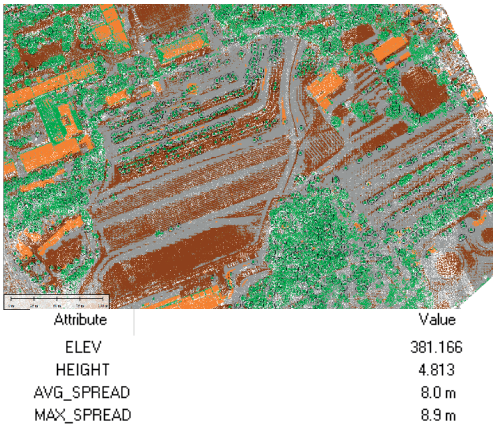

Figure 5. Tree and canopy extraction

The automated extraction of trees and canopy boundaries also presents several limitations, particularly regarding canopy delineation accuracy and trunk positioning. For example, large tree crowns may be divided into two or more individual trees, as major branches can be interpreted as separate crowns.

In Figure 6 it can be seen the Elevation-based representation A total of 1,645 trees exceeding 2.5 m in height were identified within the study area. The detected trees were distributed across different height classes, providing an overview of the vertical structure and composition of the vegetation.

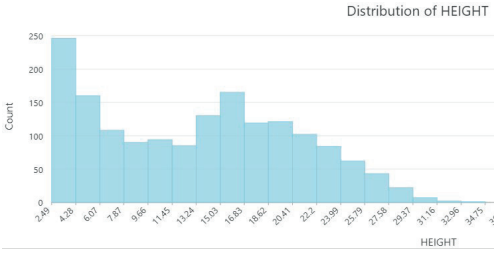

Figure 6. Elevation-based representation

Tree density map showing the distribution of trees per square meter across the study area is presented in Figure 7.

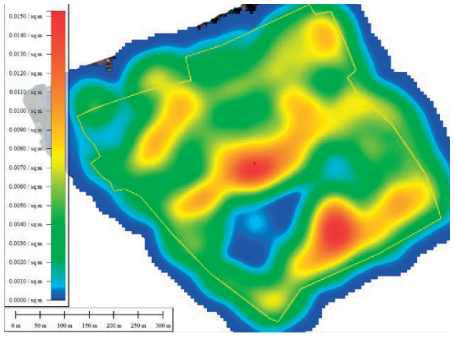

Figure 7. Tree density map

Multispectral images were acquired according to a predefined flight plan. A total of 2,796 images (RGB, Green band, Red band, Red Edge band) were collected during the survey. The study area covered approximately 262,330 m² (26.23 ha). Following image processing, a high-resolution orthomosaic was generated (Figure 8).

GNDVI quantifies vegetation health and vigour by comparing the reflectance recorded in selected spectral bands. Higher GNDVI values (approaching +1) indicate vegetation with elevated chlorophyll concentrations and intense photosynthetic activity, characteristics commonly associated with dense and healthy plant cover.

Figure 8. High-resolution orthomosaic

Intermediate GNDVI values correspond to areas with partial vegetation cover, such as grasslands or sparsely cultivated fields, where vegetation condition and density may vary. Lower GNDVI values (around 0) generally represent bare soil, built-up areas, or locations with limited vegetation cover. Negative GNDVI values are typically associated with water bodies, barren surfaces, or other non-vegetated land covers (Figure 9).

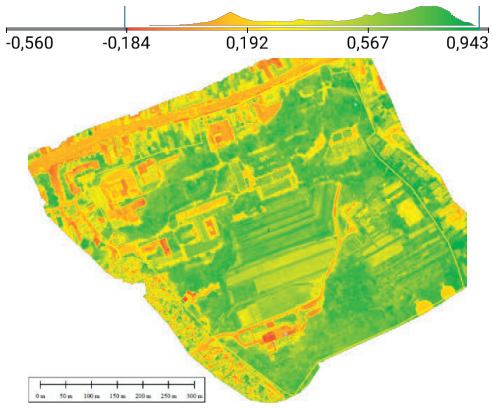

Figure 9. GNDVI

The Leaf Chlorophyll Index (LCI) is derived from the Near Infrared (NIR) and Red Edge spectral bands (Figure 10). The NIR band is particularly responsive to leaf internal structure and water content, whereas the Red Edge band is closely related to chlorophyll concentration, enabling an accurate assessment of vegetation condition. Low LCI values (grey to dark orange) generally indicate low chlorophyll concentrations and are commonly associated with bare soil, non-vegetated areas, or

vegetation affected by severe physiological stress. Moderate LCI values (yellow to light green) correspond to areas with partial vegetation cover, where reduced chlorophyll content may reflect nutrient limitations or environmental stress conditions. High LCI values (bright green) represent vigorous and healthy vegetation characterized by high chlorophyll concentrations, active photosynthesis, and strong plant development.

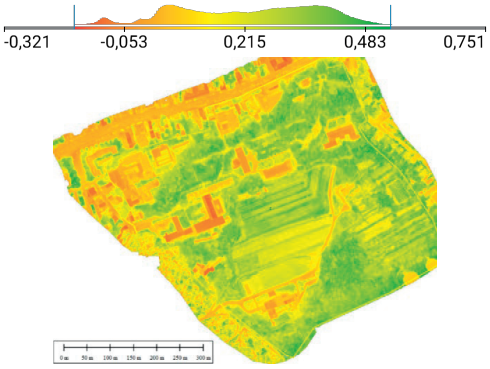

Figure 10. LCI

MCARI is highly responsive to changes in chlorophyll concentration and the Leaf Area Index (LAI), making it an effective indicator for evaluating vegetation health and detecting plant stress. High index values (dark to light green) are associated with elevated chlorophyll concentrations, reflecting healthy, vigorous vegetation with high photosynthetic activity. Moderate values (yellow to orange) indicate intermediate chlorophyll levels and may suggest the presence of mild plant stress or the onset of nutrient deficiencies. Low values (dark orange to red) are characteristic of vegetation with reduced chlorophyll content and are often linked to physiological stress, chlorosis, or diminished photosynthetic performance (Figure 11).

Because the NDRE index incorporates the Red Edge spectral band, it is particularly effective at identifying subtle changes in vegetation health before visible symptoms become apparent.

This capability makes it especially useful for precision agriculture applications, including crop health assessment, stress detection, and continuous crop monitoring. Negative values or values approaching zero (grey to dark orange) generally correspond to bare soil, non-vegetated surfaces, or vegetation in poor health.

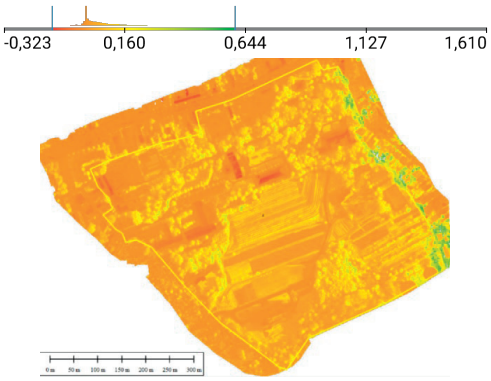

Figure 11. MCARI

Moderate values (yellow to light green) indicate the presence of vegetation with intermediate chlorophyll levels, which may reflect physiological stress or reduced plant vigour. High values (bright green) are characteristic of dense and healthy vegetation with high chlorophyll activity, indicating vigorous plant growth and optimal physiological condition (Figure 12).

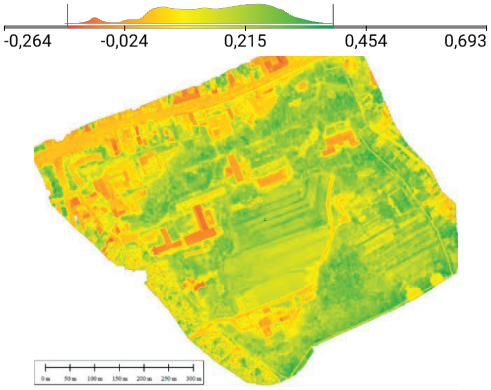

Figure 12. NDRE

In Figure 13 the NDVI applied on the studied area can be seen. High NDVI values (approaching +1) indicate dense, healthy vegetation with abundant chlorophyll content and active photosynthesis. On NDVI maps, these areas are typically displayed in bright green. Moderate NDVI values (around 0) are generally associated with sparse vegetation, grasslands, or areas with relatively low chlorophyll concentrations. These regions are commonly represented by yellow or light green shades. Low NDVI values (approaching −1)

correspond to bare soil, exposed rock, or other non-vegetated surfaces where vegetation is absent. On NDVI maps, these areas usually appear in brown or reddish colours.

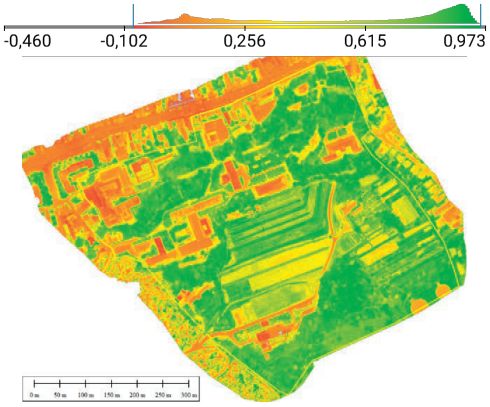

Figure 13. NDVI

The Structure Insensitive Pigment Index 2 (SIPI_2) (Figure 14) evaluates plant stress and pigment composition, particularly the carotenoid-to-chlorophyll ratio. Because it is less influenced by leaf structure, it provides a reliable assessment of vegetation health and photosynthetic performance.

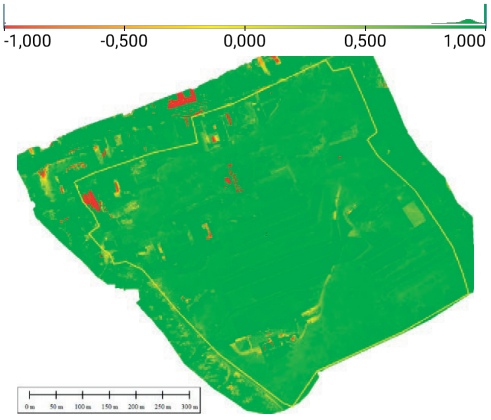

Figure 14. SIPI_2

The predominance of green areas indicates that most of the analysed vegetation is healthy and in good physiological condition.
Mean GNDVI values were calculated for each identified tree crown.
It can be observed that most trees fall within the higher GNDVI value range, indicating a generally good vegetation condition and relatively high chlorophyll content (Figure 15).

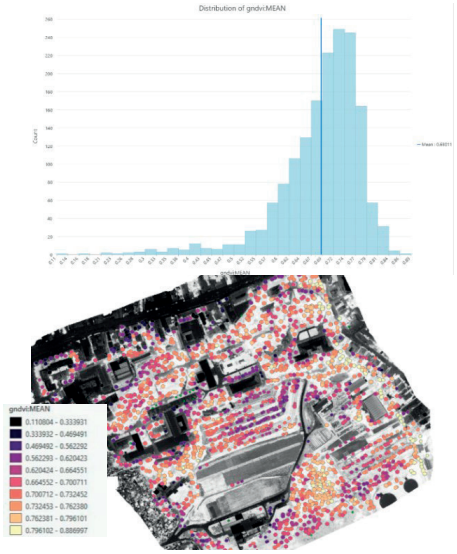

Figure 15. (Up) Mean GNDVI Values per Tree and (Down) Symbology of Mean GNDVI Values per Tree

The distribution of mean LCI values (Figure 16) appears relatively uniform across the study area, with a similar number of trees exhibiting values below and above the overall mean. This pattern suggests a relatively homogeneous distribution of chlorophyll content and vegetation condition among the identified trees.

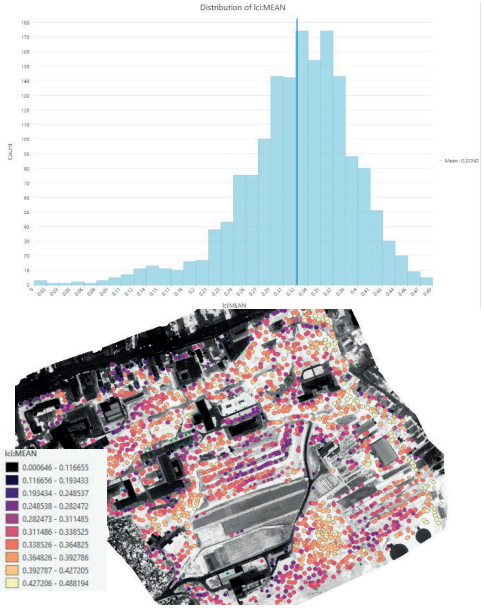

Figure 16. (Up) Mean LCI Values per Tree and (Down) Symbology of Mean LCI Values per Tree

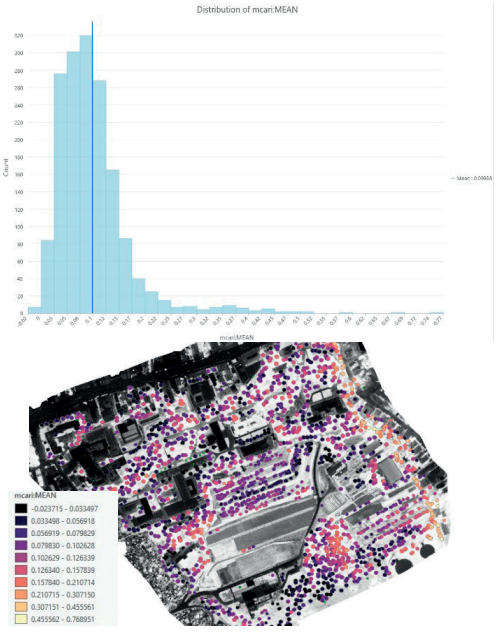
The distribution of MCARI values (Figure 17) indicates that most trees are characterized by values below the overall mean. In addition, the range of values is relatively narrow, resulting in limited differentiation between distinct value classes across the study area.



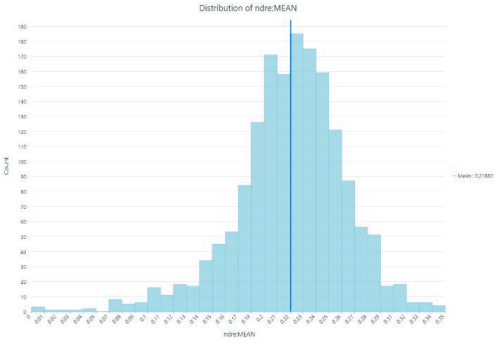


Figure 17. (Up) Mean MCARI Values per Tree and (Down) Symbology of Mean MCARI Values per Tree

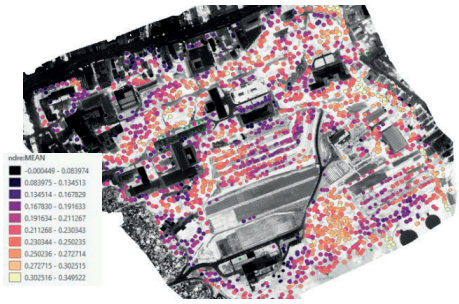
The distribution of mean NDRE values (Figure 18) appears relatively uniform across the study area, with a similar number of trees exhibiting values below and above the overall mean.



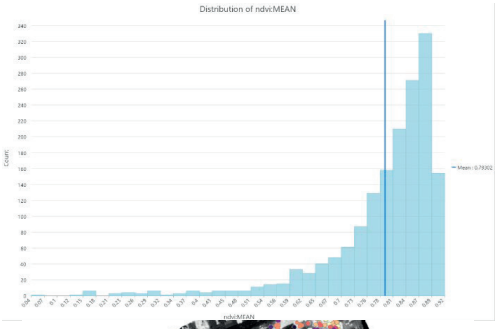


Figure 18. (Up) Mean NDRE Values per Tree and (Down) Symbology of Mean NDRE Values per Tree

The distribution of NDVI values (Figure 19) indicates that the majority of trees exhibit values above the overall mean. This suggests generally healthy vegetation conditions and a high level of photosynthetic activity throughout the study area.

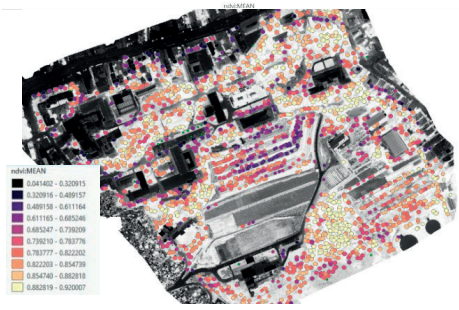

Figure 19. (Up) Mean NDVI Values per Tree and (Down) Symbology of Mean NDVI Values per Tree

The distribution of mean SIPI values (Figure 20) appears relatively uniform across the study area, with a similar number of trees exhibiting values below and above the overall mean.

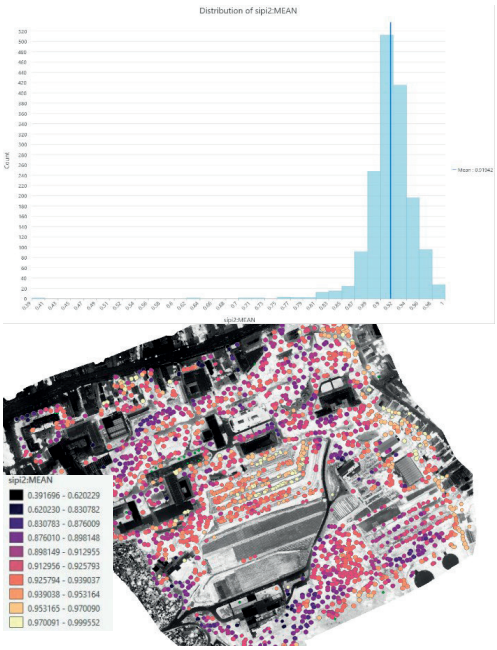

Figure 20. (Up) Mean SIPI_2 Values per Tree and (Down) Symbology of Mean SIPI_2 Values per Tree

All indices have median values close to 0 (distributed between -1 and +1, which also confirms their compliance with the theoretical thresholds), which is expected after standardization (Figure 21).

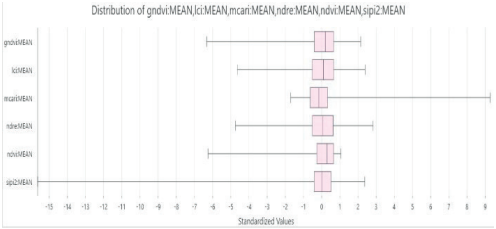

Figure 21. Boxplot Representation of Standardized Vegetation Indices

The boxplots are relatively narrow and similar in size, suggesting that most trees exhibit relatively homogeneous vegetation responses.
The main differences are observed in the length of the whiskers, which indicate the presence of trees with values that differ considerably from the rest of the population. This is most likely due to different species and unique specimens, especially those located within the agro-botanical garden area, although it may also result from canopy delineation errors.

## CONCLUSIONS

The LiDAR survey showed detailed information on both terrain and vegetation structure, thus being able to generate multiple high-value products from a single dataset. The automatic classification successfully separated ground, buildings, and vegetation, while tree and canopy extraction allowed the estimation of key dendrometric parameters, including tree height and crown dimensions.
Although the automated workflow proved efficient for processing large datasets, certain limitations were observed in the matter of canopy delineation, where large crowns were occasionally segmented into multiple individual trees. Nevertheless, the identification of 1,645 trees higher than 2.5 m and the generation of elevation and tree density maps demonstrate the potential of UAV-based LiDAR data for rapid and detailed forest inventory, vegetation analysis, and environmental monitoring.
Based on the images (in the following order: GNDVI → LCI → MCARI → NDRE → NDVI → SIPI2), a visual analysis of the consistency of tree classification can be performed.
There is no perfect correspondence between trees assigned to different classes across all images. The same tree that appears in a high-value class for one index may appear in a medium or even low-value class in another index. This is expected, as each index measures a different aspect of vegetation condition.
A partial correlation can be observed among the indices. Many trees maintain their general trend (high or low values) across several maps; however, they are not classified identically in all cases.
LCI and NDRE – The two maps exhibit a very similar distribution of values, indicating a strong correlation in identifying trees with different chlorophyll levels.
NDVI and GNDVI – Values are distributed similarly across most areas, highlighting a good correlation between vegetation vigor and chlorophyll content.
MCARI – This index reveals more pronounced differences among trees, and its results are only

partially similar to those obtained from NDVI and NDRE.

SIPI2 – The distribution of values differs the most from the other indices, suggesting that it captures distinct physiological characteristics, particularly those associated with vegetation stress.

A potential direction for future research is the correlation of vegetation indices with ground-collected data for tree species identification and condition assessment. By comparing GNDVI, LCI, MCARI, NDRE, NDVI, and SIPI2 values with direct field observations regarding species, health condition, stress level, defoliation, or the presence of degradation symptoms, it may be possible to determine whether certain species exhibit specific spectral signatures and whether they respond differently to stress factors. Such an approach would contribute both to improving species identification and to developing remote sensing–based models for monitoring tree health.

## ACKNOWLEDGEMENTS

This research work was carried out with the support of Ministry of Education and was financed through the CNFIS-FDI-2025-F-0030 project, funded by the National Council for Financing Higher Education (CNFIS).

## USE OF GENERATIVE ARTIFICIAL INTELLIGENCE (GenAI)

The authors declare the use of Generative Artificial Intelligence (GenAI) tools in the preparation of this manuscript. GenAI was used exclusively for language editing and text refinement and for the visual refinement of the sketch in Figure 1, which was previously drafted by the authors. All scientific content, data analysis, and interpretations were developed and verified by the authors.

***Abstract***

*Forests are among Earth's most important ecosystems, but unfortunately are vanishing at alarming rates. Thus, deforestation is a global challenge with serious impacts. This paper utilizes Google Earth Engine Landsat data, together with climatic and land-cover data in order to predict the annual deforestation rate in Suceava County. This is being accomplished by using deep learning techniques, more precisely by using Long Short-Term Memory Neural Networks in order to forecast the land changes. These offer distinct advantages in handling time-series data with long-term dependencies, thus making them particularly suitable for tracking changes in vegetation over time. The results have shown an average prediction of 0.45% tree cover loss every year for the next 10 years timeframe. Deforestation studies in Romania have largely focused on spatial analysis but predictive temporal modelling using LSTM remained underexplored. By leveraging the collected data, the paper demonstrates how deep learning techniques can enhance the monitoring and forecasting of forest loss, supporting more sustainable forest management and policy-making. Integrating such approaches could pave the way to anticipating risk and protecting high risk zones before deforestation occurs.*

***Key words****: climate protection, deep learning, deforestation, predictions.*

## INTRODUCTION

An important portion of the EU's biodiversity value forests lies in Romania, but unfortunately this wealth is not being protected enough. Romanian forests occupy around 6.5 million hectares, which translates to approximately 29% of the national territory (Romanian Ministry of Environment, Waters and Forests, 2023). Nowadays, thousands of hectares of forests have been logged and thus, it has emerged as a major environmental concern over the past three decades. Their symbolic value is as important as their ecological and economical one. It is being believed that up until today, illegal logging has cost Romania more than 5.7 billion dollars since the fall of the communism (Lawrence, 2015). One prime example is Suceava County in North-Eastern Romania, which has experienced significant tree-cover loss in the last few decades and which exhibits one of the highest levels of forest loss in Romania (Global Forest Watch, 2025). Yet there are no widely published, formal predictive models specifically for this county deforestation rates in the next 5-20 years available in popular sources. Using deep learning models, Suceava County can be modeled as a high-risk deforestation region, with predictions strongly influenced by past logging intensity, accessibility and climate stress.

Traditional deforestation monitoring methods rely heavily on satellite observation and manual interpretation, which can be time-consuming and less effective for early detection. Recent advances in machine learning, particularly Long Short-Term Memory (LSTM) neural networks, have made it possible to model and predict temporal patterns in environmental data. This study explores how LSTM-based models can be applied to Romanian forest data to predict future deforestation trends. As the drivers of deforestation are usually non-linear and heterogenous, neural networks might help overcome these challenges as they are very good at capturing non-linear functional forms and heterogeneity.

Romania's forests are among the most extensive and biologically diverse in Europe (European Environment Agency, 2024). Figure 1 presents an overview of the current deforestation status in all the EU countries. However, deforestation is not a problem for these countries as overall, Europe is experiencing a net reforestation.

Land-use change in Romania, particularly deforestation accelerated in the past few

decades. In Eastern Europe, land cover and use changes are a consequence of the combined conflict of economy and nature (Gurung et al., 2009). In order to analyze this and look at potential trends, spatially explicit land-use changes must be scale sensitive (Veldkamp et al., 2001; Lausch et al., 2015). Even though these forests are recognized for their exceptional diversity and vital roles in carbon storage, biodiversity conservation and sustainable resource management, the predictions for deforestation are alarming, with a significant amount of natural forest loss and a requirement for reforms to combat the underlying issue (Bohateret, 2012). This is being combined with a degradation of the land, as a result of irrational use of land resources, the abandon or even destruction of improvement systems as well as low fertization of agricultural land (Bălteanu & Popovici, 2010).

Thus, deforestation represents a critical environmental issue in Romania which needs rapid intervention and closer monitoring practices.

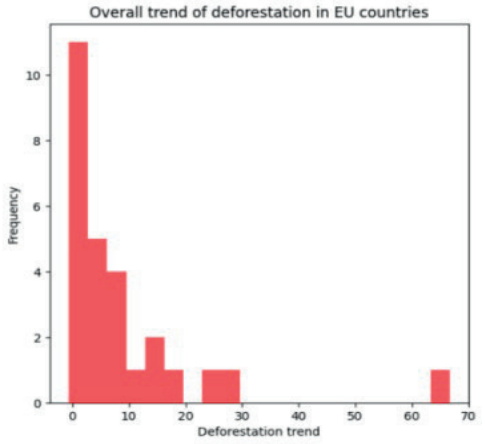

Figure 1. Overall trend of deforestation in EU

The use of AI's predictive power in deforestation forecasting represents a hot topic worldwide. This artificial intelligence enabled tools enable authorities to intervene before forest cover loss happens, providing a useful and reliable tool of real time monitoring and analysis. Similar tools have already been used by authorities in 6 countries but plans are already being developed in order to extend the usage of the AI tools to 12 countries by 2027. The Forest Foresight Model, developed by dutch scientists together with partners from Amazon Web Services aims to predict illegal deforestation up to six months before it occurs (WWF, n.d.). Also, artificial intelligence methods are embedded in platforms such as Google Earth Engine, where the satellite images are being analyzed using machine learning approaches, as well on the Global Forest Watch platform which provides real-time alerts of deforestation activities. These examples reinforce the need and importance of incorporating AI-powered systems in order to diminuate world forest loss (Chatrabhuj & Meshram, 2024).

This paper presents a methodological framework for predicting deforestation trends in Romania using Long Short-Term Memory (LSTM) neural networks. By leveraging satellite imagery, climatic variables, and land-cover data, the study demonstrates how deep learning techniques can enhance the monitoring and forecasting of forest loss, supporting more sustainable forest management and policy-making.

## MATERIALS AND METHODS

The shift from simply monitoring what's already gone to forecasting what is at risk in the future represented a breakthrough moment. Nowadays, predicting deforestation using machine learning has become a growing field. Previous studies have employed algorithms such as Random Forests, Support Vector Machines, and Convolutional Neural Networks (CNNs) on remote-sensing data. In this paper, a linear regression model has also been employed in order to forecast forest cover tree loss (Figure 2).

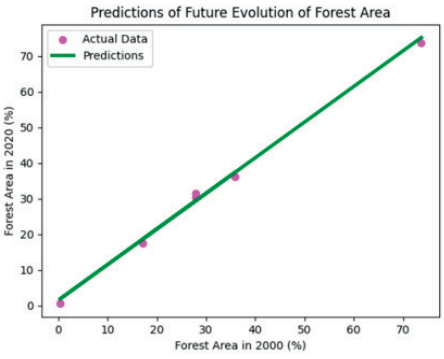

Figure 2. Forest cover loss forecast

Artificial intelligence driven deforestation prediction offers a numerous advantage over traditional monitoring techniques. By allowing less human participation for large-scale prognostic and research, it enables better and more accurate results.

The dataset used in this study includes: Landsat satellite images, collected between 2001 and 2024, vegetation indices, climatic variables, such as temperature, precipitation and soil moisture data as well as land cover data. Images are pre-processed through cloud masking, normalization, and temporal alignment. NDVI time-series are generated for each 1 km² grid cell. The dataset is then divided into training (70%), validation (15%), and test (15%) sets.

Neural networks are computational models of the brain. Artificial neurons are interconnected by edges, forming a neural network. Similar to the brain, the network receives input, internal processes such as activations of the neurons take place and the network yields output. Although these neural networks have a long history of research which dates back to 1943, the number of researchers involved was very small for the first 40 years. It was in 1983 that the funding of neural networks research began being funded in the US.

LSTM networks, a type of Recurrent Neural Network (RNN), offer distinct advantages in handling time-series data with long-term dependencies and are particularly suitable for tracking changes in vegetation over time. Deep learning is a sub-type of machine learning that uses deep neural networks to learn patterns from large amounts of data automatically. For deforestation detection, deep learning models can understand complex image features related to deforestation. Thus, more accurate detection results can be produced as a result (Yu et al., 2020). The collected and analyzed data for Suceava Country, Romania is between 2001 and 2024. Figure 3 presents the percentage of cover tree loss for the above-mentioned period of time.

Romanian forests display considerable variability, covering a broad spectrum of forest types, management approaches, and ecological characteristics, making them representative of wider European forest conditions. Deforestation is fundamentally a human process fuelled by a complex mixture of economic, political, and environmental factors (Malek et al., 2018; Rădulescu et al., 2022).

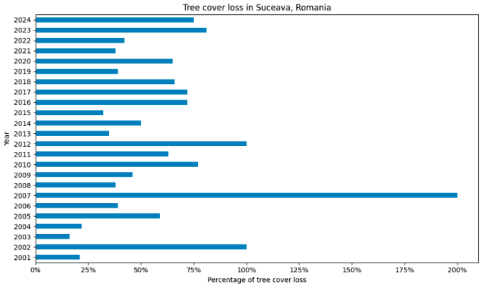

Figure 3. Tree cover loss 2001-2024 in NE Romania

Predicting deforestation is important for targeting interventions and for impact evaluation. Deforestation in general can have serious effects on the quality of life, such as: it worsens air pollution, affects biodiversity, disrupts water cycle and can even increase the risk of a pandemic. Deforestation has been proven to increase the risk of emergence of new diseases, as exemplified for the recent COVID-19 pandemic (Singhal et al., 2024). Predicting the location and timing of future loss is thus incredibly difficult (Cheval et al., 2022). In our paper, we solve this by utilizing Google Earth Engine data, together with climatic and land-cover data in order to provide accurate predictions for the analyzed region. Google Earth Engine is a cloud-based geospatial analysis platform that enables users to visualize, analyze and download satellite images. On top of providing raw imagery, Earth Engine contains several collections of associated data: SR, BAI, EVI, NBR, NDVI, and NDWI at 8-day, 32-day, and annual cadences, allowing for more in-depth analysis (Table 1). Google Earth's capabilities are further enhanced by GEE, which provides on-demand access to a large collection of remote sensing data, allowing for an in-depth and reliable analysis.

The data has been statistically processed and interpreted by building the trend line and setting up the forecast based on simulation models for the period 2025-2035. In Suceava, Romania, the annual deforestation rate has been significant in the past, with a loss of 1.1 kha of natural forest in 2024 only and thus represents a county of major interest.

Table 1. Vegetation indices, formula and description

| Index | Formula | Description |
|---|---|---|
| Normalized Difference Vegetation Index (NDVI) | $NDVI = \frac{(NIR - Red)}{(NIR + Red)}$ | Measures vegetation health by comparing NIR reflectance (healthy vegetation) with Red reflectance (chlorophyll absorption). Chosen for its widespread use in assessing vegetation cover and health |
| Shadow Index (SI) | $SI = (1 - Blue) \times (1 - Green) \times (1 - Red)$ | Custom index to detect shadowed areas in forests using visible bands. Selected to differentiate shadows from water and dark surfaces. |
| Enhanced Vegetation Index (EVI) | $EVI = \frac{(NIR - Red) \times 2.5}{(NIR - 6Red - 7.5Blue + 1)}$ | Enhances sensitivity to dense vegetation, reducing soil and atmospheric effects. Effective in monitoring forest canopy health. |
| Burn Area Index (BAI) | $BAI = \frac{1}{((0.1 - Red)^2 + (0.06 - NIR)^2)}$ | Highlights post-fire areas by assessing the spectral difference from charcoal reflectance. |
| Normalized Burn Ratio (NBR) | $NBR = \frac{NIR - SWIR}{NIR + SWIR}$ | A climatic index used to highlight burnt areas in large fire zones. |

## RESULTS AND DISCUSSIONS

As a summary, from 2001 to 2024, Romania lost around 6.0% of the 2000 tree cover area. Particularly for Suceava County, it meant a total loss of 15% from the 2000 tree cover area. Thus, Suceava County stands out as being one of the most extensively deforested areas in Romania.
The yearly forecast from 2025 to 2035 is approximately 0.45% forest cover loss for each subsequent year. The model predicts a prolongation of the incremental trend in deforestation. It represents a starting point and invites us all to take preventive actions in order to reduce the potential adverse effects deforestation has for the general population.
In this paper, a neural network, specifically the Long Short-Term Memory Neural one has been employed, together with 2001-2024 data in order to predict the deforestation trend in 2025-2035. Long Short-Term Memory Neural Networks have been specifically used for modelling the temporal data of deforestation (Hochreiter & Schmidhuber, 1997).
The LSTM model architecture is presented below in Figure 4.

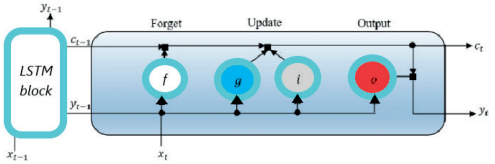

Figure 4. LSTM model architecture

The Long Short-Term Memory (LSTM) architecture is composed of linear units that include a self-recurrent connection with a constant weight of 1.0. This design enables values during the forward pass, as well as gradients during the backward pass, to be retained within the self-recurrent unit and accessed at the appropriate time step. Through this unit multiplier, the output or error from the previous time step is directly propagated to the subsequent time step. As a result, this self-recurrent unit, referred to as the memory cell, is able to store information over long temporal intervals, spanning dozens of time steps.
In our case, we have: one input layer represented by sequential NDVI and climatic data for each pixel, two hidden layers with 64 and 32 units, followed by dropout for regularization, a dense output layer represented by a sigmoid activation predicting the probability of deforestation occurrence in the next year, a binary-entropy loss function and as optimizer, Adam with a learning rate of 0.0001. The model's performance is assessed by using evaluation metrics described in Table 2.

Table 2. Evaluation metrics

| Model name | Accuracy | Precision | Recall | AUC |
|---|---|---|---|---|
| LSTM | 0.848169 | 0.848169 | 0.848169 | 0.950000 |

A variety of metrics can be employed to assess a model's performance, typically based on the counts of true positives (TP), true negatives (TN), false positives (FP) and false negatives (FN). One widely used evaluation tool is the Receiver Operating Characteristic (ROC) curve that has been plotted in order to evaluate classification performance (Figure 5). The ROC curve is a visual representation of model performance across all thresholds. It is drawn by calculating the true positive rate (TPR) and false positive rate (FPR) at every possible threshold (in practice, at selected intervals), then graphing TPR over FPR.

The trained LSTM model demonstrates high predictive accuracy, particularly in identifying high-risk zones in the Northern Eastern region of Romania and predicting the forest cover loss for the next 10 years timespan.

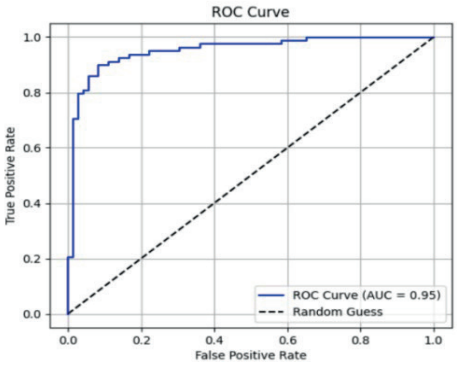

Figure 5. ROC-AUC curve

Areas in Suceava county especially show elevated predicted probabilities of deforestation due to intensive logging and road development. The model's time-series capability allows it to detect early NDVI declines indicative of forest degradation, even before clear-cutting occurs. Compared to the linear regression static model, the LSTM achieved a 10% improvement in F1-score. However, limitations include uneven data quality across regions and the difficulty of distinguishing legal from illegal logging activities. The area under the ROC curve (AUC) represents the capability of the model. The obtained value (0.95) highlights the great power and capability of the model and offers promises. In order to balance the deforestation, several countries bet on reforestation.

Figure 6 presents the differences in forest-cover distribution across European countries in 2000 and 2020, respectively.

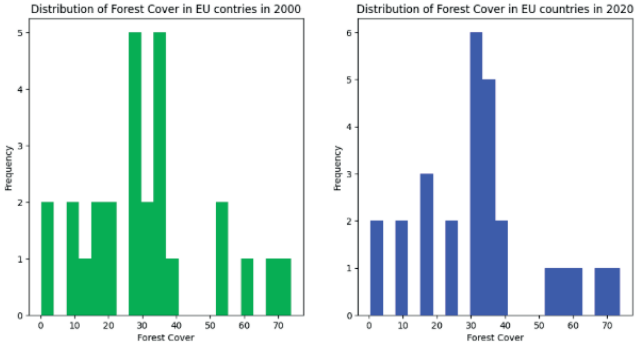

Figure 6. Distribution of Forest Cover in EU countries

Unfortunately, the reforestation trend has been going downwards lately in Romania, as last year (2024) it saw a decrease in forest regeneration efforts, with a total of 25,579 hectares reforested.

## CONCLUSIONS

Urgent attention must be paid to the problem of deforestation. However, Romanian forests face big challenges in being efficiently monitored at national scale. Thus, forecasts of deforestation risk could be a vital tool for prevention and protecting nature. Combining data collection, mapping and artificial intelligence approaches, the paper seeked to provide a 10-year overview of forest changes, a case study on the Suceava County in Northern Romania. The findings, exemplified by the percentage and impact of tree cover loss, can guide broader efforts to identify and address dangerous changes in forest cover.

This study demonstrates the feasibility and effectiveness of using LSTM networks for deforestation prediction in Romania. By analyzing temporal trends in vegetation indices and environmental factors, the model provides valuable foresight into forest loss dynamics. Future work should focus on integrating real-time data streams, expanding spatial resolution, and combining deep learning with socio-economic modelling for a more comprehensive understanding of deforestation drivers. These results provide useful insights for a better monitoring system and possible measures to be taken in advance by authorities in order to

prevent cover tree loss. This work lays the foundations of a deforestation prediction model for municipalities of Romania that combines dense neural and LSTM networks. Ultimately, this paper represents a major step forward in harnessing the power of artificial intelligence in forest monitoring and offers a pathway for better global efforts in preserving natural resources in the long-term.

***Abstract***

*This study investigates the application of Artificial Intelligence (AI) techniques in land cover classification based on satellite imagery, with the objective of improving the accuracy and efficiency of traditional geospatial workflows. The research evaluates how conventional Geographic Information System (GIS) procedures can be enhanced through the integration of machine learning algorithms, particularly those designed for raster segmentation and automated image classification. A comparative analysis between classical supervised methods and AI-based approaches was conducted to detect land use and land cover (LULC) changes in the city of Satu Mare using multitemporal satellite data. Results show that AI-driven models offer improved classification consistency and reduced manual processing efforts. The results underline the relevance of AI-assisted image interpretation for land monitoring and its potential contribution to sustainable spatial planning. The proposed approach can be transferred to similar LULC studies.*

***Key words****: Artificial Intelligence, automated classification, land use and land cover (LULC), satellite imagery, urban expansion.*

## INTRODUCTION

Land use and land cover (LULC) dynamics are the indicator of human pressure on land resources and a major driver of environmental change with direct implications for agriculture, soil functions, and ecosystem services. Sustainable land management requires accurate and timely monitoring of land cover (LC), especially in rapidly evolving urban areas (Vitale & Lamonaca, 2026).

Urban expansion and peri-urban development often compete with agricultural land through land take, fragmentation, and the conversion of open or cultivated areas into sealed surfaces. These processes can alter infiltration and runoff regimes, reduce soil water storage capacity, and constrain the long-term productivity and resilience of agroecosystems. Recent European assessments underline soil sealing and land occupation as persistent and relevant pressures linked to spatial development, reinforcing the need for robust monitoring tools that can support sustainable land management and evidence-based planning (Arias-Navarro et al., 2024).

Earth observation (EO) provides an operational framework for consistent and repeatable LULC monitoring across large areas and multi-annual time spans. Among currently available EO missions, Sentinel-2 multispectral imagery offers a well-balanced combination of spatial resolution (10-20 m), revisit frequency, and spectral capability, enabling the detection and mapping of heterogeneous land-cover patterns.

Multitemporal analyses derived from such imagery can capture trajectories of change (e.g., densification, conversion of open land into built-up areas, or shifts between vegetated and non-vegetated surfaces) when acquisition dates are chosen to minimize seasonal bias. In the underlying study that informs this paper, Sentinel-2 imagery acquired in July 2017, July 2019, and July 2024 was selected to improve cross-year comparability and reduce confounding seasonal effects.

Conventional GIS LULC mapping typically relies on supervised classification algorithms (e.g., Random Forest/Random Trees, Support Vector Machines), supported training samples

and post-classification refinement. While these approaches remain widely used and can provide reliable outputs under appropriate conditions, their performance is often sensitive to training-sample representativeness and to class separability. This limitation becomes particularly pronounced in urban and peri-urban settings where spectral mixing, shadowing, and material heterogeneity increase confusion between classes (e.g., bare soil vs. construction surfaces; bright roofs vs. exposed ground).

In the Satu Mare case study, the baseline workflow required iterative training-sample refinement to mitigate overlaps between "bare soil" and "construction zones" and to address localized reflectance anomalies (e.g., highly reflective surfaces) that can propagate classification noise.

In recent years, Artificial Intelligence (AI), and especially deep learning (DL), has advanced LULC mapping by enabling models to learn complex spectral and spatial reform imagery. Unlike pixel-wise classifiers that often treat observations independently, DL methods can exploit contextual information (texture, morphology, neighbourhood structure), which tends to improve thematic consistency and reduce the characteristic "salt-and-pepper" effect in heterogeneous landscapes (Hurskainen et al., 2019).

A comprehensive review in Remote Sensing of Environment highlights how DL has accelerated urban land use mapping in scale, automation, and accuracy, particularly when integrated with modern geospatial data ecosystems (Li et al., 2024). Within DL, semantic segmentation has become a particularly relevant paradigm for EO-based LULC mapping because it produces dense, pixel-level predictions while implicitly capturing spatial structure. Recent empirical comparisons of segmentation architectures (e.g., U-Net, DeepLabV3+) demonstrate strong performance for multi-class land-cover tasks and suggest meaningful gains in both accuracy and robustness across diverse geographic contexts (Deressu et al., 2025). Furthermore, methodological work emphasizes that careful use of spectral information (including band-selection strategies) can strengthen segmentation outputs in applications relevant to urban planning and land-use management (Jia et al., 2024). Despite these advances, the practical adoption of AI in applied LULC monitoring still raises questions regarding labelling requirements, generalization across years and acquisition conditions, and integration into established GIS workflows.

This paper investigates how traditional Geographic Information System (GIS) LULC workflows can be enhanced through Artificial Intelligence approaches for raster segmentation and automated image classification. A comparative analysis is conducted between a classical supervised method implemented in a GIS environment and AI based approaches using multitemporal Sentinel-2 imagery for the municipality of Satu Mare, Romania. To ensure cross-temporal comparability, we employed a consistent four-class LULC classification scheme represented in Figure 1, for all acquisition years.

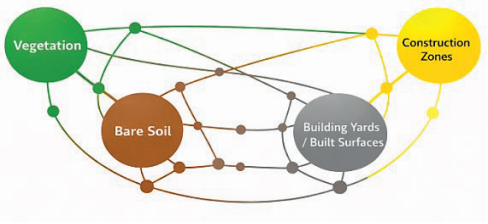

Figure 1. Land Cover classes

The study aims to evaluate improvements in classification consistency, quantify the reduction of manual effort linked to iterative training and correction, and to propose a transferable workflow for comparable LULC monitoring tasks at the urban and agricultural interface.

## MATERIALS AND METHODS

### *Study Area*

The selected case study is the municipality of Satu Mare, located in north-western Romania, in Satu Mare County, near the national borders with Hungary and Ukraine. The city is situated along the Someș River, mainly on its right bank, at approximately 47°47′24″ N latitude and 22°53′24″ E longitude. Positioned at an average altitude of about 126 m, Satu Mare lies within the lower floodplain of the Someș River, in a predominantly lowland area characterized by flat terrain.

Covering an area of approximately 120 km², Satu Mare represents an important administrative, economic, and cultural centre in the

north-western part of the country. Its geographical location, about 13 km from the border with Hungary and around 27 km from the border with Ukraine, provides the city with a strategic role as a connection point between different regions and cultural influences.
Therefore, understanding the spatial and urban evolution of Satu Mare is important for supporting future development strategies and planning, as illustrated in Figure 2.

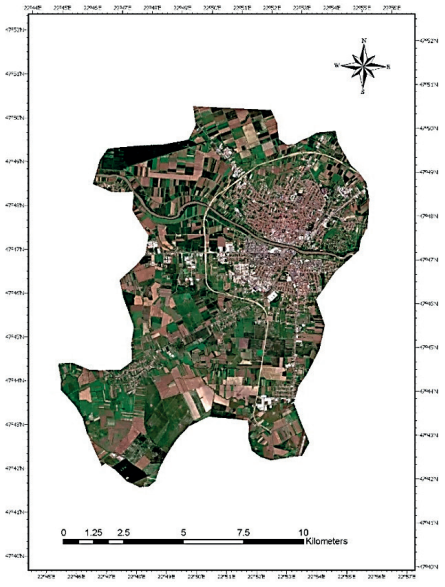

Figure 2. Localization of study area

***Evolution of AI in land cover mapping***

The methodological evolution of land use and land cover classification reflects a broader transformation in remote sensing, from conventional GIS image interpretation toward automated and data driven geospatial workflows. This transition is particularly relevant for multitemporal urban studies, where the objective is not limited to producing thematic maps, but also involves the consistent detection of spatial changes across different time periods. In the present study, focused on the city of Satu Mare, A.I is therefore approached as a complementary component of the GIS workflow, supporting the improvement of classification consistency, processing efficiency, and methodological transferability.
Classical supervised classification methods continue to provide an important basis for satellite image interpretation because they are relatively transparent, operational, and widely implemented in GIS environments. However, their performance may decrease in heterogeneous areas, where built-up surfaces, vegetation, agricultural land, bare soil, and water bodies can present overlapping spectral responses.
Recent comparative research confirms that urban LULC classification remains challenging because landscape heterogeneity directly influences feature extraction and model reliability. For this reason, comparative evaluations between traditional classifiers, machine learning algorithms, and deep-learning approaches are increasingly used to identify robust classification strategies for urban environments (Chowdhury, 2024).
The first major stage in the transition toward AI and LULC is represented by machine learning methods such as Random Forest, Support Vector Machine, and Artificial Neural Networks. These approaches are able to model nonlinear relationships between satellite-derived predictors and land cover categories more effectively than many conventional statistical methods. Their relevance is especially important in multitemporal studies, where the classification model must maintain stable performance across images acquired in different years. In this sense, machine learning contributes not only to classification accuracy, but also to the reproducibility of the change-detection workflow.
A further methodological development is represented by segmentation and object classification. Unlike the pixel methods, which classify each pixel independently, segmentation approaches group neighbouring pixels into spatially meaningful units before classification (Ma et al., 2020). This is particularly useful in urban and mixed landscapes, where land cover categories are often better represented as objects or patches rather than isolated pixels. More recently, deep learning has introduced a significant shift in classifications, by enabling automated feature extraction directly from remote sensing data. Instead of relying mainly on manually selected bands, indices, or predefined rules, deep-learning models can learn hierarchical spatial and spectral patterns from the imagery itself. This capacity is particularly

relevant for heterogeneous urban and peri-urban environments such as Satu Mare, where land-cover classes may vary in shape, texture, density, and spectral behaviour.

Recent reviews emphasize the growing role of deep learning in LULC classification using multispectral and hyperspectral Earth-observation data, while also noting persistent challenges related to training data availability, ground-truth quality, spatial resolution, and sensor-specific characteristics (Vali et al., 2020). Within this context, semantic segmentation is particularly important because it links classification with the spatial delineation of land-cover units. For raster LULC mapping, the objective is not only to assign thematic labels, but also to represent the spatial extent and configuration of land cover classes in a form suitable for change detection (Deressu et al., 2025). At a broader operational scale, AI has also evolved toward large area and frequently updated monitoring systems. Dynamic World is a relevant example of this development, providing near-real-time global LULC predictions at 10 m spatial resolution from Sentinel-2 imagery through a deep-learning workflow. Such products illustrate the movement from isolated map production toward continuous land-monitoring systems capable of supporting flexible temporal analysis and rapid interpretation of landscape change (Brown et al., 2022).

For the present research, this evolution provides the methodological foundation for comparing classical supervised GIS classification with AI assisted approaches in the multitemporal analysis of LULC change in Satu Mare. The purpose is not to replace GIS, but to enhance the geospatial workflow through greater automation, reproducibility, and classification stability. This is particularly important in urban and peri-urban change detection, where errors in individual classified maps may propagate into the final change analysis if the outputs are not produced and validated through a consistent methodological framework.

Therefore, AI classification must be supported by rigorous accuracy assessment. In LULC studies, the reliability of the final interpretation depends on the classification model, but also on the quality of reference data, sampling strategy, validation design, and the interpretation of accuracy indicators derived from the error matrix (Stehman & Foody, 2019). Consequently, the transition from classical GIS classification to AI can be understood as a progression toward more automated and reliable land monitoring workflows. In the case of Satu Mare, this approach supports the evaluation of how AI raster segmentation and automated image classification can improve the detection of land cover transformations.

***Data acquisition***

Nowadays, remote sensing applications rely on a wide range of satellite systems and observation platforms, each providing specific spatial, spectral and temporal perspectives of the Earth's surface. These multisource satellite observations, characterized by different levels of spectral and spatial detail, play an essential role in understanding landscape dynamics and monitoring land use and land cover transformations over time (Dong et al., 2020).

The methodological workflow presented in this study supports the analysis of AI land use interpretation by using Sentinel-2 satellite imagery acquired for three reference years: 2017, 2019 and 2024. The proposed approach highlights how artificial intelligence models can improve classification consistency and reduce the limitations of conventional manual geospatial procedures. By integrating multitemporal Sentinel-2 data with GIS preprocessing and AI assisted classification, the methodology provides a structured framework presented in the following Figure 3, for detecting and comparing land use and land cover changes across the selected study area.

***Sentinel-2***

The Sentinel-2 satellite constellation provides multispectral imagery composed of 13 spectral bands covering the visible, near-infrared and shortwave-infrared regions of the electromagnetic spectrum. With spatial resolutions of 10 m, 20 m and 60 m, depending on the spectral band, and a high temporal revisit frequency, Sentinel-2 data represent a valuable compromise between spatial detail, spectral information and temporal availability.

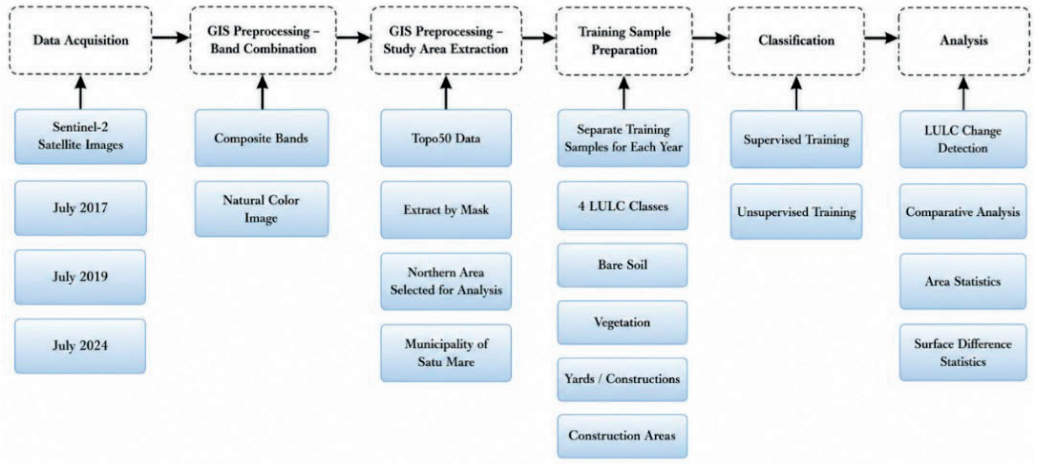

Figure 3. Worflow for AI land use interpretetion using multitemporal Sentinel-2 data in GIS

These characteristics make Sentinel-2 particularly suitable for land use and land cover mapping, especially in studies based on multitemporal image classification and comparative analysis (Vrieling et al., 2018; Rapinel et al., 2019; Le Dez et al., 2021).

In this context, remote sensing provides an efficient and reliable tool for identifying, mapping and monitoring landscape features, as well as areas affected by spatial transformation.

The analysis focuses on three reference years: 2017, 2019 and 2024 and evaluates different classification approaches in order to compare the resulting spatial patterns and highlight the main changes identified within the study area.

The satellite images used in this study were downloaded from the Copernicus platform. For the multitemporal comparative analysis, Sentinel-2 datasets were selected from dates as close as possible within the same month, but from different years, in order to minimize seasonal variations and ensure a more reliable comparison between the analysed periods. The selected images correspond to July and were chosen with 0% cloud cover so that the land surface features would not be obstructed. This selection criterion was important for improving the visual and spectral distinction between the land use and land cover classes used in the supervised classification process.

The Sentinel-2 products were downloaded in *. *safe* format, as this structure preserves the original satellite data and provides access to the complete set of spectral bands available at different spatial resolutions. Therefore, the extension format offered the necessary data quality and completeness for the subsequent preprocessing stages.

***GIS Preprocessing***

As presented in the Data Acquisition subsection in Figure 3, the GIS preprocessing stage was structured into two main components:

1. ***Band combination***;
2. ***Study area extraction*** - which involves the extraction of the study area based on official administrative boundary data.

These preprocessing steps were necessary to prepare the Sentinel-2 imagery for visual interpretation, supervised classification and subsequent comparative land use analysis.

For the first component, the Sentinel-2 datasets were imported into ArcGIS Pro, where the satellite information was available as separate multispectral bands. In order to obtain a visual representation that approximates the natural appearance of the Earth's surface, the Sentinel-2 spectral bands were combined using remote sensing processing techniques. The Natural Color composite was generated by assigning the red, green and blue spectral channels to Band 4, Band 3 and Band 2, respectively. Maintaining this band order is essential, as it ensures a correct RGB representation of the terrain. The band combination was performed in ArcGIS Pro using the Composite Bands function, which allowed the individual Sentinel-2 bands to be merged into a single multiband raster dataset.

The resulting natural color images provided a suitable basis for visual interpretation, further GIS preprocessing and subsequent land use and land cover classification.

Following the generation of the natural color composites, the study area was defined and extracted for the analysis. For this purpose, official administrative boundary data were obtained from the Geoportal ANCPI platform. The TopRo50 dataset was selected because it contains vector data representing administrative limits, including municipality boundaries. This dataset was imported into ArcGIS Pro and processed as a separate vector layer in order to identify and isolate the administrative boundary of Satu Mare Municipality, which represents the area of interest for this study.

Once the area of interest was defined, the boundary layer was used to extract the relevant portion from each Sentinel-2 natural color composite. This step ensured that the analysis was spatially limited to the selected study area and that all multitemporal datasets were processed using the same geographic extent, as illustrated in Figure 4.

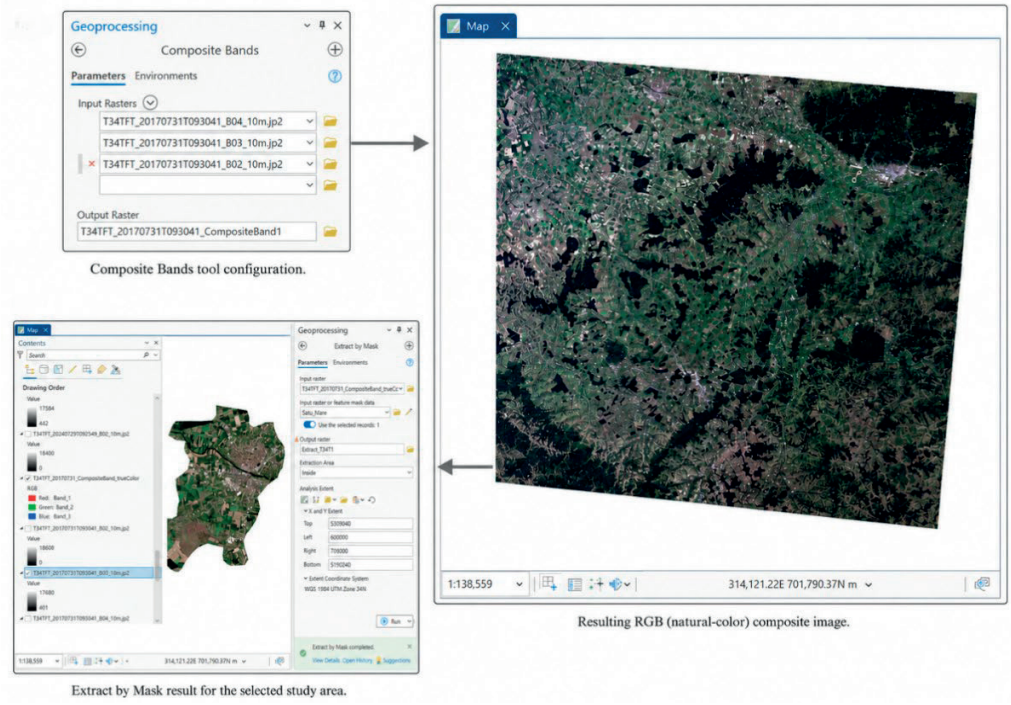

Figure 4. Band composition and study area extraction

***Training data preparation***

Training data preparation represents an essential stage in supervised land use and land cover classification, as this approach relies on labelled samples from the land cover classes of interest to train the classification algorithm (Moraes et al., 2024).

In remote sensing workflows, these samples consist of representative pixels or areas selected for each thematic category, enabling the classifier to associate the spectral characteristics of the satellite image with predefined land use and land cover classes. Their quality, spatial distribution and thematic consistency are important factors, as training sample selection and sample size can influence classification accuracy (Zhang et al., 2023).

In this study, separate training samples were created for each analysed year, namely 2017, 2019 and 2024. This approach was adopted to account for the specific spectral and spatial characteristics of each Sentinel-2 image, while maintaining a consistent classification scheme across the multitemporal analysis. Sentinel-2

imagery is widely used in land cover/use mapping due to its spectral characteristics, spatial resolution and temporal availability, which make it suitable for monitoring different types of land surface features (Phiri et al., 2020). For the differentiation of land use and land cover categories, four thematic classes were defined: *Bare Soil, Vegetation, Yards and Constructions, and Construction Areas.* These classes were selected according to the objective of the study, which focuses on identifying and comparing spatial changes. The prepared training samples were then used as reference data for the supervised classification process.

This step was carried out in ArcGIS Pro, using the Classify function available in the Imagery tab. The selected supervised classification method was Random Trees, which was applied to assign the Sentinel-2 pixels to one of the four predefined land use and land cover classes. This procedure allowed the generation of comparable thematic maps for 2017, 2019 and 2024, supporting the subsequent spatial and statistical analysis of land cover changes. The methodological approach is consistent with machine learning LULC classification, where satellite derived spectral information and predefined land cover classes are used to produce thematic maps for spatial interpretation (Talukdar et al., 2020).

***Supervised Pixel Based Classification***

Following the preparation of the training samples, the supervised classification stage was applied to transform the pre-processed Sentinel-2 imagery into thematic land use and land cover maps. This step represents the operational continuation of the training data stage, since the classifier uses the previously defined reference samples to associate the spectral characteristics of the raster pixels with the selected thematic classes. Supervised pixel-based classification is based on user defined classes within the raster dataset. The training samples are used to create spectral information that guides the classification process and supports the assignment of image pixels to the appropriate land use and land cover categories. Therefore, the reliability of this method depends on the quality of the training samples and on their capacity to represent the spectral variability of the surfaces present in the study area. According to the methodological guidelines, supervised classification relies on user-defined training samples, which are incorporated into a spectral signature file used for raster classification. The same perspective also highlights that training samples should represent the surfaces present in the study area through spectrally pure pixel samples.

In this study, the supervised classification was carried out in ArcGIS Pro using the classification tools available in the Imagery tab. The Random Trees algorithm was selected as the supervised classification method and was applied separately to the Sentinel-2 datasets corresponding to 2017, 2019 and 2024.

The classification was based on the four predefined land use and land cover categories, and a classified thematic raster was generated for each analysed year, providing the basis for the subsequent spatial comparison and statistical evaluation of land cover differences.

***Unsupervised Pixel Based Classification***

In parallel with the supervised approach, an unsupervised pixel-based classification was applied as a complementary method for interpreting the datasets. Unlike supervised classification, this method does not depend on predefined training samples. Instead, it automatically groups pixels into spectral clusters according to the similarity of their values. This makes the method useful for exploratory analysis, especially when the objective is to observe how the raster data are naturally organized based on their spectral characteristics.

The unsupervised classification process is automated, but the resulting clusters require interpretation after the classification has been completed. The methodology explains that the algorithm groups pixels according to similar spectral values, while the user must subsequently label the resulting clusters using additional raster information or visual interpretation. It also notes that the number of initial classes is often higher than the final number of visible land cover categories, because several spectral clusters may correspond to the same thematic class and may need to be merged during interpretation.

The purpose of this step was to provide an additional perspective on the spectral structure

of the images and to support the comparison between classification approaches. After processing, the spectral clusters were interpreted in relation to the main land use and land cover categories considered in the study.

***The role of AI in land use interpretation***

Artificial Intelligence techniques have become increasingly relevant in land use and land cover classification, particularly in studies based on satellite imagery and multitemporal geospatial datasets. The continuous development of remote sensing platforms, including satellite, UAV and airborne systems, has led to the generation of large volumes of spatial, spectral and temporal data. These datasets provide relevant information for understanding land surface dynamics, but their complexity requires analytical methods capable of supporting consistent and reproducible interpretation.

In this context, Geospatial Artificial Intelligence, or GeoAI, represents a methodological framework that integrates artificial intelligence, remote sensing and spatial data science. By combining machine learning and deep learning models with geospatial analysis principles, GeoAI can support the identification of spectral patterns, spatial structures and contextual relationships within heterogeneous landscapes (Dritsas & Trigka, 2026). This is particularly important in land use interpretation, as land cover classes are not defined only by individual pixel values, but also by their spatial distribution, neighbourhood relationships and variability across the landscape.

In the present study, AI is considered an algorithm implemented in the process of image. GIS methods provided the operational framework for Sentinel-2 data preparation and spatial analysis, including band composition, study area extraction, visualization, training sample preparation, map production and surface statistics. These procedures ensured that the classified rasters corresponding to 2017, 2019 and 2024 were spatially comparable and suitable for multitemporal analysis. The AI component is represented by a machine-learning classification algorithm that automatically assigns pixels to predefined LULC classes based on the characteristics learned from the training data.

Based on the training samples, the classifier learns the spectral characteristics associated with each class and applies this information to the entire raster image. In this way, AI assisted classification contributes to a more systematic interpretation of the Sentinel-2 imagery and reduces part of the repetitive manual effort involved in conventional image classification.

The use of Sentinel-2 imagery is appropriate for this type of analysis due to its multispectral characteristics and its balance between spatial, spectral and temporal resolution. Multispectral datasets such as Sentinel-2 and Landsat 8 are widely used for vegetation monitoring, land use classification and environmental assessment (Dritsas & Trigka, 2026). Within this research, Sentinel-2 data supported the supervised and unsupervised classification of the selected land cover classes and enabled the comparison of their spatial evolution over time.

Nevertheless, AI classification remains dependent on the quality of the input data, the representativeness of the training samples and the spectral separability of the selected classes. Therefore, the methodological approach adopted in this study can be understood as a GIS based land cover analysis enhanced by AI assisted classification.

## RESULTS AND DISCUSSIONS

*Multitemporal distribution of training samples*

The first stage of the results focuses on the spatial distribution of the training samples created for each analysed year as presented in the Material and Methods chapter. These samples were used to support the supervised classification process and to define the main land use categories considered in this study. Presenting the training samples separately it will allow to understand the importance of each classification and how the spectral characteristics of the study area varied across the analyses.

For the year 2017, the training samples were created according to the predefined classes. During this stage, an important classification issue was observed in relation to the Someș River, which crosses the selected study area as presented in Figure 5.

In the processed image, the river displayed a visual and spectral response similar to that of

vegetation, which generated ambiguity during the interpretation process.

As a result, parts of the river were associated with the vegetation class, highlighting one of the limitations of the pixel-based classification, when different land cover elements present similar spectral characteristics. A similar issue was also observed in other parts of the classified image, where the initial result was affected by the spectral resemblance between several classes. In particular, confusion occurred between the Bare Soil and Construction Areas classes, as exposed soil, construction surfaces and some building rooftops presented comparable pixel values. This led to partial class overlap and reduced the separability of these categories within the classification output.

Figure 5. River classification result for 2017 in ArcGIS Pro

For this reason, the workflow was returned to the previous stage, where the training samples were revised in the areas affected by classification errors. The first category that required correction was the Bare Soil class, for which additional training samples were created in order to better represent its spectral variability. These samples were adjusted and extended in the problematic areas, rather than being limited only to small and isolated polygons, because the Bare Soil class included surfaces with different tones, textures and pixel values. By incorporating a wider range of representative pixels, the revised training samples aimed to improve the separability of this class from spectrally similar categories, especially Construction Areas and certain built-up surfaces, and to obtain a more accurate supervised classification result, represented in Figure 6.

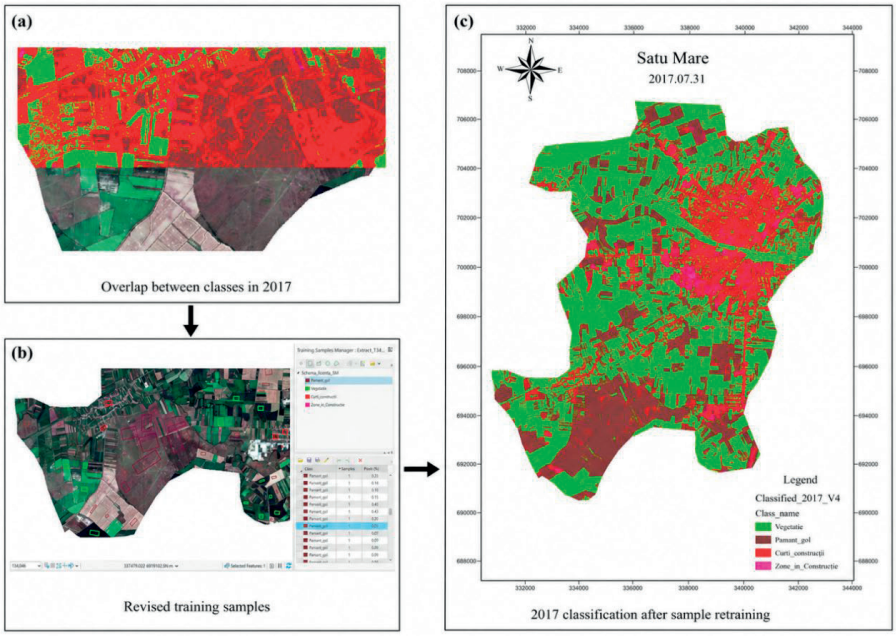

Figure 6. Overlap identification (a), training sample revision (b) and reclassified 2017 result (c)

***2019 training results***

Following the methodological approach applied to the 2017 dataset, a separate set of training samples was also created for the subsequent analysed image, using the same classification scheme and the same predefined land use and land cover classes. After the initial classification, a detailed visual assessment of the output revealed several limitations similar to those observed in the 2017 classification. The main issue was represented by the partial overlap between certain classes, which reduced the clarity and reliability of the thematic result. These inaccuracies indicated the need to refine the training samples in the areas where spectral confusion occurred, in order to improve class separability and obtain a more accurate classification output. Consequently, the workflow was returned to the training sample preparation stage. Additional samples were introduced in the problematic areas, with the purpose of better representing the local spectral variability and reducing the confusion between classes. This iterative correction process was necessary because some surface elements presented similar spectral responses, leading to misclassification in the initial result.

A particular anomaly was again observed in relation to the Yards and Constructions class as shown in Figure 7, similar to the situation identified in the 2017 dataset. In this case, the distortion may be associated with highly reflective surfaces, possibly solar panels, whose spectral response can influence the classification result and generate local errors.

Figure 7. a) Singularities identified for 2019; b) Training sample details

After revising the training samples and repeating the classification, the final output showed a visible improvement, with most of the previous class overlaps and impurities being reduced. Therefore, the corrected result provides a more reliable representation for 2019, demonstrated in Figure 8.

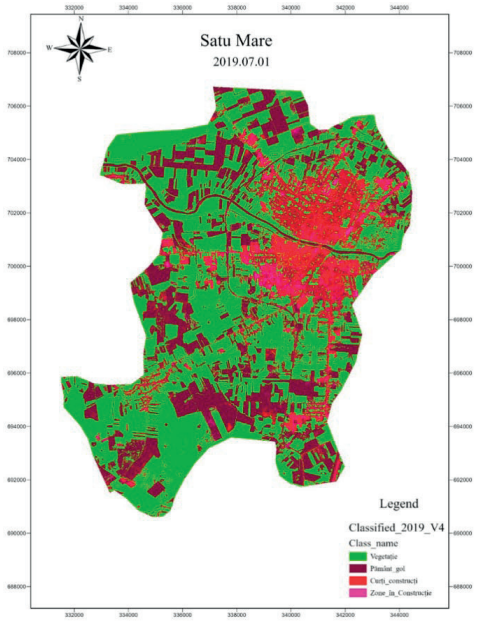

Figure 8. Final classified map for 2019

***2024 training results***

Consistent with the approach used for the previous two analysed years, the same methodological procedure was applied. The training sample preparation followed the same classification scheme used to maintain consistency across the multitemporal analysis.

However, although the images correspond to different years, the classification process revealed similar challenges related to the spectral overlap between certain land use and land cover classes. A recurrent issue identified in all three analysed datasets was the confusion between Construction Areas and Bare Soil. This overlap can be explained by the similar spectral response of exposed soil, construction surfaces and unfinished built-up areas, which makes their separation difficult in pixel-based classification. To reduce this problem, the Bare Soil class required larger and more representative training samples, capable of capturing a wider range of tones and pixel values associated with exposed soil surfaces. In contrast, for the Yards and Constructions class, smaller and more precise samples were necessary, especially in areas corresponding to rooftops and compact built-up elements. This adjustment allowed the classifier to better distinguish between surfaces that initially presented similar spectral characteristics. Therefore, as in the previous years, the 2024 classification required an iterative refinement of the training samples. The correction process was essential for reducing class overlap and improving the thematic clarity of the final classification result.

The final classified map for 2024, presented in Figure 9, illustrates the result obtained after the refinement of the training samples and the correction of the main classification inconsistencies.

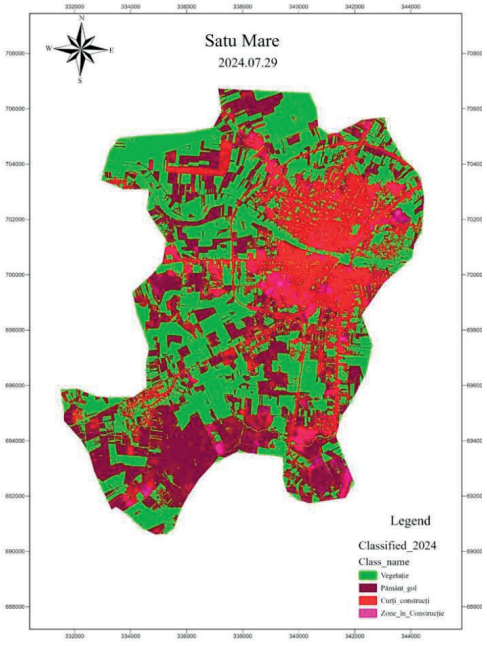

Figure 9. Classified map for 2024

***Comparative analysis based on land use classification results***

The analysis was conducted to evaluate the spatial dynamics of the selected land cover classes and to highlight the main changes

identified within the study area. The surface area of each land cover class was calculated using the raster attribute table generated after the classification process. In the classified raster, the count field represents the number of pixels assigned to each class. Since the Sentinel-2 raster used in this study has a spatial resolution of 10 m × 10 m, each pixel corresponds to an area of 100 m². Therefore, the surface area of each class was obtained by multiplying the number of pixels by 100 m² and then converting the result into hectares and square kilometres. This calculation was applied consistently to the classified rasters from 2017, 2019 and 2024, as presented in the following tables Table 1 for 2017, Table 2 for 2019 and Table 3 for 2024.

Table 1. Surfaces calculated for 2017

| Surface area of land cover classes in 2017 | | |
|---|---|---|
| Land cover class | Pixel count | Area (km²) |
| Vegetation | 598536 | 59.85 |
| Bare Soil | 414969 | 41.50 |
| Yards and Constructions | 174523 | 17.45 |
| Construction Areas | 52743 | 5.27 |
| Total | 1240771 | 124.08 |

Table 2. Surfaces calculated for 2019

| Surface area of land cover classes in 2019 | | |
|---|---|---|
| Land cover class | Pixel count | Area (km²) |
| Vegetation | 639505 | 63.95 |
| Bare Soil | 408773 | 40.88 |
| Yards and Constructions | 125082 | 12.51 |
| Construction Areas | 67411 | 6.74 |
| Total | 1240771 | 124.08 |

Table 3. Surfaces calculated for 2024

| Surface area of land cover classes in 2024 | | |
|---|---|---|
| Land cover class | Pixel count | Area (km²) |
| Vegetation | 496421 | 49.64 |
| Bare Soil | 483470 | 48.35 |
| Yards and Constructions | 209900 | 20.99 |
| Construction Areas | 50980 | 5.10 |
| Total | 1240771 | 124.08 |

The calculated surfaces show that vegetation represented the dominant class in 2017 and 2019, reaching its highest value in 2019 with 63.95 km². In 2024, vegetation decreased to 49.64 km², while bare soil increased to 48.35 km². The Yards and Constructions class also increased in 2024, reaching 20.99 km², compared with 12.51 km² in 2019 and 17.45 km² in 2017. Construction Areas remained the smallest class throughout the analysed period, with values ranging between 5.10 km² and 6.74 km².

The accuracy assessment was generated in ArcGIS Pro using the accuracy assessment points and the confusion matrix tool, resulting Figure 10.

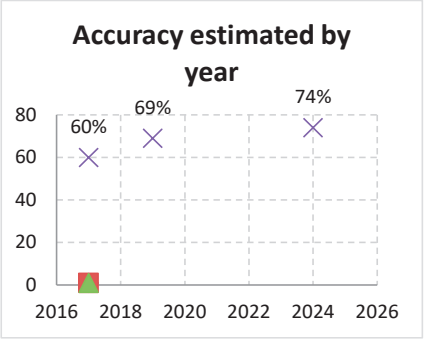

Figure 10. Accuracy estimation for each year classification

The overall accuracy increased from approximately 60% in 2017 to 74% in 2024, indicating a moderate improvement in classification performance. Given that all Sentinel-2 images were acquired using the same sensor and processed with the same classification methodology and algorithm, this improvement is associated with enhanced spectral separability among the land cover classes and the representativeness of the training samples used for each image. The accuracy assessment was performed using an independent set of validation samples, distinct from the training samples employed for model development, ensuring an unbiased evaluation of the classification performance.

In addition to these methodological aspects, the differences in accuracy may also be influenced by the climatic and phenological conditions recorded during the acquisition period. Although all Sentinel-2 images were selected from July, the spectral response of vegetation can vary from one year to another depending on precipitation, soil moisture, temperature and drought intensity. In drier years, vegetation may

show lower vigor and reduced spectral contrast, which can increase confusion with bare soil or transitional construction surfaces.

The lower accuracy obtained may therefore be partly related to the older temporal reference of the image and to possible vegetation stress during the summer period, which can reduce the spectral separability. For 2017, drought monitoring reports indicate a significant precipitation deficit in northern Romania, which may explain the lower spectral separability of vegetation. Under drought conditions, vegetation shows reduced vigor and can be more easily confused with bare soil or surfaces undergoing transformation. The year 2019 appears to have had more stable hydrological conditions for south-eastern Europe, which may support a clearer interpretation of the classes. In contrast, 2024 was characterized by very high temperatures and regional drought, factors that may introduce errors in the vegetation class, even though the image is the most recent and has better temporal relevance.

The results obtained from the classified maps were further analysed through class surface statistics, allowing the differences between the three years to be examined more clearly. The comparative Figure 11 illustrates the evolution of the identified classes.

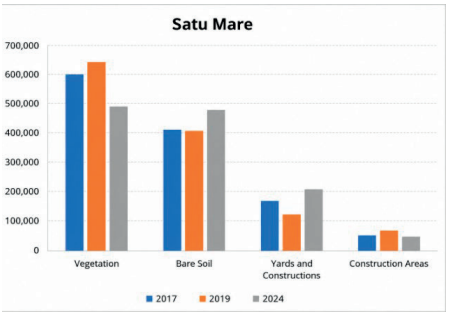

Figure 11. Surface area differences between the identified land cover classes across the analysed years

Vegetation represents the dominant class in all three analysed years, with the highest value recorded in 2019. However, a noticeable decrease can be observed in 2024, suggesting a reduction of vegetated surfaces compared to the previous two reference years. The bare soil class shows a relatively stable evolution between 2017 and 2019, followed by a clear increase in 2024. This may indicate the expansion of exposed or temporarily unused land surfaces, possibly related to land clearing, agricultural activity or areas prepared for future development.

As for the yards and constructions class, they fluctuated, decreasing in 2019 and increasing again in 2024, presented a more fluctuating evolution. A decrease was observed in 2019 compared to 2017, followed by an increase in 2024. This pattern may reflect changes in the built-up structure of the municipality, including residential, industrial or mixed-use developments.

In contrast, the areas classified as construction areas remained relatively limited in extent. The highest value was identified in 2019, while a decrease was observed in 2024. This may suggest that some of the construction sites detected in 2019 were completed by 2024 and were subsequently integrated into other classes, particularly yards and constructions. This evolution highlights the transitional character of construction areas, which often represent temporary land cover conditions rather than stable long-term classes.

## CONCLUSIONS

This study assessed the evolution of land use and land cover in Satu Mare Municipality between 2017, 2019 and 2024 through the integration of Sentinel-2 satellite imagery, GIS preprocessing and AI assisted classification methods.

The results indicate measurable variations in the spatial distribution of the analysed land cover classes. Changes were observed in the extent of Vegetation, Bare Soil, Yards and Constructions, and Construction Areas across the three reference years. These variations describe changes in the classified land cover structure of the study area, but they should not be interpreted as direct evidence of specific urban development processes, land reorganization or socio-economic transformations without additional field observations, cadastral data or planning documents.

A relevant example was identified in the southern part of the study area, where an area classified mainly as Bare Soil in 2017 was predominantly associated with Vegetation in 2019. By 2024, the same sector presented a more heterogeneous classification pattern, including Construction Areas, Bare Soil and smaller

vegetated surfaces. This research illustrates the capacity of multitemporal classification to detect changes in land cover patterns, while the causes of these changes require further validation through complementary data sources. The main contribution of the study is represented by the capacity of the proposed methodology to support a consistent multitemporal comparison. By applying the same classification scheme to the 2017, 2019 and 2024 datasets, the analysis provided both visual and quantitative information regarding land cover distribution and surface changes. This confirms the usefulness of integrating GIS preprocessing and AI assisted classification for territorial monitoring and comparative land cover analysis.

At the same time, several limitations were identified. The most important limitation is related to the spectral similarity between certain land cover classes. Confusion occurred especially between Bare Soil, Construction Areas and some built-up surfaces, while parts of the Someș River were associated with Vegetation due to similar spectral responses. These situations show that pixel classification can generate class overlap when different surface types present comparable pixel values. Another limitation is connected to the 10 m spatial resolution of Sentinel-2 imagery, which may not fully capture small or mixed urban features such as rooftops, courtyards, roads and construction materials.

Despite these limitations, the proposed workflow proved suitable for supporting multitemporal land cover analysis through the consistent processing and comparison of classified satellite imagery.

***Abstract***

*This study analyses land use and land cover changes within the administrative territory of Ineu Commune, Bihor County, Romania, over the period 1990-2025, using GIS techniques and multi-temporal Earth observation data. The methodology integrates CORINE Land Cover datasets for the years 1990, 2000, 2006, 2012, and 2018 with high-resolution Sentinel-2 imagery for 2025, processed in QGIS. To ensure temporal comparability, the 2025 classification was harmonized according to CORINE Land Cover (CLC) schemes. Quantitative indicators, including absolute change, percentage change, and average annual rate of change, were calculated. The analysis reveals a significant expansion of construction material extraction areas and associated artificial lakes, accompanied by a reduction in heterogeneous agricultural surfaces. Mineral extraction sites increased from 0 ha to 243.14 ha, while the formation of 52 anthropogenic lakes was identified. The results indicate a simplification of the agricultural landscape and a transition towards a more specialized and partially industrialized territorial structure. The study also highlights major discrepancies between official local statistics and satellite-derived data, emphasizing the importance of geospatial monitoring for sustainable spatial planning. The research provides a robust methodological framework that can be replicated in other rural areas affected by extractive activities.*

***Key words****: anthropogenic lakes, CORINE Land Cover, GIS, gravel extraction, Sentinel-2, spatial planning.*

## INTRODUCTION

Land use change represents one of the most pressing environmental and socio-economic challenges in Europe, with a particularly strong impact on rural areas affected by resource extraction activities. In Romania, the rapid expansion of sand and gravel quarries has significantly altered local landscapes, leading to the loss of agricultural land and the formation of a considerable number of anthropogenic lakes (Ghirardi et al., 2023).

Although land use dynamics have been extensively studied at national and regional scales, detailed analyses at the level of administrative-territorial units remain limited, despite the fact that transformations are often more intense and spatially heterogeneous at local scale.

Geographic Information Systems (GIS) (https://qgis.org/, 2024), Graser (2013), Mouloudi et al. (2025) and Copernicus programs, particularly CORINE Land Cover and the Sentinel missions, provide essential tools for the long-term monitoring and quantification of these changes.

This study analyses and quantifies land use changes within the Ineu administrative-territorial unit, Bihor County, Romania, over the period 1990-2025. Ineu Commune (Ineu, n.d.), located approximately 20 km east of Oradea Municipality and included within the Oradea Metropolitan Area, is subject to specific anthropogenic pressures generated by gravel extraction activities carried out in the floodplain and former riverbed of the Crișul Repede River. The research highlights the reduction of agricultural land and the emergence of 52 artificial lakes, together with other major landscape transformations.

By integrating multi-temporal CORINE Land Cover (Copernicus, 2025; ESA 2025), datasets

with high-resolution Sentinel-2 (Simonetti et al., 2021) imagery and quantitative indicators, the study proposes a robust methodological framework for assessing the impact of extractive activities and supports sustainable land management in rural areas undergoing transition.

## MATERIALS AND METHODS

The study area corresponds to the Ineu Administrative-Territorial Unit, located in the central-eastern part of Bihor County, Romania, approximately 20 km east of Oradea Municipality. The commune is part of the Oradea Metropolitan Area and includes the villages of Ineu (administrative centre), Husasău de Criș, and Botean. The total surface area is 49.51 km² (4,951 ha) (Figure 1).

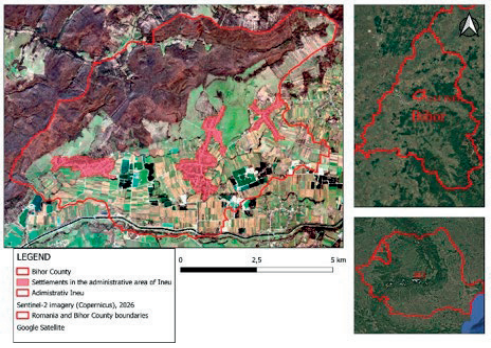

Figure 1. Geographic location of the Ineu Administrative-Territorial Unit within Bihor County, Romania (source: Sentinel-2 imagery, 2025, and administrative boundaries)

The territory is situated within the Oradea–Vad Borod Depression, on the floodplain and former riverbed of the Crișul Repede River, and is characterized by predominantly low plain relief with Quaternary deposits consisting of sands, gravels, and clays. The comparative analysis between the georeferenced historical map from 1782 and the current territorial configuration indicates a significant spatial overlap between the former riverbed of the Crișul Repede River and the main present-day mineral aggregate extraction areas (Figure 2).

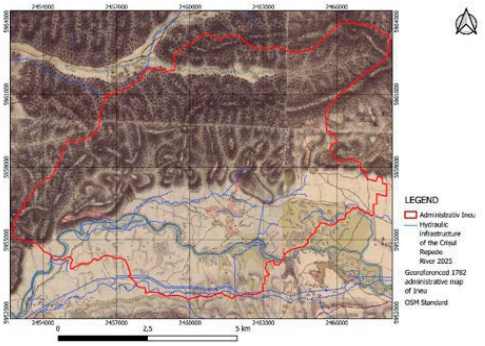

Figure 2. Comparative overlay between the 1782 historical map and the current landscape (2025), highlighting extraction areas on the former Crișul Repede riverbed

The multi-temporal analysis was based on two main categories of geospatial data and GIS processing techniques. The methodological workflow applied in the present study, including data acquisition, georeferencing, spatial processing, land use classification, vectorization, quantitative indicator calculation, and change detection analysis, is summarized in Figure 3.

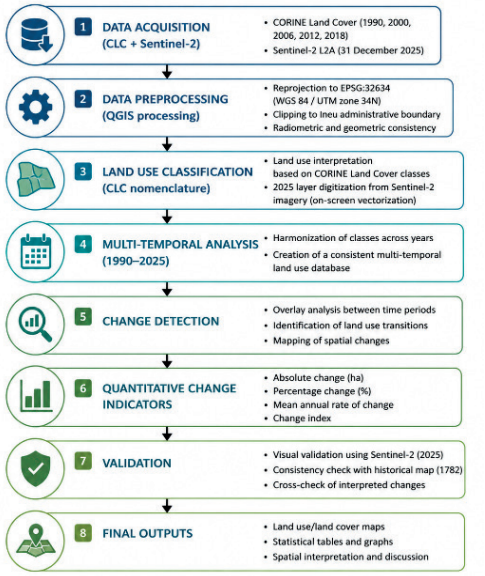

Figure 3. General methodological workflow applied for land use change analysis

CORINE Land Cover (CLC) (Copernicus, 2025; EEA, n.d.) datasets for the years 1990, 2000, 2006, 2012 and 2018 were downloaded from the Copernicus Land Monitoring Service (LandMonitoring, 2021; Şener & Arslanoğlu, 2023; Gómez-Fernández et al., 2024) (100 m spatial resolution, minimum mapping unit of 25 ha). A Sentinel-2 Level-2A multispectral image acquired on 31 December 2025 was downloaded from the Copernicus Data Space Ecosystem (10 m resolution for visible bands and 20 m resolution for vegetation bands). Applications of this type, made available to users, are employed in a wide range of fields, including urban spatial planning, forest management, water management, agriculture, food security, nature conservation and restoration, rural development, ecosystem accounting, and climate change mitigation and adaptation (Skilodimou et al., 2021; Alzurqani et al., 2024). All spatial datasets were clipped to the administrative boundary of Ineu commune. Polygon vector layers were generated through manual digitization and spatial overlay procedures in QGIS. Surface calculations were extracted from the polygon attribute tables and converted into hectares and percentages.

Land use classification was performed consistently for all six temporal reference periods using the CORINE Land Cover nomenclature (Skilodimou et al., 2021). The 2025 layer, derived from Sentinel-2 imagery, was harmonized with this nomenclature to ensure temporal comparability. The evolution of the surface areas and proportions of the main land use classes is presented in Table 1.

Table 1. Evolution of land use/land cover classes in the Ineu Administrative Territory, Bihor, Romania (1990-2025)

| CLC | CORINE LAND COVER LEGEND | 1990 | | 2000 | | 2006 | | 2012 | | 2018 | | 2025 | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | Ha | % | Ha | % | Ha | % | Ha | % | Ha | % | Ha | % |
| 324 | Transitional woodland-shrub | 0,00 | 0,00 | 0,00 | 0,00 | 0,00 | 0,00 | 30,99 | 0,60 | 30,99 | 0,60 | 90,82 | 1,83 |
| 211 | Non-irrigated arable land | 1307,33 | 26,40 | 1307,71 | 26,30 | 1804,28 | 36,40 | 1766,59 | 35,60 | 1735,00 | 35,00 | 1598,11 | 32,27 |

| 243 | Land principally occupied by agriculture, with significant areas of natural vegetation | 521,52 | 10,50 | 521,41 | 10,50 | 156,15 | 3,20 | 64,58 | 1,30 | 64,58 | 1,30 | 77,30 | 1,56 |
| 112 | Discontinuous urban fabric | 304,56 | 6,20 | 304,56 | 6,20 | 259,50 | 5,20 | 275,17 | 5,60 | 275,17 | 5,60 | 313,70 | 6,34 |
| 311 | Broad-leaved forest | 1657,78 | 33,50 | 1657,60 | 33,50 | 1618,86 | 32,70 | 1587,87 | 32,10 | 1587,87 | 32,10 | 1613,57 | 32,59 |
| 511 | Water courses | 60,34 | 1,20 | 60,34 | 1,20 | 60,34 | 1,20 | 60,34 | 1,20 | 60,34 | 1,20 | 60,34 | 1,20 |
| | **TOTAL** | | 100,00 | 4951,58 | 100,00 | 4951,59 | 100,00 | 4951,60 | 100,00 | 4951,59 | 100,00 | 4951,85 | 100,00 |

Considering the limitations of the CORINE Land Cover nomenclature at local scale, the newly formed lakes resulting from mineral aggregate extraction activities were mapped as water surfaces associated with extractive activities (Ghirardi et al., 2023).

To ensure a quantitative and comparable assessment of land use and land cover dynamics within the Ineu administrative-territorial unit over the period 1990-2025, a set of mathematical indicators was applied. These indicators allow the evaluation of both the magnitude and the intensity of changes across different land use categories.

In order to capture the specific temporal dynamics and the inflection points of landscape transformations, the quantitative indicators were calculated separately for two distinct periods: 1990-2006 (the post-communist agricultural intensification period) and 2006-2025 (the period of accelerated expansion of extractive activities and transition towards a partially industrialized landscape).

Quantitative indicators of land use change

Relative percentage change (%) of land use categories

$$\Delta P(\%) = \frac{A_{t2} - A_{t1}}{A_{t1}} \times 100$$

where:

$\Delta P(\%)$= relative percentage change of the land use category;

$A_{t1}$= area of the land use category at the initial time period (ha);

$A_{t2}$= area of the land use category at the final time period (ha).

Absolute change: $\Delta A = A_{t2} - A_{t1}$

where:

$\Delta A$= absolute change (ha);

$A_{t1}$= area at the initial time period;

$A_{t2}$= area at the final time period.

Average annual rate of change

$$R = \frac{A_{t2} - A_{t1}}{t_2 - t_1}$$

where:

$R$= average annual rate of change (ha/year);

$A_{t1}$= area at the initial time period (ha);

$A_{t2}$= area at the final time period (ha);

$t_2 - t_1$= time interval between the two reference periods (years).

Change index

$$I_c = \frac{A_{t2}}{A_{t1}}$$

where:

$I_c$= change index (dimensionless);

- $I_c > 1$= increase;
- $I_c < 1$= decrease;
- $I_c = 1$= stability.

All calculations were performed in Microsoft Excel and validated in QGIS.

Change detection was performed through post-classification analysis based on the spatial overlay of vector layers. For the year 2025, an additional validation procedure was carried out through overlay analysis with the georeferenced historical map from 1782, confirming that the majority of anthropogenic lakes were formed on the former riverbed of the Crișul Repede River.

Note: Since no official CORINE Land Cover product is available for 2025, the Sentinel-2-derived layer was manually created and harmonized with the CLC nomenclature in order to ensure temporal comparability.

## RESULTS AND DISCUSSIONS

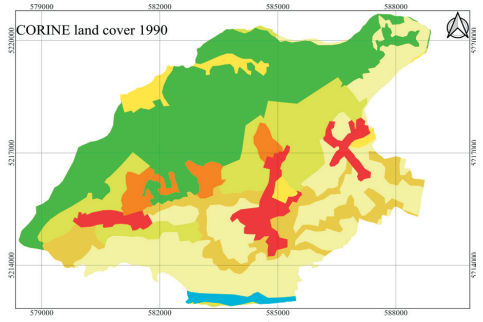
Comparison between official statistics and satellite-derived data:

According to the Sustainable Development Strategy of Ineu Commune (2021-2027) (Lillemets et al., 2025; ZMO), agricultural land represents the dominant land use category, covering 60.41% of the total surface area (2,991 ha), followed by forest areas (32.94%), built-up surfaces (3.43%), water surfaces (1.01%), and communication routes (2.20%).

The comparison with CORINE Land Cover 2018 data reveals significant differences (Bodog et al., 2024) (Table 2).

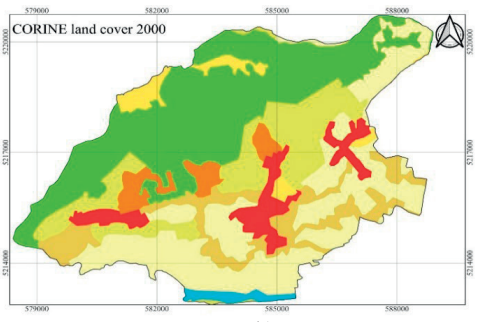
Table 2. Comparative Analysis of Land Use Categories According to the Sustainable Development Strategy of Ineu Commune (2021-2027) and CORINE Land Cover 2018

| Category | Strategy (ha) | Strategy (%) | CLC 2018 (ha) | CLC 2018 (%) | Difference (ha) | Difference (%) |
|---|---|---|---|---|---|---|
| Agricultural land | 2991 | 60,41 | 2807,99 | 56,71 | -183,01 | -3,70 |
| Forest land | 1631 | 32,94 | 1617,85 | 32,67 | -13,15 | -0,27 |
| Built-up areas | 170 | 3,43 | 320,86 | 6,48 | +150,86 | +3,05 |
| Water bodies / Lakes | 0 | 0 | 144,57 | 2,92 | +144,57 | +2,92 |
| Total | 4951,59 | 100 | 4951,59 | 100 | | |



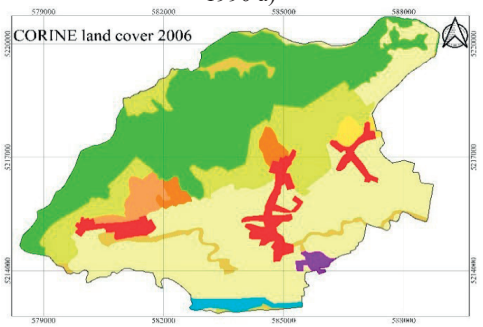
The share of agricultural land decreases to 56.71%, while built-up surfaces increase to 6.48%, and water bodies reach 2.92%. The most significant discrepancy concerns water surfaces: the local Strategy reports 0 ha of lakes, whereas satellite-derived data identify 144.57 ha, most of them representing anthropogenic lakes generated by extraction activities.

These discrepancies highlight the limitations of administrative statistics and the superiority of satellite-based monitoring in capturing recent anthropogenic transformations.



The analysis of the six temporal reference periods (1990, 2000, 2006, 2012, 2018, and 2025) highlights profound structural transformations of the landscape within the Ineu Administrative-Territorial Unit (Table 1, Figure 4). Table 3 presents the detailed evolution of the surface area and proportion of the main land use classes throughout the entire analysed period.

The general dynamics reveal two major processes:



1. Intensification and simplification of agricultural land use during the first part of the analysed period (1990-2006) (Table 3).
2. Strong expansion of extractive activities after 2006, accompanied by the formation of anthropogenic lakes and the fragmentation of agricultural land (Table 4).

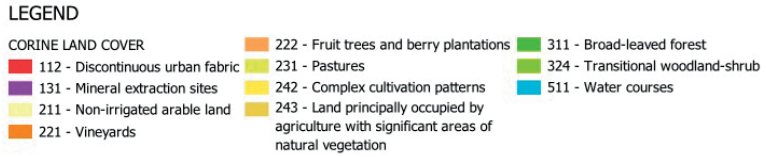

Figure 4. Temporal evolution of land use changes within the administrative-territorial unit of Ineu: 1990 a), 2000 b), 2006 c), 2012 d), 2018 e), and 2025 f). (CORINE Land Cover and Sentinel-2 data).

Table 3. Land use changes during the period 1990-2006 (16 years)

| CLC class (code) | 1990 (ha) | 2006 (ha) | Absolute change (ha) | Percentage change (%) | Average annual rate of change (%) |
|---|---|---|---|---|---|
| Non-irrigated arable land (211) | 1307,33 | 1804,28 | +496,95 | +38,01 | +2,03 |
| Pastures (231) | 745,97 | 783,98 | +38,01 | +5,10 | +0,31 |
| Vineyards + Fruit trees and berry plantations (221+222) | 192,21 | 189,85 | -2,36 | -1,23 | -0,08 |
| Complex cultivation patterns + Land principally occupied by agriculture, with significant areas of natural vegetation (242+243) | 683,26 | 201,52 | -481,74 | -70,50 | -7,45 |
| Total agricultural land (211+221+222+231+242+243) | 2928,77 | 2979,63 | +50,86 | +1,74 | +0,11 |
| Mineral extraction sites (131) | 0,00 | 33,26 | +33,26 | – | – |
| Discontinuous urban fabric (112) | 304,56 | 259,50 | -45,06 | -14,80 | -1,00 |
| Broad-leaved forest (311) | 1657,78 | 1618,86 | -38,92 | -2,35 | -0,15 |
| Water courses (511) | 60,34 | 60,34 | 0,00 | 0,00 | 0,00 |

Table 4. Land use changes in the Ineu Administrative-Territorial Unit during the period 2006-2025

| CLC class (code) | 2006 (ha) | 2025 (ha) | Absolute change (ha) | Percentage change (%) | Average annual rate of change (%) |
|---|---|---|---|---|---|
| Non-irrigated arable land (211) | 1804,28 | 1598,11 | -206,17 | -11,43 | -0,64 |
| Pastures (231) | 783,98 | 710,37 | -73,61 | -9,39 | -0,52 |
| Vineyards + Fruit trees and berry plantations (221+222) | 189,85 | 165,65 | -24,20 | -12,75 | -0,72 |
| Complex cultivation patterns + Land principally occupied by agriculture, with significant areas of natural vegetation (242+243) | 201,52 | 118,28 | -83,24 | -41,30 | -2,79 |
| Total agricultural land (211+221+222+231+242+243) | 2979,63 | 2592,41 | -387,22 | -12,99 | -0,73 |
| Mineral extraction sites (131) | 33,26 | 243,14 | +209,88 | +631,03 | +11,04 |
| Discontinuous urban fabric (112) | 259,50 | 313,70 | +54,20 | +20,89 | +1,00 |
| Broad-leaved forest (311) | 1618,86 | 1613,57 | -5,29 | -0,33 | -0,02 |
| Water courses (511) | 60,34 | 98,21 | +37,87 | +62,76 | +2,60 |

The period 1990-2006 is characterized by an intensification of agriculture on arable land (+496.95 ha, +38%), accompanied by a drastic reduction in heterogeneous and complex agricultural surfaces (-481.74 ha, -70.5%). This period reflects the transition from an extensive and fragmented agricultural system towards a more specialized form of agriculture after 1990. Mineral extraction activities emerged on a limited scale (33.26 ha), while the total agricultural surface recorded a slight increase (+1.74%).

The period 2006-2025 marks a major structural transformation of the landscape. Agricultural land experienced a continuous and significant decrease (-387.22 ha, -12.99%), particularly affecting arable land (-206 ha) and pastures (-73.61 ha). At the same time, mineral extraction sites expanded dramatically (+209.88 ha, +631%), while the surface occupied by discontinuous urban fabric increased steadily (+54.20 ha, +20.89%). The increase in water surfaces (+37.87 ha) corresponds to the formation of 52 anthropogenic lakes generated by gravel extraction activities in the former riverbed of the Crișul Repede River (Petrovszki & Timár, 2010; Pınar & Karahasan, 2024).

At the same time, important hydrotechnical interventions were carried out, especially on the

Crișul Repede River, which underwent major modifications, as well as within the secondary network of streams, ponds, canals, and drainage systems (Osei et al., 2025). The embankment and canalization of secondary watercourses were primarily intended to protect the locality of Ineu from floods (Osawa, 2024), contributing to significant alterations of the natural landscape.

These trends confirm the transition from a predominantly rural agricultural landscape towards a more specialized and partially industrialized landscape dominated by extractive activities. Similar land use transitions associated with agricultural restructuring and extractive activities have also been reported in other European rural regions (Alawode et al., 2025; Lillemets et al., 2025).

The identified transformations also highlight the increasing importance of efficient and transparent territorial governance. The guiding principles of public administration in many democratic countries include flexibility, transparency, autonomy, and efficiency, considered essential for the proper functioning of administrative systems. In the contemporary context, citizens increasingly expect public administration to become more efficient, flexible, and transparent in managing territorial resources and environmental transformations (Timofte, 2023; Timofte & Racz, 2025).

Spatial analysis indicates that the most significant transformations are concentrated within the floodplain and former riverbed of the Crișul Repede River.

The expansion of gravel quarries and the formation of 52 anthropogenic lakes have led to a pronounced fragmentation of agricultural land and to the reconfiguration of the local hydrographic network (Figures 5 and 6).

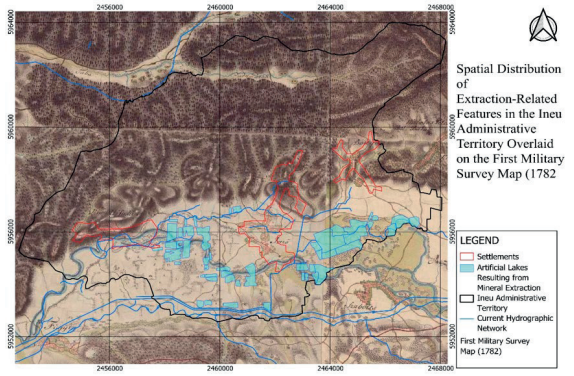

Figure 5. Comparative overlay between the 1782 historical map and the current situation (2025), highlighting the location of quarries on the former Crișul Repede riverbed.

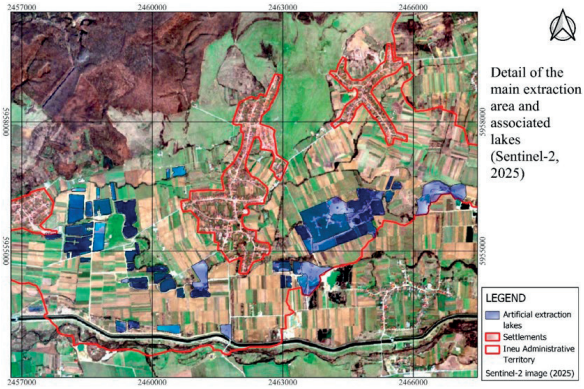

Figure 6. Detail of the main extraction area and the associated anthropogenic lakes. (Sentinel-2, 2025).

The results indicate a clear transition from a heterogeneous agricultural landscape (1990) towards a more specialized and partially industrialized system (2025), dominated by extractive activities.

The identified transformations present a dual character:

- *Negative aspects*: reduction of high-quality agricultural land, landscape fragmentation, and potential impacts on food security.
- *Opportunities:* economic benefits generated by extractive activities, recreational and fishery potential of anthropogenic lakes, and the possibility of using water resources for irrigation purposes.

The integration of high-resolution satellite monitoring (Sentinel-2) with CORINE Land Cover data and quantitative indicators provides a robust methodological framework for local spatial planning and for supporting public policies in rural areas affected by extractive activities.

## CONCLUSIONS

This study provides a comprehensive assessment of land use and land cover changes within the Ineu Administrative-Territorial Unit, Bihor County, during the period 1990-2025, through the integration of CORINE Land Cover data, Sentinel-2 satellite imagery, and quantitative indicators.

The results highlight a significant structural transformation of the landscape, marked by the transition from a heterogeneous agricultural system towards a more simplified and partially industrialized landscape. The most important change is represented by the expansion of mineral extraction sites, which led to the formation of 52 anthropogenic lakes and to a major reconfiguration of the territorial structure. At the same time, heterogeneous agricultural land recorded a pronounced decline, indicating a process of agricultural simplification and the gradual disappearance of traditional mixed farming systems. Arable land experienced a moderate increase, while broad-leaved forest areas remained relatively stable, demonstrating the structural resilience of natural landscape components. Quantitative analysis confirms that extractive activities represent the main pressure factor affecting land use, influencing both the spatial configuration and the functionality of the landscape.

The study also reveals significant discrepancies between official local statistics (Sustainable Development Strategy 2021-2027) and satellite-derived data, emphasizing the need to integrate geospatial technologies into territorial monitoring and spatial planning processes. The systematic use of satellite imagery and GIS analyses can contribute to a more objective evaluation, closer to the actual situation in the field, facilitating the development of public policies and administrative decisions based on updated and verifiable data.

From a socio-economic perspective, the identified transformations generate both challenges and opportunities. The reduction of high-quality agricultural land may affect the long-term productive capacity of the area, while the emergence of anthropogenic lakes creates new opportunities for economic diversification through tourism, recreation, and aquaculture.

The methodological approach applied in this study - combining standardized CORINE datasets, high-resolution Sentinel-2 imagery, and quantitative indicators - provides a robust and replicable framework for analysing land use dynamics at local scale, applicable to other rural areas affected by extractive activities. Future research should focus on the integration of higher-resolution datasets, field validation, and environmental impact assessment, particularly regarding soil degradation, water quality, and microclimatic changes.

In the context of the identified transformations, the study results underline the necessity of a rational and balanced use of land resources, especially in rural areas affected by extractive activities. The conversion of agricultural land towards industrial or extractive uses should be carried out on the basis of clear, objective, and sustainable criteria, ensuring the balance between economic development, environmental protection, and the conservation of agricultural resources. At the same time, the regulatory framework governing extractive activities could consider the introduction of territorial indicators and limits adapted to local carrying capacity, including by relating exploited surfaces to the total available agricultural land.

In conclusion, the study highlights the need for sustainable land management strategies capable

of reconciling economic development with environmental protection and the preservation of agricultural productive capacity. Satellite monitoring and quantitative analysis should become essential components of local and regional spatial planning, ensuring informed decision-making in the context of increasingly intense anthropogenic pressures.

***Abstract***

*Accurate topographic data are essential for the assessment and planning of interventions along small streams and narrow valleys, where traditional survey methods are often constrained by limited access, dense vegetation, and complex terrain. Airborne LiDAR represents a reliable solution, producing high-density point clouds that capture topographic variations, channel geometry, old hydraulic works, and subtle landscape features often missed by conventional techniques. This study aims to demonstrate the workflow for UAV-LiDAR data acquisition and processing, including flight planning, PPK data processing, point cloud classification and filtering, and the generation of high-resolution Digital Terrain Models (DTMs). These results provide a basis for hydrological analysis, planning, and regulatory approvals, supporting engineers and hydrologists in intervention design planning.*

***Key words****: design planning, Digital Terrain Models, LiDAR, small streams, UAV.*

## INTRODUCTION

Small streams represent essential components of fluvial systems, providing important ecological, hydrological, and socio-economic functions in fluvial landscapes. Despite their relatively small size, these watercourses contribute significantly to watershed connectivity, sediment transport, nutrient cycling, and ecosystem services, supporting both natural habitats and human activities (Ferreira et al., 2023). In many regions, small tributaries are particularly vulnerable to morphological alterations and channel instability, driven by both natural processes and anthropogenic pressures. These factors can increase flood susceptibility, accelerate bank erosion, and affect the performance of existing hydraulic infrastructure (Lin et al., 2020; Wang et al., 2021).

These processes are closely linked to the dynamic nature of fluvial environments, where erosion, sediment transport, and deposition continuously reshape channel and floodplain configuration. The interaction between natural processes and anthropogenic influences controls river corridor evolution and flow behaviour. Understanding these mechanisms allows a more accurate evaluation of channel stability and contributes to effective river management strategies (Sabou et al., 2025).

Accurate terrain representation is therefore required for the assessment, planning, and design of river engineering interventions, since topography governs flow direction, velocity, and water distribution. Digital Terrain Models (DTMs) are commonly used as input for hydraulic simulations, including flood modelling, channel morphology assessment, and hazard mapping (Muhadi et al., 2020). In small stream environments, where micro-topographic variations can significantly alter flow patterns, the quality and resolution of topographic data strongly influence modelling reliability (Li et al., 2021).

Conventional surveying methods, such as Global Navigation Satellite System (GNSS) receivers and total station measurements, face significant limitations in small stream environments, where restricted accessibility, dense vegetation, and steep terrain reduce data

coverage and increase acquisition time, often resulting in incomplete terrain representation (Sestras et al., 2025a). Traditional cross-sectional surveying approaches, although accurate, are time-consuming, costly, and may involve operational risks, while also failing to provide spatially continuous and sufficiently dense topographic representation of river environments (Gou et al., 2026). These constraints highlight the need for alternative approaches capable of capturing detailed topographic information in complex conditions.

LiDAR (Light Detection and Ranging) technology has proven to be an effective solution for acquiring high-resolution topographic data, as it generates dense three-dimensional point clouds that capture terrain morphology, channel geometry, and surrounding features (Marotta et al., 2021). Unlike photogrammetric methods, LiDAR data can be acquired under a wide range of conditions, including low-light or cloudy environments, while its capacity to penetrate vegetation enables the extraction of ground points in densely vegetated and urban areas, supporting the generation of reliable DTMs (Muhadi et al., 2020). At the same time, the integration of UAV photogrammetry and LiDAR enhances terrain modelling by leveraging the strengths of each method, enabling more accurate representation under varying surface and environmental conditions (Sestras et al., 2025b).

The development of unmanned aerial systems has further extended the use of LiDAR in environmental and engineering applications. UAV (Unmanned Aerial Vehicle) platforms enable flexible data acquisition at high spatial resolution, particularly in areas where existing elevation data are limited or insufficient in detail for accurate analysis (Trepekli et al., 2022). These systems are increasingly applied in flood modelling and terrain representation, especially in small basins where detailed topography is required for reliable simulations (Annis et al., 2020; Li et al., 2021). UAV-based LiDAR surveys can achieve centimetric accuracy, enabling the detection of topographic features such as small channels, roads, or surface irregularities that influence flow behaviour and flood propagation (Li et al., 2021).

High-density LiDAR datasets enable a detailed representation of terrain morphology, including channel features and floodplain topography, improving the accuracy of flood simulations. These datasets also support the identification of stream channels and tributary networks, as well as the extraction of morphological characteristics of river corridors (Grau et al., 2021). LiDAR-derived data have proven effective in generating Digital Elevation Models (DEMs) for hydraulic modelling and flood hazard assessment, particularly when integrated with simulation tools such as HEC-RAS (Mihu-Pintilie et al., 2019; Stoleriu et al., 2020).

The application of hydraulic models is often constrained by the need for large volumes of input data, including detailed stream geometry and flow characteristics, which are not always available in small or urban stream environments (Bolick et al., 2023). Most modelling studies also focus on larger river systems, while small streams are less frequently analysed, mainly due to the limited availability of consistent high-resolution topographic data, which increases uncertainty in hydrological and hydraulic analyses (Annis et al., 2020).

Beyond terrain modelling, LiDAR data support the analysis of geomorphological processes and terrain dynamics. Repeated acquisitions enable the detection of surface changes and the quantification of erosion and deposition through Digital Elevation Model of Difference (DoD) approaches (Li et al., 2024). The reliability of such analyses depends on factors such as point density and local terrain variability, which influence the accuracy of detected changes.

LiDAR-derived products also support advanced terrain analysis and feature extraction workflows. High-resolution Digital Elevation Models enable the identification of drainage patterns, small channels, and geomorphological structures through terrain analysis and machine learning techniques (Regmi et al., 2024; Busarello et al., 2025). These approaches support the analysis of channel morphology and geomorphological processes. LiDAR data also facilitate the monitoring of channel adjustments and bank erosion, providing insight into river dynamics over time (El-Khoury et al., 2025; Andualem et al., 2024).

The integration of Digital Surface Models (DSMs) and DEMs allows the selective incorporation of structural features such as embankments, bridges, and other built

structures, improving the representation of their hydraulic influence on flow behaviour and flood extent (Lee et al., 2025).

Despite these advantages, the use of high-resolution LiDAR point clouds also introduces practical limitations. Sub-meter resolution leads to large data volumes, often requiring simplification, such as subsampling, or scale adaptation for efficient use in hydrological applications, particularly over extended areas (Almeida et al., 2024). LiDAR systems are also limited in water-covered areas, as laser pulses are reflected by the water surface, preventing the acquisition of reliable information on channel bed morphology (Gou et al., 2026).

This study presents a complete UAV-LiDAR workflow for small stream assessment and rehabilitation, from data acquisition and point cloud processing to the generation of topographic products and hydraulic modelling inputs. The proposed methodology was applied to an urban stream sector requiring rehabilitation works and resulted in the generation of a classified point cloud, vectorized topographic features, a Digital Terrain Model and cross-sections used for hydraulic modelling. The generated datasets supported both the preparation of the topographic documentation submitted for technical acceptance by the Office of Cadastre and Real Estate Publicity (OCPI) and the evaluation of existing and proposed hydraulic conditions in HEC-RAS.

## MATERIALS AND METHODS

### *Study area*

The study area is located in north-western Romania, within Bihor County, in the built-up area of Peștiș village, administratively belonging to Aleșd town (Figure 1). The investigated watercourse is Valea Secătura, also known locally as Valea Șinteu, cadastral code III.1.44.19.2.0.0, situated within the Crișul Repede River basin. Figure 1 illustrates the geographical location of the study area at multiple spatial scales, including the position of Bihor County within Romania (Figure 1A), the location of Aleșd administrative territory within the county (Figure 1B), and the hydrographic context of Valea Secătura within the local drainage network (Figure 1C).

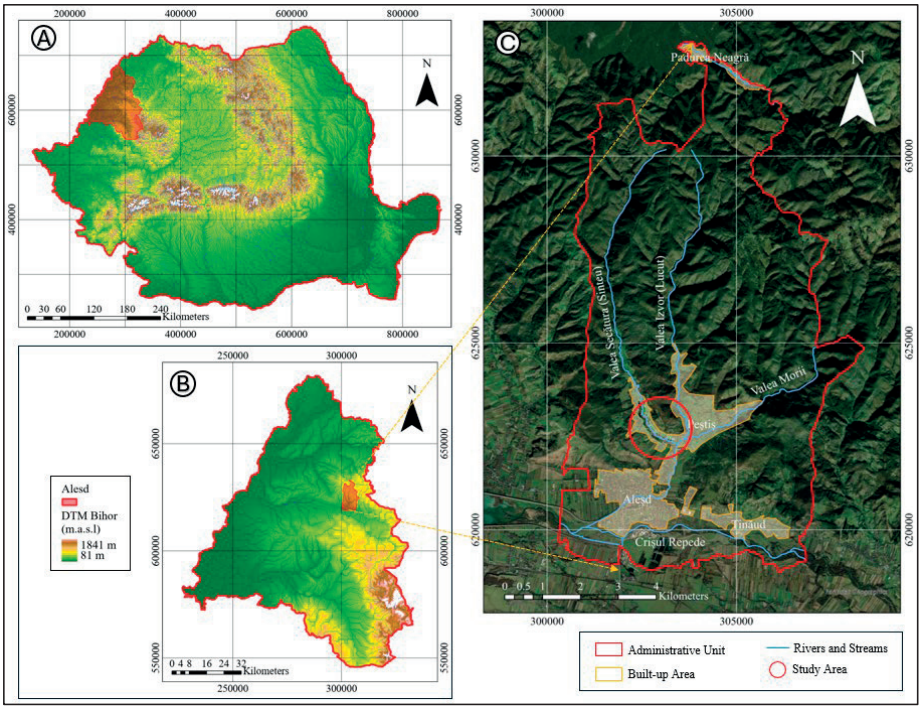

Figure 1. Geographic location of the study area and hydrographic context of Valea Secătura

According to the national hydrographic data and the technical documentation prepared for the rehabilitation project, Valea Secătura is a right-bank tributary of Valea Izvor (locally known as Valea Lucut), while Valea Izvor also collects the waters of Valea Morii (Valea Peștiș) in its upstream sector. Through this drainage network, the waters of Valea Secătura and Valea Morii are collected by Valea Izvor and ultimately discharge into the Crișul Repede River.

Based on cadastral records, Valea Secătura has a total length of approximately 9.6 km and drains a catchment area of about 14 km². The present study focuses on a 1.7 km sector of Valea Secătura situated within the built-up area of Peștiș village. The UAV-LiDAR survey covered the entire investigated sector, including the area targeted by the rehabilitation project entitled *"Amenajarea Valea Secătura (Șinteu)"*, for which engineering design and topographic documentation were required. The proposed rehabilitation works are concentrated on a channel sector of approximately 1 km located within the LiDAR survey corridor. In the built-up area of Peștiș village, the stream corridor is strongly influenced by anthropogenic activities and existing infrastructure, including local roads, residential properties, access crossings, bridges, retaining walls, and other hydraulic protection structures, as illustrated in Figure 2.

Figure 2. Aerial view of the investigated sector of Valea Secătura within the built-up area of Peștiș village

As a result, the channel is highly constrained and its morphology is largely controlled by previous engineering interventions. The technical documentation describes the watercourse as being bordered by roads and adjacent properties throughout the regulated sector. Existing hydraulic structures and the current channel configuration are presented in Figure 3.

Figure 3. Existing hydraulic infrastructure and anthropogenic constraints

Many of the existing hydraulic structures were originally constructed as part of the *"Regularizare Valea Izvor și afluenți"* project in 1987. Subsequent technical inspections revealed substantial deterioration of the hydraulic infrastructure, including damage to retaining walls, erosion of the channel bed and banks, discontinuities within existing protection works, sediment accumulation within the channel, and local reductions in flow capacity caused by bridges, footbridges, and access crossings. Combined with recurrent flood events, these processes progressively reduced the functionality of the existing works and highlighted the need for rehabilitation measures.

The rehabilitation project developed for the investigated sector proposes the demolition of approximately 1,819 m of existing retaining walls, reprofiling of 1,028 m of channel, and the construction of 2,056 m of new bank protection structures. Additional measures include the rehabilitation of existing crossings and the reconstruction of channel stabilization works designed to improve flow capacity and enhance the long-term stability of the channel.

Given the complexity of the site, the presence of ageing hydraulic infrastructure, and the need for detailed geometric information to support engineering design, the study area provides an appropriate framework for demonstrating the applicability of high-density UAV-LiDAR surveys in stream rehabilitation projects. The generated topographic datasets support the creation of high-resolution Digital Terrain Models, the extraction of engineering features, and the preparation of hydraulic modelling inputs required for stream assessment and rehabilitation works.

***UAV-LiDAR data acquisition and processing workflow***

The methodological framework adopted in this study integrates UAV-LiDAR data acquisition, GNSS-supported trajectory correction, LiDAR data processing, and the generation of topographic products required for hydraulic modelling and rehabilitation design. The complete workflow adopted in this study is presented in Figure 4.

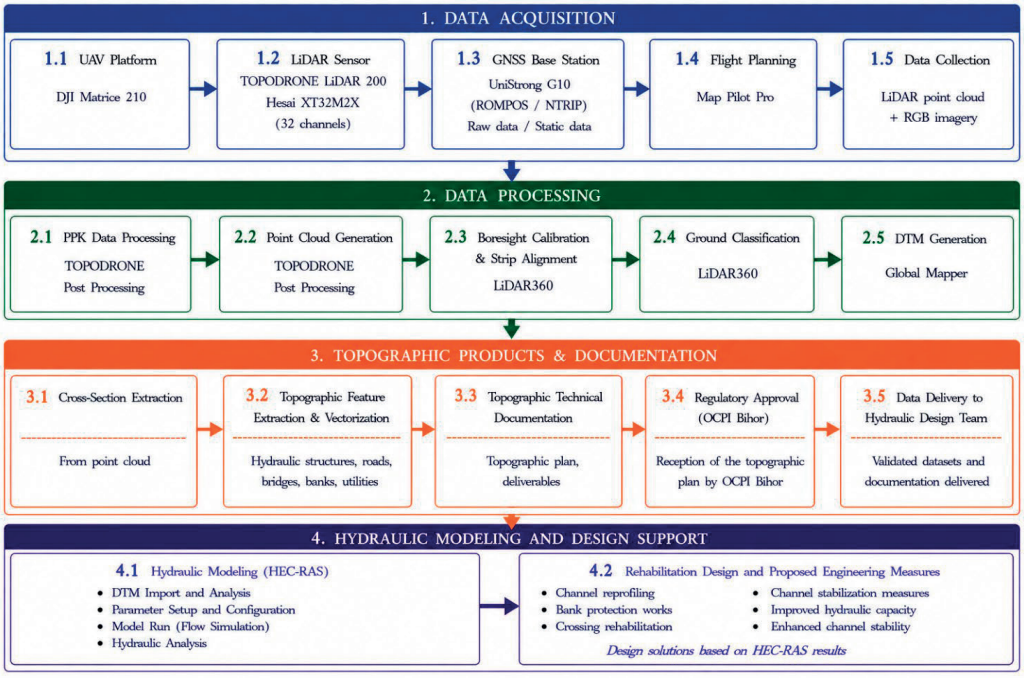

Figure 4. UAV-LiDAR data acquisition and processing workflow

The UAV-LiDAR survey was designed to acquire high-density airborne LiDAR data suitable for the generation of detailed topographic products required for stream assessment, hydraulic analysis, and rehabilitation planning along Valea Secătura. Attention was given to ensuring complete coverage of the stream corridor and adjacent infrastructure, including retaining structures, bridges, access crossings, roads, and neighbouring properties, while maintaining a consistent point density throughout the surveyed area.

Data acquisition was carried out using a DJI Matrice 210 unmanned aerial platform equipped with a TOPODRONE LiDAR 200 system integrating a Hesai XT32M2X laser scanner. The sensor incorporates 32 laser channels and a maximum acquisition rate of up to 640,000 points per second, enabling the collection of high-density point clouds suitable for detailed terrain modelling and the representation of both natural and engineered features within the investigated stream corridor. Simultaneously, RGB imagery was acquired using the onboard Zenmuse X4S camera. Although the primary objective of the survey was the acquisition of LiDAR data, the imagery was subsequently used for orthophoto generation and RGB colorization of the LiDAR point cloud.

Flight planning was performed in Map Pilot Pro using terrain-following functionality based on the Copernicus DEM. The mission was conducted at an average altitude of 100 m above ground level, allowing the UAV to maintain a nearly constant distance from the terrain surface throughout the survey. This approach reduced variations in point density associated with terrain elevation changes and improved the geometric consistency of the acquired dataset. The survey covered the entire 1.7 km study corridor along Valea Secătura, extending

beyond the proposed rehabilitation sector in order to capture the surrounding terrain and infrastructure necessary for the preparation of topographic documentation and hydraulic analyses. The main UAV-LiDAR mission parameters are presented in Table 1.

Table 1. UAV-LiDAR mission parameters

| Parameter | Value |
|---|---|
| Flight mission | Linear mission |
| Survey area | 30.22 ha |
| Survey corridor length | 3.45 km |
| Flight altitude (AGL) | 100 m |
| Flight speed | 6.0 m/s |
| Flight duration | 11 min 15 s |
| Number of flight lines (passes) | 2 |
| Forward/Side overlap | 75% / 75% |

The flight configuration consisted of two parallel flight lines following the longitudinal axis of the watercourse, ensuring complete coverage of the investigated corridor and sufficient overlap between the LiDAR strips.
The flight plan and survey coverage area are presented in Figure 5.

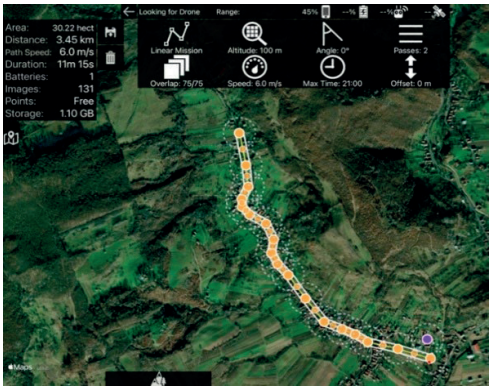

Figure 5. UAV-LiDAR mission planning

A dual-frequency UniStrong G10 GNSS receiver was installed at a location providing favourable satellite visibility and connected to the Romanian Positioning System (ROMPOS) through the Networked Transport of RTCM via Internet Protocol (NTRIP) service. The coordinates of the receiver position were initially determined using Real-Time Kinematic (RTK) positioning, after which the receiver was switched to static mode and continuously recorded raw GNSS observations during the survey. Following the initialization of the GNSS base station, the UAV-LiDAR survey was conducted while both the ground receiver and the onboard GNSS receiver (Helix antenna) simultaneously recorded raw satellite observations.
Data acquisition was conducted under favourable meteorological conditions, characterized by low wind speeds and the absence of precipitation. These conditions reduced vegetation movement during scanning and improved the quality of the acquired LiDAR data, supporting subsequent point cloud processing and ground classification.
Raw GNSS observations recorded by both the reference station and the onboard UAV receiver were processed using Post-Processed Kinematic (PPK) techniques to refine the flight trajectory and improve the positional accuracy of the LiDAR dataset. The TOPODRONE LiDAR Post Processing interface and the main processing parameters are presented in Figure 6.

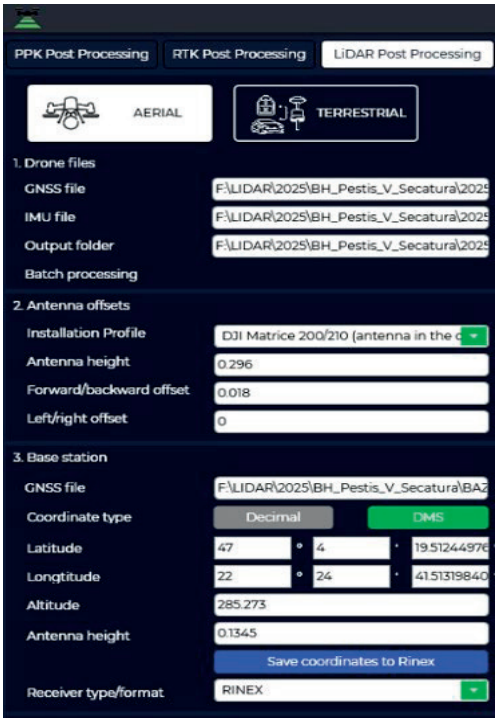

Figure 6. TOPODRONE LiDAR Post Processing interface and configuration parameters

The observations collected by the UniStrong G10 reference station were exported and converted to Receiver Independent Exchange Format (RINEX) files before being imported

into TOPODRONE Post Processing software together with the GNSS and Inertial Measurement Unit (IMU) data recorded by the UAV platform. The processing procedure incorporated UAV data files, antenna offsets, reference station coordinates, and the corresponding RINEX file to compute a corrected trajectory. The resulting solution enabled accurate reconstruction of the UAV trajectory and precise positioning of the LiDAR observations throughout the survey.

Following trajectory refinement, the LiDAR observations stored in PCAP format and the corresponding POS trajectory file were imported into TOPODRONE software for point cloud generation. This procedure integrated the corrected trajectory with the LiDAR measurements, enabling the calculation of the spatial coordinates of individual laser returns and the generation of the point cloud, as illustrated in Figure 7.

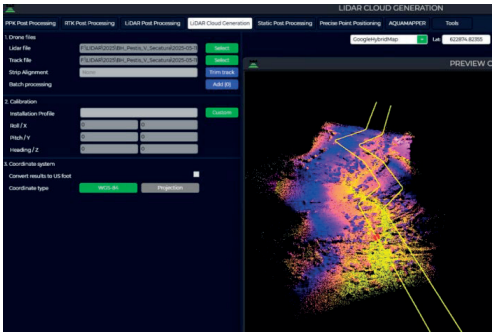

Figure 7. Point cloud generation in TOPODRONE software

The generated point cloud was processed in LiDAR360. Point cloud segments affected by increased positional uncertainty during UAV manoeuvres at flight-line transitions were excluded from further processing. These areas are typically associated with larger roll and pitch variations, which may introduce geometric distortions and reduce local accuracy. Boresight calibration was then performed to compensate for residual angular offsets between the GNSS receiver, IMU, and LiDAR sensor. Strip alignment procedures were subsequently applied to minimize positional discrepancies between overlapping flight strips. The aligned point cloud and a cross-sectional view of the dataset are presented in Figure 8.

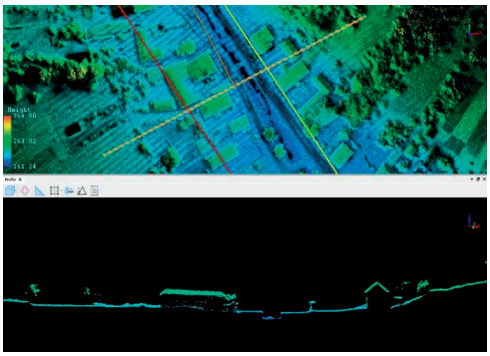

Figure 8. Strip alignment results and cross-sectional view of the LiDAR point cloud

The effectiveness of the calibration and strip alignment procedures was evaluated using the alignment statistics generated in LiDAR360. Boresight corrections involving roll, pitch, and heading adjustments were applied during the calibration process. The adjustment process reduced the maximum alignment error from 2.073 m to 0.079 m and the RMSE from 0.820 m to 0.029 m. The calibration report and alignment statistics are shown in Figure 9.

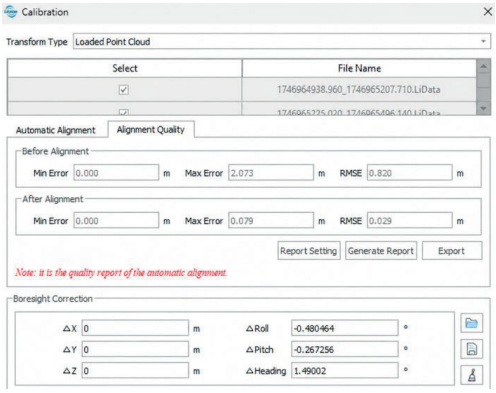

Figure 9. Calibration report and alignment statistics obtained in LiDAR360

The calibrated point cloud was further classified in LiDAR360 using the ground filtering algorithm to separate ground points from vegetation and other non-terrain features. Accurate ground classification is particularly important in stream environments, where riparian vegetation may significantly influence terrain representation and obscure the underlying terrain surface. Non-ground points were subsequently removed and the ground

class was extracted to generate a filtered dataset representing the bare-earth surface.

The extraction of the ground class represents a necessary stage in the LiDAR processing workflow, as the accuracy of the Digital Terrain Model depends on the correct identification of terrain points. Inaccurate classification may result in the inclusion of vegetation or other non-terrain features within the terrain model, potentially introducing local distortions in channel geometry and bank morphology. Particular attention was therefore given to the inspection of the classified dataset to ensure a continuous representation of the terrain throughout the surveyed corridor, including areas characterized by dense riparian vegetation. The resulting ground-filtered point cloud is presented in Figure 10.

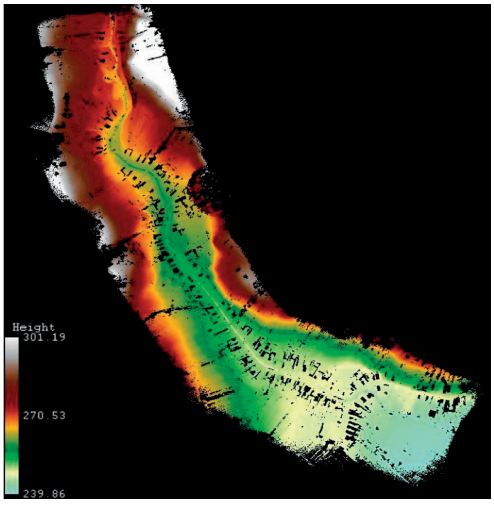

Figure 10. Ground-classified LiDAR point cloud

The ground-classified point cloud was processed in Global Mapper to generate the DTM. The terrain model captured the geometry of the stream channel, bank morphology, adjacent infrastructure, and surrounding terrain, providing spatial information for topographic and hydraulic applications. The density of the UAV-LiDAR dataset allowed the preservation of fine-scale terrain characteristics that are often difficult to identify using conventional surveying methods. The DTM generated for the investigated sector together with an example cross-section extracted from the terrain model are shown in Figure 11.

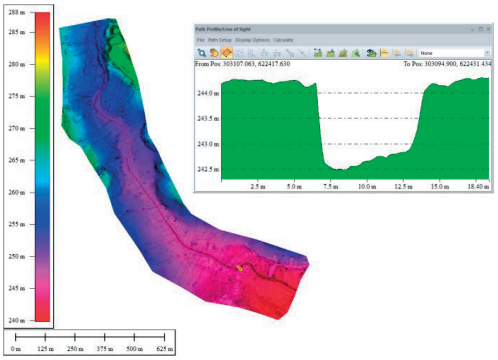

Figure 11. Digital Terrain Model and sample cross-section derived from the terrain model

Classified ground point cloud was used to derive the topographic information required to satisfy the beneficiary's requirements. Using the longitudinal axis of the watercourse as a reference, a total of 52 cross-sections were automatically generated in 3Dsurvey software and manually reviewed to identify and remove potential geometric irregularities resulting from the extraction process. Vector features required for topographic mapping, including points, breaklines, and other terrain elements, were extracted from the classified point cloud. The extracted datasets were used for the preparation of the topographic documentation submitted for technical acceptance by the Office of Cadastre and Real Estate Publicity (OCPI). Following acceptance, the approved topographic plan, together with the DTM and extracted cross-sections, was delivered to the beneficiary and subsequently used by the design team as input data for hydraulic analyses and the development of rehabilitation solutions for the investigated sector. The resulting products and their applications are presented in the following section.

## RESULTS AND DISCUSSIONS

### *Topographic products*

The generated topographic products provided the geometric information required for both engineering documentation and hydraulic modelling. These products included the classified point cloud, DTM, cross-sections, and the topographic plan submitted for technical acceptance by OCPI. A portion of the generated topographic plan is shown in Figure 12.

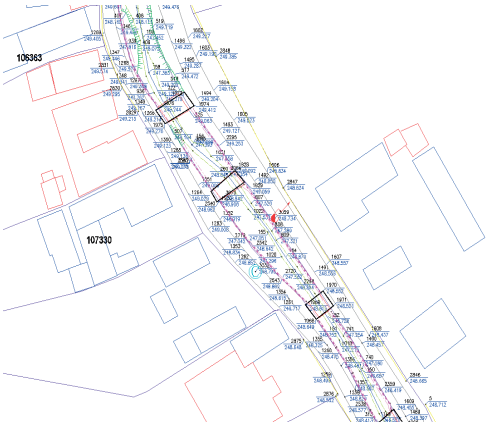

Figure 12. Topographic plan derived from the UAV-LiDAR survey.

The level of detail provided by the generated products enabled the identification of channel banks, hydraulic structures, road crossings, and other natural and anthropogenic features required for hydraulic modelling. The resulting DTM preserved subtle terrain variations along the stream corridor, allowing local morphological features to be represented with a level of detail that is difficult to achieve using conventional surveying methods. Similar findings have highlighted the importance of accurate ground point classification for generating reliable DTM suitable for engineering applications (Oniga et al., 2024).
The adopted workflow and the obtained results demonstrate that UAV-LiDAR surveys provide the topographic information required for engineering projects developed along narrow stream corridors. Comparable findings have been reported for the use of high-density LiDAR datasets in detailed terrain characterization supporting hydraulic analyses and river management applications (Stoleriu et al., 2020; Li et al., 2021).

***Hydraulic assessment of existing conditions***

The topographic products derived from the UAV-LiDAR survey constituted the basis for hydraulic modelling of the investigated sector.
The DTM, extracted cross-sections, and vectorized infrastructure elements were integrated into the HEC-RAS modelling environment to simulate hydraulic conditions corresponding to the climate change-adjusted design discharge with a 1% exceedance probability (Q1% = 47.70 m³/s). Two hydraulic modelling scenarios were analysed: the existing channel conditions at the time of the UAV-LiDAR survey and the proposed engineering solution developed for the investigated sector.
The hydraulic modelling results for the existing channel conditions and the proposed engineering solution are presented in Figures 13 and 14, respectively.

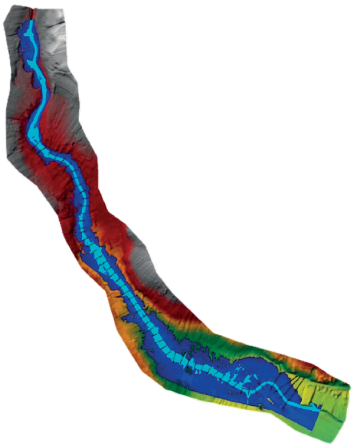

Figure 13. HEC-RAS hydraulic model of the investigated sector under existing conditions

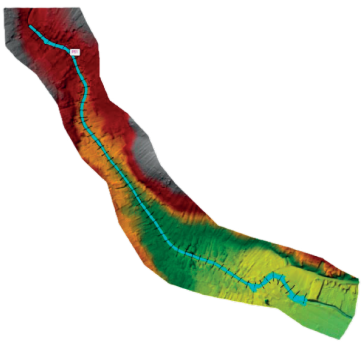

Figure 14. HEC-RAS hydraulic model of the proposed engineering solution

The comparison of these scenarios enabled the evaluation of the expected hydraulic performance of the proposed rehabilitation measures under identical hydrological conditions.
Simulation of the existing channel conditions revealed the influence of local geometric constraints associated with ageing hydraulic structures, channel degradation, sediment accumulation, and the consequent reduction in

flow conveyance capacity within several sections of the investigated corridor.

The reliability of hydraulic simulations is strongly dependent on the quality of the DTM and the geometric datasets used to construct the hydraulic model, including extracted cross-sections and vectorized infrastructure elements. Previous studies have demonstrated that high-resolution UAV-derived topographic datasets improve terrain representation and provide a reliable geometric basis for hydraulic modelling, flood hazard assessment, and the evaluation of engineering solutions (Mihu-Pintilie et al., 2019; Bilașco et al., 2021). The results obtained in the present study are consistent with these findings, demonstrating that the generated DTM and extracted cross-sections provided the geometric detail required for a realistic representation of hydraulic conditions within the investigated stream corridor.

### *Rehabilitation design and hydraulic performance*

Based on the hydraulic assessment, a rehabilitation solution was proposed for the investigated sector of Valea Secătura. The proposed design comprised channel reprofiling over approximately 1 km, reconstruction of bank protection structures with a total length of approximately 2 km, replacement of deteriorated retaining walls, and additional stabilization measures intended to improve hydraulic performance and channel stability.

The main hydraulic parameters for the representative cross-section (P20) under existing and proposed conditions are compared in Table 2. Both simulations were performed using the same climate change-adjusted design discharge (Q1% = 47.70 m³/s), allowing the differences in the hydraulic response to be attributed exclusively to the proposed channel geometry.

Table 2. Comparative hydraulic indicators for representative cross-section P20

| Hydraulic parameter | Existing | Proposed |
|---|---|---|
| Design discharge (m³/s) | 47.7 | 47.7 |
| Channel bed elevation (m) | 244.45 | 243.37 |
| Wetted area (m²) | 22.44 | 14.42 |
| Wetted perimeter (m) | 26.33 | 10.49 |
| Hydraulic radius (m) | 0.85 | 1.37 |
| Roughness coefficient (left bank) | 0.04 | 0.02 |
| Roughness coefficient (channel) | 0.04 | 0.03 |
| Roughness coefficient (right bank) | 0.04 | 0.02 |
| Mean flow velocity (m/s) | 2.13 | 3.31 |
| Maximum water level (m) | 246.65 | 245.69 |

Figure 15 presents the representative cross-section (P20), showing the existing ground profile together with the proposed engineering solution. The trapezoidal channel geometry was designed to provide adequate flow capacity while accommodating the local topographic and infrastructural constraints. The proposed design also accounted for existing crossings, adjacent properties, and the demolition and reconstruction of deteriorated hydraulic structures as part of the planned rehabilitation works.

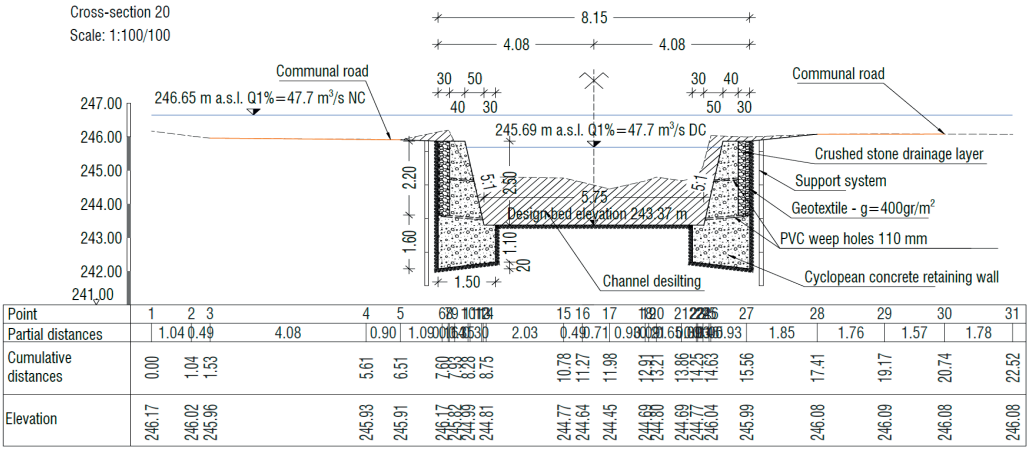

Figure 15. Designed cross-section (P20)

The comparison between the existing and proposed channel conditions demonstrated the importance of detailed topographic information for evaluating the hydraulic response of the investigated sector prior to implementation. High-resolution UAV-LiDAR datasets enabled the realistic representation of channel geometry and surrounding infrastructure, providing the basis required for hydraulic modelling and engineering design. Similar integrated approaches combining detailed terrain models, GIS analyses, and hydraulic simulations have been shown to support the evaluation and optimization of river rehabilitation solutions (Bilașco et al., 2021).

## CONCLUSIONS

This study demonstrated the applicability of UAV-LiDAR technology for acquiring high-resolution topographic data to support small stream assessment and rehabilitation planning. The proposed workflow, integrating PPK trajectory correction, LiDAR point cloud generation and calibration, ground classification, and terrain modelling, produced high-resolution topographic datasets suitable for cadastral documentation and hydraulic modelling.

The adopted methodology generated a DTM, a classified ground point cloud, vectorized topographic features required for the preparation of the topographic plan, and 52 cross-sections along the investigated sector of Valea Secătura. The resulting topographic plan was submitted for technical acceptance by the OCPI. Following technical approval, the approved topographic plan, together with the DTM, classified point cloud, and extracted cross-sections, was delivered to the design team.

Integration of these topographic datasets into the HEC-RAS modelling environment enabled the evaluation of existing hydraulic conditions and the assessment of the proposed engineering solution under the climate change-adjusted design discharge. The resulting analyses supported the identification of channel deficiencies and the design of channel reprofiling, bank protection structures, retaining walls, and additional stabilization measures adapted to the characteristics of the investigated sector.

The obtained results confirm that UAV-LiDAR surveys provide an efficient alternative to conventional topographic surveying methods for engineering projects involving small watercourses. The high density of the acquired point cloud enabled detailed representation of channel geometry, surrounding infrastructure, and terrain morphology.

At the time of manuscript preparation, the rehabilitation solution developed using the generated topographic and hydraulic datasets is under implementation within the investigated sector. This demonstrates the practical applicability of the proposed workflow and highlights the value of integrating UAV-LiDAR technology with hydraulic modelling to support real-world small stream rehabilitation projects.

***Abstract***

*Early identification of weed infestation is essential for improving the efficiency and sustainability of crop protection practices. This paper presents a spatial assessment of weed infestation in arable crops based on vegetation indices derived from unmanned aerial vehicle (UAV) multispectral imagery. UAV flights were conducted during early crop development stages, and the acquired data were processed to generate NDVI-based spatial maps. Spatial variability analysis was applied to differentiate crop-dominated areas from zones affected by weeds and to identify infestation hotspots within the field. The results indicate that UAV-derived vegetation indices provide valuable information for early weed detection and support site-specific management decisions. The proposed approach contributes to reducing unnecessary agrochemical inputs and promotes more environmentally responsible weed control strategies. This work highlights the potential of UAV-based monitoring as a practical tool for supporting precision agriculture and integrated weed management in arable farming systems.*

***Key words****: NDVI, precision farming, spatial analysis, UAV, weed infestation.*

## INTRODUCTION

Weed infestation remains a major constraint on crop productivity, input-use efficiency, and the sustainability of arable farming systems. Because weeds are rarely distributed uniformly within a field and instead tend to occur in patches, uniform herbicide application often leads to unnecessary chemical use, higher production costs, and greater environmental pressure. Site-specific weed management addresses this limitation by targeting interventions only where weed pressure justifies treatment, provided that reliable spatial information is available at the appropriate stage of crop development (López-Granados, 2011; Peña et al., 2013).

In this context, unmanned aerial vehicles (UAVs) provide an effective remote-sensing platform for early weed assessment in arable crops. Their flexibility in acquisition timing, low flight altitude, and centimetre-level spatial resolution make them especially useful during early growth stages, when crop and weed plants are still small and spatially distinguishable. When equipped with multispectral sensors, UAVs can capture reflectance in the visible, red-edge, and near-infrared regions, enabling the calculation of vegetation indices such as NDVI, NDRE, GNDVI, and chlorophyll-related metrics that support vegetation discrimination, crop vigor assessment, and the detection of anomalous zones associated with weed infestation (Clevers & Gitelson, 2013; Schlemmer et al., 2013; Stroppiana et al., 2018). Even so, spectral information alone is rarely sufficient for reliable weed discrimination, because crops and weeds may show similar reflectance patterns at early developmental stages. For this reason, vegetation indices are most useful when interpreted together with spatial variability analysis, crop-row structure, field observations, and management-zone delineation. This integrated approach strengthens weed mapping, hotspot identification, and the practical implementation of targeted herbicide application or other

integrated weed management strategies. Weed mapping is therefore one of the most promising UAV applications in precision agriculture, although its wider use still depends on robust classification under variable field conditions (López-Granados, 2011).

Despite the increasing number of studies addressing UAV-based weed mapping, several methodological limitations remain insufficiently resolved. First, many approaches rely on vegetation indices as direct indicators of weed presence, although crop and weed plants may exhibit similar spectral responses during early growth stages. Second, the transition from spectral variability maps to agronomically meaningful weed-management zones is not always clearly described, particularly in relation to crop-row structure, vegetation masking, and hotspot delineation. Third, the operational feasibility of these workflows remains uneven, as some studies emphasize classification accuracy while providing limited discussion on radiometric calibration, field-side processing, and practical decision-support outputs. These gaps indicate the need for an integrated methodological framework that links UAV-derived vegetation indices with spatial analysis, crop geometry, validation requirements, and site-specific weed management decisions.

The practical relevance of UAV multispectral imagery in arable systems lies in its narrow spectral bands, typically including blue, green, red, red-edge, and near-infrared wavelengths, as used by platforms such as the MicaSense RedEdge family and DJI agricultural multispectral systems (MicaSense, 2024a). These bands support both conventional vigor indices and chlorophyll-sensitive or soil-adjusted metrics that become increasingly informative as canopy conditions vary. Therefore, the aim of this study was to evaluate how UAV-derived vegetation indices can be integrated with spatial analysis for the early assessment of weed infestation in arable crops. The specific objectives were: (i) to develop a structured image-processing workflow for generating radiometrically corrected vegetation-index maps; (ii) to assess the complementary role of NDVI, red-edge, chlorophyll-sensitive, and soil-adjusted indices in identifying vegetation variability; (iii) to translate index-based outputs into probable weed hotspots and management-oriented spatial layers; and (iv) to discuss the operational relevance, limitations, and scientific contribution of UAV-based weed assessment for site-specific weed management. The working hypothesis was that vegetation indices alone are insufficient for reliable weed discrimination, but their integration with crop-row structure, spatial aggregation, and field validation can improve the interpretation of weed infestation patterns and support more targeted crop-protection decisions.

Among lightweight multispectral solutions used in agricultural UAV applications, the Parrot Sequoia and Sequoia+ sensors are notable for integrating four narrow spectral bands - green, red, red-edge, and near-infrared - with an RGB camera and a sunshine sensor for radiometric correction. This configuration supports the generation of vegetation indices under changing illumination conditions and makes the system suitable for crop monitoring, vigor assessment, and weed-mapping workflows in precision agriculture (Parrot, 2025).

## MATERIALS AND METHODS

### *Study design and data acquisition*

Multispectral data acquisition was designed for photogrammetric reconstruction rather than routine RGB inspection. Flight plans followed grid missions with about 75% frontlap and 75% sidelap, extended beyond the field boundary, and, where crop rows were clearly visible, were oriented perpendicular to the rows to improve both row detection and image alignment. Illumination conditions were controlled by scheduling flights close to local solar noon and avoiding rapidly changing cloud cover. Reflectance-panel images were collected immediately before and after each mission, and these observations were complemented, when available, by downwelling light sensor measurements. Ground observations recorded during the flights were used to label crops, weed, mixed-vegetation, and bare-soil samples and to provide independent validation for the final maps (MicaSense, 2024b).

### *Orthomosaic generation and analytical workflow*

After image acquisition, the dataset was processed into a radiometrically corrected orthomosaic and, where useful, a digital surface

model, since UAV-derived 3-D information can support the structural interpretation of vegetation patterns and crop canopy variability (Torres-Sánchez et al., 2015). The workflow comprised reflectance calibration, image alignment, camera optimization, dense reconstruction, orthomosaic generation, and the derivation of vegetation-index layers for subsequent analysis. This sequence is consistent across the main software environments used for multispectral UAV processing, including Pix4D, Agisoft Metashape, OpenDroneMap/WebODM, and ArcGIS Drone2Map, even though implementation details differ among platforms (Agisoft, 2026).

For weed assessment, the analytical workflow moved from calibrated imagery to management-oriented outputs. Vegetation masks were created first, followed by crop-row or crop-object detection, and vegetation occurring outside expected crop positions was classified as probable weed cover. Where crop and weed signatures overlapped, additional multispectral, textural, or structural features were used to improve discrimination. The final weed layers were then aggregated into management cells to identify hotspots and support prescription mapping, in line with established UAV weed-mapping approaches in row and narrow-row crops (Torres-Sánchez et al., 2014).

***Image processing and vegetation index formulas***

*Radiometric and geometric preprocessing*

Radiometric and geometric preprocessing was treated as a prerequisite for any meaningful vegetation-index analysis. Raw multispectral values were first normalized and then corrected for sensor-specific effects such as black level, exposure, gain, and vignette distortion before conversion to radiance and reflectance. Panel-based calibration was used to scale imagery to certified reflectance values, while incident-light measurements provided an additional correction pathway for platforms equipped with light sensors. Band co-registration was then applied to ensure spatial correspondence among spectral channels before index calculation (DJI, 2020; DJI, 2023; MicaSense, 2026; MicaSense, n.d.).

$$p_n = \frac{DN}{2^N}$$

where DN is the raw pixel value and N is the sensor bit depth. This normalization step follows standard radiometric calibration workflows for multispectral sensors (MicaSense, 2026).

A practical panel-based reflectance conversion can then be expressed as:

$$k_\lambda = \frac{\rho_{\text{panel},\lambda}}{\bar{L}_{\text{panel},\lambda}}$$

$$R_\lambda(x,y) = k_\lambda\, L_\lambda(x,y)$$

where: ρpanel,λ is the certified reflectance of the calibration panel at wavelength λ, L̄panel,λ is the mean radiance measured over the panel region, and Rλ(x,y) is the reflectance image for that band. This panel-scaling approach is consistent with published multispectral image-processing workflows (MicaSense, n.d.).

If the sensor platform uses an incident light sensor, the reflectance formulation can be written in ratio form:

$$R_\lambda \propto \frac{X_{\text{camera},\lambda}}{X_{\text{incident},\lambda}}$$

Incident-light formulations estimate band reflectance as the ratio between reflected and incoming radiation, with band-specific calibration parameters used for sensor harmonization in DJI multispectral systems (DJI, 2023).

A generic vignette correction can be modeled with a radial polynomial:

$$I_c(x,y) = I(x,y)(k_6 r^6 + k_5 r^5 + \cdots + k_1 r + 1)$$

where is the distance from the optical center and is the corrected image. Radial-polynomial vignette correction and band co-registration through homography-based alignment are standard steps in DJI multispectral image processing (DJI, 2020).

$$\begin{bmatrix} x' \\ y' \\ w' \end{bmatrix} = H \begin{bmatrix} x \\ y \\ 1 \end{bmatrix}, \qquad (x_r, y_r) = \left(\frac{x'}{w'}, \frac{y'}{w'}\right),$$

where is the alignment matrix estimated between bands, consistent with DJI multispectral preprocessing workflows (DJI, 2020).

*Vegetation indices appropriate for weeds and crop vigor*

NDVI was retained as the principal indicator because it is well suited to early crop development and sparse to moderate canopy cover, which matches the objective of early weed detection. To reduce the known limitations of NDVI under dense canopies or strong soil background, the analysis also included red-edge, chlorophyll-sensitive, and soil-adjusted indices.

Together, these indices provide a more stable description of vegetation status, chlorophyll-related variability, and partial soil exposure than NDVI alone (MicaSense, 2024c).

$$NDVI = \frac{NIR - Red}{NIR + Red}$$

$$NDRE = \frac{NIR - RedEdge}{NIR + RedEdge}$$

$$GNDVI = \frac{NIR - Green}{NIR + Green}$$

$$SAVI = \left(\frac{NIR - Red}{NIR + Red + L}\right)(1 + L)$$

$$MSAVI2 = \frac{1}{2}\left[2(NIR + 1) - \sqrt{(2NIR + 1)^2 - 8(NIR - Red)}\right]$$

$$VARI = \frac{Green - Red}{Green + Red - Blue}$$

$$CI_{green} = \frac{NIR}{Green} - 1$$

$$CI_{red-edge} = \frac{NIR}{RedEdge} - 1$$

$$MTCI = \frac{B6 - B5}{B5 - B4}$$

These formulas correspond to index definitions described in sensor documentation, GIS platforms, and remote-sensing literature. NDVI and NDRE are detailed by MicaSense and Esri, while GNDVI, SAVI, MSAVI2, VARI, $CI_{green}$, $CI_{red\text{-}edge}$, and related indices are available in common geospatial processing environments used for vegetation analysis (MicaSense, 2024a; Esri, 2026).

In interpretive terms, NDVI was used to characterize vegetation presence and overall crop vigor, whereas NDRE, GNDVI, and chlorophyll indices were used to capture chlorophyll-related variation when foliage became denser and NDVI sensitivity declined. SAVI and MSAVI2 improved performance in areas with partial soil exposure, and VARI remained a useful visible-band alternative when only RGB data were available. The combined use of these layers provided a more robust basis for weed discrimination under varying crop and soil conditions (Clevers & Gitelson, 2013; Schlemmer et al., 2013; MicaSense, 2024a; 2024c; Esri, 2026).

***Software ecosystems and real-time workflows***

*Photogrammetry and geospatial processing software*

The software ecosystem was organized by analytical function rather than by brand name. Photogrammetric reconstruction and orthomosaic generation were supported by platforms such as PIX4Dfields, Agisoft Metashape, DJI Terra, ArcGIS Drone2Map, and OpenDroneMap/WebODM, all of which provide multispectral processing, radiometric correction, and export of index layers. GIS and raster analysis were then used for thresholding, map algebra, and spatial aggregation, while Python- and AI-based tools supported more advanced feature extraction and weed classification when row geometry alone was insufficient. This functional workflow reflects current practice in multispectral crop analysis and allows both standard mapping and more advanced computer-vision pipelines to be integrated within the same methodological framework (DJI, 2024; Agisoft, 2026; QGIS Project, 2026; Pix4D, n.d.).

***Real-time and near-real-time processing options***

Real-time implementation was considered as a spectrum of processing speeds rather than a single technical mode. The most operationally mature approach remains near-real-time fieldside processing, in which imagery is transferred to a laptop immediately after landing and processed into orthomosaics and index maps using software such as PIX4Dfields, DJI Terra, or ArcGIS Drone2Map. Fully onboard edge inference is increasingly feasible with embedded GPU platforms such as NVIDIA Jetson devices, particularly for lightweight detection or segmentation models, while cluster or server reconstruction remains useful when multispectral datasets are too large for rapid single-machine processing. In practical terms, near-real-time fieldside mapping currently offers the best balance between speed, robustness, and field usability for multispectral weed monitoring (DJI, 2024; Pix4D, 2024; NVIDIA, n.d.).

***Chlorophyll and weed quantification***

*Chlorophyll calculations*

Chlorophyll estimation from UAV multispectral imagery was approached as a calibrated remote-sensing problem rather than as a fixed biochemical conversion. The most defensible indicators for arable crops were chlorophyll-sensitive and red-edge indices such as $CI_{green}$,

$CI_{red\text{-}edge}$, MTCI, and NDRE, which have been shown to respond well to canopy chlorophyll and nitrogen variation. Because the relationship between index values and chlorophyll content depends on crop type, growth stage, canopy architecture, illumination, and soil background, empirical calibration against field or laboratory measurements remained necessary for quantitative interpretation (Clevers & Gitelson, 2013; Schlemmer et al., 2013; Tian et al., 2025).

$$CI_{green} = \frac{NIR}{Green} - 1$$

$$CI_{red-edge} = \frac{NIR}{RedEdge} - 1$$

$$MTCI = \frac{B6 - B5}{B5 - B4}$$

$$NDRE = \frac{NIR - RedEdge}{NIR + RedEdge}$$

$$\widehat{Chl} = \beta_0 + \beta_1 CI_{red-edge} + \varepsilon$$

$$\widehat{Chl} = f(NDRE,\ CI_{green},\ MTCI,\ texture,\ height)$$

$$C_a = 12.25A_{663.2} - 2.79A_{646.8}$$

$$C_b = 21.50A_{646.8} - 5.10A_{663.2}$$

$$C_{x+c} = \frac{1000A_{470} - 1.82C_a - 85.02C_b}{198}$$

These spectrophotometric equations provide a laboratory reference for chlorophyll a, chlorophyll b, and total carotenoid determination and may be used to validate UAV-derived chlorophyll-sensitive indices when destructive pigment analysis is available (Lichtenthaler & Buschmann, 2001).

*Weed calculations*

Weed quantification translated spectral outputs into agronomically meaningful metrics. A binary vegetation mask was first generated from an index threshold, after which crop-row geometry was used to separate probable weeds from crop vegetation. Weed cover, weed pressure, and weed density were then calculated within grid cells or management zones to support hotspot detection and variable-rate treatment decisions. Where needed, a combined stress layer integrating weed presence with crop physiological status was used as a decision-support indicator. Validation focused on weed-specific accuracy measures such as overall accuracy, omission error, and commission error, which provide a more useful assessment of management performance than visual interpretation alone (Torres-Sánchez et al., 2014; Stroppiana et al., 2018; Esri, 2026).

$$M_v(i) = \begin{cases} 1, & VI(i) \geq T_v \\ 0, & VI(i) < T_v \end{cases}$$

$$M_w = M_v \wedge \neg M_c$$

$$WC_j = \frac{A_{\text{weed},j}}{A_{\text{cell},j}} \times 100$$

$$WP_j = \frac{A_{\text{weed},j}}{A_{\text{weed},j} + A_{\text{crop},j}} \times 100$$

$$WD_j = \frac{n_{\text{weed},j}}{A_{\text{cell},j}}$$

$$H_j = z(WC_j) - z(CI_{red-edge,j})$$

$$OA = \frac{TP + TN}{TP + TN + FP + FN}$$

$$OE = \frac{FN}{TP + FN}$$

$$CE = \frac{FP}{TP + FP}$$

## RESULTS AND DISCUSSIONS

The proposed workflow illustrates how UAV-derived vegetation indices can provide a consistent basis for the early spatial assessment of weed infestation in arable crops. As shown in Figure 1, NDVI provided a useful first screening of vegetated areas and highlighted within-field variability that would not be captured by uniform field inspection. When interpreted alone, however, NDVI could not fully separate crop and weed signals, particularly where crop cover was already developing or where soil background remained visible.

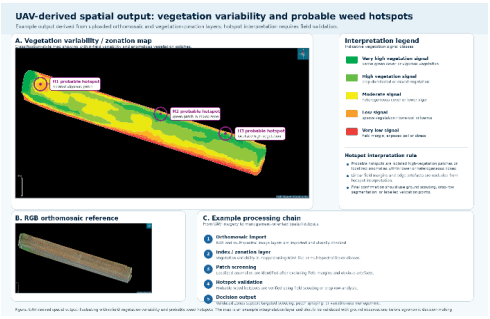

Figure 1. Example of a UAV-derived spatial output highlighting vegetation variability and probable weed hotspots within an arable field

The most informative interpretation was obtained when index maps were combined with crop-row structure and field observations, allowing anomalous vegetation outside expected crop positions to be interpreted more confidently as probable weed patches.

A second important result concerns the complementarity of the vegetation indices. As summarized in Table 1, NDVI remained useful for broad vegetation detection, but red-edge and chlorophyll-sensitive indices such as NDRE, GNDVI, $CI_{green}$, and $CI_{red-edge}$ added interpretive value where canopy density reduced NDVI sensitivity.

Table 1. Comparative relevance of selected vegetation indices for weed assessment in arable crops

| Ind | Veg. | Soi. | Den. | Ch | Wee | Prac |
|---|---|---|---|---|---|---|
| NDVI | High | Modera te | Moderate | Low | High | Initial screening |
| NDRE / red-edge | High | Modera te | High | High | High | Dense-canopy use |
| SAVI / MSAVI2 | Moderate | High | Moderate | Low–mod. | Modera te | Soil correction |

Soil-adjusted indices, including SAVI and MSAVI2, were particularly relevant during early growth stages or in sparsely covered areas, where bare soil influenced reflectance patterns. Taken together, these layers produced a more stable representation of crop vigor and weed-related spatial anomalies than any single index alone, improving the agronomic relevance of the resulting weed maps.

From an operational perspective, the main value of the approach lies in its ability to transform multispectral imagery into management-oriented outputs. Once vegetation masks and crop-row information were integrated, the analysis could delineate localized weed hotspots and aggregate them into treatment zones suitable for targeted intervention. This is directly aligned with site-specific weed management, where the objective is not only to detect weeds but also to support variable-rate herbicide application and reduce unnecessary chemical use. In this sense, the results reinforce the practical role of UAV monitoring as a decision-support tool for precision agriculture rather than as a purely descriptive remote-sensing exercise.

The hotspot labels indicate probable areas requiring field verification rather than confirmed weed infestation classes.

The results demonstrate that UAV-derived vegetation indices should be interpreted not only as descriptive indicators of vegetation vigor, but also as spatial decision-support layers for weed assessment. In scientific terms, the main significance of the workflow lies in its capacity to convert multispectral reflectance variability into agronomically interpretable patterns. NDVI provided an initial map of vegetation presence and within-field heterogeneity, while red-edge, chlorophyll-sensitive, and soil-adjusted indices helped refine the interpretation under variable canopy density and soil-background conditions. This supports the view that weed assessment cannot rely on a single spectral index, but requires a multi-layer interpretation that combines spectral, spatial, and agronomic information.

The internal validation of the proposed approach can be assessed against the study objectives and working hypothesis. The methodological workflow generated the expected sequence of outputs: calibrated imagery, vegetation-index layers, vegetation masks, probable weed hotspots, and management-oriented spatial units. At the same time, the analysis supported the working hypothesis that vegetation indices alone are not sufficient for robust weed discrimination. Their value increases when they are combined with crop-row geometry, spatial aggregation, and field observations. This confirms that the scientific contribution of the study is not the isolated use of NDVI, but the integration of vegetation-index mapping into a structured weed-assessment workflow.

The findings are consistent with previous UAV weed-mapping studies carried out in different crop systems. Peña et al. (2013) demonstrated the importance of object-based UAV image analysis for early-season weed mapping in maize, while Torres-Sánchez et al. (2014) showed that multitemporal UAV imagery can support early site-specific weed control in narrow-row crops such as wheat. Similarly, Stroppiana et al. (2018) highlighted the relevance of multispectral UAV data for early-season weed mapping in rice crops. Compared with these studies, the present approach emphasizes the methodological link between vegetation-index selection, crop-row interpretation, chlorophyll-sensitive indicators, and management-zone delineation. This comparison suggests that UAV-based weed assessment is transferable across crop systems, but its reliability depends on adapting the workflow to crop architecture, canopy closure, weed distribution, and the timing of image acquisition.

From a conceptual perspective, the study contributes to the advancement of site-specific weed management by framing UAV-derived vegetation indices as components of an integrated diagnostic system rather than as standalone classification tools. The proposed workflow connects remote-sensing outputs with practical weed-management decisions by moving from pixel-level vegetation variability to hotspot delineation and treatment-zone prioritization. This is important because the scientific and practical value of UAV monitoring depends not only on detecting spectral differences, but also on translating those differences into actionable agronomic decisions. In this sense, the study contributes a methodological bridge between UAV multispectral imaging, spatial weed ecology, and precision crop-protection planning.

Several limitations should nevertheless be acknowledged. First, the interpretation of probable weed hotspots remains dependent on field validation, because spectral similarity between crop and weed vegetation may lead to classification uncertainty. Second, the workflow is sensitive to illumination conditions, sensor calibration, flight altitude, crop growth stage, and the presence of exposed soil. Third, within-row weeds remain more difficult to detect than between-row weeds, especially in dense cereal crops or in fields with irregular crop emergence. Future research should therefore include larger multi-date datasets, ground-truth weed-density measurements, quantitative accuracy assessment, and comparison between index-based, object-based, and machine-learning classification approaches. Additional work is also needed to evaluate the feasibility of near-real-time processing under operational farm conditions and to connect UAV-derived weed maps with variable-rate herbicide application systems.

## CONCLUSIONS

This study addressed the need for a more integrated interpretation of UAV-derived vegetation indices in weed assessment by linking multispectral image processing, vegetation-index analysis, crop-row structure, and management-zone delineation. The results support the working hypothesis that NDVI and related indices are valuable for early vegetation screening but are insufficient as standalone weed-detection tools. Their scientific and practical relevance increases when they are combined with red-edge and chlorophyll-sensitive indicators, soil-adjusted indices, spatial aggregation, and field validation. NDVI remains an effective primary screening layer because it captures general vegetation presence and within-field variability, but it should not be used in isolation. Red-edge and chlorophyll-sensitive indices, including NDRE, $CI_{red\text{-}edge}$, and MTCI, become more informative when canopy density increases or when the objective extends beyond simple vegetation detection to physiological differentiation. Soil-adjusted indices further strengthen early-season analysis under partial soil exposure (Clevers & Gitelson, 2013; Schlemmer et al., 2013; MicaSense, 2024c).

Methodologically, the analysis supports the interpretation that multispectral data alone are rarely sufficient for reliable weed discrimination in complex arable scenes. Classification becomes more robust when spectral information is combined with crop-row geometry, spatial aggregation, and field-based validation, especially where weeds and crops share similar reflectance during early growth. This also helps explain why UAV weed mapping is often more straightforward in wide-row crops than in dense cereal systems, where plant separation is inherently more difficult (López-Granados, 2011; Torres-Sánchez et al., 2014; Stroppiana et al., 2018).

From an operational perspective, near-real-time fieldside processing currently offers the most practical balance between speed, robustness, and agronomic usefulness, whereas fully onboard inference remains promising but more constrained by model complexity and hardware limitations. Overall, the most effective framework combines calibrated multispectral acquisition, NDVI-based screening, complementary red-edge and chlorophyll-sensitive indices, row-aware weed calculations, and management-zone aggregation. In this form, UAV-based monitoring can support more precise herbicide application, reduce unnecessary chemical inputs, and strengthen the implementation of site-specific weed management in arable farming systems (López-

Granados, 2011; DJI, 2024; Pix4D, 2024; Bohra et al., 2025; NVIDIA, n.d.).

## ACKNOWLEDGEMENTS

This work was carried out with the institutional support of the National Institute of Research and Development for Food Bioresources – IBA Bucharest and the University of Agronomic Sciences and Veterinary Medicine of Bucharest. The study was developed in connection with research activities on integrated weed management and precision agriculture carried out within the ADER 2.1.4 project.

## USE OF GENERATIVE ARTIFICIAL INTELLIGENCE (GENAI)

The authors declare the use of Generative Artificial Intelligence (GenAI) tools in the preparation of this manuscript. GenAI was used for language editing, text refinement, formatting support, and drafting assistance. All scientific content, data interpretation, methodological assumptions, references, and final conclusions were reviewed and verified by the authors.

***Abstract***

*Road infrastructure can alter the spatial continuity of protected areas by subdividing habitat blocks and increasing edge-related pressures. This study aims to assess road-induced structural (spatial) fragmentation - derived from GIS analysis rather than from measures of functional ecological connectivity - in Natura 2000 sites in Romania using a GIS-based screening approach focussed on motorways, express roads and national roads. Natura 2000 site boundaries were overlaid with the major road network to identify crossed sites, quantify the number of road segments located within each site, and analyse the spatial distribution and area of the resulting fragments in selected highly affected sites. The analysis showed that 119 out of 232 Natura 2000 sites were crossed by at least one major road segment, while several were traversed by multiple segments. Four sites were selected for detailed interpretation: ROSCI0290 Ialomița Corridor, ROSAC0162/ROSPA0071 Lower Siret Floodplain, ROSCI0206 Porțile de Fier/ROSPA0080 Almăjului-Locvei Mountains and ROSPA0091 Babadag Forest. Although the study does not quantify direct ecological effects, it provides a spatial screening framework that can support field surveys, roadkill monitoring, connectivity assessment and mitigation planning.*

***Key words:*** *ecological connectivity, GIS, Natura 2000, road infrastructure, spatial fragmentation.*

## INTRODUCTION

Road infrastructure is one of the most widespread forms of linear infrastructure and can produce important changes in habitat continuity. Roads generate direct habitat loss, edge effects, noise, light pollution, wildlife mortality, barriers to movement and increased human access. These effects may extend beyond the physical footprint of the road and can influence the functional integrity of protected areas.

In landscape ecology, fragmentation is not limited to the geometric division of a polygon. It has a structural component, related to the size, number and distribution of fragments, and a functional component, related to species movement, permeability and ecological connectivity. Road networks are therefore frequently treated as drivers of both landscape subdivision and ecological isolation.

Classical road ecology studies have shown that roads may have ecological effects disproportionate to the area that they occupy (Forman & Alexander, 1998; Trombulak & Frissell, 2000). Later reviews emphasised that roads affect species abundance, behaviour and population persistence through multiple pathways, including mortality, avoidance and reduced connectivity (Coffin, 2007; Fahrig & Rytwinski, 2009; Benítez-López et al., 2010).

In protected areas, the issue is particularly important because legal designation does not automatically guarantee ecological coherence. Natura 2000 sites are designated for the conservation of habitats and species of Community interest, but their spatial continuity may be affected where major roads cross or dissect protected landscapes. European studies have used GIS-based approaches to assess the role of roads and roadless areas in protected networks, including Natura 2000 sites (Selva et al., 2011; Votsi et al., 2012; Zomeni & Vogiatzakis, 2014; Kati et al., 2020).

However, these studies have largely addressed roadlessness and road density at continental scale or within individual Mediterranean countries, and have generally treated protected areas as units characterised by an aggregate

pressure index rather than as geometries physically subdivided by infrastructure.
Furthermore, no comparable screening exists for Romania, which hosts one of the largest and most biodiverse Natura 2000 networks in the EU. The present study addresses this gap by quantifying road-induced structural fragmentation across all Romanian Natura 2000 sites and by identifying the most affected sites as priorities for subsequent field-based and functional connectivity assessment.
The present study does not aim to demonstrate direct ecological impacts on species or habitats, because it does not include field surveys, roadkill monitoring, telemetry, species movement data or habitat-quality measurements. Instead, it provides a GIS-based spatial screening of potential road-fragmentation pressure in Natura 2000 sites in Romania. The purpose is to identify where the major road network crosses protected areas and where more detailed ecological assessment may be justified.

## MATERIALS AND METHODS

### Study scope

The study was designed as a GIS-based screening of road-induced spatial fragmentation in Natura 2000 sites. The analysis focused on the geometric relationship between protected-area boundaries and the major road network. Results were interpreted as spatial indicators of potential pressure and not as confirmed biological impacts.

### Spatial data and coordinate reference system

Two spatial datasets were used. The boundaries of the Romanian Natura 2000 sites (Sites of Community Importance/Special Areas of Conservation and Special Protection Areas) were obtained from Ministry of Environment, Waters and Forests - Romania, https://mmediu.ro/portal-gis/date-spatiale/arii-naturale-protejate-de-interes-national-si-international/, downloaded on 15.01.2025. The major road network of Romania was obtained from geo-spatial.org, https://geo-spatial.org/vechi/download/re-eaua-rutiera-na-ionala-a-romaniei-set-de-date-vectorial, downloaded on 16.01.2025. From the road dataset, only the categories relevant to the present screening were retained, namely motorways, express roads and national roads; county roads, communal roads and forest roads were excluded. The source geometries were not edited, generalised or topologically corrected, in order to preserve the reproducibility of the results against the original datasets. All spatial layers used for area calculations were processed in the Romanian national projected coordinate reference system Stereo 70 (EPSG:3844). This metric coordinate system is suitable for calculating areas and distances on Romanian territory.

### Operational definition of fragmentation

For this study, road-induced fragmentation was defined operationally as the intersection of a Natura 2000 site by one or more motorway, express-road or national-road segments, resulting in the spatial subdivision of the protected-area polygon into two or more fragments. This definition captures spatial fragmentation and should not be interpreted as a direct measure of ecological isolation or species-level impact.

### GIS workflow

• all spatial analyses were performed in QGIS Desktop 3.12.1.
• harmonisation of spatial datasets in Stereo 70 / EPSG:3844;
• selection of the major road categories: motorways, express roads and national roads;
• overlay of the major road network with Natura 2000 site boundaries;
• identification of sites crossed by at least one major road segment;
• counting of major road segments crossing each Natura 2000 site (i.e. the road sections resulting from the intersection of the road network layer with the site polygon, located within the site boundary);
• spatial subdivision of selected sites into fragments obtained by splitting the site polygon with the major road segments located inside it;
• calculation of fragment areas in hectares;
• selection of highly subdivided sites for detailed cartographic interpretation;
For the selected case-study sites, the conservation-management context was also cross-checked with official Romanian conservation documents, including ANANP Decision No. 125/2022 for the Lower Siret

Floodplain and ANANP Decision No. 144/2021 for the Porțile de Fier site, together with the official ministerial notes on minimum conservation measures for Ialomița Corridor and Babadag Forest (ANANP, 2021, 2022; Ministry of Environment, Waters and Forests, 2021, 2023).

**Screening indicators**

The analysis was based on four indicators, all derived exclusively from the GIS overlay: (i) the number of Natura 2000 sites crossed by the major road network; (ii) the number of major road segments located within each site; (iii) the number of fragments resulting from the subdivision of the selected case-study sites; and (iv) the area of the largest and smallest fragment in each selected site.

**Supporting contextual information**

Conservation-status information was not used as a screening indicator. It was consulted only as qualitative background for the interpretation of the four case-study sites and did not contribute to any calculation, to the ranking of sites or to the selection of the case studies. Conservation status was not used to infer causality between roads and species condition.

## RESULTS AND DISCUSSIONS

**National GIS screening of sites crossed by major roads**

The GIS overlay indicated that the major road network intersects a substantial number of Natura 2000 sites in Romania. According to the source dataset, 119 out of 232 analysed sites were intersected at least once by a major road. This result indicates that the spatial overlap between the major road network and the Natura 2000 network is widespread at the national level. The ecological significance of this overlap cannot be inferred from the geometric analysis alone, and the presence of a major road segment within a site should therefore be interpreted as a spatial warning signal rather than as evidence of high ecological impact (Figure 1).

A second GIS layer isolated the road segments located inside Natura 2000 site boundaries, providing a clearer spatial view of the road sections located within protected-area boundaries (Figure 2).

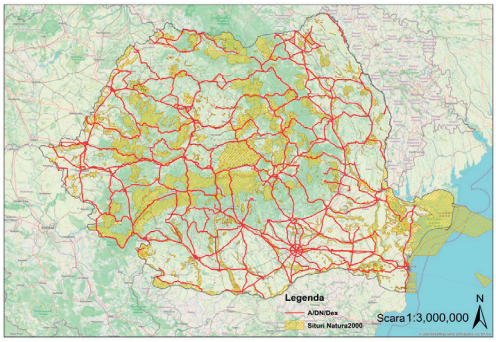

Figure 1. Natura 2000 sites crossed by the major road network in Romania

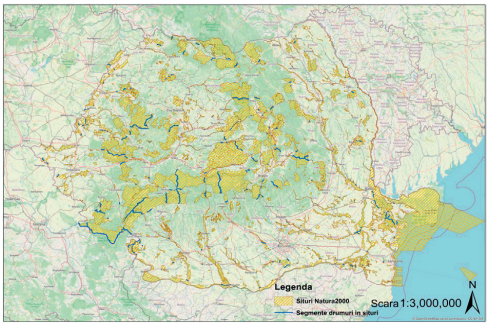

Figure 2. Major road segments located within Natura 2000 sites in Romania

**Number of major road segments per site**

The frequency distribution shows an uneven pattern of road-induced spatial subdivision. Most crossed sites contain one or two major road segments, whereas a smaller group of sites contains a larger number. Sites containing several road segments should be prioritised for detailed connectivity analysis because multiple crossings may reduce internal continuity and increase edge-related pressures (Figure 3).

**Selected case-study sites**

Four sites were selected for detailed spatial interpretation on the basis of two combined criteria. First, all four belong to the group of sites showing the highest number of major road segments identified in the national screening. Second, within this group the sites were selected so as to represent contrasting spatial configurations: a corridor-like protected area (ROSCI0290 Ialomița Corridor), a riparian system (ROSAC0162/ ROSPA0071 Lower Siret Floodplain), a large protected-area complex

(ROSCI0206 Porțile de Fier/ROSPA0080 Almăjului - Locvei Mountains) and a forested landscape (ROSPA0091 Babadag Forest). The selection is therefore illustrative of the most subdivided group of sites and of the diversity of geometric situations encountered, and it does not constitute an exhaustive ranking of the most fragmented sites in the national network.

Two distinct quantities are reported for each case-study site. The number of major road segments located within the site boundary was obtained by intersecting the road network layer with the site polygon, whereas the number of fragments was obtained separately by splitting the site polygon with those road lines. The two are not equivalent: a segment that fully traverses a site produces two fragments, a segment terminating inside the site produces none, and two segments intersecting within the same site may produce more than two. On this basis, the GIS screening identified 7 major road segments crossing the Ialomița Corridor, dividing the site into 9 fragments ranging from 59.59 to 11,078.09 ha; 7 segments within the Lower Siret Floodplain, giving 9 fragments of 58.16-17,413.10 ha; 7 segments within Porțile de Fier/Almăjului-Locvei Mountains, giving 7 fragments of 441.52-94,966.59 ha; and 5 segments within Babadag Forest, giving 6 fragments of 29.74-21,258.49 ha. The values reported for each case-study site refer to the number of major road segments located within the site boundary, obtained by intersecting the road network layer with the site polygon.

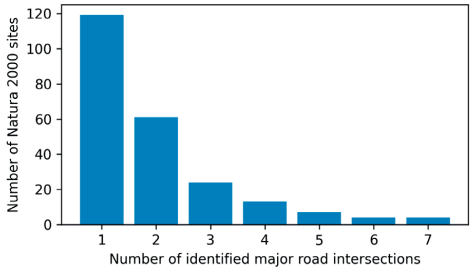

Figure 3. Distribution of Natura 2000 sites according to the number of major road segments located within the site boundary

The cartographic outputs for the selected sites show that multiple road segments may occur both in corridor-like sites and in large protected-area complexes. The maps also indicate strong differences in the spatial distribution of fragments, from narrow riparian sections to large habitat blocks (Figures 4-7).

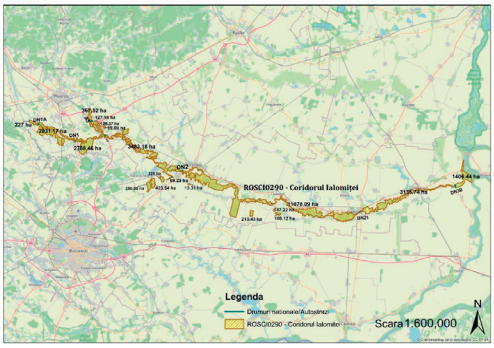

Figure 4. Road-induced spatial subdivision of ROSCI0290 Ialomița Corridor

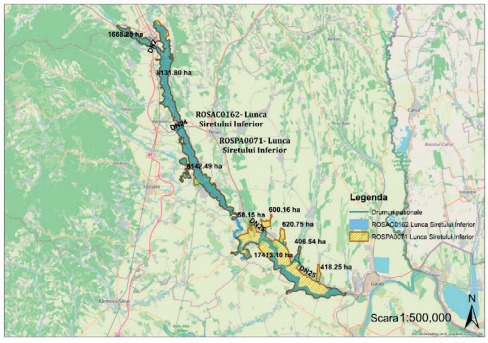

Figure 5. Road-induced spatial subdivision of ROSAC0162/ROSPA0071 Lower Siret Floodplain

Figure 6. Road-induced spatial subdivision of ROSCI0206 Porțile de Fier/ROSPA0080 Almăjului-Locvei Mountains

Figure 7. Road-induced spatial subdivision of ROSPA0091 Babadag Forest

## Interpretation of fragment size and site geometry

The results indicate that the number of road crossings alone is not sufficient to characterise the degree of spatial subdivision of a site. Fragment-size distribution and site geometry are equally important. Corridor-like and riparian sites, such as Ialomița Corridor and Lower Siret Floodplain, may be particularly sensitive to transversal road crossings because such crossings can interrupt longitudinal continuity. Conversely, large protected-area complexes may retain extensive fragments but still require analysis of permeability, wildlife crossing opportunities and roadkill risk (Figure 8).

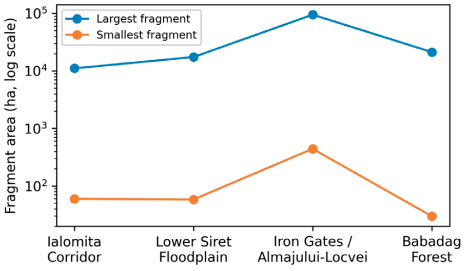

Figure 8. Contrast between the largest and smallest fragments in selected Natura 2000 sites

The contrast between the largest and smallest fragments is relevant for management. Very small fragments may be more exposed to edge effects, human access and functional isolation, even when their contribution to total site area is limited. Therefore, screening outputs should be interpreted together with local habitat maps, species data and field observations.

## Conservation-status context

The conservation-status graphs and official conservation context were treated as supporting background, based on the available site-specific documents, including ANANP decisions for the Lower Siret Floodplain and Porțile de Fier sites and official ministerial notes for Ialomița Corridor and Babadag Forest (ANANP, 2021, 2022; Ministry of Environment, Waters and Forests, 2021, 2023). The available conservation-status information was not interpreted as proof of a causal relationship between road fragmentation and species condition. In some sites, the presence of unfavourable or unknown conservation status indicates that spatial fragmentation overlaps with areas already requiring conservation attention, but additional ecological data are necessary to assess biological effects (Figure 9).

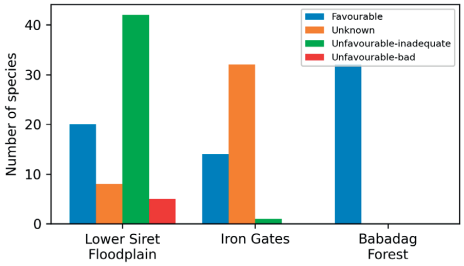

Figure 9. Conservation-status context for selected Natura 2000 sites, based on the values extracted from the existing graphs

## Management relevance

The GIS screening can support Natura 2000 management by identifying sites where detailed ecological assessment is justified. Priority actions may include field verification of road-crossing zones, roadkill monitoring, permeability assessment, mapping of existing culverts and bridges, habitat-connectivity modelling and evaluation of the need for wildlife passages or ecological bridges.

The approach is particularly useful as a preliminary planning tool because it is transparent, reproducible and based on spatial layers that can be updated as road networks or protected-area boundaries change. However, it should be complemented by ecological surveys before site-specific mitigation measures are designed.

## CONCLUSIONS

This study provides a GIS-based screening of road-induced spatial fragmentation in Romanian Natura 2000 sites. The analysis shows that a substantial number of sites are crossed by the major road network and that several sites are divided into multiple fragments. These findings do not demonstrate direct ecological impact, but identify the sites in which the geometry of the protected area is subdivided by the major road network, and in which a subsequent assessment of habitat continuity and of functional ecological connectivity would therefore be justified. Whether this structural subdivision translates into a reduction of functional connectivity can only be established through species-specific data on movement, permeability and mortality, which fall outside the scope of the present screening.

The selected case studies show that the degree of spatial subdivision depends not only on the number of road crossings, but also on-site geometry and on the size distribution of resulting fragments. The results can support the prioritization of detailed ecological surveys, roadkill monitoring, connectivity modelling and mitigation planning in Natura 2000 management.

## ACKNOWLEDGEMENTS

This study was developed as part of the doctoral research of Răzvan Lucian Voicu, carried out within the Doctoral School of Engineering and Management of Plant and Animal Resources - University of Agronomic Sciences and Veterinary Medicine of Bucharest.

Corresponding author email: nalboiu@gmail.com

***Abstract***

*The paper is a general presentation of the studies undertaken as part of a research project focused on a solution used for energy dissipation applied to free surface currents. The research has involved a series of studies on special shaped artificial roughness elements proposed by the authors of the preset paper. Several placement patterns of these elements were tested. Based on the result, conclusions could be drawn regarding the effects that these elements and their placement have on the flow. Based on the results obtained experimentally, new research directions are possible to be developed, which are aiming at new building materials and maybe a more versatile implementation technology compared to the classical one.*

***Key words****: artificial roughness, energy dissipation, free surface current, water current.*

## INTRODUCTION

Dissipation of free surface kinetic energy is a necessity when certain flow conditions, specific to hydropower structures, gutters and channels adjacent to highways, roads and water transport systems used in agriculture are met. Uncontrolled discharge of water is a major threat for both the integrity of hydrotechnical and water transport infrastructure, and for the environment such as riverbeds, lake basins, and coastal areas. From the hydro engineering point of view, the general purpose of dissipating the kinetic energy of water streams is the reduction of riverbed erosion, structural protection and flood control by reducing the water velocity. Another category of problems for which energy dissipation is necessary is related to the ecology field. For example, the protection of aquatic habitats.

Several energy dissipation solutions were developed over time. Each situation has its own particularities. Broadly speaking, establishing the energy dissipation solution is related to the particularities of the flow and the generating cause that produces a high kinetic energy flow. Common, widely applied technical solutions for dissipating the kinetic energy of water streams are: *stilling basins* - reinforced pools placed at the base of structures like spillways, that use the hydraulic jump as main mechanism of dissipation; *stepped spillways* - a series of steps placed on the downstream face of the hydro-structure that divide the main high energy stream in small waterfalls will have a dissipative effect due to aeration and friction (Kiselev, 1988; Chanson, 2021; Mei et al., 2025); *baffle/chute blocks* (Figure 1) - obstacles placed in the channel to break the water stream reducing thus the water velocity; *bucket dissipators* - deflectors with a curved shape that lunch a water jet which energy is dissipated due to the resistance, water-air friction and finally as a result of the impact with the downstream water surface; c*heck dams* - small structures designed to break the riverbed slope reducing thus the stream velocity; *tumbling flow systems* - a sequence of concrete elements/obstacles or small steps which create falls and pools along steep channels (10 - 35% channel slope). Out of the above-mentioned solutions, as they increase the flow resistance, baffle blocks and chute blocks represent *artificial roughness* (Figure 1) methods of energy dissipation. Beside those two types of blocks, the artificial roughness category includes also *sills and ribs* - horizontal ridges built into the bed of the channel that act as a brake for the lower layer of water, and *rip-rap or boulders* - anchored rocks used in channels to enhance friction zones.

Although they have been studied and successfully applied for many years, these techniques continue to be of interest to researchers in the field of hydraulics. The

problems that remain open are related to the problem of cavitation, but also to the optimization of dissipative elements, a fact confirmed by recent research carried out in the last decade.

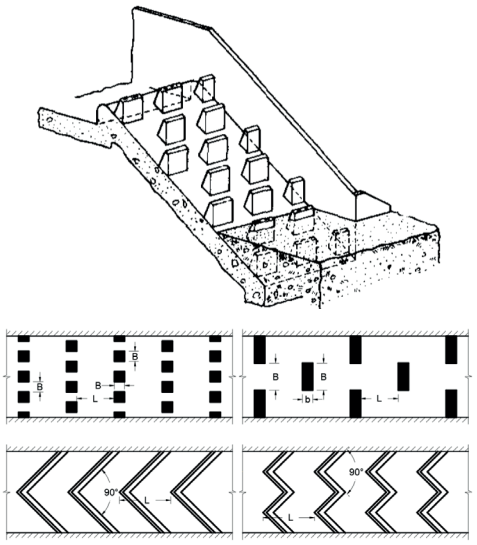

Figure 1. Example of baffle blocks (Peterka, 1984) and some increased artificial roughness types (Cioc, 1975) used for energy dissipation

Besides the presented solutions, a different but interesting dissipation method addressed to spillways, called *pre-aerated stilling basin spillway* (PSBS) is studied and presented in (Zhou et al., 2025).

Considering the technological evolution in the field of hydraulic phenomena research, both experimental and numerical (CFD), but also the evolution of building materials and execution technologies, the authors of this paper proposed a new shape of artificial roughness elements used for energy dissipation.

The research is focused on induced tumbling flow by using these elements. The development of the studies involved a succession of activities based on which the most efficient methods and approaches were used to draw valid conclusions regarding the behavior of the proposed roughness elements under operation conditions.

The research is a part of the *National Research Grants of the Technical University of Civil Engineering Bucharest GnaC ARUST 2024, DERA project, number TUCEB- No.1411/2025*.

## MATERIALS AND METHODS

To carry out the proposed research, both theoretical and experimental methods were considered.

*The theoretical studies* involved preliminary evaluations on which the future experimental research was developed. The subjects of interest were related on one hand to the main physical quantities used to describe and quantify free surface water streams and on the order hand to the potential effect of the roughness elements on a theoretical stream. Both evaluations were used to establish the future experimental framework and to provide a qualitative picture of the fluid flow kinetics in the presence of the artificial roughness elements.

For the numerical evaluation of the flow the well-known analytical relationships and the HEC-RAS software were used (Cioc, 1975; French, 1986). The qualitative relative effect of the roughness elements was evaluated prior to any test via the COMSOL Multiphysics CFD software. The analysis was based on a hypothetical scenario. Under this scenario four types of roughness elements were compared. The shape of the compared elements is shown in Figure 2.

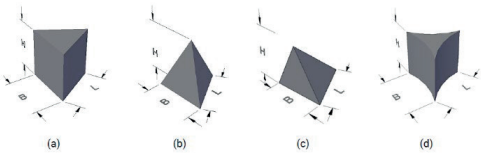

Figure 2. Shapes of the evaluated artificial roughness elements

All the four elements shown in figure 2 are considered 10 cm high (H) and 10 cm wide (B). The characteristics of the modeled domain are 1.5 m length and 1.2 m width. The artificial roughness elements were placed alternately as a single row, facing the water stream at 0.3 m downstream from the inlet of the domain. Considering the characteristics of the studied problem, a RANS k-ε turbulence model was used.

Based on the results of the qualitative, relative, evaluation, the shape depicted by image (d) was chosen for the future experimental tests (Figure 3).

The elements were made from plastic sheets cut on CNC machines and subsequently glued together. To obtain a uniform average roughness between the elements, the resulting pieces were wrapped in adhesive aluminum foil. Twenty-two central elements were placed in the flow field, and 4 lateral elements were placed near the channel walls.

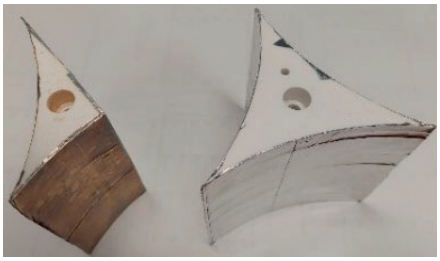

Figure 3. Lateral and central artificial roughness elements selected for the experimental study

*The experimental studies* were carried out in the „Dumitru Cioc" Hydraulics Laboratory (HL) part of the Technical University of Civil Engineering Bucharest (TUCEB).
To perform these experimental studies, some of the main infrastructure of the HL was used, namely the variable slope channel, the pumping station and the related hydraulic network.
The characteristics of the variable slope open channel are: a rectangular cross section, 1.20 m wide and 0.75 m depth (of which 0.65 m is the usable depth), the total length of the channel is 33.20 m, the maximum elevation difference at the downstream end, compared to the horizontal position, is 0.35 m that corresponds roughly to a channel slope of 1% (Figure 4).

Figure 4. The variable slope channel - „Dumitru Cioc" Hydraulics Laboratory; TUCEB

The pumping station is equipped with four centrifugal pumps, ensuring a maximum flow rate of 0.6 $m^3/s$.
The flow rate is measured using electromagnetic flowmeters placed on the laboratory water supply network pipes. The supply of the variable slope channel is ensured by two pipes connected to the tank placed at the upstream end. Each of these is equipped with a flow meter and a control valve. The diameters of these pipes are 200 mm and 250 mm, respectively.
To carry out the experimental study, a series of adjustments were necessary which mainly consisted of doubling the bottom of the channel and creating a well-defined experimental area. The solution to doubling the bottom was considered the only acceptable option for fixing the artificial roughness elements in a safe manner that would not affect the integrity of the channel. Three plastic plates were placed in the upstream area of the channel and fixed with metal strips to its walls. The total length occupied by these plates is 6.5 m. The first and last plates do not present any particularities. However, the central plate was provided with recessed nuts, their role is to ensure fixing of the roughness elements. The arrangement of the fixing nuts makes it possible to achieve a placement of the artificial roughness elements at a minimum distance of 10 cm on both main directions of the horizontal plane.
The theoretically obtained results regarding the flow characteristics were used as a starting point for the planning of future experiments. Thus, the precise experimental framework was established.
The measurements monitored the main physical quantities that are used for the description, characterization and classification of free surface currents, namely flow rates, depths and local velocities.
For flow rate measurements, the flow meters placed on the water supply pipes were used. The water depth was monitored using an ultrasonic probe, and the local velocity using an acoustic Doppler velocimeter (ADV) and, subsidiary, a Pitot tube connected to a pressure transducer (Figure 5).

Figure 5. Measuring equipment used

Due to the low water depth, a 2D side looking ADV probe was used. the acquisition frequency

of the measured values was set at 20Hz. To avoid measuring errors related to noise and sampling faults and post processing, several bibliographic works were consulted, including (Kazemi et al., 2021; Park & Hwang, 2021; Chen et al., 2024).

The first action aimed to establish the framework for the tests to be carried out. In this regard, the theoretical estimates initially made were experimentally verified. Based on these tests, the flow-depth-slope relationship which ensures the desired experimental framework was established.

First, to obtain high velocity values for the water stream the maximum possible slope ($i_{max}$) of the channel was set ($i_{max}$ = 1%). The experimental medium flowrate was Q = 0.096 $m^3/s$. The measured mean depth along the channel was $h_{med}$ = 0.10 m. For this setup, an unfavorable aspect that was observed was the deformation of the third bottom plate because of the lifting force generated by the water current.

The solution chosen to avoid this issue was to set a smaller slope for the channel and to increase the velocity of the water strictly in the first part of the experimental zone, by placing a sluice gate at the inlet section of the channel (Figure 6).

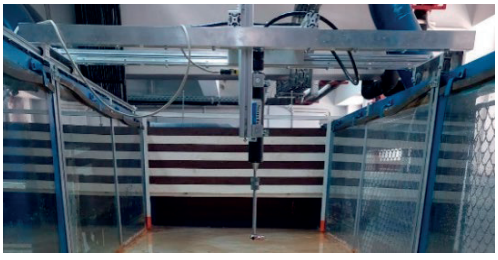

Figure 6. The sluice gate placed
at the upstream of the testing zone

After computation and experimental tests, the convenient experimental setup was established (Dumitrescu & Răzvan, 1972; French, 1986): the channel slope *i = 0.1%;* the experimental medium flow rate Q = 0.096 m3/s; the gate opening *a = 7 cm.* For the experiments a single arrangement and three different orientations (patterns) were considered (Figure 7).

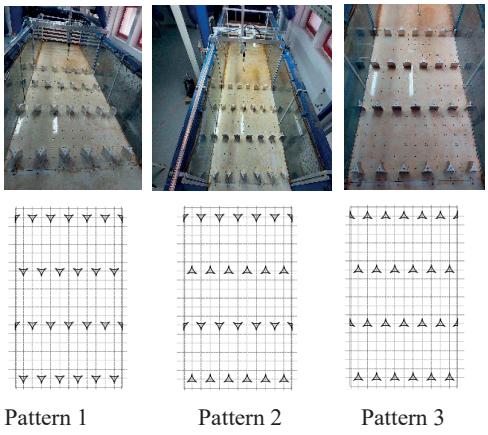

Figure 7. Patterns used for experimental test

The single arrangement for the three patterns is justified by the dissipation mechanism that is studied, namely tumbling flow.

For further reference of the studied arrangement, we will use the following names Pattern 1, Pattern 2 and Pattern, as shown in Figure 7, and for the "free" channel, i.e. without roughness elements, we will use the name Pattern 0.

Experiments carried out in the past by various researchers on alternatingly placed concrete cubes and the experience gained by applying this solution show, according to (Certousov, 1966; Dumitrescu & Răzvan, 1972; Morris & Wiggert, 1972; Peterka, 1984; Kiselev, 1988; Novak et al., 2005) referenced literature, recommended ratios between the height of the element and the depth of the current at the design flow rate and distances for placing the roughness elements in the direction of the current and transverse to it.

Although we proposed a new shape for the roughness elements, we considered these recommendations a rational starting point. However, a determined criterion was also the size of the area designated for mounting the roughness elements, this being used to the maximum extent. Considering the height of the elements, the longitudinal, the transversal spacing and the water depth, the studies were driven on a prototype (geometric scale coefficient $\alpha_l$ = 1).

## RESULTS AND DISCUSSIONS

*The CFD results* obtained on the modeling that assumes a hypothetical scenario, allowed a general qualitative analysis of the influence of the four roughness elements geometry. The conclusions are strictly valid within the assumptions and numerical conditions adopted. In the absence of experimental validation, the results cannot be considered from a quantitative point of view. Thus, they were used only as a starting point for choosing the geometry of roughness element used for future experimental tests.

The experimental tests were performed along the flow axis, tracking velocities at various depths for two relevant monitoring sections. The placement of those monitoring sections, $S_{ust}$ and $S_{dst}$, are upstream and respectively downstream the bottom plate where the roughness elements are fixed (Figure 8).

Figure 8. Measuring equipment placed at $S_{ust}$ and at $S_{dst}$

A first image of the effect generated by the three patterns compared to the "free" channel is plotted in Figure 9.

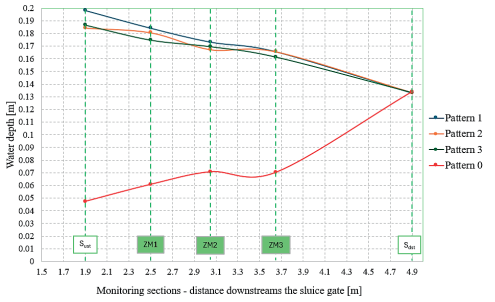

Figure 9. Comparative plot of the free surface shape

As shown in Figure 9, each of the Patterns P1, P2 and P3 are modifying the water depth along the experimental area. The water depth increases significantly in all the first three monitoring sections. In the last one, $S_{dst}$, the water reaches the same depth for all four patterns (Table 1).

Table 1. Water depth values along the experimental area

| Monitoring section | $S_{ust}$ | ZM1 | ZM2 | ZM3 | $S_{dst}$ |
|---|---|---|---|---|---|
| Water depth [m] | | | | | |
| Pattern 0 | 0.047 | 0.061 | 0.071 | 0.070 | 0134 |
| Pattern 1 | 0.198 | 0.184 | 0.173 | 0.166 | 0.133 |
| Pattern 2 | 0.184 | 0.181 | 0.167 | 0.166 | 0.133 |
| Pattern 3 | 0.187 | 0.175 | 0.170 | 0.161 | 0.133 |
| Water depth difference – Reference "Pattern 0" [m] | | | | | |
| Δ h1 | 0.151 | 0.123 | 0.102 | 0.096 | ≈0 |
| Δ h2 | 0.137 | 0.120 | 0.096 | 0.096 | ≈0 |
| Δ h3 | 0.140 | 0.114 | 0.099 | 0.091 | ≈0 |

After the $S_{dst}$ section the flow becomes uniform with a normal depth of roughly 0.16 m.

The presence of the artificial roughness generates a local resistance which influences the channel's flow rate. As the water depth rises upstream the artificial roughness elements, the orifice created by the sluice gate become submerged. Thus, the orifice head ($H_{orif}$) changes with respect to the degree of submergence. This fact is reflected in the flow rate (Table 2).

Table 2. Values influenced by orifice submergence

| Pattern | $h_{ust}$ | $H_{orif}$ | $Q$ |
|---|---|---|---|
| | [m] | [m] | [m$^3$/s] |
| 0 | 0.047 | 0.22 | 0.0955 |
| 1 | 0.198231 | 0.3 | 0.0950 |
| 2 | 0.184333 | 0.285 | 0.0947 |
| 3 | 0.186583 | 0.255 | 0.0945 |

The flow rate values shown in Table 2 are plotted in Figure 10 against orifice head ($H_{orif}$) by which the flow rate changes due to the head upstream the orifice are obtained.

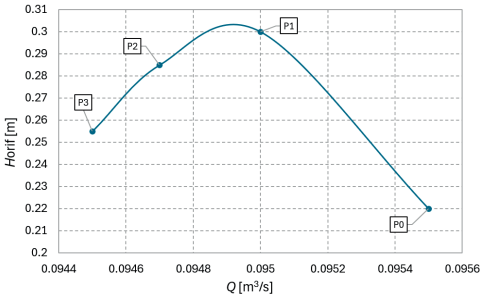

Figure 10. Flow rate curve Q($H_{orif}$)

Also, the flow rate plotted against the water depth in the $h_{uts}$ monitoring section, which is placed downstream the sluice gate, is useful to observe this influence (Figure 11).

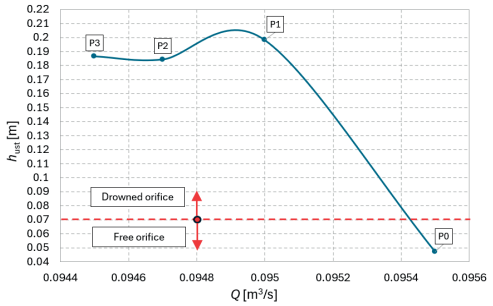

Figure 11. Flow rate curve Q($h_{ust}$)

Starting from the observation on the drowning effect of the gate orifice, the experiments on the dissipative effect generated by the three patterns were carried out at a same flowrate value, namely Q = 0.095 m3/s.

As the present paper focuses only on the whole ensemble of artificial roughness elements, the data obtained for the monitoring sections $S_{ust}$ and $S_{dst}$ are analyzed and discussed.

For Pattern 0 (Figure 9), the water depth is increasing significantly between $S_{ust}$ and $S_{dst}$. The shape of the water surface and the Froude number upstream ($Fr_1$ = 6.33) and downstream ($Fr$ = 0.36) are highlining a hydraulic jump. The flow upstream the testing area is supercritical and downstream the testing area is subcritical.

Thus, the goal of the artificial roughness is to reduce the kinetic energy of the water stream at $S_{ust}$ and to ensure a similar specific energy to the normal flow conditions one at $S_{dst}$. The graph in Figure 9 suggests the achievement of this goal.

A comparison between the values obtained for monitoring section $S_{ust}$ is shown in Table 3.

Table 3. Monitoring section $S_{ust}$ - values obtained for the main quantities

| Pattern | $h_{ust}$ [m] | $\Delta h_{ust}$ [m] | $V_{ust}$ [m/s] | $\Delta V_{ust}$ [m/s] | $KT_{ust}$ [m] | $\Delta KT_{ust}$ [m] |
|---|---|---|---|---|---|---|
| P0 | 0.047 | - | 1.815 | - | 0.168 | - |
| P1 | 0.198 | 0.151 | 0.338 | -1.477 | 0.006 | -0.162 |
| P2 | 0.184 | 0.137 | 0.510 | -1.304 | 0.014 | -0.154 |
| P3 | 0.187 | 0.140 | 0.368 | -1.446 | 0.007 | -0.161 |

The values shown in Table 3 for the four analyzed patterns are the water depth $h_{ust}$, the mean velocity $V_{ust}$ resulted from averaging the values obtained through local measurements and $KT_{ust}$ the specific kinetic energy value of the generalized Bernoulli equation. Also, the difference between a considered reference value, which corresponds to pattern P0, and the corresponding value obtained for the other three patterns are presented. The notations used are $\Delta h_{ust}$ for the obtained water depth difference, $\Delta V_{ust}$ for the mean velocity difference and $\Delta KT_{ust}$ the specific kinetic energy difference.

As shown in Table 1 and Table 3 the water depth increases due to the presence of any of the three patterns of the artificial roughness (P1, P2 and P3). Obliviously, this increase of the water depth generates a decreasing of the water velocity and consequently of the specific kinetic energy. The minus sign of those two differences is showing this decrease. The velocity decreases 81.37% for P1, 71.88 % for P2 of and 79.71% for P3. Also, a significant decrement is noticed for specific kinetic energy: for P1, 96.36%, for P2, 91.94% and for P3, 95.84%.

As a general conclusion, all the data obtained confirms the expected changes in the water surface profile for patterns P1 to P3. Namely, the presence of a high roughness area leads to rise in upstream water level and decrease in the downstream water level.

The analysis of the general effect produced by the presence of artificial roughness is driven by comparing the main quantities derived from the water depth and the water velocity measurements (Bekheet et al., 2025; Ghomri et al., 2023; Yang et al., 2025).

The first driven physical quantity was the difference of the total head corresponding to $S_{ust}$ and respectively to $S_{dst}$, for each of the three patterns of artificial roughness. This friction loss was obtained by applying the energy equation (the generalized Bernoulli equation) between the two monitoring sections. The results obtained are shown in Figure 12.

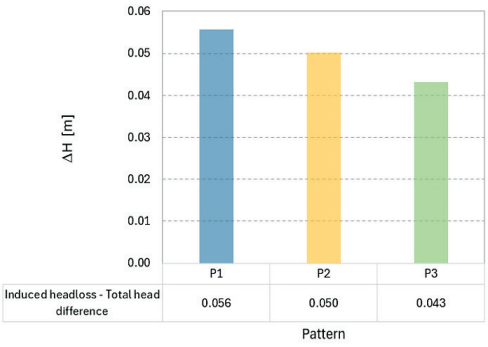

Figure 12. Fiction loss $\Delta H$ induced by the three patterns

As shown in Figure 12, pattern P1 induces a drop of the hydraulic head of 5.6 cm. Compared to this value, the drop generated by P2 is 10.71% less, and the third one, P3, 23.22% lower than P1.

Another way to quantify the dissipative effect between Sust and Sdst is by using the dissipated power (Figure 13).

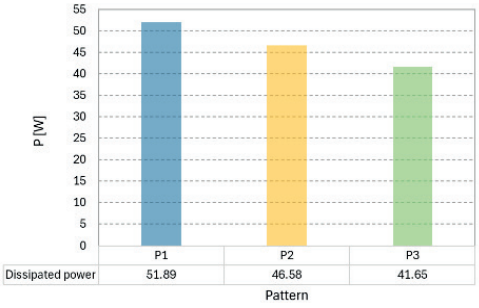

Figure 13. Dissipated power by the three patterns

The results obtained on the efficiency of each of the three patterns are plotted in Figure 14.

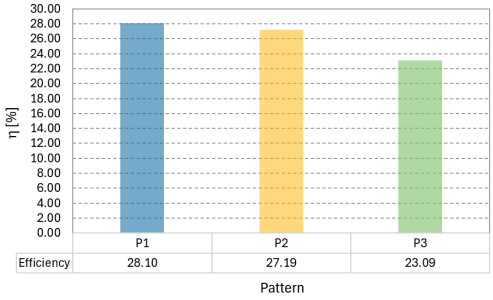

Figure 14. Efficiency of each of the three patterns

As shown in Figure 14, the most effective pattern is P1. Compared to P1, the dissipation efficiency decreases 3% for P2 and 17.83 % for P3.

## CONCLUSIONS

The experimental tests carried out in the „Dumitru Cioc" Hydraulics Laboratory, part of the Technical University of Civil Engineering Bucharest, are seen as a starting point for future tests.

The results obtained are considered encouraging for developing future research on the shapes proposed for the roughness elements.

The future possible research may follow two paths. The first one continues the hydraulic experimental tests with different flow rate values, diverse channel slopes and various distances between the artificial roughness elements. To obtain a complete image of the flow in the wake of the experimental area, transvers measurements at different depths are necessary. Also, the evaluation of turbulence like studies on turbulent kinetic energy and Reynolds stress provides important information about energy dissipation and is considered for future research.

A shortcoming of the experiments was the reduced number of available artificial roughness elements and consequently the low extent of the test area. Also, the lifting phenomenon of the bottom plates has dictated the maximum velocity value that can be used for the experiments (1.82 m/s). After correcting the previously mentioned aspects a comparative study, carried out in the same flow condition, on the behavior of the proposed artificial roughness elements and a classical shape like cubic elements is considered useful.

The second path that can be followed is related to the use of new materials for building the artificial roughness elements. New materials and new technologies are now available. A series of interdisciplinary studies involving the hydraulics laboratory personnel and the chemistry and building materials department of the TUCEB are considered of interest.

***Abstract***

*There are many discussions globally related to the efficient use of agricultural land. An important role in the valorization of these agricultural lands is represented by the size of the exploited plot of land. Through this work, the concentration of agricultural areas in units of optimal size was achieved to allow the application of modern agricultural methods and technologies. This paper presents a way of agricultural land consolidation of the plots of land in the category of arable use belonging to the cadastral plots T225-T226-T227, Izbiceni locality, Olt county, South-West Oltenia region of Romania. From the documents studied, the initial situation presented for the three cadastral plots a total area of 419.33 ha and a number of 517 individual lots, and for an individual lot there was an average area of 8110.83m$^2$, less than 1 ha, which determines the difficulty in the efficient exploitation of agricultural land. Through agricultural land consolidation, the individual plots were grouped into 9 fields of similar size, and the resulting average area for these fields being 46.48 ha, a corresponding area for optimal exploitation. At the same time as the analysis and sizing of the exploitation areas, the natural conditions (soil type, climate, vegetation) specific to the area were also analysed, in order to identify the crops suitable for the area and establish the crop rotation. Two field crop rotations were carried out: crop rotation C1 (185.61 ha), consisting of 4 fields and 4 crops (corn, barley, rapeseed, wheat) for a 4-year period, and crop rotation C2 (233.72 ha), consisting of 5 fields and 5 crop groups (sunflower, barley, soybeans, peas and wheat) for a 5-year period. The aim was for these crops to also meet the requirements of the agricultural products market.*

***Key words****: agricultural land, crop rotation, territory organization.*

## INTRODUCTION

Territorial organization is clearly defined as the set of measures, actions and works that intervene in a given territory in order to efficiently use the existing potential and ensure a coordinated development of economic and social activities (Bold, 1994). Territorial organization and agricultural planning plans represent the only way in which the coordination of spatial elements and the adopted solutions are aimed at improving the technical and economic organization of space, in order to adapt it to the various purposes foreseen by society (Brumar, 2006).

According to Eurostat (2026) and according to the latest baseline data from 2023, the EU had 8.8 million farms, of which 2.9 million, or 32.6%, were located in Romania alone – more than twice as many as in the next Member State, Italy, which had 1.3 million farms, or 14.3% of the EU total, followed by Poland with 1.2 million (14.5%) and Spain with 0.8 million (9.1%). The size of farms across the EU is small: almost two-thirds of farms had less than 5 hectares (ha) in 2023, respectively 62.8%, while at the opposite pole only 7.6% of farms reached 50 ha or more, and these accounted for 68.3% of the EU's utilised agricultural area (UAA). The average size of agricultural holdings at EU level was 17.8 ha, a threshold reached or exceeded by about 17% of farms (Eurostat, 2026).

Political, economic and social changes have a direct influence on the use of agricultural land over time (Ovreiu et al., 2021).

In Romania, the way of using and exploiting agricultural land was influenced by the following events:

1) Between 1949 and 1990 the land passed into the administration of the state. The socialist agricultural system appeared, characterized by the exploitation of large and homogeneous agricultural areas by categories of use. This period had a significant influence on the measures of organization and exploitation of the territory that are still felt today. Each agricultural unit in that period was obliged to

carry out a Territorial Organization Project and to review it periodically. Through this project, the following were carried out: the sizing of the plots, the realization of the circulation network, the characterization of the soils, the establishment of soil improvement measures, the establishment of the categories of use according to the creditworthiness notes, the arrangement of the irrigation surfaces, the drainage and elimination of flooded areas, the sizing of the production units, the regularization of water courses, etc.

2) After 1990, the political evolution led to the elimination of the centralized exploitation of agricultural land, the elimination of those agricultural cooperatives. During this period, private property was reconstituted through massive expropriations, which led to transformations in the exploitation of agricultural land, determining a high degree of fragmentation of agricultural areas (Ovreiu et al., 2021). This aspect generated economic disadvantages, caused the degradation of agricultural land and influenced the way agricultural land was exploited. The fragmentation of agricultural land, after 1990, also had a negative effect on the surface arranged with a drainage system. The cultivation of the land without taking into account the position of the network of drainage canals and sometimes even impossible to take into account due to the small size of the plot, caused the reappearance of excess moisture, which led to low crop yields (Oprea, 2022).

3) Romania's accession to the European Union (2007) was characterized by the existence of funds and subsidies for agriculture. New farms were developed that gradually increased the areas. New high-performance machinery was purchased that offers high yields on large areas. Farmers are starting to apply long-term sustainable technologies.

Fragmented use of agricultural land leads to high operating expenses but also low productivity, resulting in inefficient use and poor agricultural performance, but property fragmentation increases the trading value (Isenhardt et al., 2025). Land fragmentation plays an important role in determining the productivity of a farm, and the higher the weighted average of the plots worked, the higher the productivity of the farm (Looga et al., 2018).

The analysis of agricultural land fragmentation is multidimensional, encompassing several aspects: the number of plots that a farm operates, the size of these plots, how regular their shape is, the distance from the farm premises, and how dispersed the plots are from each other. Greater fragmentation tends to increase production costs while reducing yields, income, profitability and overall efficiency (Latruffe & Piet 2014).

A study by Valtiala et al. (2023) in Finland reviewed previous results on the relationship between plot size and exploitation efficiency. They found that there is an increase in labour efficiency in larger plots, and once a plot exceeds around 20 ha, any further increase in size brings few additional technical benefits.

Spatial planning is a way of exploiting agricultural land according to specific rules, determining the necessary measures for the conservation and improvement of land quality, a way of managing property rights and a solution for the development of agricultural businesses (Moteva & Marinova, 2020).

When there are good quality soils, characterized by high fertility, which have a favourable structure, texture and porosity, they can only provide high crop yields by applying appropriate technologies to normal environmental conditions (Balan et al., 2024).

Agricultural Land Use Planning involves the spatial organization of agricultural land for the purpose of rational exploitation, it involves the rational use of agricultural machinery, it involves the preservation of the natural properties of soils, it determines the economic efficiency of farms and the prosperity of rural areas (Moteva & Spalevic, 2016).

From the research carried out by Dorosh et al., 2020, on spatial planning and organization of agricultural land use in Ukraine, it follows that the rational use of land to ensure ecological and economic sustainability must be achieved by analysing the following indicators: territory – landscape – plot of land – soil (Dorosh et al., 2020).

The diversity of the relief, the intensity of anthropogenic productive activities and climate change favour the extension of soil degradation processes, with significant effects on agricultural productivity, and agricultural performance is directly influenced by the way

the territory is organized (Balan & Nitu, 2025).
The spatial organization of the territory aims at the most efficient use of agricultural land, by maintaining their balance, achieving a stable environment within the agroecosystems and at the same time the main goal being to obtain a maximum yield (Shkuratov et al., 2020).
Agricultural land is efficiently exploited by achieving high yields, these are influenced by the biological material used and the technology applied, as well as by environmental factors, climate, soil type, relief, etc. Soil fertility can be limited to varying degrees of limitations caused by human or industrial actions, which can sometimes act negatively (Oprea & Curea, 2022).
Within this work, the aim was to organize and arrange arable land for an arable area in Izbicéni, Olt County, Romania. This work offers a partial solution for the exploitation of agricultural land. It should be noted that the work refers to the identification of an optimal solution in terms of the size of a plot of land as a production unit, not in terms of the general size of the agricultural farm.
Through the works of organizing the arable territory, the amalgamation of agricultural land is also carried out. Romania is the country with the most fragmented agricultural territory in Europe (Eurostat, 2026), there has been an attenuation of this phenomenon in recent years, but progress is still needed to this end. The amalgamation of agricultural land can be influenced by legislative actions (mandatory) and by the free will of the land owner (optional actions). Currently, in Romania, private initiative is the only option that determines the amalgamation or grouping of arable areas, through sale-purchase contracts, association, lease, rental, but not according to a specific law, but according to the legislation regulating civil law. All these laws do not impose mandatory rules for the organization and location of parcels, which is why these actions result in random areas in size and with minimal effects on agricultural performance. Another problem that has arisen is the reduction of crop diversity at farm level, or the practice of a short rotation, farms have emerged that cultivate one, two or maximum three species of wheat, rapeseed, corn or sunflower. To this end, the European Parliament has tried to condition those direct payments to farmers (subsidies) on compliance with crop rotation and the minimum area.
This study aims to reduce the level of fragmentation of agricultural land in the analysed area, to create plots of optimal size and to draw up a crop rotation over a period of four years, in accordance with economic requirements and agrotechnical criteria. Such an approach ensures an economic development of the farm as well as the possibility of using irrigation in the future (Cioboată et al., 2023). In that area there is an irrigation system that requires small repairs.

## MATERIALS AND METHODS

The documentation for the organization and arrangement of agricultural land for agricultural farms aims to highlight the main factors that ensure the optimal framework for development in agricultural production. From a technical point of view, this is achieved through two stages: 1. Identification/ knowledge of the land fund (owner, category of use, conditions and natural resources) and grouping the neighbouring plots or lots in compact areas of larger size, establishing the boundaries and maintaining the obligatory limits; 2. Grouping the land by quality classes, establishing the crops and their rotation within fields adapted to the natural conditions and the economic criteria specific to the competitive market. All these should be achieved by observing the scientific criteria of territorial organization (Order no. 212, 2002)
In order to achieve the objectives of the work, the stages were followed according to the technical norms for the preparation of projects for the organization of the territory of agricultural holdings, as well as the indications in the specialized literature.
The present documentation is expressed by the cadastral plans scale 1:10000, 1:5000, the material base in digital and analogue format existing at the Olt Cadastre and Real Estate Advertising Office and at the Izbiceni Local Council.
Based on these, the cartographic documents (analogue and digital) that were made available by the Olt OCPI and the Izbiceni Local Council for the plots T225, T226, T227 were examined,

in question: orthophoto plan; cadastral plans 1:5000-1:10000; property titles; cadastral documentation resulting from the registration process; database resulting from the PAD conversion; other graphic and textual data possessed by OCPI and the Izbiceni Local Council, for the plots T225, T226, T227.

The identification of the site was achieved by locating it in the field.

Then the limits of the plots were established through direct measurements on the ground. The target of this action was to precisely determine the limits of the plots from T225 to T227, through measurements on the ground in order to be able to determine the location, respectively the surface. Topographic measurements were carried out in the coordinate system of the state geodetic network.

The accuracy of determining the points was determined according to ODG no. 634 and Decision no. 1 regarding the performance of kinematic GNSS measurements, issued by the director of the Directorate of Geodesy and Cartography within the ANCPI.

The measurements were performed with a GPS receiver, type Leica GS08 CS 10, of the dual-frequency geodetic accuracy class, the method used was RTK.

The processing of GPS measurements was carried out using the specialized Leica GeoOffice program, for the calculation of the coordinates at the determined points, observations from the permanent stations CORA (CORABIA) and SLA (SLATINA) were used.

The conversion of coordinates from the WGS 84 system to the STEREO 1970 projection system was carried out using the TransDat RO program.

Following the measurements with the GPS device, stereographic coordinates were obtained on the WGS 84 ellipsoid, these coordinates being transformed in the official reference system of Romania, using the coordinates of the existing geodetic points.

The plans were drawn up at a scale of 1:5000, 1:10000, using the BricsCAD V13 program.

The determination of the areas for each individual owner and on each plot was carried out through multiple detachments according to the parcel tables, using the TopoLt automatic program. Also in this program, simulations were made to identify the optimal option for organizing the agricultural territory, respectively for sizing the plots (soles/fields) for crop rotation. Several variants of dividing the total area into approximately equal plots were analyzed, but only 2 variants are presented in the paper that are exposed in the chapter results and discussions.

In order to establish the crop rotation, it is necessary to carry out the evaluation of agricultural land and its grouping in Homogeneous Ecological Territory (TEO), this is done on the basis of the creditworthiness grades calculated with the help of data from soil studies (Order no. 212, 2002). The following indicators are used: temperature, precipitation, texture at 20 cm depth, gleying, pseudogleying, salinization/alkalinization, pollution, slope, landslides, groundwater depth, flood susceptibility, subsidence, carbonate content, soil reaction, degree of saturation, edaphic volume, humus content, and excess moisture. The homogeneous ecological territory (TEO) for T225-T226-T227 in Izbiceni, Olt County, have been determined.

## RESULTS AND DISCUSSIONS

### Presentation of the studied area

The analysed territory belongs to the south-western Oltenia region of Romania, the category of use – arable. Official statistics show that, at the level of the entire region, the categories of land use have undergone significant changes after 1990 (Miluț et al., 2020). The increase in non-productive areas is interesting, another observation that must be taken into account is related to the accentuation of land degradation phenomena, so in this context it is necessary to identify sustainable land monitoring measures that balance agricultural productivity with environmental protection (Călina et al., 2025). In order to implement measures to mitigate land degradation, it is necessary to identify the spatial spread and intensity of these processes at a landscape level (Filipciuc et al., 2019).

The reconstitution of the right of ownership, after the application of Law 18/1991, determined the appearance of plots with small widths of 8-10-12 m, in the form of strips, in the N-S or E-W directions, and on different

lengths, this aspect determined the decrease of the yield per hectare (Popescu & Bălan, 2024).
The commune of Izbiceni consists of a single locality, bearing the same name, being placed on the right bank of the Olt River, in the Romanați Plain, a sub-branch of the Oltenia Plain, in the southern part of Olt County (Figure 1).
The commune is positioned on the northern latitude 43°49'; eastern longitude 24°39' and the maximum altitude 48.2 m on the mound in the northwest of the estate and the minimum 39.9 m at the water level of the Olt River, the north of the Danube river.

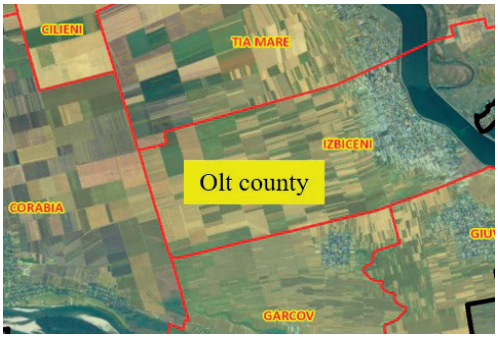

Figure 1. Location of Izbiceni (https://geoportal.ancpi.ro)

The area of Izbiceni commune is 5115 ha, of which 4130 ha are agricultural land and 985 ha are non-agricultural lands. The number of existing households in Izbiceni is 1320.
The climatic factors found in the commune of Izbiceni are:
- the average annual temperature oscillates between 10-12 degrees;
- precipitation is different from one year to the next and also from one season to another (the annual average being 450-570 mm/m$^2$);
- wind: the north wind blows intensely in winter, blowing snow, forming squalls (it reaches speeds of 60-70 km/h, in the northeast to southwest direction); the south wind, the second most important wind, blows more in spring, being humid and warm in the cold season and dry in the warm season (it reaches speeds of 20-30 km/hour, in the west-east); Bălțărețul, blows in the warm season from the southeast to the northwest; Zephyr blows from the south and brings heat. Austrul, Baltărețul and Zephyr are the winds with the main role in pollinating flowering plants.

The most common groups of soils in the locality are: chernozem; sandy soils; marshy soils, resulting from the rotting of plants, buried with the passage of time (Popescu, 2016).
The local flora is diversified, here we find the steppe combined with the flora of the lowlands (acacia, mulberry, apricot, chervil, sycamore, quince) which are combined with willow, poplar, mulberry, etc. and on the other hand, the places cultivated with cereals are often interspersed with places where meadow plants grow freely. Here we find numerous trees, vines, plants of all kind.
Characterization of soil types**.** According to the observations and determinations in the field and the results of the analyses obtained from the samples taken, we can state that the soils of the Izbiceni communal territory are part of soil unit 9 (US 9).
Soil unit 9 (US9), which is found on the territory of the plots T225-T226-T227, is the chernozem, cambic chernozem, very deep profile, with a loamy, loamy-sandy or loamy-clayey texture, the parent material is represented by loess, loess-like material, clays, marls, alluvial-proluvial deposits, etc., extremely rich in basic elements. The relief is a plain, which is characterized by flat or slightly undulating surfaces.
Chernozem properties (Popescu, 2017):
Am horizon: 40-60 cm; blackish colour (chromes and values less than or equal to 2); loamy, sandy loam or clayey loam texture; medium and large, well-formed glomerular structure; porous medium; compact medium; intense biological activity; gradual transition.
ACk horizon: 80-100 cm; brown-gray colour, with chromes and values <3.5 at least in the upper half; loamy texture, sometimes sandy loam or clayey loam depending on the nature of the parent material; less well-formed glomerular structure; porous medium; compact medium; frequent whitish stains and streaks of calcium carbonate; obvious effervescence; gradual transition.
Horizon Cca: 80-100 cm; lighter colour, different texture; unstructured; frequent spots and calcium carbonate concretions; strong effervescence.
For the evaluation of the agricultural land in plots T225-T226-T227 in Izbiceni, Olt county, only one TEO unit resulted, and the results obtained are presented in Tables 1-3.

From the studied documents, the owners of the lands in the T225-T226-T227 plots were identified as follows: T225 = 171 owners and a measured area of 1377559 $m^2$; T226 = 183 owners and a measured area of 1438009 $m^2$; T227 = 163 owners and a measured area of 1380317 $m^2$ (Figure 2). In order not to upload the document, the data referring to the parcel tables were not included.

Table 1. Eco pedological indicators of soil quality

| No. TEO | US 9 |
|---|---|
| Temperature | 10-12 |
| Precipitation | 400-500 |
| Gleying | Umed |
| Pseudogleying | 0 |
| Salinization/alkalinization | 0/0 |
| Texture at 20 cm depth | Loamy |
| Pollution | 0 |
| Slope | 1 |
| Landslides | 0 |
| Groundwater depth | Small |
| Flood susceptibility | 0 |
| Subsidence | unsettled |
| Carbonate Content | Medium |
| Soil Reaction | Weakly Alkaline |
| Degree of Saturation | High |
| Edaphic Volume | Very high |
| Humus Content | Very high |
| Excess Moisture | Permeable |

Table 2. Ratings and quality classes of TEO

| No. TEO US9 arable land (surface = 419.33 ha) | Ratings | Quality classes |
|---|---|---|
| Wheat | 70 | II |
| Barley | 71 | II |
| Corn | 81 | I |
| Beans | 75 | II |
| Potato | 59 | III |
| Sugar beet | 76 | II |
| Soybean | 80 | II |
| Peas | 70 | II |
| Flax | 77 | II |
| Rape | 90 | I |
| Hemp | 70 | II |
| Alfalfa | 77 | II |
| Clover | 56 | III |
| Vegetables | 62 | III |

| No. TEO | | US9 |
|---|---|---|
| Surface | | 419.33 ha |
| Area by suitability classes | I | 0 |
| | II | 419.33 |
| | III | 0 |
| | IV | 0 |
| | V | 0 |
| | VI | 0 |
| Indicative requirements for improvement work | | Irrigation |

The initial situation of the land areas within the three plots before the organization of the territory was presented: in T225 the average area of a plot was 8,055.90 $m^2$; in T226 the resulting average area was 7,857.90 $m^2$, and in T227 the average area was 8,468.20 $m^2$.

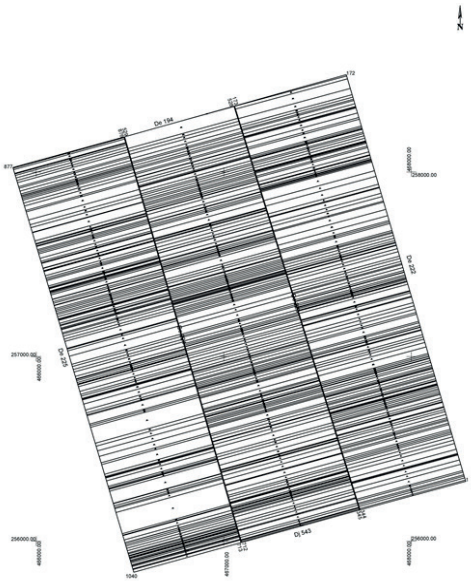

Figure 2. Summary presentation of the land fund

Using the automatic TopoLt program, the detachment of each area was carried out, simulations were carried out in order to achieve areas that correspond to the criteria for crop rotation, respectively for their sizing according to the arable land organization plans.

**Organization and arrangement of arable land**

The territory proposed for the organization is identified as part of the arable use category, belonging to the Izbiceni commune, Olt County and is recognized by the parcels from T225 to T227, and the demarcation in the field was carried out by the measurement sheet and by the exploitation roads.

Legally, these areas are privately owned. Currently, the studied area is entirely leased by an agricultural company. For the most efficient exploitation of the land, according to the principles of arable land organization (Brumar, 2006), two variants of dividing the

topographically raised land into approximately equal plots have been proposed.

The first variant of the territorial arrangement (Figure 3) includes 3 soles/fields/plots that have the areas of: Sola 227 = 1380317 m$^2$; Sola 226 = 1438009 m$^2$; Sola 225 = 1377559 m$^2$.

The roads cover the area of: De 223 – 9072 m$^2$; De 224 – 9500 m$^2$.

Figure 3. First variant of organizing and arranging agricultural land through crop rotations

The existing exploitation roads were preserved: De 223 and De 224 and the existing plots of land were divided into 3, resulting in 3 plots with an area almost to 140.00 ha, (137.75 ha; 138.03 ha; 143.80 ha). This variant is difficult to exploit, because it leads to the opening of very large plots, but also a crop rotation of only 3 years, and the shape of the resulting plots offers a very large gap between length and width.

The second variant proposed and recommendation for the exploitation of the territory (Figure 4) is characterized by the construction of a road De 194/1 with an area of 2484 m$^2$ and the maintenance of the existing ones (De 223 and De 224), as well as the division into nine soles, represented as follows:

- Sola I C1 (T 227) = 46.26 ha;
- Sola II C1 (T 227) = 46.22 ha;
- Sola III C1 (T 226) = 46.40 ha;
- Sola IV C1 (T 225) = 46.73 ha;
- Sola I C2 (T 226) = 48.04 ha;
- Sola II C2 (T 225) = 46.05 ha;
- Sola III C2 (T 225) = 44.97 ha;
- Sola IV C2 (T 226) = 49.11 ha;
- Sola V C2 (T 227) = 45.55 ha.

It is worth mentioning that the entire area subject to development is surrounded by existing exploitation roads that were not taken into analysis, but which can serve the surface.

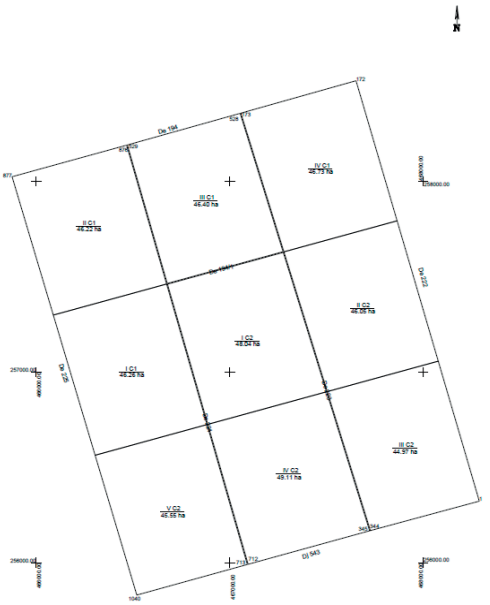

Figure 4. Second variant of organizing and arranging agricultural land through crop rotations

The roads cover the following areas: plot 223 – 9,072 m²; plot 224 – 9,500 m²; and plot 194/1 – 2,484 m².

In order to obtain the best possible results and to comply with the rules of arable land organization, the most suitable option is the second option (Figure 4), which helps to rotate the crops as well as possible, grouping the entire area in a crop rotation with 9 fields distributed in approximately equal areas, between 44.97 ha and 49.11 ha (Tables 4 and 5). These areas are very close to the size of 50 ha, a size recommended by the specialized literature and by many studies. The shape of the 9 fields resulting from the second variant is a shape close to the square, but due to the obligatory limits existing in the area (irrigation

canals, exploitation roads) parallelograms with 4 sides resulted, and the ratio between length and width (L:W) being a maximum of 1:0.8.

In order to ensure the most efficient circulation and flow throughout the exploitation of arable land, it was considered to keep the already existing exploitation roads, as well as the establishment of a new De 194/1 road, so that access on at least 3 sides for monitoring and exploitation is possible for each field. The result was a set of fields with at least two parallel sides.

Due to market trends, the organization of crops for the next period is influenced by the large share held by cereals (corn, wheat, barley) and oilseeds (rapeseed, sunflowers), but the introduction of plants that play a role in nitrogen fixation (peas and soybeans) was also taken into account. In selecting the crops to be introduced into rotation, their suitability for the analyzed area was also taken into account according to the data in Table 2.

From the analysis of the natural conditions specific to the area, it was found that for the entire area there is the same soil category. This aspect does not impose restrictions in terms of crop rotation. A very important aspect that was taken into account in designing the crop rotation, as presented below, was the compliance with agrotechnical principles. Thus, the alternation of cereals with row crops, the alternation of plants with different resistance to diseases and pests, the observance of the restrictive conditions of rotation (rapeseed-sunflower, barley-wheat, the recovery time of a crop), the time between harvest and sowing of the next plant, the required interval before returning the same crop to a field, the alternation of the root system, etc.

In terms of field size-of the surfaces, nine fields were delineated, meeting the technical requirements for agricultural land organization, thus it is proposed to divide the studied area into two crop rotations: C1 (crop rotation 1) with 4 fields and C2 (crop rotation 2) with 5 fields. The C1 crop rotation includes the fields (plots): I C1(T 227), II C1(T 227), III C1(T 226), IV C1(T 225), and the C2 crop rotation is made up of the fields (plots): I C2(T 226), II C2(T 225), III C2(T 225), IV C2(T 226), V C2(T 227).

The C1 and C2 crop rotations have in their configuration crops of wheat, corn, rapeseed, sunflower, barley, peas and soybeans, they are developed for a period of 4 years for the C1 rotation and for 5 years for the C2 rotation, or even 9 years.

The rotation for both rotations, C1 and C2, as well as the location and composition of the crops is described in Table 4 and Table 5.

Table 4. C1 organization and crop rotation

| Crop organization and rotation C1 (185.61 ha) | | | | | |
|---|---|---|---|---|---|
| Sola | | 1 | 2 | 3 | 4 |
| Field | | 227 | 227 | 226 | 225 |
| Surface (ha) | | 46.26 | 46.22 | 46.40 | 46.73 |
| Year | 1 | Corn | Barley | Rape | Wheat |
| | 2 | Barley | Rape | Wheat | Corn |
| | 3 | Rape | Wheat | Corn | Barley |
| | 4 | Wheat | Corn | Barley | Rape |

Table 5. C2 organization and crop rotation

| Crop organization and rotation C2 (233.72 ha) | | | | | | |
|---|---|---|---|---|---|---|
| Sola | | 1 | 2 | 3 | 4 | 5 |
| Field | | 226 | 225 | 225 | 226 | 227 |
| Surface (ha) | | 48,04 | 46,05 | 44,97 | 49,11 | 45,55 |
| Year | 1 | Sunflower | Barley | Soybeans and peas | Wheat | Wheat |
| | 2 | Barley | Soybeans and peas | Wheat | Wheat | Sunflower |
| | 3 | Soybeans and peas | Wheat | Wheat | Sunflower | Barley |
| | 4 | Wheat | Wheat | Sunflower | Barley | Soybeans and peas |
| | 5 | Wheat | Sunflower | Barley | Soybeans and peas | Wheat |

Territorial organization plans comprise a set of measures aimed at managing agricultural land efficiently, making effective use of its existing potential, and further improving it (Cioboată & Brumar, 2022).

## CONCLUSIONS

Through this work, the land area of approximately 419.33 ha, in the Izbiceni locality, Olt County, located in the southwestern part of the locality, was arranged and organized, being identified as part of the arable use category.

The researched area is located in a excessively continental climate zone, characterized by a temperate climate, with frosty winters and slushy snows and warm and generally dry

summers with sufficient precipitation but not being distributed everywhere throughout the year, being deficient in moisture in the months of March, April, August, September and October.

Following the identification on the ground and subject to the organization of the territory, the soils are part of the class of chernisols, more precisely chernozem and cambic chernozem.

Due to the high fertility and favourable climate, cereals and legumes can be grown in the studied area. Thus, wheat, rapeseed, sunflower, barley, soybeans and peas and, last but not least, corn were included in the rotation.

In the first proposed variant, a three-year field rotation was established with three approximately equal soils close to 140 ha (Figure 3), being inadequate.

In the second proposed variant, two land rotations were established, one for four years and one for five years, with approximately equal plot areas, close to 50 ha (Figure 4).

Through crop rotation, a combination of territorial conditions and the production potential of the land has been determined, the efficient use of agricultural machinery and equipment has been ensured, and hydro-ameliorative systems (irrigation) can be put into practice.

Carrying out such work at the level of an agricultural holding provides numerous advantages from an administrative and economic point of view:

- clear record of the areas and owners in each plot;
- the possibility of ordering and monitoring lease or sale-purchase transactions with agricultural land;
- identification of the type of soil present within the studied plot;
- the possible use of agricultural machinery equipped with satellite guidance infrastructure, resulting from the identification of coordinates;
- the advantage of easily creating a business plan in the following periods;
- the ratio of crops and also the cost over a period convenient for the rotation.

## ACKNOWLEDGEMENTS

This research work was conducted without external support or funding.

***Abstract***

*This article investigates the role of three-dimensional building modelling as a digital tool for promoting rural tourism and enhancing the visibility of underrepresented destinations. Rural areas often face challenges related to limited accessibility, low digital presence, and insufficient promotional resources, which constrain their tourism potential. To address these issues, the proposed approach integrates high-resolution spatial data, photogrammetry, and geographic information systems to generate accurate and interactive 3D building models of rural settlements. The methodology emphasizes cost-effective data acquisition and scalable modelling workflows suitable for small municipalities. The resulting 3D models are deployed within web-based visualization platforms and virtual tour environments to support destination marketing and visitor engagement. Results indicate that the use of 3D building models significantly improves the perceived attractiveness and spatial understanding of rural areas, facilitating remote exploration and informed travel planning. The study demonstrates that 3D modelling constitutes an effective and sustainable digital strategy for strengthening rural tourism promotion.*

***Key words****: 3D building modelling, rural tourism, digital heritage, spatial visualization, destination promotion.*

## INTRODUCTION

Nowadays, we face an increasing tourism, weather it is urban or rural. The challenges in rural tourism promotion refer mainly to limited visibility, low digital presence, fragmented information, and lack of immersive visitor experiences, and therefore a division between urban and rural tourism destinations.

Digital technologies of three-dimensional modelling play an important role in promoting tourism destinations. In this context, it is important to mention the evolution from two-dimensional maps and static images to immersive three-dimensional environments (eg. VR, AR, or web-based platforms) that allow users to visualize, explore, manipulate, and experience virtual worlds in real-time and lead to a growing relevance of 3D building models in smart tourism, virtual tourism, and tourism destination marketing (Rosmani, 2014; Caciora et al., 2021).

3D building modelling generates detailed, three-dimensional digital representations of structures integrating both geometric form and semantic information (meaning/attributes), used to simulate, visualize, and analyse buildings as tourism offer. Digital models are characterized by their Level of Detail (LoD) – which determines the precision of their geometry – and their semantic richness, which defines the level of information embedded within the model, such as material, function, or interior layout (Brenner, 2005; Biljecki et al., 2016). Three-dimensional building models come with many advantages over conventional models, especially where tourism is considered. 3D models offer immersive, interactive experiences, such as virtual tours, 360° videos, and holographic projections, that improve marketing and destination, cultural heritage, and touristic attraction exploration. These digital techniques allow for detailed, realistic, and accessible, or "pre-visit" exploration, finally increasing visitor engagement, satisfaction, and intent to travel (Rosmani, 2014; Caciora et al., 2021).

However, comparing to urban digital tourism promotion, there are limited empirical studies on the application of three-dimensional building modelling specifically for rural tourism promotion. There is also a lack of evaluation frameworks linking three-dimensional models to tourism attractiveness and visitor engagement.

Considering all the aspects mentioned above, the present paperwork aims to investigate how 3D building modelling can function as a digital strategy to enhance rural tourism promotion. The main objective is to assess its role in improving touristic rural destination visibility, visitor understanding, and promote rural and natural values (Rosmani, 2014; Caciora et al., 2021).

## MATERIALS AND METHODS

Due to the times we live in and the innovative opportunities offered by modern equipment currently available, the chosen topic for the present paperwork is the 3D modelling of an agritourist guesthouse located in a mountain hamlet, Apuseni Mountains, Romania, specifically for the purpose of promoting rural tourism. The preservation of this place through modern digital methods is the main priority, in order to promote it to all those who wish to understand and preserve the rural culture of our country, which is gradually disappearing due to the limited resources allocated to it.

The guesthouse in question is called "La Mărișcuța Citeră". It is a traditional house built in 1849, referred to by locals as the "Monument" House, located in the hamlet of Citeră, which belongs to the town of Zlatna, Alba County. The building represents a valuable source of traditions and historical heritage of the rural landscape. The "Monument" House holds particular importance as it is the oldest building on the site. It consists of two rooms and a basement and was constructed using adobe (a mixture of clay soil, straw, and equine/bovine manure), wood, and a manually crafted shingle roof. The foundation of the building is made of stone, while the interior structure is made of wooden posts and beams (Lacitera, n.d.).

Since 2021, many rehabilitation activities have been carried out, aiming to restore the site and transform it into a tourist area, which now comprises a total of ten buildings. The three-dimensional representation of the "Monument" House will be used to document, preserve, and facilitate the complete restoration of this building, both in the present and for future studies, through the creation of a virtual tour that will stimulate the public's imagination regarding such a place and encourage visitation (Lacitera, n.d.).

**Data collection**

The creation of high-quality three-dimensional models of buildings is contingent on the data collection method employed. Whether the images are meant for use in the field of architecture, cultural heritage, construction, or real estate, the manner in which they are captured has a direct impact on the accuracy, level of detail, and practical utility of the obtained model.

Terrestrial imaging is the process where images are captured from ground level. This method offers high detail for vertical surfaces, ornaments, entrances, and interiors. In order to achieve optimal results, it is essential to ensure consistent lighting, to avoid motion blur, and to maintain overlap of 60-80%. Terrestrial photogrammetry is a process that offers numerous advantages, including the capability to produce high-resolution textures for facades, comprehensive interior coverage, enhanced control over exposure and focus, but also a range of limitations, such as restricted access to roofs or elevated areas and a more protracted time commitment in the field (Brenner, 2005; Rosmani, 2014).

Conversely, the most prevalent technique for building reconstruction is aerial photogrammetry, which is ordinarily executed through the utilisation of drones. This method is highly effective in the image capture of roofs, facades, and the surrounding environment, with a particular emphasis on oblique photos. In order to achieve best results, it is imperative to adhere to the established flight parameters, with particular emphasis on the side overlap. The range of forward overlap was found to be between 75-85%, whilst the altitude was between 80-90%. It varies between 30 and 60 metres, contingent upon the height of the structure. Aerial photogrammetry has been proven to offer significant advantages, including efficient coverage of large areas, access to rooftops, and RTK/GNSS accuracy. However, it is important to note that there are also limitations, such as the capture of less detailed façade data and the restriction to narrow urban canyons (Brenner, 2005; Rosmani, 2014).

In the context of the present paperwork, the most reliable method for building reconstruction is hybrid, combining aerial and terrestrial imagery. This approach is suites best for restoration of

historical buildings, ensuring optimal coverage and detail across all elements of the structure. The integration of terrestrial and aerial imagery produces a high-fidelity 3D model, incorporating comprehensive details both of the roof, walls, and ground. The quality of the reconstruction is contingent not solely on the quantity of images available, but also on the consistency, overlap, lighting, and perspective variation of these images. The selection of capture methods and parameters should be made with consideration for factors such as the accessibility of the site, the level of detail required, and the availability of tools (Dreghici et al., 2016; Coza, 2025).

**3D Modelling Workflow**

The initial phase in the three-dimensional modelling workflow is the pre-processing one. During this first step, captured images and correlated data are analysed all together, and growth errors are eliminated. The photo histogram is uniformised, and images are calibrated if deemed necessary. Subsequently, the proper conversion of photographs into three-dimensional models is undertaken, adhering to the established workflow (Dreghici et al., 2016; Coza, 2025):

- The software's 'align photos' function involves the calculation of camera positions, resulting in the generation of a sparse point cloud. Following processing, a sparse point cloud representing the 3D space captured by the photographs will be displayed – Figure 1 a.
- The densifying of the point cloud enhances the intricacy of the model. In this step, the quality settings are configured, and depth filtering is established – Figure 1 b.
- The mesh is a 3D surface generated from the dense point cloud, which is used as the source data. Given that the model is a 3D object, not a terrain, the selected surface type is arbitrary. Upon completion, the model will possess a complete 3D geometry – Figure 1 c.
- Textures are a crucial element in achieving a realistic colour and appearance in the model. The texture will be mapped directly onto the 3D mesh, thereby enhancing visual realism – Figure 1 d.

While the software can generate high detail 3D models from captured images, it should be noted that the results are often presented in an arbitrary unit scale, unless the scale is set accordingly. It is important to recognise that, without scaling, measurements of distances, areas, and volumes will invariably differ from their real-world dimensions. The scale calibration is of high importance and is widely regarded as the best approach to ensure precision. The 3D model has emerged as a versatile solution that finds application in diverse domains, including surveying, archaeology, construction, mining, and numerous other fields (Coza, 2025).

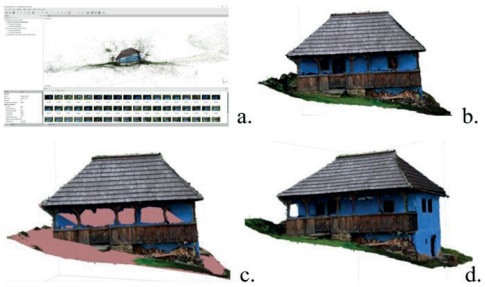

Figure 1. 3D modeling workflow: a. Photos alignment; b. Point cloud densifying; c. Mesh generation; d. Texture application (Coza, 2025)

By default, the software builds models based on image geometry, meaning measurements are relative rather than absolute. The process of converting the scale to real-world units is of high importance in achieving the needed transformation. This step is of crucial importance, as measurements become meaningful, allowing the calculation of distances, areas, and volumes in metric units, not inarbitrary values as opposed. The model is shown to be consistent with other datasets, thus allowing for integration with GIS data, CAD files and engineering designs. When executed with appropriate scaling, the model is capable of achieving both visual accuracy and reliability for quantitative analysis (Borsan et al., 2025; Coza, 2025).

**Web-Based Visualization**

The final step in the process will be the creation of a brief video comprising a 360-degree tour of the building (Figure 2). This will be used in future to promote both the area and the building on the guesthouse's official website. The software incorporates fundamental animation tools. The camera track feature allows the

generation of animations flythrough that is akin to those produced by professional studios. These animations are suite well to a variety of purposes, including presentations, reports, and online visualizations. Animated flythroughs have been demonstrated to enhance the visual appeal of three-dimensional models (Coza, 2025).

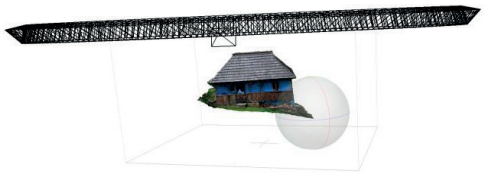

Figure 2. Video tour creation for web-based visualization (Coza, 2025)

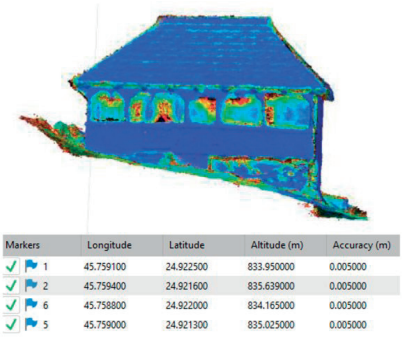

The usage of animated videos in professional contexts, including architecture, archaeology, land surveying, construction monitoring, and tourism promotion, represent a valuable tool. These videos present the capability to visualize the terrain and 3D building models from different angles, guide utilizers through a designated visualization route, virtually articulate model characteristics within online portfolios or client meetings and generate promotional information or instructional visuals.

In order to promote rural virtual tourism, it is essential to integrate the 3D model into digital platforms. Firstly, the 3D model must be rendered in a web-based visualisation format. Finally, the utilisation of mobile or VR-based tourism applications is necessary. The focus of mobile applications for rural tourism is on enhancing the physical experience through augmented reality (AR) and smart, location-based data, while virtual reality (VR) allows users to experience rural environments remotely, offering a "sense of presence" and emotional connection, which can inspire future travel or provide a substitute for those with limited mobility (Parra-Sanchez & Viviescas-Jaimes, 2024; Ilie et al., 2025).

**Evaluation Methods**

The evaluation of a 3D model is a process which is multi-layered in constitution, necessitating a balance between mathematical precision and visual and functional integrity. Regardless of whether one's profession lies within the fields of gaming, engineering, or 3D printing, the evaluation process is typically divided into three primary categories. The following aspects must be given due consideration (Grande et al., 2024; Coza, 2025):

- Geometric and structural accuracy (Figure 3). Geometric and structural accuracy metrics are utilised to ascertain the degree to which the three-dimensional data corresponds with its intended real-world dimensions or a reference "ground truth" model.
- Topology and performance (Figure 4). The evaluation of the model's construction is pivotal in determining its efficacy in software environments, such as game engines, or in the realm of animations.
- Visual and aesthetic quality. From the perspective of visual and aesthetic quality, the model's appearance under illumination is as significant as its structural design.

| Markers | Longitude | Latitude | Altitude (m) | Accuracy (m) |
|---|---|---|---|---|
| 1 | 45.759100 | 24.922500 | 833.950000 | 0.005000 |
| 2 | 45.759400 | 24.921600 | 835.639000 | 0.005000 |
| 6 | 45.758800 | 24.922000 | 834.165000 | 0.005000 |
| 5 | 45.759000 | 24.921300 | 835.025000 | 0.005000 |

Figure 3. Geometric and structural accuracy assessment (Coza, 2025): the confidence level of points in the dense point cloud and accuracy of control markers

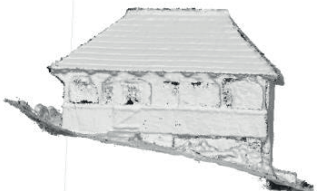

Figure 4. The class of points in the dense point cloud (Coza, 2025)

The evaluation of the 3D model from the perspective of tourism promotion entails the measurement of perceived attractiveness, usability, and engagement. Furthermore, a comparative analysis is to be conducted between

2D promotional materials and 3D models. Finally, qualitative feedback from tourists and local stakeholders is to be considered (Ahtik et al., 2025).

## RESULTS AND DISCUSSIONS

The following results are derived from the 3D model of the "monument" house. The model's output is characterised by its accuracy, realism and level of detail (LOD) (Shashi & Jain, 2007; Rahman & Cahyono, 2023):

- The 3D model of the building that has been generated offers a high level of accuracy, with a margin of error of between 1 and 3 centimetres. Whilst it is generally acknowledged that this method provides slightly less precision than alternative techniques, such as LiDAR, it is nevertheless highly cost-effective and sufficient for applications in the field of rural tourism promotion. The accuracy of the generated 3D model depends primarily on three key elements: the resolution of the input images, the level of overlap between consecutive photographs, and the operator's level of experience.
- The 3D model of the building, obtained through photogrammetric methods, provides a high degree of realism, as it preserves authentic textures, colours, and geometric details derived directly from real-world data.

Comparing to manual modelling, this process generates a digital twin characterised by high-fidelity detail, thus it has been set as a standard in the area of web visualisation.

- The level of detail (LOD) is the degree to which real-world objects are abstracted, ranging from raw footprints to sophisticated three-dimensional models. The present case study of the paperwork demonstrates that the 3D model generation, with high levels of detail (LoD), is optimised by the integration of aerial photogrammetry for roofs and site context with terrestrial (ground-based) imagery for facade, vertical, and complex details. This hybrid approach provides a complete coverage, bridging the gap between low-accuracy offered by aerial views and high-resolution offered by ground images, in order to achieve accurate LoD3 models.

In recent practice, 3D modelling together with interactive GIS maps and virtual visualisation tools has been increasingly applied to the presentation of major tourism sites, particularly historic houses. The use of these technologies improves the quality of documentation and at the same time makes the visitor experience more engaging. At the same time, they make it possible to develop digital twin models that support virtual visits, easier navigation within historical spaces, and spatial analyses useful for both heritage conservation and tourism promotion. The following visualisation techniques are to be employed for the purpose of promoting tourism at historic houses: the utilisation of three-dimensional modelling techniques in the preservation and marketing of historic structures enables users to observe these structures from diverse angles and levels of detail, web-based maps facilitate the spatial visualisation of historic houses across the designated territory, thereby enhancing identification and accessibility, and digital platforms have the capacity to curate the narrative surrounding historic houses, integrating visual data with historical, architectural and personal narratives to enhance user engagement (Ugwitz et al., 2021; Kourtit et al., 2025).

In the context of user perception and engagement, survey results have been demonstrated to reveal changes in destination understanding, interest in visiting, and perceived authenticity. These changes can be confirmed through statistical or thematic analysis of feedback (Ugwitz et al., 2021; Kourtit et al., 2025).

A comparison of three-dimensional models and traditional promotional tools, including brochures, photographs and maps, has been undertaken previously. The results of this comparison demonstrate that three-dimensional models significantly outperform traditional promotional tools in modern marketing, by the engender higher customer engagement, faster conversion rates and superior adaptability. Whilst conventional tools boast lower initial expenses and authenticity, three-dimensional visualisations have been demonstrated to enhance conversion rates. A preponderance of users has been observed to demonstrate a predilection for interacting with three-dimensional views as opposed to static images. The utilisation of three-dimensional models enables users to manipulate their environment through rotations and zooms in real-time, thereby sustaining attention for extended periods when compared with two-dimensional

media that is static and passive. Virtual tours represent a significant development in the realm of tourism promotion, offering visitors the opportunity to view the internal and external design of a destination prior to their physical arrival. In the domain of tourism, three-dimensional site models facilitate the provision of interactive, 360-degree views of the surrounding area, terrain, and amenities, thereby offering enhanced contextual information in comparison to two-dimensional maps. Whilst the initial financial outlay required for the creation of a 3D model may be significant, such an investment is frequently justified by the long-term benefits that such a model can deliver. Substantial research has demonstrated that, on average, three-dimensional imaging is six times more cost-effective than traditional photography when used in complex campaigns (Forbes Technology Council, 2021; Ugwitz et al., 2021; Kourtit et al., 2025).

The use of three-dimensional building modelling has been shown to improve spatial awareness and emotional connection by transforming abstract, two-dimensional building plans into tangible, virtual immersive environments that simulate reality. The technology in question is designed to facilitate an intuitive understanding of proportions and flow, in addition to promoting the development of a personal bond through the use of realistic lighting, textures, and interactive, personalised experiences. Three-dimensional modelling has been demonstrated to offer a superior, more intuitive grasp of space than its 2D counterpart, as well as impacting experiences, and thus provides several key benefits (Esri, n.d.; Gómez-Tone et al., 2021):

- It is possible for users to comprehend the true scale, volume, and proportions of a space.
- Interactive walkthroughs and 360° virtual tours have been shown to empower users by allowing them to "walk through" buildings and understand the flow and organisation of the layout.
- The capacity to manipulate, zoom and rotate models has been proven to facilitate superior spatial reasoning, as it enables viewers to observe the structure from different angles, thereby overcoming the limitations imposed by a single static viewpoint.
- Three-dimensional modelling also enables the consideration of environmental aspects, including daylight conditions and nearby contextual features. In this way, a clearer understanding of the relationship between the studied building and its surrounding environment can be obtained.
- The use of virtual 3D models generates a strong sense of presence for the user, who may perceive the simulated space in a manner similar to physical experience. As a consequence, emotional and perceptual reactions tend to be more pronounced.
- Furthermore, three-dimensional animation can be applied in the development of guided tours with narrative support, contributing to a better perception of spatial rhythm and continuity within the analysed space. The integration of these components within the framework of 3D modelling transforms the architectural design process from a technical undertaking to an emotional and experiential journey (Esri, n.d.; Gómez-Tone et al., 2021).

## CONCLUSIONS

Three-dimensional building modelling can transform rural tourism promotion by shifting from passive representation to immersive, spatially informed digital experiences. The case study of the "monument" house concluded that the combination of aerial and terrestrial photogrammetry is an effective method for creating an accurate, high-quality 3D model. This model can be utilised for the promotion of the area and the tracking of the construction's progress over time. The application of the present study may also be utilised in the future for the purpose of a past and present comparison, as well as in designing the future appearance of the construction (Coza, 2025).

The present study brings a relevant contribution to both the scientific and applied domains, with a particular focus on digital rural tourism and geospatial visualisation. The paper proposes a practical framework addressed to specialists involved in rural tourism activities and may be considered a useful reference for both academic research and professional practice (Coza, 2025).

The use of modern three-dimensional visualisation technologies in rural tourism promotion is gradually transforming the traditional approach to nature-based tourism by integrating digital, interactive and immersive

components. These tools enable tourists to virtually explore rural landscapes, agricultural areas and cultural heritage objectives from a distance, while also enhancing on-site visits through access to real-time information. In this context, such technologies contribute to the development of rural tourism in a more sustainable, educational and accessible manner. The main advantages of 3D modelling are presented below (Parra-Sanchez & Viviescas-Jaimes, 2024; Coza, 2025; Ilie et al., 2025).

- The utilisation of realistic visualisation techniques facilitates prospective visitors' ability to visualise the appearance of the destination prior to their arrival.
- The utilisation of three-dimensional modelling in the design and architectural professions has been demonstrated to have numerous advantages, including the potential for cost and time reduction in instances where renovation is necessary. This is due to the ability of designers and architects to modify an object without the need for physical reconstruction, thus ensuring a more efficient process.
- The process of monitoring the progression of construction projects over time is undertaken for the purposes of conducting studies or implementing rehabilitation work.
- 3Dmodelling sets out the argument for the importance of digital documentation and preservation for monuments and heritage sites.
- The calculation of volume is imperative for the planning and execution of excavation in case of intervention works.
- The creation of three-dimensional reconstructions of buildings is a key component of cadastral plan development, facilitating the creation of interactive maps.
- The promotion of tourism is achieved through the creation of virtual tours of areas intended for promotion.
- 3D models allow virtual tours of the touristic attractions, such as historic wooden churches or cultural sites, providing a way to virtually visit and appreciate them remotely.
- Modern technologies are used for interactive marketing, generate captivating experiences that increase interest in destinations.
- 3D models help in mapping and preserving architectural heritage, making it accessible for education and research.
- 3D models provide realistic, detailed views, helping tourists better understand the layout of destinations and, consequently, improving their overall experience.
- 3D models, such as 3D mesh models, are being used for interactive, web-based, or VR-driven, 360° virtual, and 3D web-based experiences, that are often more engaging than 2D and can also be used in city-wide planning.

The following key benefits and impact of the project are identified (Parra-Sanchez & Viviescas-Jaimes, 2024; Coza, 2025; Ilie et al., 2025):

- The provision of digital alternatives by modern technologies has been demonstrated to reduce the environmental impact of physical over-tourism in fragile rural areas.
- The removal of barriers for individuals with physical or financial constraints by modern technologies has been shown to provide access to remote or rugged rural locations.
- Digital technologies assist in the preservation of rural cultural identities and the promotion of local products, thereby fostering economic growth and the development of new business models within rural communities.
- The integration of physical and digital experiences, often termed 'hybrid' or 'phygital', has been demonstrated to enhance visitor satisfaction and emotional engagement with rural cultural heritage.

Three-dimensional modelling has also its limitations, which must be considered when undertaking such projects (Coza, 2025):

- The expense of high-quality projects involving large-scale work can be considerable, including the cost of drones, 3D scanners and software licenses for each device.
- The processing time for complex work requiring high precision can be lengthy, necessitating the purchase of high-performance computers capable of supporting and processing data at a high level.
- The use of such equipment and software requires advanced technical skills.
- The outcome is dependent on weather and lighting conditions for photogrammetry.
- The process is susceptible to loss of accuracy if the correct steps are not followed in data processing.
- The limitations imposed by a single case study.

- The existence of dependencies in the technological and infrastructural domains.

The following prospective research directions are hereby put forward (Coza, 2025):

- In order to facilitate the access to equipment such as photogrammetric equipment and high-precision devices, collaboration with local institutions, including universities and heritage NGOs, is imperative.
- The promotion of tourism is achieved through the creation of interactive virtual tours of various tourist attractions within a specific geographical area, such as a city or county.
- The creation of training courses and workshops is a collaborative endeavour undertaken in conjunction with construction, planning, and design companies for the benefit of educational institutions.
- The creation of a database or thematic map for the purpose of promoting tourism is hereby proposed. The objectives of this initiative would include the incorporation of this case study.
- The integration of AR/VR and metaverse tourism platforms is a subject that has been the focus of much recent discussion.
- The long-term ramifications on tourist arrivals and local economies must be given due consideration.
- The scalability of 3D modelling approaches for wider rural regions is a subject that merits further investigation.

# A DECISION-SUPPORT FRAMEWORK FOR SUSTAINABLE MANAGEMENT OF NATURAL SPORTS TURF UNDER TEMPERATE-CONTINENTAL CONDITIONS - A REVIEW AND CASE STUDY

**Alexandru DUMITRU, Mihai Sorin CÎMPEANU**

University of Agronomic Sciences and Veterinary Medicine of Bucharest,
59 Mărăști Blvd, District 1, Bucharest, Romania

Corresponding author email: dumitrualexandrumail@gmail.com

***Abstract***

*Managing natural sports turf under a temperate-continental climate requires maintenance operations to be sequenced within short climatic windows and triggered by measured site conditions rather than by a fixed calendar. This review synthesizes the scientific and technical literature on aeration, scarification, topdressing, fertilization, evapotranspiration-based irrigation, integrated pest and disease management and monitoring technologies, and organizes it into a circular decision-support framework with five components: diagnosis, planning, intervention, monitoring and adjustment. The framework is made operational through a seasonal calendar and a set of alert thresholds, and is applied in a case study of a 9,600 m² natural-turf rugby field with loamy sand soil, no subsurface drainage and a history of low-input maintenance. For this field, the case study derives the annual maintenance programme and the expected 12-month changes in five turf-quality indicators. The operating parameters of the framework fall within the ranges recommended in the literature, and the expected changes agree in direction with published empirical results. Because these changes are estimates rather than measured outcomes, monitoring of the field over several seasons is needed to validate the framework.*

***Key words****: decision-support framework, sports turf management, turf maintenance operations, alert thresholds, temperate-continental climate, case study.*

## INTRODUCTION

Natural turf sports fields remain, for football and rugby, the technical and functional benchmark against which every alternative surface is judged: they offer a combination of impact absorption, controlled traction, evaporative cooling and ecological reversibility that synthetic surfaces reproduce only partially (Cumberbatch et al., 2025). Unlike a construction material, sports turf is a living system, permanently subject to the combined action of climatic factors, the mechanical stress generated by matches and training, and the maintenance resources available.

The temperate-continental climate of much of Central and Eastern Europe, including Romania, adds a further layer of complexity. Large annual temperature ranges, winters with freeze–thaw episodes and summers with drought and heatwaves, together with increasingly variable precipitation driven by climate change (Hatfield, 2017), require intervention windows that differ from those recommended in manuals developed for oceanic or Mediterranean climates. The updated Köppen-Geiger classification of Beck et al. (2018) places most of Romania within the humid continental climate classes, with warm summers in the hilly and plateau regions and hot summers in the southern lowlands. For the cool-season species used on sports fields, this pattern restricts active growth mainly to spring and autumn, with summer heat and drought stress and winter dormancy in between (Fan et al., 2020; Braun et al., 2022). Observations on a football pitch in south-western Romania illustrate this seasonal pressure: frequent spring rainfall disrupted mowing, weed control and fungicide applications, and the disease resistance of the sward declined during spring (Corlan et al., 2019).

There is a recognized gap, both in the scientific literature and in the practice of sports field management, between technical knowledge of effective maintenance operations and their

systematic application on the ground: correct operations, applied at the wrong time or without justification based on measurements, produce poorer results than a coherent programme based on diagnosis and explicit decision thresholds. International standards for natural turf, such as the FIFA Quality Programme for Natural Playing Surfaces (FIFA, 2021), the FIFA Natural Turf Guidelines (FIFA, 2023) and the Sport England guidance on natural turf (Sport England, 2011), set targets for surface hardness, stability, evenness and agronomic condition, but only partially prescribe the temporal and decisional logic through which these targets can be achieved and maintained under specific climatic conditions.

This study pursues two complementary objectives. The first is to synthesize critically the scientific and technical literature on the maintenance methods applied to sports turf, organized around the five components of a decision cycle: diagnosis, planning, intervention, monitoring and adjustment. The second is to apply the resulting framework in a case study of a natural-turf rugby field, deriving its maintenance programme and expected effects, and to compare these with the ranges reported in the literature.

## MATERIALS AND METHODS

This article combines a narrative review of the scientific and technical literature with a case study. Sources were identified through searches in academic databases and publisher platforms (Wiley Online Library, ScienceDirect, SpringerLink, MDPI, Taylor & Francis Online, Emerald, PubMed and Google Scholar) and through direct consultation of technical documents issued by FIFA, World Rugby, Sport England, FAO and the European Commission. Search terms included: turfgrass management, sports turf, soil compaction sports field, turfgrass wear tolerance, turfgrass irrigation evapotranspiration, turfgrass integrated pest management, decision support system turfgrass, remote sensing turfgrass monitoring and turfgrass biodiversity pollinators, alone and in combination. The search covered publications from 2000 to 2026, together with a small number of standard reference texts on turf science. Sources were included if they were peer-reviewed articles, scientific monographs or technical documents of sports governing bodies and public authorities; dealt with cool-season turfgrass or with soil, water and pest processes transferable to sports turf; and reported quantitative results or operational recommendations. Studies on warm-season species were excluded.

The case study applies the framework to a natural-turf rugby field of 9,600 m² (120 × 80 m, including in-goal areas and run-off zones), with loamy sand soil, no subsurface drainage and a history of low-input maintenance. For this field, the authors established the starting condition, the annual maintenance programme, and the expected changes in five turf-quality indicators after 12 months. The expected changes are estimates made by the authors, not field measurements, and are reported as such in the **Results and discussions** section. The case study concerns a natural-turf rugby field located in Oltenia Plain. The starting values were obtained from field measurements carried out in March - April, penetration resistance with a cone penetrometer (0-10 cm), infiltration rate with a ring infiltrometer, and thatch thickness on soil cores, at 15 points distributed over the playing area. The expected changes after 12 months were estimated by applying to these starting values the effect ranges reported in the literature for the same operations (Table 3).

The literature was synthesized thematically, around the main groups of maintenance operations and the five components of the decision-support framework. For each theme, the relevant contributions were identified and, where possible, compared with the corresponding operating parameters of the framework, in order to show both where they agree and the limits of the comparison.

Within the framework, each intervention (aeration, scarification, topdressing, fertilization, irrigation, deep decompaction and drainage, overseeding, integrated pest and disease management) uses operating parameters taken from the specialized literature (Table 1). The authors' contribution lies in integrating these parameters into a seasonal calendar adapted to the temperate-continental climate and into a set of decision rules based on

alert thresholds that are measured periodically and recorded in a field register (Table 2). An operation is scheduled only when the diagnosis or a threshold exceedance calls for it, which avoids both under- and over-maintenance and makes management decisions transparent, justifiable and adjustable from one season to the next.

## RESULTS AND DISCUSSIONS

### 1. Soil physical properties: compaction, aeration, topdressing and drainage

Soil compaction, generated by repeated traffic from players and maintenance equipment, is consistently identified as one of the main causes of sports turf degradation, through reduced porosity, gas exchange and water infiltration (Adams & Gibbs, 1994; Christians et al., 2016). The review by Hamza and Anderson (2005) on soil compaction in cropping systems confirms, at a more general scale, the same physical mechanisms: reduced macroporosity, restricted root growth and decreased infiltration.

Mechanical aeration is the reference operation for counteracting compaction. Recent research refines the effectiveness of different aeration technologies: Dalsgaard et al. (2020) compared Shockwave-type aeration with conventional core aeration on athletic fields and found relevant differences in surface disruption and infiltration recovery, while Isom and Thompson (2026) analysed, on putting greens, the effect of aerator-pass frequency on sand incorporation and organic-matter accumulation. Sand topdressing complements aeration: Chen et al. (2025) showed, on creeping bentgrass, that the fineness of the topdressing sand significantly influences turf quality and surface characteristics, while the monograph edited by Stier et al. (2013) synthesizes the mechanisms of thatch formation and the options for its control. Surface and subsurface drainage are treated as structural components of performance sports fields, since the capacity for rapid water removal directly determines the number of available playing hours (Adams & Gibbs, 1994; Puhalla et al., 2020).

The framework translates these principles into explicit operating parameters (Table 1): two to four aeration passes per year within the April-May and September-October windows, scarification at a depth matched to the thatch layer, and topdressing with fine quartz sand at 1-3 mm per application. Within each window, the actual date is set by field conditions rather than by the calendar: operations are carried out while the turf is actively growing and the soil is neither frozen nor saturated. This level of operational detail, rarely made explicit in review articles, shows how general recommendations from the literature can be turned into an applicable annual programme.

Table 1. Operating parameters used in the framework for the main maintenance operations applied to sports turf (values set by the authors on the basis of the cited literature)

| *Operation* | Operating parameters | Optimal window (temperate-continental climate) | References |
|---|---|---|---|
| *Mechanical aeration* | Solid tines 5-10 cm, core aeration 8-12 cm, or pneumatic 10-20 cm; 2-4 passes/year | April-May; September-October | Beard, 2002; Christians et al., 2016; Dalsgaard et al., 2020 |
| *Scarification / verticutting* | Working depth 5-15 mm, matched to the depth of the thatch layer; 1-2 passes/year | April; September | Christians et al., 2016; Stier et al., 2013 |
| *Topdressing* | Quartz sand 0.2-0.8 mm (70-90%) + organic matter (10-30%); 1-3 mm/application, 2–3 applications/year | After aeration, spring and autumn | Chen et al., 2025; Stier et al., 2013 |
| *Fertilization* | N 15-25 g/m²/year, $P_2O_5$ 5-8 g/m²/year, $K_2O$ 15*20 g/m²/year, in 4-6 applications; rates adjusted to annual soil analysis | Seasonal programme (spring-summer-autumn) | Carrow et al., 2001; Carey et al., 2012 |
| *Irrigation* | ETc = Kc × ETo, with Kc 0.90–0.95 for cool-season turf; irrigation when depletion reaches 40% of available soil water (p = 0.40) | April-September, during active growth | Allen et al., 1998; Braun et al., 2022; Leinauer et al., 2025 |
| *Deep decompaction and drainage* | Deep decompaction 40-60 cm (every 5-10 years); drains 80-110 mm at 30-60 cm depth | Outside the competition period, on soil neither frozen nor saturated (late summer-early autumn) | Adams & Gibbs, 1994; Puhalla et al., 2020 |
| *Overseeding* | 10-20 g/m² (general), 20-40 g/m² (worn areas), mainly *Lolium perenne* | April-May; September | Christians et al., 2016; Corlan et al., 2019 |
| *Integrated pest management (IPM)* | Intervention thresholds: 2-5% affected area (diseases); about 30-120 larvae/m², depending on species (soil-dwelling larvae) | Continuous monitoring; targeted treatment | Potter, 1998; Sapkota et al., 2022; Batistič & Trdan, 2025 |

## 2. Species selection, nutrient management and water management

Turfgrass species and cultivar selection is a structural decision with long-term effects on a field's capacity to withstand intense traffic. Wear tolerance is determined by anatomical and morphological factors, analysed in detail by Głąb et al. (2015). Under actual tennis match play, Ebdon et al. (2021) found that Kentucky bluegrass and perennial ryegrass had the highest wear tolerance and carrying capacity among the cool-season species tested, well above fine fescues. Fan et al. (2020) synthesize, at a more general level, the physiological mechanisms of environmental-stress tolerance in turfgrass.

Balanced fertilization supports turf density, colour and recovery capacity, but excess nitrogen is associated with losses through leaching and runoff, with implications for water quality (Carey et al., 2012). Fertilizer rates are best adjusted to the nutrient status measured by soil analysis rather than applied as a fixed routine (Carrow et al., 2001). Scheduling irrigation from reference evapotranspiration is a documented alternative to fixed-calendar irrigation. FAO-56 gives crop coefficients of 0.90-0.95 and an allowable depletion fraction of 0.40 for cool-season turf (Allen et al., 1998); Leinauer et al. (2025) developed and tested variable crop coefficients, and Meza et al. (2025) showed, using high-resolution imagery, the spatial relationship between turf quality and actual evapotranspiration. The review by Braun et al. (2022) on water requirements and drought-stress responses provides a directly applicable reference for the cool-season species used in the temperate-continental climate.

The fertilization programme of the framework follows the same seasonal logic: balanced NPK in spring, reduced nitrogen and increased potassium in summer (for tolerance to heat and drought stress), and potassium and phosphorus in autumn, with annual nitrogen rates of 15-25 g/m² split into four to six applications. Splitting moderate rates into several applications is one of the practices that Carey et al. (2012) associate with a lower risk of nitrogen losses.

## 3. Integrated pest and disease management

Integrated Pest Management (IPM) is established as the best-practice standard for sports turf protection: cultural and preventive measures come first, the field is monitored regularly, and chemical treatments are used only when intervention thresholds are exceeded. The recent review by Batistič and Trdan (2025) highlights both the effectiveness of combining cultural and biological methods and the growing influence of climatic variability on disease dynamics. Microdochium patch and pink snow mould (*Microdochium nivale*), favoured by cool, wet weather and prolonged snow cover, whose virulence was recently investigated at genome scale by Tsers et al. (2023), and dollar spot (*Clarireedia jacksonii*), favoured by warm, humid weather, long periods of leaf wetness and low nitrogen fertility (Sapkota et al., 2022), illustrate the phytosanitary challenges of the temperate-continental climate. The framework uses intervention thresholds of 2-5% of the affected area for diseases and about 30-120 larvae/m² for soil-dwelling larvae, the latter corresponding to the species-dependent thresholds of roughly 3-12 larvae per square foot used in turfgrass entomology (Potter, 1998). The exact thresholds remain dependent on species, cultivar, irrigation and regional context.

## 4. Quality standards, safety and monitoring technologies

International sports organizations have developed technical standards for the quality and safety of playing surfaces. For natural turf, the FIFA Quality Programme for Natural Playing Surfaces (FIFA, 2021) assesses surface hardness, stability and evenness, ball–surface interaction and agronomic condition, while the FIFA Natural Turf Guidelines (FIFA, 2023) describe construction and maintenance practices adapted to local climate and soil. In rugby, impact-attenuation requirements are defined mainly for artificial surfaces through World Rugby Test Method 01, whose head injury criteria were recently re-examined by Colino et al. (2026); these values are a useful benchmark for natural turf, although they were not developed for it. The link between surface quality and injury risk is supported by a worldwide survey in which elite football players associated specific surface characteristics with injury (Mears et al., 2018),

although perception data cannot by themselves establish causality.

For monitoring technologies, the framework proposed by Helps et al. (2024) for evaluating pest management decision support systems offers criteria that can be transferred to sports turf management, while the review by Benos et al. (2021) on machine learning in agriculture shows a rapid expansion of predictive models. Alahmad et al. (2023) document how Internet of Things (IoT) sensors and big-data analysis support precision crop production, a direction with potential for large sports facilities. The review by Parra et al. (2024) on drones for turfgrass monitoring highlights the usefulness of multispectral imaging for early detection of drought stress, while Huang et al. (2021) draw attention to the interpretive limits of the NDVI index. The framework, in turn, uses a field register (date, indicator, value, operation applied), which applies the principles of a decision support system on a smaller scale.

## 5. Sustainability, circular economy and biodiversity

The EU Soil Strategy for 2030 (European Commission, 2021) sets explicit objectives on soil health and the reduction of compaction, which also apply to sports infrastructure. Strandberg et al. (2012) identify environmental regulation, pressure on water, energy and land, ecosystem services and biodiversity, integrated pest management and adaptation to climate change as priorities for sustainable turfgrass management, and argue that managers who minimize labour, energy and agronomic inputs are best placed to respond. Lower inputs are consistent with circular-economy principles, as illustrated by the recovery of organic matter through composting (Manea et al., 2024). The comparison between natural and synthetic turf by Cumberbatch et al. (2025) shows that natural turf offers relevant ecological advantages, provided that it is actively and continuously managed. For biodiversity, Lerman et al. (2018) showed that mowing less often increased bee abundance and diversity in suburban lawns, a result that may be transferable to the non-playing margins of sports facilities, while Lindsey et al. (2025) synthesize the broader ecological benefits of turfgrass in urban landscapes.

## 6. An integrated decision-support framework

The literature reviewed in sections 1-5 converges on a common principle: effective sports turf management is not mainly a matter of access to individual technologies, but of sequencing and triggering operations on the basis of up-to-date diagnostic information. This is consistent with the criteria for effective decision support systems identified by Helps et al. (2024). The framework proposed here puts this principle into practice in five stages (Figure 1).

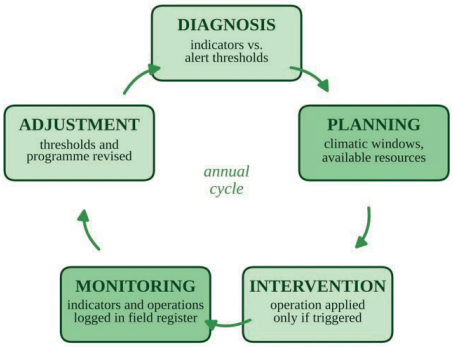

Figure 1. The five-stage decision-support cycle for natural sports turf management

Diagnosis establishes the condition of the field through indicators measured at set intervals (Table 2). Planning places the required operations within the climatic windows of the temperate-continental climate (Table 1) and within the resources available. Intervention applies an operation only when an alert threshold is exceeded. Monitoring records indicator values and the operations applied in the field register, and adjustment uses these records to revise the thresholds and the programme for the next cycle.

The five stages form a loop rather than a sequence: monitoring results feed into adjustment, and adjustment redefines the diagnosis and planning of the following cycle. This adaptive design is needed under a climate with marked year-to-year variability (Hatfield, 2017), where the same calendar cannot be applied unchanged from one season to the next. The thresholds in Table 2 are operational values set by the authors on the basis of the literature cited in sections 1-3; they are starting points to be recalibrated with the data accumulated in the field register.

Table 2. Indicators, alert thresholds and triggered operations in the decision-support framework (operational thresholds set by the authors)

| *Indicator (method)* | Monitoring frequency | Alert threshold | Triggered operation |
|---|---|---|---|
| *Penetration resistance, 0–10 cm (cone penetrometer)* | Spring and autumn, before the aeration windows | > 2.0 MPa | Core or solid-tine aeration; if compaction persists after two aeration cycles, deep decompaction is recommended |
| *Infiltration rate (ring infiltrometer)* | Spring and autumn | < 10 mm/h | Aeration + sand topdressing; drainage works if < 5 mm/h after two cycles |
| *Thatch thickness (soil cores)* | Spring and autumn | > 10 mm | Scarification; > 15 mm: scarification + topdressing in both windows |
| *Soil water balance (ETo, rainfall)* | Weekly, April–September | Depletion ≥ 40% of available water | Irrigation replacing ETc |
| *Turf cover (visual or image-based, % of area)* | Monthly and after matches | < 90% cover, or bare patches in high-wear areas | Overseeding and spot repair |
| *Disease incidence (% of area affected)* | Weekly in high-risk periods | 2-5% | Targeted fungicide treatment |
| *Soil-dwelling larvae (soil sampling)* | Late summer | About 30-120 larvae/m², depending on species | Targeted insecticide or biological control |
| *Soil nutrient status and pH (soil analysis)* | Annually, late winter | Below sufficiency range | Adjustment of the fertilization programme |

## 7. Application of the framework: case study of a natural-turf rugby field

The case study applies the framework to a 9,600 m² natural-turf rugby field in Oltenia Plain (120 × 80 m, including in-goal areas and run-off zones) with loamy sand soil, no subsurface drainage and a history of low-input maintenance (see Materials and methods). The starting conditions for the field were: penetration resistance of 3.2 MPa, infiltration rate of 7.8 mm/h and a thatch layer of 18 mm. All three values exceed the alert thresholds in Table 2, so the diagnosis called for aeration, scarification and topdressing in both growing-season windows.

The programme can be scaled to three levels of intensity (minimum, standard and premium) according to the resources available, in line with the emphasis placed by Strandberg et al. (2012) on minimizing labour, energy and agronomic inputs; heavy works (drainage, deep decompaction) are planned separately. The case study presents the standard level.

At the standard level, the annual programme combines core and solid-tine aeration, scarification, topdressing, fertilization in five applications, general overseeding and spot repairs, and two phytosanitary treatments planned for the case in which thresholds are exceeded. After 12 months, the authors expect the infiltration rate to increase from 7.8 to 17.2 mm/h (+121%), penetration resistance to fall from 3.2 to 1.8 MPa (−44%), thatch thickness to fall from 18 to 8 mm (−56%), turf density to increase by 39% and weed cover to fall by 76% (Figure 2), while the recovery time after heavy rain is expected to drop from about 48 hours to under 24 hours. These values are estimates, not field measurements, and serve as the targets against which the monitoring stage will assess the programme. The expected reductions in penetration resistance and recovery time are at the upper end of what can be achieved without subsurface drainage and depend on the deep decompaction work carried out separately.

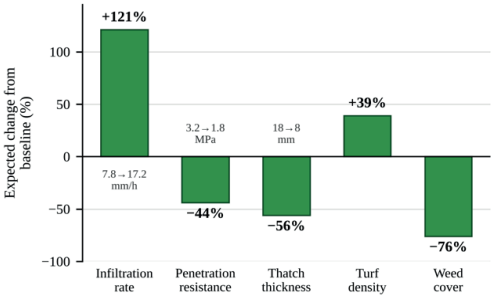

Figure 2. Expected changes in turf-quality indicators after 12 months of the standard programme on the case-study field (authors' estimates)

The direction of these changes is consistent with the effects reported in the empirical literature reviewed above: the improvement in infiltration through combined aeration and topdressing agrees with the comparative results of Dalsgaard et al. (2020) and Craft et al. (2017), and the reduction in weed cover through a denser sward agrees with the general principle that a dense, wear-tolerant sward is the most effective barrier to weed

establishment (Christians et al., 2016; Ebdon et al., 2021). The magnitude of the expected changes cannot, however, be generalized: it refers to a single combination of soil, climate and intensity of use, and for most of these indicators the literature does not offer reference ranges narrow enough for a strict quantitative comparison (Table 3). The agreement is therefore one of direction and plausible order of magnitude; it does not amount to an empirical validation of the framework, which requires repeated measurements on the field.

Table 3. Trends reported in the international literature compared with the parameters and expected results of the case study

| Parameter | Trend / range reported in the literature | Value in the case study | References |
|---|---|---|---|
| Aeration frequency | Recommended within active-growth windows, typically a few times per year | 2–4 passes/year (April–May, September–October) | Beard, 2002; Christians et al., 2016 |
| Nitrogen application (annual) | Moderate rates, split applications; controlled-release sources as best practice | 15–25 g N/m²/year, in 4–6 applications | Carey et al., 2012 |
| Infiltration rate (response to aeration + topdressing) | Consistent improvement, magnitude study-dependent | +121% expected (7.8 → 17.2 mm/h) | Craft et al., 2017; Dalsgaard et al., 2020 |
| Penetration resistance (response to aeration) | Reduced compaction, magnitude variable with soil and technique | −44% expected (3.2 → 1.8 MPa) | Hamza & Anderson, 2005; Craft et al., 2017 |
| Thatch thickness (target) | Below 10 mm considered non-limiting; above 10–15 mm requires intervention | 18 → 8 mm expected, through scarification + topdressing | Stier et al., 2013 |

## CONCLUSIONS

This review shows that the management of natural sports turf under a temperate-continental climate depends on sequencing maintenance operations within short climatic windows and on triggering them by measured field conditions. The literature supports the following conclusions:

(i) aeration, scarification and topdressing are the main operations for controlling compaction and thatch accumulation, and are best carried out in the April–May and September–October windows, while the turf is actively growing;

(ii) fertilization and irrigation should be treated as decision variables conditioned by soil analyses and reference evapotranspiration, not as calendar routine;

(iii) integrated pest and disease management, with explicit intervention thresholds, is the recommended approach for reducing reliance on chemical treatments;

(iv) international quality standards and remote-sensing tools provide reference values and data for the monitoring stage, although standards developed for artificial turf can serve only as benchmarks for natural turf;

(v) the case study shows how the five-stage framework (diagnosis, planning, intervention, monitoring and adjustment) translates into an annual programme and measurable targets for a specific field, and the expected effects agree in direction with published empirical results.

The main limitations of this study are that the case-study effects are estimates rather than measured outcomes, and that the reviewed literature comes largely from other climatic and institutional contexts, with few studies from Central and Eastern Europe. Monitoring the case-study field over several seasons and testing the framework on other soil types in the temperate-continental zone are the next steps, together with the integration of remote-sensing data into the diagnostic stage and an assessment of the cost–benefit ratio of precision monitoring on small and medium-sized fields.

***Abstract***

*Agrosilvopastoral systems represented alternative and differentiated systems of exploitation of lands with reduced fertility, especially in the non-collectivized areas of medium and high hills. As a result, in these land exploitation systems, the productive potential of the land is exploited through agricultural, horticultural, forestry and zootechnical production. The objectives of the work are represented by the study and analysis of the works necessary for the rehabilitation of the exploitation process of agrosilvopastoral systems in the area of medium and high hills, abandoned after 1989, in the locality of Vîrfurile, Arad county, an area that was not collectivized. Consequently, field observations, inventories, analyses of information from the agricultural register and from the plot plan of the buildings in the study area were carried out. Also, a series of works necessary for the rehabilitation of the exploitation of agro-forestry and pastoral systems were experimented on experimental areas, making a series of comparisons with their situation prior to 1989. In conclusion, the rehabilitation of these land exploitation systems can be efficiently achieved by establishing owners' associations and respectively by accessing financing projects.*

***Key words****: agricultural production, agrosilvopastoral systems, forestry production, horticultural production, land exploitation systems, livestock production, non-collectivized area.*

## INTRODUCTION

Optimizing the exploitation of arable land has an important influence in ensuring the production of quality, healthy food in optimal quantities, the adequate and secure provision of ecosystem services (e.g. biodiversity, clean air and water) as well as in effectively mitigating and removing the negative effects of climate change (Smith et al., 2022).

The worrying evolution of climate change and the modest standard of living in rural areas, especially in developing countries, require a change towards new, high-performance strategies, relating to agricultural practices and collaboration between farmers and, respectively, to the relationships between them and nature (Cialdella et al., 2023).

Adaptive management of agricultural activities related to arable land needs to be achieved without expanding existing cultivated land areas, in parallel with the protection and conservation of natural resources, but by promoting efficient, systemically integrated production technologies. Consequently, paradoxically, these multiple problems are very clear and relatively easy to solve, at least at the algorithmic level, they represent one of the greatest obstacles facing humanity today (Smith et al., 2022).

Agrosilvopastoral systems are cropping systems that integrate agricultural crops, fodder, woody perennials with livestock, on the same plot of land, promoting a more efficient and sustainable use of resources, compared to monocultures, as a consequence of the structural and functional diversification of the components (Fahad et al., 2022; Chappa et al. 2024).

Integration of forest trees and, respectively, fruit trees in the arable land exploitation system, optimizes soil fertility and its physical, biological and chemical properties, and ensures

the production of fruits, seeds, wood, fodder and animal protection (Fahad et al., 2022).

Relatively recent research shows that agroforestry systems have the capacity to store 3-4 times more carbon in the soil than in biomass, and agro-silvopastoral systems achieve a more efficient, respectively higher, storage of carbon in both soil and biomass, compared to the former. These results show that climatic zones and soil type directly influence carbon stocks and sequestration rates within agro-silvopastoral systems (Ribeiro et al., 2023; Mazumder et al., 2025).

By creating a specific habitat, characterized mainly by the particularities of each type of activity (crop), the microclimate associated with these complex land use systems can optimize biodiversity more than monocultures. Consequently, the internal restoration potential of activities in agro-silvopastoral systems is high, being able to offer effective solutions for inefficiently exploited lands (Fahad et al., 2022). Also, agrosilvopastoral and agrosilvopastoral systems substantially increase functional diversity and overall biodiversity within agricultural landscapes, consequently being necessary and appropriate priority programs and strategies in European agri-environmental financing schemes (Santos et al., 2022).

From the analysis of the component elements of agrosilvopastoral systems, they can be integrated into all agricultural systems, from various areas of Europe. Currently, the way to obtain them can be achieved relatively simply and efficiently, by planting trees, shrubs and fruit trees on agricultural land, by introducing agriculture (agricultural systems) in existing forests, wooded pastures (e.g. silvopastures) and in existing orchards (https://euraf.isa.utl.pt/about/ agroforestry-europe).

On the European continent there is currently a unique heritage of traditional agroforestry and agrosilvopastoral systems, which are characterized by a high ecological and cultural value. Similarly, in Europe, in the last two decades, the activities of research centers related to agroforestry activities have facilitated the promotion of modern and innovative agroforestry systems, capable of optimally exploiting the productive potential of agricultural and forestry land (https://euraf.isa.utl.pt/about/agroforestry-europe).

Agrosilvopastoral systems can be classified according to several criteria, established according to their location, structural and functional characteristics. As a result, depending on their age and tradition, they can be classified into traditional and innovative (Smith et al., 2022).

Traditional exploitations are made up of agricultural, horticultural and forestry crops as well as animal husbandry activities, long-term production activities, which are ultimately managed for the production of quality, diversified food, generally of an ecological nature.

The most representative agrosilvopastoral system known on the world map is the Spanish dehesa (Figure 1) (or montado in Portuguese) existing since the Neolithic period, first mentioned in 924 AD.

Figure 1. Dehesa agrosilvopastoral system (https://www.madr.ro/attachments/article/495/ADER-1521-FAZA-I.pdf).

Although traditional, it is constantly updated, and is perceived as one of the most efficient systems, because it harmoniously combines biodiversity conservation and sustainable rural development. The area related to this type of exploitation is approximately 3.5-5.5 million ha in Spain and Portugal and 1-1.5 million ha in Italy, Greece, western North America, and the specific habitat is characterized by the Mediterranean climate and low soil fertility (https://www.madr.ro/attachments/article/495/ADER-1521-FAZA-I.pdf).

The type of dehesa system in Spain and montado in Portugal, used for the extensive raising of animals, especially cattle, on meadows with rare trees, can also be called a pastoral-silvo-agricultural system, and is carried out on very poorly productive (with very low fertility) or non-agricultural lands. Also, in these farms, firewood, branches, acorns, cork can be

obtained, and various cereals such as oats, barley, rye, wheat are often cultivated, to supplement animal feed and to combat a series of shrubs that invade permanent pastures (https://www.madr.ro/attachments/article/495/ADER-1521-FAZA-I.pdf).

Innovative agrosilvopastoralism refers to multifunctional systems, designed to obtain biomass, ecosystem services and integrated wood (Smith et al., 2022). Some current representative variants of farms are represented by alley groves, alley crops and raising forest hens (Budău et al., 2023).

Although agroforestry and agrosilvopastoral exploitations have been known and have been operating for thousands of years, the agroforestry research field is relatively young and presents a number of opportunities, due to the importance of the context in which agroforestry practices develop, and their future trend (Cialdella et al., 2023).

In Romania, with the exception of forest curtains protecting arable land with various crops, which expanded considerably in the mid-20th century, some authors consider that agroforestry and agrosilvopastoral systems represent a new concept, which is not perceived, for example, as an independent science (Popovici et al., 2018; Budău et al., 2023), although the activities related to agroforestry and agrosilvopastoral exploitations in many historical provinces of our country are known at least two centuries ago (Crainic et al., 2023a).

On hilly lands with relatively low fertility, the promotion of agrosilvopastoral systems can mitigate huge soil losses, and can promote carbon sequestration with high efficiency, ultimately contributing decisively to increasing farmers' income (Sirimalle et al., 2025).

In western Romania, especially in hilly and mountainous areas that were not collectivized, a number of lands were efficiently exploited within agrosilvopastoral systems until 1989, after which the management method gradually changed. As a result, a number of lands were exploited inappropriately, and others were abandoned, for various reasons. The reasons are represented by the depopulation of the areas, economic instability, the drastic reduction of the number of animals, the lack of subsidies, the lack of adequate facilities, the high degree of fragmentation of the plots that prevented the creation of associations, the low fertility of the soils, the trend of climatic conditions in the last three decades, and last but not least the socio-political context.

The paper aims to analyze the climatic conditions, the works and measures necessary for the rehabilitation and reintroduction into the productive circuit of degraded agro-silvopastoral systems and respectively ensuring the premises for their sustainable exploitation.

## MATERIALS AND METHODS

Vârfurile village is located in the east of Arad County, in the commune of the same name. The commune also includes the villages of Avram Iancu, Vidra, Măgulicea, Lazuri, Groși, Mermești and Poiana. Geographically, Vârfurile village is located in the northwest of the Hălmagiu Depression in the Apuseni Mountains, being situated at the foot of the Zarandului, Codru-Moma and Bihor Mountains, in the valley of the Crișul Alb River. Vârfurile Commune has an area of 136 $km^2$ and a population of over 2,200 inhabitants (https://primariavirfurile.ro/despre-noi/prezentare/; https://ro.wikipedia.org/wiki/Comuna_Vârfurile_Arad).

The Hălmagiu Depression is connected to the northwest with the Zarandului Depression. The latter, having a wide opening to the west, towards the Western Plain, favors the easy penetration of humid, oceanic air masses coming from western Europe, but also of Mediterranean air masses, which cause abundant precipitation. As a result, Vârfurile Commune has a temperate-continental, moderate climate, with slight Mediterranean influences, the winters being milder, and the summers being cooler. The commune's location in the shelter of the mountains, in the depression sector, means that it is protected from storms, but during the winter this causes frequent thermal inversions, associated with dense fogs. During the hot summer months, when continental-tropical air masses penetrate southwestern Romania, droughts can also occur in this territory. Overall, the thermally moderate climate with abundant rainfall makes the region well forested (Pop, 2005; https://primariahalmagiu.ro/download/urvqbaO3Rf0Eh7w9f690f8ugJ6lAzB8W4JBO4a7g.pdf).

In the present paper, meteorological data on the monthly and annual average air temperature and the monthly and annual amount of precipitation were used, from the closest weather station to Vârfurile village, respectively Gurahonț. The station has the geographical coordinates 46°27' N latitude, 22°33' E longitude, the code 15182 and the altitude 177 m (www.meteomanz.com). The analyzed period was 1990-2025 (36 years). The deviations of the annual average values of air temperature and precipitation from the multiannual average of the period 1966-2025 (60 years) were calculated (expressed in °C and in mm, respectively). Reporting to the multiannual average of a longer period than the one analyzed better highlights the climatic fluctuations of recent years. The temporal variability of the positive and negative annual deviations of temperature and precipitation, the linear trend of the annual deviations of air temperature and the polynomial trend of the annual deviations of precipitation were analyzed. Subsequently, the maximum and minimum values of monthly average temperatures and monthly precipitation amount from the period 1990-2025 were analyzed.

All meteorological data used in the paper came from the database of the National Meteorological Administration (N.M.A.) of Romania and from the rp5.ru (https://rp5.ru/) and Meteomanz.com (www.meteomanz.com) websites.

The observations were made on the route and respectively at the representative points of the agrosilvopastoral systems studied and analyzed in the Vârfurile commune, using cartographic materials and cadastral records in analog and digital format.

For a complex analysis of the agrosilvopastoral systems, their components were analyzed separately, and in order to establish and propose the necessary rehabilitation works, a similarity was made with the related activities in the agricultural, forestry and zootechnical sectors.

To simulate the spatial structure related to the tree biogroups within the agrosilvopastoral systems, inventories were carried out in experimental areas, and the data recorded in the field were processed with the PROARB 2.0 program (Popa, 1999), obtaining the related spatial profiles.

The recording on digital support of edifying images for the objectives of the case study was used for an objective presentation of the reality in the field.

Finally, the comparative analysis of the current components of the abandoned agrosilvopastoral systems with the functional ones was used to rigorously justify and substantiate the works necessary for their efficient rehabilitation.

The logistical base used is represented by treaties, publications and specialized papers, statistical data from the agricultural register, data from cadastral records, time and production norms for activities in the agroforestry sector, the EXCEL program, the PROARB 2.0 program for generating the structure of forest stands, digital cameras.

## RESULTS AND DISCUSSIONS

The multiannual average air temperature for the period 1990-2025 (10.9°C) was higher than the multiannual average temperature of the period 1966-2025 (10.5°C), at the Gurahonț weather station.

Figure 2 shows the positive and negative deviations of the annual average air temperature from the multiannual average of the period 1966-2025 (10.5°C), considered "normal". Warm years (with positive deviations > 0.5°C), cold years (with negative deviations < -0.5°C) and normal years (with deviations between -0.5 and 0.5°C) are highlighted. It is observed that most years of the period 1990-2025 have positive deviations from normal (23 years out of 36). In the 1990-2006 interval, negative deviations prevailed. But only 5 years are cool, 3 years are warm (1994, 2000 and 2002), and 9 are normal.

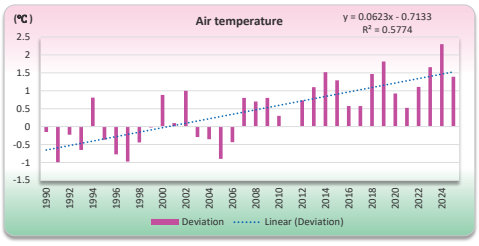

Figure 2. Deviations of the annual average air temperature (1990-2025) from the multiannual average (1966-2025), at the Gurahonț weather station; the linear trend of deviations

Starting with 2007, only positive annual deviations are present. Only 2 years are normal (2010 and 2011), the others being warm or hot. There are 9 hot years, with a deviation of more than 1°C. Of these, 4 years have a deviation of more than 1.5°C: 2024 (+2.3°C), 2019 (+1.8°C), 2023 (+1.7°C) and 2014 (+1.5°C). These are the hottest years of the period 1990-2025.

The linear trend of annual deviations of air temperature is strongly upward (Figure 2). The period 1990-2025 was a very warm one, the 2007-2025 interval being the warmest.

The multiannual average amount of precipitation for the period 1990-2025 (747.5 mm) was slightly lower than the multiannual average amount of the period 1966-2025 (752.0 mm), at the Gurahonț weather station.

Figure 3 shows the positive and negative deviations of the annual precipitation amounts from the multiannual average of the period 1966-2025 (752.0 mm), considered "normal". There are 17 years with positive deviations of precipitation and 19 years with negative deviations. The highest positive deviations exceed 100 mm. There are 9 years with a rainfall surplus of over 100 mm, of which 3 years with over 200 mm: 2005 (+244.2 mm), 2001 (+224.4 mm) and 2004 (+215.5 mm). These are the rainiest years of the period 1990-2025. The highest negative deviations exceed 100 mm, also. There are 8 years with a rainfall deficit of over 100 mm, of which 3 years with over 200 mm and 1 year with over 300 mm: 2025 (-313.6 mm), 2024 (-268.7 mm), 2000 (-257.4 mm) and 2011 (-218.4 mm). They are the driest years of the period 1990-2025.

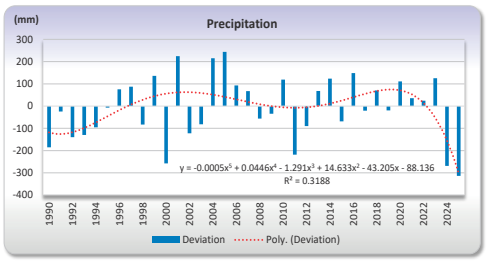

Figure 3. Deviations of the annual precipitation amounts (1990-2025) from the multiannual average (1966-2025), at the Gurahonț weather station; the polynomial trend of deviations

It is noted that the negative deviations are greater than the positive ones – as is usually recorded at the weather stations in Romania. The polynomial trend, represented using the 5th order polynomial, highlights the existence of two long rainy periods (1995-2007 and 2013-2023), interspersed with short dry periods (1990-1994, 2008-2012 and 2024-2025) (Figure 3).

Figure 4 shows the multiannual monthly average air temperature, as well as the highest and lowest monthly average temperatures recorded at the Gurahonț station, during the period 1990-2025. The highest monthly average temperatures were recorded in summer, in July 2024 (24.0°C), July 2012, July 2021, August 1992, August 2024 (all with 23.8°C). They especially occurred towards the end of the analyzed period, in hot weather conditions generated by the advection of the very hot and dry continental-tropical air masses, coming from northern Africa. The lowest monthly average temperatures were reported in winter, in Feb. 2012 (-5.3°C), Jan. 2017 (-5.0°C), Jan. 2000 (-4.0°C), Feb. 2003 (-3.9°C), Dec.1991 (-3.4°C). They occurred due to the advections of continental-arctic or polar air masses, which generate cold waves.

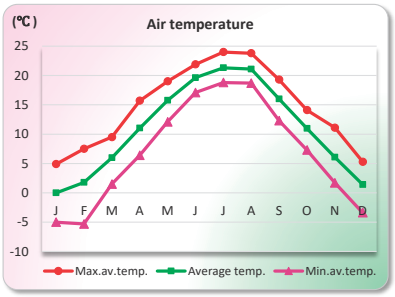

Figure 4. Multiannual monthly average air temperature and the highest/lowest monthly average temperatures, at the Gurahonț weather station (1990-2025)

The highest monthly precipitation amounts exceeded 100 mm, even 200 mm (218.2 mm in June 2020 - the month of the rainfall maximum) (Figure 5). The highest values were reported in the June-September interval (over 150 mm): July 2001 (184.6 mm), July 2011 (181.0 mm), July 2014 (180.4 mm), etc. Such large amounts are linked to the presence of very active cold fronts, which occur after a very hot period. The lowest monthly precipitation amounts ranged between 0 and 26.4 mm. Such small amounts occur when the anticyclonic baric formations persist, generating droughts.

During the period covered by the study, the components of agrosilvopastoral systems were affected by a series of disturbances, which were caused by abiotic and biotic factors, as well as by significant changes in the political and social context.

Consequently, their exploitation changed considerably, with implications for the efficient and sustainable use of the land.

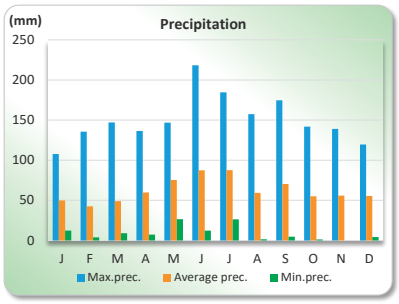

Figure 5. Average, maximum and minimum multiannual monthly amounts of precipitation, at the Gurahonț weather station (1990-2025)

Thus, a series of areas, which were used for grazing animals, in the period after 1989, were partially abandoned, with shrubs and trees of pioneer and invasive species settling on them (Crainic, 2017), which affected the production capacity of the respective lands (Figure 6).

Figure 6. Species of trees and shrubs that have settled on pasture areas within agrosilvopastoral systems

Replacing degraded pastures with agrosilvopastoral systems, especially on lands with clay soils, contributes to increasing soil organic carbon stocks and optimizing microelement circuits, ensuring the premises for sustainable management of these complex systems, against the backdrop of climate change, which is becoming increasingly evident (Ribeiro et al., 2023).

The specific work of rehabilitating agrosilvopastoral systems and reintroducing them into the productive circuit presents a particular specificity, since it is necessary to know the dynamics of how the different components interact during their complex production cycles (Lehmann et al., 2020).

As a result, the works related to the agricultural component, the forestry component, the livestock breeding component (zootechnics) will be analyzed, and last but not least, the aspects related to the sustainable use of the products obtained.

The works necessary for the rehabilitation of the agricultural component of the respective areas are represented by: cutting bushes, shrubs and thin trees, removing stumps by uprooting, works to fill holes and level the land following the uprooting of stumps, plowing the land, cultivating crops for green rotation and for animal feed, respectively. These will be carried out on those areas intended for agricultural crops, meadows and pastures for animal feed (Maruşca, 2018), and classic fruit tree orchards.

Cutting of bushes, shrubs and thin trees, can currently be done mechanized (Table 1), with high efficiency, and the resulting material will be transported and stored at a maximum distance of 20 m from the harvesting site, for recovery, depending on the owner's options.

To remove the stumps, by manual uprooting, excavations will be carried out with hand tools around them, the lateral roots and the central pivot will be cut, the stump will be dislocated and raised on the edge of the pit, later being transported and stored on a specially arranged surface (Table 2), for recovery. Finally, works will be carried out to plug the pits and level the land following the uprooting of the stumps (Table 3).

To achieve the necessary crops, the soil will be plowed with a three-furrow plow at a plowing depth of 29-31 cm (Table 4), since it has been experimentally proven that the largest carbon reserves in the soils of agrosilvopastoral systems are found at a depth of 0-15 cm (Salazar et al., 2024). The plowing work will also be carried out with a harrow pulled by a tractor (Table 5).

A particularly important work is represented by the fertilization of the areas intended for crops and grazing, respectively (Maruşca, 2022). Recent research has shown that on the land areas exploited in the agrosilvopastoral system, the application of chemical fertilizers has been limited to the point of total elimination (Tsufac, et al., 2022). Consequently, organic fertilizer represented by manure will be used, or where possible, mulching will be carried out.

Manure fertilization can be carried out with specialized trailers of the MIG type (Figure 7a), of different capacities, depending on the topography of the land and the surface being worked. In areas relatively difficult to access for mechanized means, animal-drawn means can also be used successfully, especially those with hypotraction.

Figure 7a. Fertilization with manure, using the MIG trailer

The use of manure spreading at present, in the studied location, is currently reported on relatively small areas, due to the low number of cattle and sheep, but it can be expanded in the context of establishing associations between livestock breeders, and submitting financing projects for the development of these activities.
The increasing complexity of agrosilvopastoral systems, as a result of the way the soil is worked, with direct implications on enzymatic activities, nutrient availability, texture, fertility and implicitly on production diversification, actively contributes to optimizing synergies between the nutrient cycle and soil organic carbon storage (Steinfeld et al., 2023; Ngaba et al., 2024).
Fertilization works are also assimilated to those in the forestry sector, carried out in nurseries and plantations, and respectively on areas intended for obtaining complementary food for fauna of hunting interest. The incorporation of seeds into the previously processed soil, for the crops to be installed, can be done manually or mechanically, depending on their specifics. To ensure peace and protection of the crops grown, temporary or permanent fences can be made, depending on the way the land is exploited and the available material possibilities. Currently, a modern variant of making fences is represented by the electric fence (Maruşca, 2022).
The provision of complex ecosystem services, such as diversified fruit production, resistant to diseases and pests, will be of particular importance in the future, given climate change and the growing interest in food security (Špulerová et al., 2025). The specific works for fruit tree cultivation refer to the maintenance of traditional orchards, which are partially or totally abandoned, and to the restoration of some that have been destroyed, or which are at the upper limit of longevity, being dry or in the process of drying (Figure 7b).

Figure 7b. Orchard of local plum varieties in the process of drying, in which specimens of common juniper *Juniperus comunis* L. have been installed, and which needs to be restored

As a result, these works explicitly refer to maintaining optimal tree vegetation conditions and, respectively, to the appropriate management of their crowns, in order to obtain optimal fruit production. In this context, it is necessary to clear the biogroups of woody, shrubby and subshrubby species (Figure 8; Table 1), remove and utilize them, if possible, as well as administer natural fertilizers, namely manure, over the entire surface, with a periodicity of 3-5 years, depending on the soil type.

Figure 8. Apple orchard where black locust specimens *Robinia pseudacacia* L. are being installed, and where crown pruning is required

For the proper management of the crowns, regeneration, management and formation works are necessary, depending on the age, growth and development vigor and respectively the phytosanitary condition of the trees (Figure 9). These works will be assimilated to those related to the formation, maintenance and correction cuts of the crowns in the plantations and seed orchards related to deciduous species (Table 6).

Figure 9. Example of a local apple variety that was grown in a traditional orchard, requiring specific pruning of the crown and removal of surrounding tree vegetation

Also, if the orchards are totally or partially destroyed, they will be restored by planting some fruit tree specimens, if possible, from the original species, or from other local species, which are successfully acclimatized and naturalized in the area. It is preferable to promote in culture trees grafted on freely generative rootstocks, from the apple and pear species. These rootstocks are obtained from seeds, and are optimal for vigorous, long-lived and frost and drought-resistant trees, developing a deep taproot, presenting high adaptability to less fertile soils, representing the perfect solution for the creation of traditional orchards (https://pomfruct.ro/blog/informatii-privind-caractéristiques-portaltoiului/), and present an increased resistance to diseases and pests.

In this situation, the work of obtaining planting material by grafting (Table 7) and respectively its planting (Table 8) can be assimilated to those in the forestry sector, carried out in nurseries, plantations and forest seed orchards.

Consequently, the rehabilitation and preservation of classic (traditional) orchards is very important, because in addition to producing high-quality, organic fruits, it contributes to the preservation of regional traditions and identity, attractive places for recreation, aesthetic appreciation, inspiration for artists, for locals as well as for potential tourists, from the country and abroad (Špulerová et al., 2025).

The works related to the forestry component of agrosilvopastoral systems (Figure 10) refer to:

- ensuring an appropriate phytosanitary condition of the biogroups formed by trees belonging to the fundamental natural forest type;
- appropriate regulation of intraspecific and interspecific competition,
- artificial pruning and trimming works for trees that present an excessive crowning process;
- controlling the succession process of pioneer and invasive species;
- regeneration of tree biogroups that have reached their physiological limit.

[1]Working conditions are determined by soil texture and moisture, skeletal content, degree of weed and woody species coverage, and terrain slope. [2]Light conditions 5-7 points. [3]Medium conditions 8-11 points. [4]Heavy conditions 12-15 points.

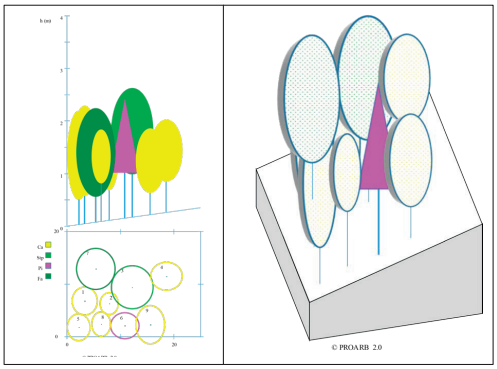

Figure 10. Tree biogroups within an agrosilvopastoral system in Vârfurile locality, Arad county.
The identified species are: Ca - *Carpinus betulus* L., Stp - *Quercus robur* L., Pi - *Pinus sylvestris* L., and Fa - *Fagus sylvatica* L.

The regeneration of tree biogroups, which build the fundamental natural type of forest bordering agrosilvopastoral systems, can be achieved naturally, from certified seed, coming from seed reserves (Crainic et al., 2023b), or mixed, also using bare-root forest seedlings (Dorog & Crainic, 2015). As a result, the tree species of *Quercus robur*, *Quercus ceris*, *Quercus petraea*, *Acer campestre*, *Fagus sylvatica*, *Carpinus betulus*, *Prunus avium*, and *Alnus glutinosa* will be regenerated, which are native species and have a very important role in improving and maintaining soil fertility and in the efficient functioning of the land exploitation system (Cheruto et al., 2025). Also, the wood that will be obtained from these tree species can be valued differently, depending on the needs of the owners. The aforementioned interventions will comply with the recommendations of the technical norms related to activities in the forestry sector, as well as some technical solutions offered by local experience, which have been shaped over decades of exploitation (activity).

It is also aimed at removing biogroups of shrubs and subshrubs that cannot be exploited, and which frequently colonize considerable areas.

The wood resulting from the application of the interventions mentioned above can be exploited

in compliance with the regulations in force regarding forest vegetation outside the national forest fund (Forestry Code - Law 331/2024), and the cultivation of some fruit tree species, such as walnut and cherry. Agrosilvopastoral systems have a high potential to store more carbon and improve the physical and chemical characteristics of the soil, compared to conventional pastoral systems (Salazar et al., 2024). Consequently, at present, the zootechnical component, namely animal husbandry, must be maintained and rehabilitated in these complex land use systems in the studied area, and for this reason.

The works related to the zootechnical component mainly refer to the partial redevelopment of animal shelters, watering places and, last but not least, the design of modern enclosures and electric fences, activities that can be carried out relatively easily by the owners, given the current logistical possibilities. To make the process of monitoring the exploitation and health of agro-forestry systems, and carbon sequestration more efficient on a large scale, remote sensing applications can be used with high efficiency (Sirimalle et al., 2025).

Although the elements related to the specifics and cost of the mentioned works have been assimilated to those in the corresponding activity sectors, however, currently the economic evaluation of the activities presented is carried out through direct negotiation between the owner and the provider, or they can be carried out by the owner himself, including a series of expenses determined by various materials, fuels, taxes, etc.

For the plains and low hills, the value of the works related to the installation of oat crops is approximately 2100 lei (407.76 euros) per hectare of land, and in the high hills area, where the case study was conducted, the value of these works is currently estimated at 2600 lei (504.85 euros) per hectare.

These aspects, regarding the method used to evaluate the works, are relevant for the correct quantification of all expenses and obviously for establishing an efficient financing approach.

It is known that at the European level, for example in Switzerland, the valorization of the productions of meadows and orchards related to agroforestry systems is declining, although these are managed within the framework of extensive agri-environmental schemes (SAE) (Nishizawa et al., 2022).

At the national level, although part of the areas exploited in the agrosilvopastoral system are declared for APIA subsidies (www.agroinfo.ro, www.agrointel.ro, Table 9), their amount can only finance (financially support) a relatively small percentage of the works necessary for their rehabilitation and introduction into the productive circuit.

Table 9. General summary of APIA support (€/ha), for hill and mountain areas (www.apia.org.ro)

| Use category | Estimated payment range (€/ha) |
|---|---|
| Permanent grassland (simple) | 120 - 180 |
| Mountain/alpine grassland | 200 - 300 |
| Agri-environmental grassland | 250 - 350 |
| Traditional orchards | 150 - 300 |

The revival of activities in this type of exploitation requires an efficient strategy for the valorization of the products obtained.

Although the production of animal and plant-based foods related to agro-silvopastoral systems is of superior quality, with some products being organic, in some situations production costs are higher, which may influence market competitiveness.

But the quality of the products, namely the taste, healthy character, naturalness, flavor, seriously attract the attention of consumers, who are interested in these essential characteristics. Consequently, consumers, through the actions of purchasing products, can support the activity in these systems (Philipp & Zander, 2023).

In this context, the creation of a modern, efficient system for the valorization of animal products, especially a series of dairy products from cattle, (represented by milk, cream, fresh cheese) which are sold locally, through a vending machine and a retail store, respectively, was initiated. As a result, the companies Lazurana Lact SRL and Lazurana Ferm Lact Agricultural Cooperative represent a local producer located in Lazuri Village, Vârfurile ATU, Arad County, which processes milk from local farms within the Vârfurile ATU, Arad County, and which exploits the lands in an agrosilvopastoral system, producing a wide range of organic dairy products.

Also, to capitalize on the fruits obtained from traditional orchards that are exploited in agro-

forestry systems, a complete line with industrial capacity was purchased for processing fruits and obtaining various types of pasteurized and unpasteurized, organic juices in the locality of Măgulicea, UAT Vârfurile, Arad County.

Agrosilvopastoral systems are characterized by a high level of biodiversity and superior production capacity, but their related activities require considerable time and financial effort, in order to optimally and sustainably capitalize on the productive potential of the land (Philipp & Zander, 2023).

The climatological analysis presented above shows that the period 1990-2025 was very warm, with 2/3 of the years analyzed having positive thermal deviations from normal. The 2007-2025 interval was the warmest, recording only positive annual temperature deviations. That caused the linear trend of annual thermal deviations to be strongly upward. The precipitation analysis highlighted that the negative annual deviations were greater than the positive ones, but the rainy periods were longer than the dry ones. However, the rainfall extremes were very well highlighted in the analyzed period 1990-2025: there were very rainy and excessively rainy years interspersed with very dry or excessively dry years. As a result, the very high temperatures and long droughts in the dry years negatively influenced the plant and animal yield in the studied area, and the excessive rains in the rainy years favored obtaining rich yields.

The necessary works for the rehabilitation and introduction into the productive circuit of the abandoned agrosilvopastoral systems have to be carried out in an integrated manner, for each of their components, depending on the objective reality on the ground. The specifics of the works and the way they are carried out have to be correlated with the technical and financial possibilities of the owners. Also, the way of valorizing the products of plant and animal origin obtained have to be optimal, in order to efficiently support the expenses related to the production process, with a view to sustainable management of these complex systems. The financing options that can be accessed through various projects or non-refundable payments and interventions, constitute an important support for the owners of agrosilvopastoral systems. According to the aspects presented above, it follows that the objectives of the study have been achieved.

The results obtained in this study contributed to the advancement of scientific knowledge in the addressed field, by the fact that for the rehabilitation and introduction into the productive circuit of the abandoned agrosilvopastoral systems, an integrated approach to the necessary works is required, depending on the specifics of the system component, in direct correlation with the vegetation conditions and the yield obtained, making it possible to predict the expenses and income obtained, with high accuracy.

The extension of research to other locations in Vârfurile Commune, Arad County, is mainly limited by the way in which agrosilvopastoral systems are exploited, which differs from one owner to another, with several differences regarding the exploitation of the productive potential of each component of the systems. Research may also be limited by the refusal of owners to facilitate the access to information from the agricultural register and to information relating to the plant and animal yields obtained.

Research and studies on agrosilvopastoral systems can be continued in the future for each village in the Vârfurile commune, in order to analyze their condition and the real possibilities for their rehabilitation and introduction into the productive circuit.

## CONCLUSIONS

The period 1990-2025 was a very warm one, the 2007-2025 interval being the warmest. Most years of the period 1990-2025 had positive deviations of the annual average air temperature from normal. Compared to the precipitation recorded in the period 1966-2025, the period 1990-2025 was relatively rich in precipitation, but in which the rainfall extremes were highlighted (there were very rainy and excessively rainy years interspersed with very dry or excessively dry years). Thermal and rainfall extremes are very damaging to forests, representing a major stress for them, weakening the resistance of trees and favoring the emergence of diseases and pests.

Agro-silvopastoral systems in uncultivated areas of medium and high hills were exploited differently over time, and after 1989, interest in

productive activities gradually decreased, some of them being abandoned, even today.

The work required to rehabilitate these complex land valorization systems has specific features for their functional components, requiring considerable financial support.

Although the measures that need to be adopted are relatively easy for owners, in order to make them more efficient, it is necessary to achieve an ownership, at least at the village level.

The initiation of the valorization of animal and plant products resulting from productive activities, mostly locally, in an organized manner, given the facilities that are currently available, represents for the studied area a definite possibility of rehabilitation and reintegration into the productive circuit of agro-silvopastoral systems.

## ACKNOWLEDGEMENTS

For the support given to the optimal development of the case study, we would like to thank the management of the Local Council of the Vârfurile City Hall, Arad County, the managers of the commercial companies Lazurana Lact SRL and Lazurana Ferm Lact Agricultural Cooperative. We would also like to thank the owners of the agrosilvopastoral systems that are currently carrying out productive activities, for facilitating access on the ground and to a series of information regarding the local experience accumulated over decades of activity.

***Abstract***

*Molhaşul de la Râşca - Dealul Negru is a montane oligotrophic peatbog complex in Cluj County (1042-1070 m a.s.l.), within the alpine biogeographical region of north-western Romania. Covering 35 ha, it comprises a mosaic of Sphagnum-dominated peat-forming communities, and for S. affine is the only site in Romania. The structure and hydrology of the site have been slightly altered by past drainage, grazing pressure, surrounding land-use changes and the expansion of woody vegetation, leading to anthropogenic habitat fragmentation and partial isolation from the neighbouring Râşca Răchitiş mire. Based on new field surveys, the present study documents the diversity, distribution patterns and habitat preferences of Sphagnum species across the active raised bog and evaluates the conservation value of Molhaşul de la Râşca - Dealul Negru as one of the regional reference sites for Sphagnum-dominated ecosystems in the Gilău Massif.*

***Key words****: Molhaşul de la Râşca, Natura 2000, peatbog, Romania, Sphagnum.*

## INTRODUCTION

Peatlands represent critical reservoirs of carbon worldwide, covering about 3.0% of the total land area but storing much more carbon than any terrestrial ecosystem (Scharlemann et al., 2014; Keane et al., 2025). One of the key ecosystem services that peatlands provide is biodiversity support, or even refugia for some rare species. Alongside climate regulation, water management and cultural heritage, this makes peatlands essential for sustainable environmental stewardship and long-term conservation. These ecosystems host a unique variety of species, many rare, endangered, or even adapted to wet, acidic, and nutrient-poor environments (Joosten et al., 2017). Therefore, protecting increasingly threatened peatlands thus directly supports biodiversity conservation.

Molhaşul de la Râşca - Dealul Negru Peatbog (CJ-016) represents one of the largest peatbogs in the Apuseni Mountains (21.59 ha).

From a historical perspective, E. Pop first described Molhaşul de la Râşca Peatbog (also known as *Mohuş-ul de la Dealul Negru* or *"Lágyas"*) in 1947 as being the only Apuseni site with natural *Pinus sylvestris*, though it was already invaded by trees (*Picea*, *Pinus*, *Betula pendula*, *B. pubescens,* and *Populus tremula*) and generally drier (with *Calluna vulgaris*, *Empetrum nigrum*, and *Vaccinium myrtillus*) (Pop, 1947). He noted early signs of degradation due to the nearby village (Pop, 1947; Pop, 1960). Later, he reported a 2.2 m-thick peat layer (ca. 120,000 $m^3$ formed mainly of sub-Atlantic origin, pH 3.90-5.00), along with some crises: underground peat burning (1910-1912) and exploitation from 1952 onwards (Pop, 1960).

Concerning the bryophyte flora of the study site, Györffy and Péterfi (1919) recorded two *Sphagnum* taxa from "*Lágyas*": *Sphagnum compactum* var. *squarrosa* and *Sphagnum imbricatum* var. *cristata* fo. *fuscescens*. Between 1936 and 1946, E. Pop collected additional *Sphagnum* species from Molhaşul de la Râşca and nearby sites, later determined and published by T. Ștefureac (1958) as *S. acutifolium* Ehrhardt (*S. nemoreum* Scop.), *S. capillaceum* (Weis.) Schrank (1936) and var. *versicolor* Warnst. (1936), and *S. magelanicum* Brid. (currently referred to as *S. medium* Limpr; 1936).

*Sphagnum* represents one of the most dominant plants in many peatlands. It engineers favourable conditions for its proliferation through moisture retention via capillary action,

nutrient efficiency, acidification, slow decomposition (due to the polyphenol content), and microbial suppression by specialized metabolites (Keane et al., 2025). As a *Sphagnum*-dominated peatbog, Molhașul de la Râșca - Dealul Negru`s accumulated organic matter - peat - is composed of a high percentage of this specific decomposed species due to its known resistance to decomposition (Kuhry & Vitt, 1996).

Some *Sphagnum* species from this site have a conservative importance, being the keystone of the ecosystem. *Sphagnum affine* Renauld & Cardot holds NE (not evaluated) conservation status in Romania due to data deficiency (Ștefănuț & Goia, 2012; Hodgetts et al., 2020). Recently confirmed in one site in Romania (Molhașul de la Râșca - Dealul Negru), therefore the conservation status changed from NE to CR (critically endangered) B1ab (ii, iii) + B2ab (ii, iii) (Sabovljević et al., 2025; Sass-Gyarmati et al., 2025; Ștefănuț et al., 2026). *S. affine*`s occurrence could be underestimated due to morphological similarities with *S. palustre*, particularly as they co-occur (Figure 1). Until now, we could consider *S. affine* a threatened species nationally, and it should have a protected conservation status.

Figure 1. *Sphagnum affine* mixed with *S. palustre,* Molhașul de la Râșca - Dealul Negru, 6.10.2025 (photo by Ștefănuț S.)

Similarly, *Hamatocaulis vernicosus* (Mitt.) - varnished hook-moss - is listed in Annex II of the EU Habitats Directive (European Union. Council Directive 92/43/EEC), with a 'Vulnerable' status in the Red Data Book of European Bryophytes (European Committee for the Conservation of Bryophytes) and the Red List of Romanian Bryophytes (Ștefănuț & Goia, 2012).

It faces a projected pessimistic future scenario of major range losses due to climate change (Ștefănuț et al., 2025), underscoring the need to protect it alongside peatland habitats.

Even though many Romanian peatlands face severe degradation, Molhașul de la Râșca Peatbog represents a rare functional oligotrophic system with Atlantic affinities (Sass-Gyarmati et al., 2025).

Despite historical documentation, no comprehensive bryophyte inventories have existed for over several decades. This data deficiency for conservation assessments of Molhașul de la Râșca Peatbog shaped this study`s objectives: (1) inventory bryophyte biodiversity, (2) assess PeatRO-identified pressures and conservation priorities, and (3) propose management measures for long-term protection. These efforts provide the scientific basis for the integration of Molhașul de la Râșca Peatbog within Apuseni Natural Park (RONPA0004) or its designation as a Natura 2000 Site of Community Importance (SCI).

## MATERIALS AND METHODS

### Study Area and Site Importance

Molhașul de la Râșca - Dealul Negru (CJ-016; 46.710460° N, 23.050730° E) lies within Râșca commune, Cluj County, Romania. Biogeographically, it belongs to the alpine region, situated in the northwest of Romania on the Dealul Negru plateau between Călata and Râșca valleys 1042-1070 m a.s.l., Gilău Massif, covering 35 ha (Figure 2). The site is located at 0.6 km to Apuseni Natural Park (RONPA0004) and Apuseni Natura 2000 site (ROSCI0002).

Figure 2. Geographical limits of Molhașul de la Râșca - Dealul Negru (grey). In blue is the Apuseni Natural Park

Pop (1947) positioned Molhașul de la Râșca – Dealul Mare and Molhașul de la Călățele (the largest peat bogs in the area) opposite each other across adjacent watersheds drained by Valea Călățele (Figure 3, a and b). Geologically, he describes the parent rock in the area as consisting primarily of nutrient-poor Eocene sandy clay, with exceptional outcrops of crystalline schists in contact with sandstone substratum (Pop, 1960).

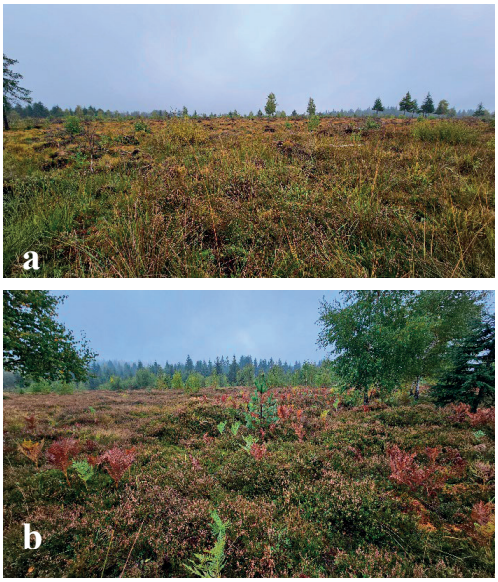

Figure 3. Molhașul de la Râșca Peatbog, ground view (a and b), 6.10.2025 (photo by Ștefănuț S.)

Currently, the general aspect of the site is an oligotrophic bog, with a deficient water regime. Dominant vegetation includes mosses (mainly *Sphagnum*) and the presence of some nano-phanerophytes such as *Calluna vulgaris*, *Empetrum nigrum*, *Vaccinium myrtillus*, *V. vitis-idaea,* and *Juncus squarrosus* - the latter representing its only national occurrence as an Atlantic species (Frink et al., 2017; Sass-Gyarmati et al., 2025; PeatRO Project).

**Field survey and sample collection**

Molhașul de la Râșca Peatbog was selected due to underreported bryophyte diversity, highlighting the need for additional conservation assessments. To inventory bryophytes, a field survey was made in order to collect samples on 6 October 2025.

For each species population, we recorded GPS coordinates (Garmin 64s, <50 cm accuracy), captured aerial imagery (DJI Mini 2 drone), and integrated the ground-based data to map habitat distribution.

The collected samples of bryophytes were morphologically identified under the light microscope, and the nomenclature of *Sphagnum* species was made after Hodgetts et al. (2020) and Hassel et al. (2025).

**Pressures and threats**

As a part of the PeatRO Project (2015-2017), Molhașul de la Râșca - Dealul Negru (CJ-016) and 215 other Romanian peatlands were evaluated for their conservation status in order to inform national strategies limiting biodiversity loss. Anthropogenic and environmental pressures noted during this project included drainage, cattle grazing, land-use changes and woody vegetation encroachment. Main threats comprise climate change and habitat fragmentation linked to the adjacent Râșca Răchitiș mire. Subsequent to the identification of these existing pressures, the project proposed restoration measures aimed to mitigate these pressures and to preserve the habitats.

## RESULTS AND DISCUSSIONS

During our field surveys, we identified a number of ten *Sphagnum* species, of which many are specific to the peat bogs of the Apuseni Mountains, and others are bryophyte species with great conservation potential, such as *Hamatocaulis vernicosus*.

***Sphagnum affine*** Renauld & Cardot

The species was first reported from Molhașul de la Râșca Peatbog as *Sphagnum imbricatum* Hornsch. var. *cristata* fo. *fuscescens* Warnst Comit. Kolozs: in turfosis Lágyas supra Magyarvalkó, alt. cca 920 m.s.m., 1915.25.X., leg. & det. Györffy I. and Péterfi M., BP (Budapest Herbarium) 7450/S, 7451/S, rev. Ștefănuț M-M. (Györffy & Péterfi, 1919; Sabovljević et al., 2025).

The species was rediscovered at the same site on 26 July 2013 (46.70849° N, 23.05224° E, 1070 m a.s.l.), *leg*. Sass-Gyarmati A., Jakab G., *det*. Sass-Gyarmati A., 2014, EGR (Eger

Herbarium), CL (Cluj-Napoca Herbarium), reported on 30 June 2025 (Sass-Gyarmati et al., 2025), BUCA (Institute of Biology Bucharest Herbarium), *B12946* (*conf.* Ștefănuț M.-M., 23 June 2025).

Both records were a compelling reason for us to look further for *S. affine* (Figure 4) in Molhașul de la Râșca peatbog, being the only location in Romania where it has been reported. Therefore, we confirmed its presence on 6 October 2025 at Molhasul de la Râsca - Dealul Negru, 46.709174° N, 23.049022° E, 1053 m a.s.l., *leg*. Ștefănuț M.-M., Moroșanu A.-M., Ștefănuț S., *det*. Ștefănuț M.-M., confirmed by Ștefănuț S., BUCA *B12617* (Ștefănuț et al., 2026).

Figure 4. *Sphagnum affine*, close-up (photo by Ștefănuț S.)

***Sphagnum compactum*** Lam. & DC.

An Atlantic species which was previously reported as *Sphagnum compactum* DC. var. *squarrosa* Russ., *Comit Kolozs: in turfosis Lágyas prope pagum Magyarvalkó, alt. 1000 m.s.m.* (25.10.1915), by Györffy and Péterfi (1919), confirmed by Sass-Gyarmati et al. (2025).

We also found *S. compactum* at Molhașul de la Râșca Peatbog, 46.708450° N, 23.051975° E, 1063 m a.s.l., 6.10.2025, *leg*. Ștefănuț M.-M., Moroșanu A.-M., Ștefănuț S., *det*. Ștefănuț M.-M., confirmed by Ștefănuț S., BUCA *B12671-B12672* (Figure 5).

We did not find two *Sphagnum* species previously recorded: *Sphagnum platyphyllum* (Lindb. ex Braithw.) Warnst. (Meleshko et al., 2025; Sass-Gyarmati et al., 2025), and *S. subsecundum* Nees (Meleshko et al., 2025).

Figure 5. *Sphagnum compactum*, close-up (photo by Ștefănuț M.-M.)

***Hamatocaulis vernicosus*** (Mitt.) Hedenäs

Even though drier, but an oligotrophic peatbog, Molhașul de la Râșca proved to be a suitable host for *H. vernisosus*, as it prefers such habitat conditions. We recorded for the first time this species in this site, 46.707762° N, 23.051411° E, 1065 m a.s.l., 6.10.2025, *det*. Ștefănuț S., Moroșanu A.-M., Ștefănuț M.-M. Also, we confirm the presence of *H. vernisosus* in Dâmbu Negru – La Pod site, 46.691190° N, 23.037044°E, 1079 m a.s.l., 7.10.2025, *det*. Ștefănuț S., Moroșanu A.-M., and Ștefănuț M.-M. (Figure 6).

Figure 6. *Hamatocaulis vernicosus,* close-up (photo by Moroșanu A.-M.)

Also, we found *Sphagnum angustifolium* (C.E.O. Jensen ex Russow) C.E.O. Jensen, *S. capillifolium* (Ehrh.) Hedw. (Figure 7), *S. divinum* Flatberg & Hassel (Figure 8), *S. girgenshonii* Russow, *S. inundatum* Russow (Figure 9), *S. medium* Limpr. (Figure 10), and *S. palustre* L. (Figure 11).

Figure 7. *Sphagnum capillifolium*, close-up (photo by Ștefănuț M.-M.)

Figure 8. *Sphagnum divinum*, close-up (photo by Ștefănuț S.)

Figure 9. *Sphagnum inundatum*, close-up (photo by Ștefănuț M.-M.)

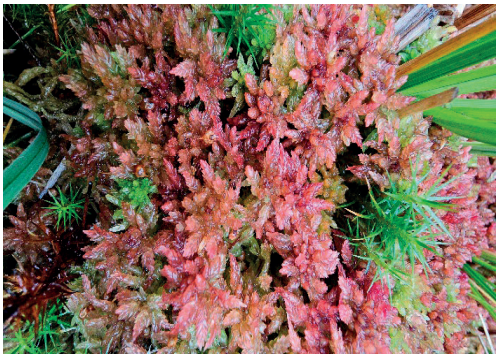

Figure 10. *Sphagnum medium*, close-up (photo by Ștefănuț S.)

Figure 11. *Sphagnum palustre*, close-up (photo by Ștefănuț M.-M.)

**Management recommendations**

The relatively dry conditions mentioned several decades ago by Pop (1947), also currently observed, alongside the decreasing abundance of peat-forming bryophytes, will materialise into a reduction of the peat accumulation and therefore a significant atmospheric carbon release. Bryophytes thus serve as key indicators for the structure and function of the peatland ecosystems (Vitt & House, 2021).

Furthermore, the vascular plant encroachment proved to be an early indicator of peatland degradation, a warning signal of warming- and drought-driven *Sphagnum* decline which accelerates ecosystem transition (Yu et al., 2026).

Considering all the anthropogenic and environmental pressures identified during the PeatRO Project (2015-2017), we consider that some priority conservation measures are

essential across short-, medium- and long-term periods, supported by a national legal framework, in order to protect the site and its biodiversity.

Short-term measures include grazing prohibition (fencing) and control of woody encroachment (manual removal), while medium-term measures include rehydration (dam construction and restoring the hydrological connectivity with Râșca Răchitiș mire CJ-017) and periodic monitoring efforts. In the long-term, the legal designation of Molhasul de la Râsca-Dealul Negru (CJ-016) as a Site of Community Importance (SCI) under the Natura 2000 umbrella or integration within Apuseni Natural Park (RONPA0004).

## CONCLUSIONS

Molhașul de la Râșca - Dealul Negru is remarkable as a key reference site for oligotrophic peat bogs in Apuseni Mountains, housing Romania`s unique *Sphagnum affine* (CR) population, alongside other rare bryophytes (*S. compactum*, *Hamatocaulis vernicosus* - VU).

This study inventories eleven *Sphagnum* species, bridging historical records while highlighting populations` resilience despite the PeatRO-identified pressures.

Current reports underscore the importance of continuous monitoring, given the anthropic pressures and habitat fragmentation.

Priority management measures recommended are short-term (grazing prohibition and control of woody encroachment), and medium-term (rehydration efforts and monitoring), which, alongside long-term legal measures (integration within Apuseni Natural Park RONPA0004 or designation as a SCI Natura 2000), will contribute to site conservation in a declining climate change context.

***Abstract***

*All science is connected and the main connection is through the language of mathematics. Some of the most spectacular scientific results are obtained transdisciplinary. The relationship between geometry and physics is one of the most profound in science, evolving from a tool for measurement into the very language used to describe the fundamental laws of the universe. Geometry and physics are deeply intertwined disciplines, where geometry provides the formal language and structural framework for physical laws, while physics often drives the development of new mathematical theories. Differential geometry, for example, is essential for understanding gauge theories in particle physics and Riemannian geometry is fundamental in cosmology. Other branches of mathematics, such topology and Lie groups contribute to both classical and modern physics. In this article we investigate some geometric results obtained via physical methods and we emphasize some other links between geometry and physics.*

***Key words****: geometry, physics, string theory, theory of relativity, vectors.*

**"As far as the laws of mathematics refer to reality, they are not certain; and as far as they are certain, they do not refer to reality"- Albert Einstein, 1921**

## INTRODUCTION

The deep and enduring relationship between geometry and physics has played a central role in the development of modern scientific thought. From the early formulation of classical mechanics to the emergence of contemporary theories of spacetime, geometric concepts have provided a powerful language for describing the fundamental structure of physical reality. In particular, the use of mathematical frameworks such as Euclidean and non-Euclidean geometry has enabled physicists to model space, motion, and interactions with increasing precision and abstraction.

In classical physics, geometry was primarily viewed as a static and absolute stage upon which physical processes unfold. However, this perspective underwent a profound transformation with the advent of modern physics. The development of theories such as general relativity demonstrated that geometry is not merely a passive background, but an active and dynamic component of the physical universe. In this context, the curvature of spacetime becomes directly related to the distribution of mass and energy, illustrating a deep interplay between geometric structures and physical phenomena.

Geometry lies at the very heart of relativity, transforming it from a theory about forces into one about the structure of spacetime itself. In special relativity, the geometry is that of Minkowski space, where time and space are unified into a four-dimensional continuum with a non-Euclidean metric that determines invariant intervals between events. General relativity deepens this connection by describing gravity not as a force, but as the curvature of spacetime induced by mass and energy. The mathematical language of differential geometry-manifolds, metrics, geodesics, and curvature tensors-provides the framework for this description. Objects move along geodesics, which generalize the notion of straight lines to curved spacetime, and the Einstein field equations relate the geometric properties of spacetime directly to the physical distribution of matter and energy.

Geometry plays a central and indispensable role in string theory, where the fundamental objects are not point particles but one-dimensional strings whose vibrational modes depend sensitively on the geometry of the space in

which they propagate. In this framework, spacetime is typically extended beyond four dimensions, and the extra dimensions are assumed to form compact geometric spaces, often modelled by Calabi-Yau manifolds. The specific shape and topology of these compact spaces determine crucial physical properties, such as particle spectra and interaction strengths. Moreover, concepts from modern geometry-such as complex geometry, topology, and mirror symmetry-are deeply intertwined with the structure of string theory, revealing surprising dualities between seemingly distinct physical models. In this way, geometry is not merely a background setting, but an active ingredient that shapes the physical content of the theory itself (Steiner, 1992; Bailly et al., 2011; Rédei, 2020). This paper aims to explore fundamental connections between classical geometry and physics, highlighting how geometric methods contribute to our understanding of physical laws. By examining key theoretical frameworks and their applications, we seek to demonstrate that geometry is not only a mathematical tool, but also an essential foundation for the formulation and interpretation of physical theories.

## MATERIALS AND METHODS

### I. Vectors in geometry

In mathematics and physics, vectors are the same, as numerical support, but in physics they have an interpretation in some phenomena.

From the algebraic point of view, a *vector* is an element $x = (x_1, x_2, \dots, x_n) \in \mathbb{R}^n$. Vectors can naturally be added, substracted and multiplied by a scalar, in the same way as matrices, so $\mathbb{R}^n$ has a natural structure of vectorial space.

From the geometric point of view, a vector (Figure 1) is an "arrow" between two points (Berger, 1987).

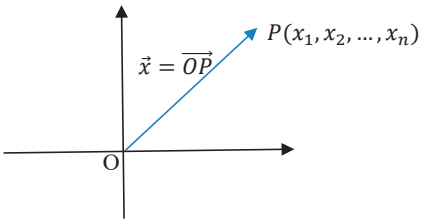

Figure 1. Vector

The Euclidian *scalar product* of two vectors $x, y \in \mathbb{R}^n$ is defined by the equality

$$x \cdot y = x_1 y_1 + x_2 y_2 + \cdots x_n y_n.$$

The Euclidian *norm* of a vector is

$$\|x\| = \sqrt{x_1^2 + x_2^2 + \cdots + x_n^2}.$$

*Remark 1.* $x^2 = x \cdot x = \|x\|^2$.

From *Cauchy-Buniakovski-Schwarz* inequality we have

$$|x \cdot y| \leq \|x\| \cdot \|y\|.$$

Thus, the angle between the two vectors is defined by

$$\cos\theta = \frac{x \cdot y}{\|x\| \cdot \|y\|} \in [-1, 1].$$

*Remark 2.* $x \perp y \Leftrightarrow x \cdot y = 0$.

### II. Mass centers

It is well known that the mass center G of system of material points in plane, of coordinates $P_i(x_i, y_i)$ in which there are concentrated the weights $m_i \geq 0,\ i = \overline{1,n}$ is given by (Solomentsev, 2001),

$$x_G = \frac{m_1 x_1 + m_2 x_2 + \cdots m_n x_n}{m_1 + m_2 + \cdots m_n}$$

and

$$y_G = \frac{m_1 y_1 + m_2 y_2 + \cdots m_n y_n}{m_1 + m_2 + \cdots m_n}$$

Therefore, considering the masses $m_i = m\ (constant)$ in the vertices of a triangle ABC, the mass center of the system

$$S = \{A(m), B(m), C(m)\}$$

has the same coordinates of the geometric mass center of the triangle ABC, which is the intersection of its medians:

$$x_G = \frac{x_A + x_B + x_C}{3}$$

and

$$y_G = \frac{y_A + y_B + y_C}{3}$$

The mass center of the plate ABC is $G(x_G, y_G)$, where.

$$x_G = \frac{\iint_{ABC} x\, \rho(x,y)\, dxdy}{\mu}$$

and

$$y_G = \frac{\iint_{ABC} y\,\rho(x,y)dxdy}{\mu}$$

where the mass of the plate ABC is

$$\mu = \iint_{ABC} \rho(x,y)\,dxdy.$$

***Definition 1.*** We consider the points $P_i(x_i, y_i) \in \mathbb{R}^2$, forming a polygon $P_1P_2 \dots P_n$. If

$$x_m = \min_{i=\overline{1,n}} x_i\ ,\ x_M = \max_{i=\overline{1,n}} x_i,$$

$$y_m = \min_{i=\overline{1,n}} y_i \text{ and } y_M = \max_{i=\overline{1,n}} y_i$$

then we call the rectangle

$$D_{P_1P_2\dots P_n} = [x_m, x_M] \times [y_m, y_M]$$

the ***rectangle cover*** of the polygon $P_1P_2 \dots P_n$.

## APPLICATIONS

### I. Applications of physics in geometry

***Theorem of Pythagoras*** (Figure 2)

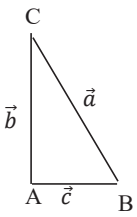

Figure 2. Rectangle triangle

By denoting $\overrightarrow{AB} = \vec{c},\ \overrightarrow{CB} = \vec{a}$ and $\overrightarrow{CA} = \vec{b}$, and $AB = c,\ BC = a\ and\ AC = b$ we have

$$\vec{b} + \vec{c} = \vec{a}\Big|^2$$

$$\vec{b}^2 + 2\underbrace{\vec{b}\cdot\vec{c}}_{0} + \vec{c}^2 = \vec{a}^2$$

$$\left\|\vec{b}\right\|^2 + \|\vec{c}\|^2 = \|\vec{a}\|^2$$

Thus, we obtain the theorem of Pythagoras.

$$b^2 + c^2 = a^2$$

***Stewart's relation*** (Figure 3)

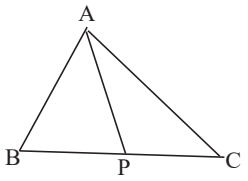

Figure 3. A scalene triangle with a cevian

By denoting $\overrightarrow{AB} = \vec{c},\ \overrightarrow{CB} = \vec{a}$ and $\overrightarrow{CA} = \vec{b}$, $\overrightarrow{AP} = \vec{p}$, and $AB = c, BC = a\ and\ AC = b$.

If $\frac{BP}{BC} = k \in (0,1)$, then $\frac{PC}{BC} = 1 - k$

$$\vec{c} = \vec{p} + k\vec{a}$$

$$\vec{b} = \vec{p} + (k-1)\vec{a}.$$

By raising the above equalities to square, we obtain

$$\vec{c}^2 = \vec{p}^2 + k^2\vec{a}^2 + 2k\vec{a}\vec{p}\ |\cdot(1-k)$$

$$\vec{b}^2 = \vec{p}^2 + (1-k)^2\vec{a}^2 + 2(k-1)\vec{a}\vec{p}\ |\cdot k$$

After the multiplication, we add the relation and it results an equivalent to Stewart's theorem:

$$AB^2 \cdot PC + AC^2 \cdot PB - BC^2 \cdot PA = PA \cdot PB \cdot PC$$

**Theorem 1**. Let ABC be a triangle with all the angles smaller than 120°. Then the point P in the plane of the triangle, for which the sum

$$PA + PB + PC = minimum$$

is the one which has the property that

$\widehat{APB} = \widehat{APC} = \widehat{BPC} = 120^o$, denoted by T
(the *Torricelli point* of the triangle - Figure 4)

*Proof*. We consider in the plane of the triangle ABC, assumed parallel to the ground, 3 threads tied at a point P, equal in length, passing through the points A, B and C and having the same weight $m$ at the other end. The forces $\overrightarrow{F_1}, \overrightarrow{F_2}$ and $\overrightarrow{F_3}$ that act on the point P are equal in module to the gravitational forces $\overrightarrow{G_1}, \overrightarrow{G_2}$ and $\overrightarrow{G_3}$.

This system of forces reaches the equilibrium state when its potential gravitational energy is minimum. If we denote by $h_1, h_2$ and $h_3$ the distances from the weights to the ground then the potential gravitational energy is

$$E_p = mgh_1 + mgh_2 + mgh_3$$
$$= mg(h_1 + h_2 + h_3)$$

Therefore, the sum

$h_1 + h_2 + h_3$ is minimum,

which implies that

$PA + PB + PC$ is minimum.

Also, at equilibrium

$$\overrightarrow{F_1} + \overrightarrow{F_2} + \overrightarrow{F_3} = \vec{0}$$

which proves that the angles between these forces are all equal with $120^o$ and ends the proof (Nicolescu & Boskoff, 1990).

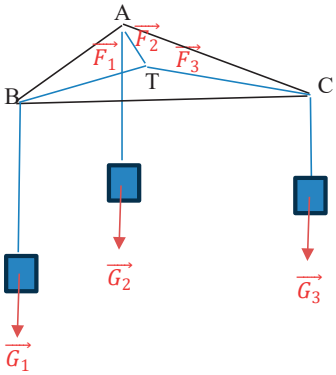

Figure 4. Torricelli's point

## II. Aplications of geometry in physics

**Theorem 2**. Considering a fixed triangle ABC in a plane, and the variable masses $m_1, m_2, m_3 \geq 0$, not all nulls, the mass center of the system $S = \{A(m_1), B(m_2), C(m_3)\}$ can be any point of the rectangle $D_{ABC}$ (Figure 5).

*Proof.*

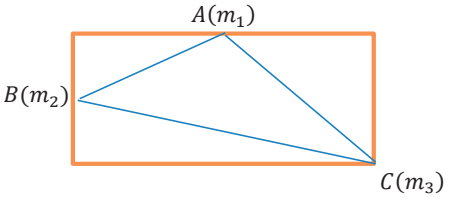

Figure 5. The rectangle cover of a triangle

We consider the points

$$A(x_1, y_1), B(x_2, y_2), C(x_3, y_3) .$$

Without loss of generality, we can assume that

$$m_1 + m_2 + m_3 = 1.$$

Otherwise, we can replace them with

$$m_i' = \frac{m_i}{m_1+m_2+m_3},$$

which have the property

$$m_1' + m_2' + m_3' = 1.$$

We observe that the mass center of the system $S = \{A(m_1), B(m_2), C(m_3)\}$ verifies the inequalities:

$$x_G = \frac{m_1x_1 + m_2x_2 + m_3x_3}{m_1 + m_2 + m_3} = m_1x_1 + m_2x_2 + m_3x_3 \geq (m_1 + m_2 + m_3)x_m = x_m$$

and also

$$x_G = \frac{m_1x_1 + m_2x_2 + m_3x_3}{m_1 + m_2 + m_3} = m_1x_1 + m_2x_2 + m_3x_3 \leq (m_1 + m_2 + m_3)x_M = x_M$$

Thus $x_G \in [x_m, x_M]$ and in the same way it can be shown that $y_G \in [y_m, x_M]$ .

So

$$G(x_G, y_G) \in [x_m, x_M] \times [y_m, y_M] = D_{ABC}.$$

Now we show that any point $(a, b) \in D_{ABC}$ is the mass center of a unique system $S = \{A(m_1), B(m_2), C(m_3)\}$, with $m_1 + m_2 + m_3 = 1$.

In this scope, we have to prove that the system of linear equations:

$$\begin{cases} m_1x_1 + m_2x_2 + m_3x_3 = a \\ m_1y_1 + m_2y_2 + m_3y_3 = b \\ m_1 + m_2 + m_3 = 1 \end{cases}$$

has a unique solution

$$(m_1, m_2, m_3).$$

This is true, by Cramer's rule, because the determinant of the system's matrix is

$$\Delta = \begin{vmatrix} x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \\ 1 & 1 & 1 \end{vmatrix}$$

and $\Delta \neq 0$, as $Area\,(ABC) = \frac{1}{2}|\Delta| \neq 0$, which ends the proof.

**Theorem 3**. Considering a fixed triangle ABC in a plane, with the sides [AB], [AC] and [BC] made of homogenous materials of masses $\mu_1, \mu_2, \mu_3 \geq 0$, the mass center of the the triangle ABC can be any point of $D_{MNP}$, where M, N and P are the middle points of the sides [AB], [AC] and [BC].

*Proof.* From the physical point of view, the triangle ABC can be viewed as mass equivalent to the the system $S = \{M(\mu_1), N(\mu_2), P(\mu_3)\}$ and, by applying Theorem 1, we obtain the desired result.

**Theorem 4**. Let be a triangular plate ABC, where A, B and C are fixed points in a plane and we assume that the density function $\rho: ABC \to \mathbb{R}_+$ is integrable. Then, any point of $D_{ABC}$ can be the mass center of such a triangle plate.

*Proof.* The mass center of the plate ABC is $G(x_G, y_G)$, where

$$x_G = \frac{\iint_{ABC} x\,\rho(x,y)dxdy}{\mu}$$

$$y_G = \frac{\iint_{ABC} y\,\rho(x,y)dxdy}{\mu}$$

and the mass of the plate ABC is

$$\mu = \iint_{ABC} \rho(x,y)\,dxdy.$$

The triangle ABC, along with its interior, is a compact set in $\mathbb{R}^2$, as it is closed and bounded and we consider the projections

$x_m = \min pr_{Ox}ABC$ , $x_M = \max pr_{Ox}ABC$, and

$y_m = \min pr_{Oy}ABC$ , $y_M = \max pr_{Oy}ABC$

We have the inequalities:

$$x_m \le x \le x_M, \forall\, x \in \text{ABC}$$

Therefore, by integrating, we obtain

$$x_m = \frac{x_m \iint_{ABC} \rho(x,y)\,dxdy}{\mu} \le x_G$$

$$\le \frac{x_M \iint_{ABC} \rho(x,y)\,dxdy}{\mu} = x_m$$

Analogue,

$$y_m \le y_G \le x_M.$$

Now, for a fixed point $(a,b) \in D_{ABC}$, we consider the case from the Theorem 1, which ends the proof.

## CONCLUSIONS

The interplay between geometry and physics reveals a profound unity between mathematical abstraction and the description of the natural world. The results presented in this paper reinforce the idea that geometric frameworks are not merely auxiliary tools, but essential components in the formulation of physical theories. Through the analysis conducted, it becomes evident that physical phenomena can often be more deeply understood when interpreted through a geometric lens.

Moreover, the continued development of modern physics suggests that geometry will remain a fundamental pillar in future theoretical advancements. As new models and approaches emerge, the refinement of geometric methods will likely play a crucial role in addressing unresolved questions and extending the boundaries of current knowledge (Jost, 2009; Landi et al., 2017).

Ultimately, this article highlights the enduring significance of geometry in physics, emphasizing its capacity to unify concepts, clarify complex relationships, and provide insight into the understanding the structure of reality, because physics and geometry are inseparable.

***Abstract***

*Clean water and sanitation are one of the Sustainable development goals of the United Nations, and this resource needs constant monitoring due to its importance for human health. The aim of this paper was to assess the potential use of functional microbiome method to identify the geographical differences in functional microbiome in Lake Vârșolț, from Sălaj county. Basal community showed small-daily changes due to incubation, which represents a constant activity for the general microbial population. Guild activities presented a 50-100% increase each 24 hours, which sustain both the phenomenon of adaptation to substrate and proliferation due to favorable conditions. In terms of separate activities for functional groups, a different pattern of activity increases was observed for the entire 96 period of incubation. In terms of total microbial activity, the growth curves were 4-5 times in 96 hours, which represents an efficient indicator for short-term monitoring potential microbial development. The analysis of the entire database showed that functional profile is a suitable tool that enables the detection of difference in the microbiome assemblage and the forecasting of functional shifts in the community.*

***Key words****: activity patterns, functional microbiome, geographical distribution, guild and group assemblage, water monitoring.*

## INTRODUCTION

Microbial communities are essential components of aquatic ecosystems, playing a major role in global energy fluxes and biogeochemical cycles (Falkowski et al., 2008). They exhibit high species and genetic diversity, which makes them sensitive to environmental disturbances (Amann & Rossello-Mora, 2016; Levi et al., 2017; Ren et al., 2017). In lakes, the balance of external nutrient loading influences microbial functional genes and associated metabolic processes (Liu et al., 2020).

Microorganisms populate nearly all aquatic ecosystems and are usually among the first to respond to physical and chemical disturbances. As a result, changes in the microbial community structure frequently led to broader changes in the overall health and stability of the environment.

One of the most important services performed by microbial communities in aquatic ecosystems, is the regulation of energy flows and biogeochemical cycles, with bacteria playing a central role. The microorganisms in these ecosystems exhibit high diversity and considerable biomass (Whitman et al., 1998; Battin et al., 2003; Lennon & Locey, 2016).

In lake ecosystems, most microorganisms are found in benthic biofilms, where they play a key role in organic matter mineralization, nutrient, and contaminant transformation (Schiller et al., 2007; Findlay, 2010; Buchkowski et al., 2015). Microbial communities exhibit high genetic diversity, and their taxonomic and functional changes are visible in the flow of ecosystem processes (Newton et al., 2011; Ylla et al., 2014; Hayden & Beman, 2016; Peter & Sommaruga, 2016).

Community-level physiological profiling (CLPP) is a proven approach for identifying spatial and temporal variations in aquatic microbial communities (Nowak et al., 2025; Torrús-Castillo et al., 2026). In the studies of applied ecology, EcoPlates™ are commonly used to assess the stability of microbial communities and detect functional changes triggered by environmental disturbances.

The aim of this paper is to analyze the structure of the functional microbiome within a lake ecosystem based on the community-level physiological profiling approach. The

hypotheses tested were proposed to answer a series of research questions:
i) Is there a difference between functional microbiomes due to geographical distance within the same ecosystem?
ii) Can continuous monitoring of functional activity reveal changes in the community stability?
iii) Do the dominant functional groups show shifts within the community during the incubation time?

## MATERIALS AND METHODS

EcoPlate™ contains 31 organic carbon substrates and a control well, each in three replicates, with redox-sensitive tetrazolium dye, used for community-level physiological profiling (CLPP) of metabolically active heterotrophic bacteria (Stefanowicz et al., 2006). Key CLPP indicators include average well color development (AWCD), which reflects total metabolic activity, and the Sum of activities, which shows both the physiological diversity of microbial communities and the ability of a microbiome to metabolize different substrates (Kenarova et al., 2014; Muniz et al., 2014). Three sampling points were chosen in the lake and analyzed with the EcoPlate tool to score the difference between functional microbiomes recorded on a 96 hour incubation period.
The guilds used in the description of microbial metabolic activity follow the proposal of Stoian et al. (2022). The list of them is separated in 5 large guilds; CX - Carboxylic & acetic acids; AA - Amino acids; CH - Carbohydrates; PX - Polymers; AM - Amines/amides to which is added the SUM, as total metabolic activity; Water - bazal respiration; AWCD-average well color development.
All data were analysed with RStudio (R Core Team, 2024), with a flow of tests created to explore the trends of activity and community assemblage from a general view to an in-depth one. Data from 24, 48, 72 and 96 hours were supposed to a Principal Component Analysis (PCA), in "vegan" package, for the assessment of community stability and differences between sampling points (Oksanen et al., 2022). The ordinations of microbiome and environmental fitting of guild vectors were projected to determine the links between guilds and community stability. A second step for data analysis was performed with "agricolae" package, from which ANOVA and LSD tests were used to record the significant differences between sampling points in terms of guild activity and the total activity (de Mendiburu, 2023). The plate was read continuously every 24 hours up to 120 hours using a BioTek Epoch plate reader at an optical density of 590 nm.
The third step in data analysis was to extract the group with the highest activity within each guild, separately for each sampling point and incubation period. This procedure was performed to create a pattern analysis that can be developed further into a screening for indicator groups at different incubation time.
Biolog EcoPlates were selected for their power to characterize the entire microbial community in environmental matrices and providing insights on spatio-temporal changes and the kinetics of microbiome response to a set of standardized substrates (Zhao et al., 2021; Angelova et al., 2025).

## RESULTS AND DISCUSSIONS

Principal Component Analysis (PCA) highlighted a clear functional differentiation between the three sampling points (W1, W2, and W3), demonstrating the ability of functional microbiome profiling to differentiate geographical variations within the lake (Figure 1, Table 1). The first principal component (PC1) explained most of the variability and distinctly separated the samples from W3 from those from W1 and W2, suggesting the existence of a functional ensemble specific to this area and a different pattern of substrate use. W1 and W2 showed relatively similar profiles, being positioned in the negative region of PC1, but a moderate separation on PC2 indicates subtle differences in the dynamics of microbial activities. The more pronounced dispersion of samples from W1 suggests higher functional variability, while the compact grouping of samples from W2 indicates a more stable structure. The vectors associated with the model highlight the differentiated contribution of certain metabolic activities to the total explained variance (95%). Both Sum and CH vectors were oriented parallel with Axis 1, showing a high degree of importance of CH guild within the

entire community activities. At the opposite, AA vector associated with W3 show an angle toward PC1, which indicate the potential of this guild to reshape the entire microbiome and gain a higher importance within community.

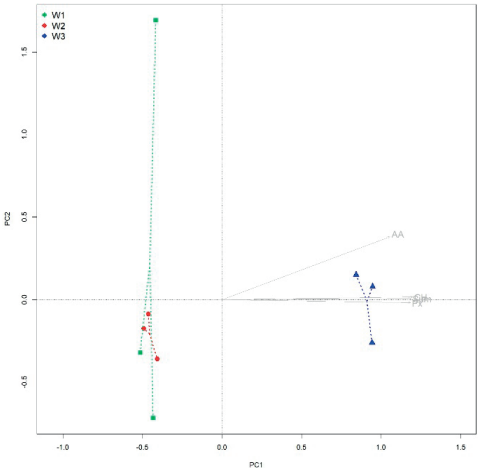

Figure 1. PCA projection of microbial communities and guild vectors at 24 h of incubation

Table 1. Vector fitting and importance on PCA projection (24 h)

| | PC1 | PC2 | r2 | p.val | |
|---|---|---|---|---|---|
| Sum | 0.99999 | 0.00518 | 0.9795 | 0.002 | ** |
| PX | 0.99987 | -0.01593 | 0.974 | 0.005 | ** |
| CH | 0.99992 | 0.01284 | 0.9973 | 0.001 | *** |
| CX | 0.64094 | -0.76759 | 0.05 | 0.887 | |
| AA | 0.94095 | 0.33854 | 0.875 | 0.002 | ** |
| AM | -0.58727 | -0.80939 | 0.6007 | 0.066 | . |

Note: * - significant; ** - distinct significant; *** - very significant. Variance explained by Axis 1=92.64% and Axis 2=2.76%.

PCA analysis highlights a clear separation of the three sampling points along the PC1 axis (Figure 2, Table 2). W3 is positioned in the positive region of PC1 and is associated with variables oriented in the same direction (particularly AM, AA, PX, and Sum), suggesting increased intensity of metabolic activities corresponding to these functional groups. In contrast, W1 and W2 are located in the negative region of PC1, indicating functional profiles distinct from W3. The separation on PC2 further differentiates W1 (negative values) from W2 (positive values), suggesting differences in the dynamics of microbial activities between these two locations. Longer vectors indicate a significant contribution of certain metabolic activities to the total variation explained by the model, confirmed by the existence of pronounced functional heterogeneity between the analyzed points.

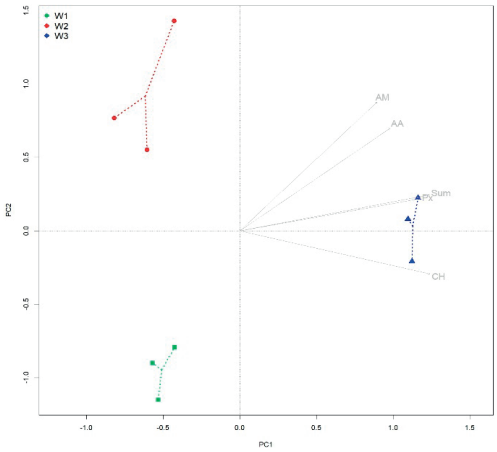

Figure 2. PCA projection of microbial communities and guild vectors at 48 h of incubation

Table 2. Vector fitting and importance on PCA projection (48 h)

| | PC1 | PC2 | r2 | p.val | |
|---|---|---|---|---|---|
| Sum | 0.98097 | 0.19416 | 0.9571 | 0.001 | *** |
| PX | 0.983 | 0.18362 | 0.8653 | 0.011 | * |
| CH | 0.97276 | -0.23183 | 0.9766 | 0.001 | *** |
| CX | 0.63794 | 0.77009 | 0.5259 | 0.103 | |
| AA | 0.81389 | 0.58102 | 0.8735 | 0.001 | *** |
| AM | 0.7142 | 0.69994 | 0.9454 | 0.001 | *** |

Note: * - significant; ** - distinct significant; *** - very significant. Variance explained by Axis 1=77.68% and Axis 2=11.62%.

The variance explained by the two axis is 89%, indicating both the dispersion of data in the ordination plan and the amplification of differences between communities. The Sum of activities and PX guild have coupled vectors, indicating the potential perturbation role of this guild within community. AM and AA vectors are oriented toward the higher part of the ordination and their opposite direction against W2 and W1 indicate the reduced activity within community. CH vector makes an angle with these two guilds, with a lower trend of direction. This guild is associated with one of the W3 points, indicating the potential arise of a different assembled community. Both W1 and

W3 show community similarity and stability, due to the low dispersion of points, and only small differences due to the group-activity pattern.

In this analysis, the separation on PC1 is even more pronounced, with W3 showing a clear separation in the positive area of the axis and correlated with the variables AA, AM, and PX, indicating a specific functional profile characterized by metabolic activity oriented to these substrates. W1 and W2 are grouped in the negative area of PCA but show a clear separation through PC1 and a corner position (Figure 3, Table 3).

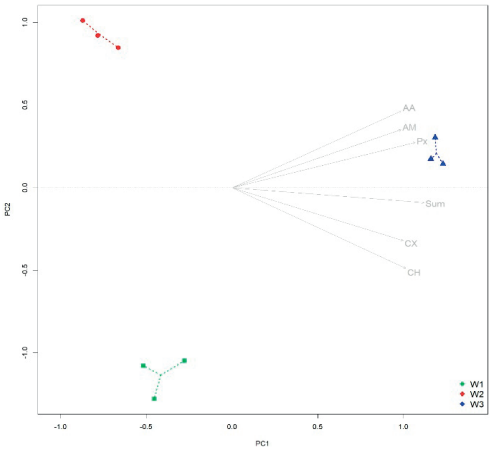

Figure 3. PCA projection of microbial communities and guild vectors at 72 h of incubation

Table 3. Vector fitting and importance on PCA projection (72 h)

| | PC1 | PC2 | r2 | p.val | |
|---|---|---|---|---|---|
| Sum | 0.9968 | -0.07997 | 0.9949 | 0.001 | *** |
| PX | 0.96861 | 0.24857 | 0.9584 | 0.012 | * |
| CH | 0.90068 | -0.43448 | 0.9954 | 0.001 | *** |
| CX | 0.95199 | -0.30614 | 0.8663 | 0.001 | *** |
| AA | 0.90497 | 0.42548 | 0.9366 | 0.001 | *** |
| AM | 0.94205 | 0.33549 | 0.8627 | 0.018 | * |

Note: * - significant; ** - distinct significant; *** - very significant. Variance explained by Axis 1=66.78% and Axis 2=18.58%.

The 85% of variance explained by the entire PCA is associated with the increased general activity (Sum vector), while all three communities became stable. The differences between communities are more visible due to their position in different quadrants. In the upper part of the ordination, AA, AM and PX guilds are associated within the same community, and their position makes them the candidates for W3 shift. All the guild vectors have an orientation against W1 and W2, indicating that a mix of group activities are responsible for the community specific assemblage.

PC1 represents the central axis of geographical differentiation, clearly separating W3 from W1 and W2 (Figure 4, Table 4). The samples from W3 are strongly positively correlated with the AA and AM, suggesting a functional profile characterized by increased metabolic activity. W1 and W2 are in the negative section of PC1, but they're different on PC2, showing extra variation in functional dynamics. W1 shows more negative values on PC2, while W2 is in the positive area, indicating a different structure of microbial activities. The direction of the vectors in the positive area of PC1 confirms the important role of certain functional groups in the spatial separation of microbial communities.

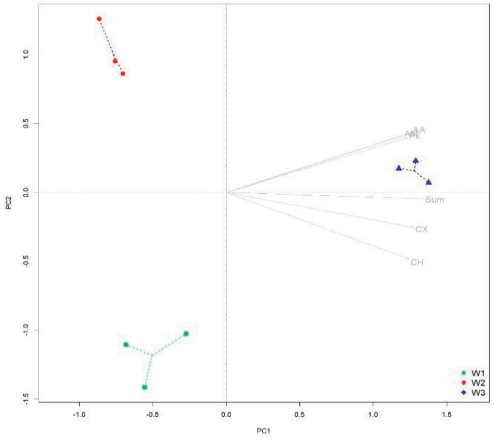

Figure 4. PCA projection of microbial communities and guild vectors at 96 h of incubation

At plateau phase, the variance explained reach 82%, with the Sum vector being the only very significant one. This vector is closed to PC1, in the middle of the angel formed by AA+AM and CH+CX vectors. This indicate that each of the two community types can be observed during the continuous evolution of the microbiome. While AA and AM are closed to each other, indicating a correlated evolution of this community type, in the case of CX and CH, a small angle can be observed, which indicates a direction to one of these guilds.

Table 4. Vector fitting and importance on PCA projection (96 h)

| | PC1 | PC2 | r2 | *p* - value | |
|---|---|---|---|---|---|
| Sum | 0.9994 | -0.03458 | 0.9962 | 0.001 | *** |
| PX | 0.95188 | 0.30647 | 0.9248 | 0.005 | ** |
| CH | 0.93178 | -0.36302 | 0.9817 | 0.001 | *** |
| CX | 0.98066 | -0.19573 | 0.9333 | 0.011 | * |
| AA | 0.94472 | 0.32789 | 0.98 | 0.002 | ** |
| AM | 0.94688 | 0.3216 | 0.8845 | 0.007 | ** |

Note: * - significant; ** - distinct significant; *** - very significant. Variance explained by Axis 1=65.54% and Axis 2=16.51%

In the initial phase (Table 5), all groups (CH, CX, PX, AA, AM) show low values, which are characteristic of the period of substrate adaptation. CH and AA have more significant contributions in W1 and W2, indicating initial activity focused on the use of more easily metabolizable compounds. CX shows moderate variability between samples, with no significant differences, while PX and AM record the lowest values, suggesting limited activity of these guilds in the initial phase. W2 has the highest total value (SUM), which suggests a community with more active initial metabolic potential, but the overall.

Table 5. General and guild activity at 24 h of incubation

| Sample | CH | CX | PX | AA | AM | SUM |
|---|---|---|---|---|---|---|
| W1 | 0.27±0.16 b | 0.06±0.03 a | 0.14±0.08 b | 0.21±0.12 b | 0.13±0.07 a | 0.51±0.29 b |
| W2 | 0.33±0.19 b | 0.34±0.19 a | 0.17±0.10 b | 0.20±0.11 b | 0.01±0.00 a | 0.86±0.49 b |
| W3 | 0.23±0.13 a | 0.13±0.07 a | 0.12±0.07 a | 0.14±0.08 a | 0.03±0.02 a | 0.53±0.30 a |

After 48 hours, all guilds show significant increases, indicating the start of the proliferation phase (Table 6). CH and CX are dominant, especially in W3, where they show the highest values and contribute significantly to the increase in total activity. PX and AA also show a clear intensification of activity, suggesting an expansion of the range of substrates used. The AM guild, although still lower in number than the others, begins to grow more visible, suggesting the activation of additional metabolic pathways. The differences between samples become clearer, with W3 highlighted by a higher functional response.

Table 6. General and guild activity at 48 h of incubation

| Sample | CH | CX | PX | AA | AM | SUM |
|---|---|---|---|---|---|---|
| W1 | 6.52±0.36b | 4.56±0.26a | 1.96±0.27b | 2.74±0.11b | 0.49±0.10b | 16.2±0.84b |
| W2 | 4.43±0.59c | 5.47±0.43a | 2.38±0.31b | 4.07±0.95ab | 1.27±0.23a | 17.6±2.19b |
| W3 | 11.0±0.16a | 5.68±0.36a | 4.04±0.15a | 5.62±0.20a | 1.71±0.17a | 28.0±0.27a |

Note: Different letters after means ± SE indicate significant differences at $p<0.05$ based on LSD test.

CH and CX remain dominant in the functional profile, especially in W3, where values are significantly higher compared to W1 and W2 (Table 7). PX and AA show constant increases, suggests a diversification of metabolism and a more complex use of available substrates. AM becomes better represented, which may indicate microbial succession processes and trophic interactions. W2 shows the lowest values for most groups, suggesting a limited metabolic capacity.

Table 7. General and guild activity at 72 h of incubation

| Sample | CH | CX | PX | AA | AM | SUM |
|---|---|---|---|---|---|---|
| W1 | 8.94±0.34b | 7.25±0.13b | 2.39±0.28b | 3.54±0.09b | 0.71±0.20b | 22.8±0.84b |
| W2 | 4.01±0.55c | 6.02±0.29b | 2.66±0.25b | 4.48±0.21b | 1.03±0.19b | 18.2±0.85c |
| W3 | 12.4±0.13a | 8.71±0.52a | 5.63±0.15a | 6.95±0.46a | 2.52±0.25a | 36.2±0.76a |

At 96 hours, the highest values for all groups are observed, and the differences between samples are most evident at this stage (Table 8). W3 has the highest values for CH, CX, PX, AA, and AM, which indicates a higher capacity to utilize different types of substrates. CH and CX remain the dominant groups, but PX, AA, and especially AM also increase significantly, indicating a more advanced microbial community structure and a more diversified use of resources. W1 has an intermediate level of activity, and W2 has the lowest values for most groups. The evolution of groups over time shows consistent functional differences between sampling locations and confirms the value of group analysis in the determination of variations in the microbial community (Table 9).

Seasonal stratification is a major factor influencing the dynamics of microbial communities, especially in deep lakes, where temperature, oxygen, and nutrient gradients form distinct ecological niches (Winder & Sommer, 2012; Liu & Santamarina, 2024). Microbial communities are influenced by both deterministic, niche-based processes and stochastic mechanisms, including environmental selection and ecological drift (Chase & Myers, 2011; Stegen et al., 2013; Zhang et al., 2021).

Flowing water systems (rivers – lotic ecosystems) and standing water systems (lakes – lentic ecosystems) are essential components of terrestrial aquatic ecosystems, playing a major role in global biogeochemical processes (Maavara et al., 2020; Battin et al., 2023).

Hydrological factors, such as flow rates, water levels, retention times, and precipitation, influence the nutrient cycle and, shaping the structure of bacterial communities, can lead to biodiversity decline (Shabarova et al., 2021; Zhang et al., 2021; Chen et al., 2023).

## CONCLUSIONS

The study highlights that functional analysis of the aquatic microbiome is an effective tool for identification of spatial differences between microbial communities in lake ecosystems. Results from CLPP analysis with EcoPlate™ showed distinct metabolic profiles between the sample points (W1, W2, and W3). PCA analysis revealed a distinct separation of samples, especially from W3, which indicates the existence of a functional profile specific to this location and a different pattern of organic substrate utilization. While points W1 and W2 showed relatively similar functional profiles, W3 was characterized by higher metabolic intensity and a greater capacity to utilize different types of substrates.

The functional dynamics of microbial communities showed a progressive increase in metabolic activity during incubation. In the initial stage, the values of all functional groups (CH, CX, PX, AA, and AM) were low, which reflects the period of adaptation of microorganisms to the substrate. After 24 hours, a significant increase in metabolic activity was observed, mainly for the CH and CX groups, which were dominant in the functional profile. As incubation progressed, all groups showed a gradual increase in metabolic activity, suggesting a diversification of metabolism and a more complex use of available resources.

At 96 hours, the highest values were recorded for all functional groups, with differences between sampling points being more evident. W3 showed the highest metabolic activity and substrate utilization capacity, which indicates a more active and diverse microbial community. In contrast, W2 recorded the lowest values for most functional groups, suggesting a lower metabolic capacity or a faster stabilization of microbial activity.

The results show that the analysis of functional groups and substrate utilization can highlight important differences between microbial communities in different areas of the lake. These methods are useful for understanding the metabolic dynamics and adaptation of the microbiome to environmental conditions, confirming the value of functional analyses for monitoring spatial variations and ecological changes in aquatic ecosystems.

The results support the fact that functional analysis is an effective tool for identifying spatial heterogeneity and monitoring potential functional changes in microbial communities in lake ecosystems.

## ACKNOWLEDGEMENTS

This paper is part of a PhD study in the thematic area of *"Microbiological quality of water and its role in ensuring the safety of agri-food products"*, conducted by the first author P.P., under the coordination of Prof. dr. Roxana Vidican (R.V.).

***Abstract***

*A sustainable green future depends on developing competencies in advanced technologies across energy, agriculture, and industry for graduate students of Master`s and Doctoral programs. This study aimed to assess graduate students' perceptions from three European universities regarding the key sustainability strategies through a structured survey focusing on digitalisation, agriculture, biodiversity conservation, and the circular economy. The majority of graduate students agreed that renewable energy reduces carbon footprint, air and water pollution, and enhances public health. Students demonstrated a clear understanding of the EU Green Agriculture objectives, emphasizing food security and environmental footprint reduction. Positive perceptions extended to biodiversity conservation, with support for effective management, monitoring, and clear conservation goals. Respondents endorsed circular economy principles, including resource efficiency, material redesign, and waste recapture, and aligned with the EU's industrial strategy for a progressive and sustainable economic transition. These findings indicate that the graduate students possess both awareness and favourable attitudes toward advanced technological solutions for sustainability. The results underscore the successful implementation of digital resources developed in academic curricula for students from Master`s and Doctoral programs from three European universities.*

***Key words****: graduate student competencies, green agriculture, sustainable.*

## INTRODUCTION

In the context of the profound structural transformations driven by the European Green Deal, European higher education plays a major role in shaping a new professional elite capable of operationalising the transition towards a climate-neutral economy (Borel-Saladin et al., 2013). The success of complex macro-structural initiatives such as the Common Agricultural Policy (CAP) or the "Farm to Fork" strategy is directly contingent upon the translation of theoretical directives into applied technical competencies and digital literacy (Matthews, 2013). These policy frameworks increasingly rely on data-driven decision-making, sustainability metrics, and cross-sectoral knowledge integration (Pe'er et al., 2020). Agricultural digitalisation (smart agriculture), precision farming systems, and the integration of Geographic Information Systems (GIS) are widely recognised as fundamental pillars of modern agro-ecosystem management (Wolfert et al., 2017; Mathenge et al., 2022). In parallel, advanced biotechnologies such as genomics, bioinformatics, and molecular breeding, alongside Big Data analytics and artificial intelligence infrastructures, are reshaping the resilience and productivity of primary production systems (Kamilaris et al., 2017; Liakos et al., 2018). These technological paradigms collectively underpin the ongoing transition towards Agriculture 4.0 and data-intensive sustainability governance (Klerkx et

al., 2019). To mitigate these asymmetries and ensure integrated training, an advanced educational programme was designed and implemented in the form of an intensive course, type blending learning with digital tools. This course adopted an interdisciplinary approach, addressing the pillars of sustainable development, the application of digital technologies in optimising primary production systems, and policy mechanisms for biodiversity conservation and ecosystem resilience The studies performed aimed to assess the competencies of doctoral and master's students in advanced technologies related to a sustainable green future in energy, agriculture, and industry, within the context of completion of a short intensive training program type blending learning, regarding the European Green Deal, using an anonymous cross-sectional survey

## MATERIALS AND METHODS

The studies performed were based on cross-sectional survey questionnaires involving 51 doctoral and master's students from five universities that participated at a short intensive learning training teaching program in the field of the European Green Deal. At the end of this session, participants in the intensive courses were invited to answer a specific survey questionnaire anonymously in order to assess their competencies in advanced technologies for a sustainable green future in energy, agriculture, and industry.

The participants (students) belong to the following universities:

- University of Agronomic Sciences and Veterinary Medicine of Bucharest (USAMVB), Romania;
- National University of Sciences and Technology Politehnica of Bucharest (UNSTPB), Romania;
- University Autonoma de Barcelona Spain (UAB Spain);
- University of Porto Portugal (UPorto Portugal);
- Uzhhorod National University Ukraine (Uzhhorod Univ_Ukraine).

Each group consisted of at least 10 participants per university.

The Survey Questionnaires were completed anonymously. Data were structured in a survey questionnaire based on a 5-point Likert scale, as follows:

1 = No, not at all;
2 = Only to a certain extent;
3 = More or less;
4 = Mostly yes;
5 = Yes, always.

The questionnaire assessed the students' perceptions regarding the following sentences:

B1: Do you think that the utilization of renewable energy reduces carbon footprint, air pollution and water environmental impact, but also improves public health?

B2: Do you think that remote sensing and GIS-based technologies for sustainable management of agriculture are important?

B3: Do you consider that the main objective of the EU Green Agriculture politics is to ensure food security by reducing environmental footprint and assuring competitive sustainability from farm to fork?

B4: Do you agree that the EU's Common Agricultural Policy is central to the EU Green Deal & its Farm to Fork and Biodiversity strategies?

B5: Do you think that genomics, bioinformatics, and big data in sustainable food production are useful for agriculture and food production systems

B6: Do you think that the EU target for Biodiversity conservation is effectively managing all protected areas, defining clear conservation objectives and measures, and monitoring them appropriately?

B7: Do you think that digitalization can be useful in the Global Biodiversity Assessment

**Statistical analysis**: All data are presented as means ± standard errors.

## RESULTS AND DISCUSSIONS

The results highlight a high level of student awareness regarding the role of digital technologies and European policies in promoting agricultural sustainability, biodiversity conservation, and the transition towards a green economy. With respect to the environmental impact of renewable energy sources (Figure 1), most respondents assigned

high scores (4 and 5), with 80% of responses falling within these categories. This finding indicates a solid understanding of the benefits of renewable energy in reducing carbon emissions, pollution, and natural resource degradation. Similar results have been reported in studies examining environmental literacy among European students, which indicate growing awareness of renewable energy as a key component of sustainable development and climate change mitigation strategies (Probst, 2022; Sanchez et al., 2025). The increasing visibility of renewable energy within European sustainability policies may further contribute to students' positive perceptions of its environmental benefits. Regarding the importance of GIS in agriculture (Figure 2), responses were largely positive, with 80% of students assigned scores of 4 or 5. This fact indicates strong awareness of the role of geospatial technologies in agricultural monitoring and management optimisation. This result is consistent with recent research demonstrating that GIS, remote sensing, precision agriculture, and artificial intelligence technologies contribute significantly to improving resource-use efficiency, crop monitoring, and sustainable land management practices (Finger, 2023; Wójcik-Gront et al., 2024).

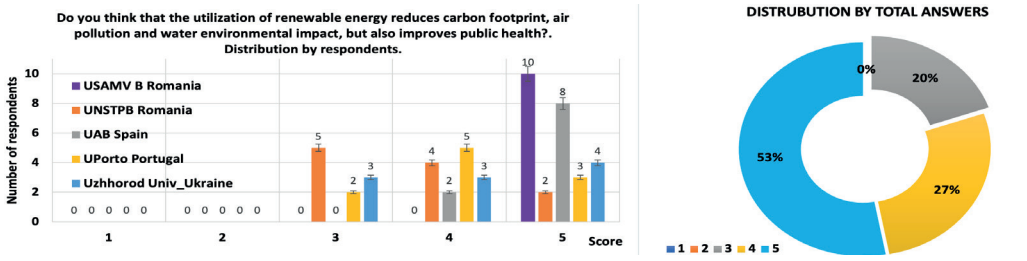

Figure 1. Assessment of the students' perceptions regarding the environmental impact of renewable energy sources

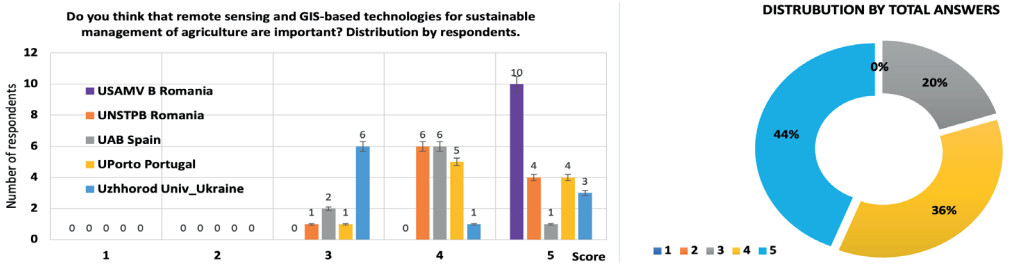

Figure 2. Assessment of the students' perceptions regarding the importance of GIS in agriculture

The high level of agreement observed among respondents suggests that students increasingly understand and recognise the importance of Agriculture 4.0 technologies in supporting sustainable and resilient agricultural systems. Assessment of students' perceptions regarding the objectives of EU green agricultural policies in relation to food security, the reduction of environmental impacts, and the promotion of sustainable competitiveness throughout the food supply chain is presented in the Figure 3.

The predominance of answers with scores 4 and 5 (71%) suggests that respondents understand and recognise the strategic importance of these policies in balancing food security with environmental sustainability This perception aligns with the objectives of the European Green Deal and the Farm to Fork Strategy, which aim to transform food systems by reducing environmental pressures while ensuring food security, economic viability, and social sustainability (Guyomard et al., 2023; Hamam et al., 2021; Radu et al., 2007; Radu et al., 2020). The relatively high proportion of moderate-agreement responses may reflect uncertainties about the practical implementation, economic feasibility, or long-term effectiveness of these measures.

Regarding the connection between the Common Agricultural Policy (CAP) and European Green Deal (Figure 4), the results reveal a predominantly positive perception of the CAP as a key policy instrument supporting the EU Green Deal, the Farm to Fork Strategy, and the Biodiversity Strategy too.

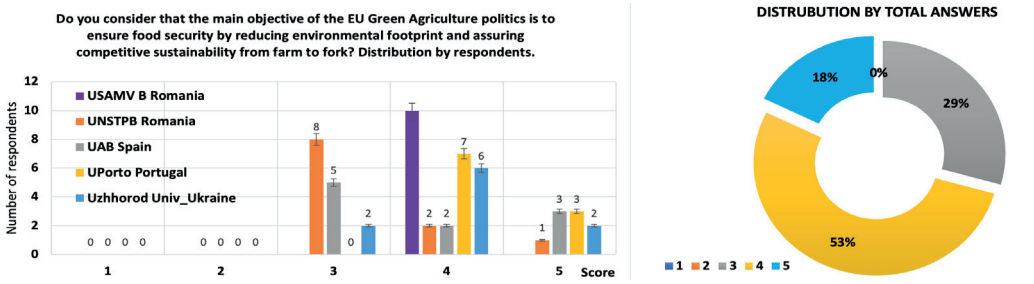

Figure 3. Assessment of students' perceptions regarding the objectives of EU green agricultural policies in relation to food security, the reduction of environmental impacts, and the promotion of sustainable competitiveness throughout the food supply chain

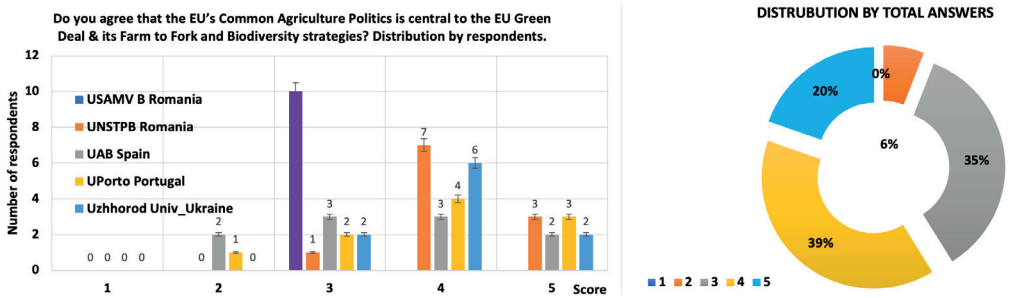

Figure 4. Assessment of the students' perceptions regarding the connection between the Common Agricultural Policy (CAP) and European Green Deal

The combined proportion of agreement and strong agreement responses (59%) demonstrates substantial support for the CAP's role in advancing sustainable agricultural development and environmental objectives across Europe. Similar findings have been reported by (Probst, 2022; Sanchez et al., 2025), who observed that university students increasingly recognise the importance of policy instruments in achieving sustainability transitions within agri-food systems. However, 35% of respondents selected score 3, indicating a moderate level of agreement. The overall findings suggest moderate-to-high awareness of the relationship between agricultural policy and sustainability goals. Responses concerning the contribution of genomics, bioinformatics, and big data to sustainable food systems (Figure 5) were predominantly positive, with 66% of respondents assigning scores of 4 or 5. This finding suggests that students acknowledge the potential of advanced biotechnologies to improve sustainability, productivity, and resource-use efficiency. Recent studies have highlighted the growing role of genomics, artificial intelligence, and data-driven approaches in supporting climate-smart agriculture, precision farming, and sustainable food production systems (Finger, 2023; Getahun et al., 2024; Ronzhin et al., 2025). These technologies are increasingly regarded as essential tools for addressing global challenges related to food security, environmental degradation, and climate change. Biodiversity conservation policies (Figure 6) were strongly acknowledged, with nearly 67% of responses receiving scores of 4-5, suggesting a high level of awareness of ecosystem protection priorities and conservation strategies. This result is in agreement with the increasing of biodiversity conservation within international policy agendas, particularly following the adoption of

the Kunming-Montreal Global Biodiversity Framework, which established ambitious targets for halting biodiversity loss by 2030 (Hughes & Grumbine, 2023).

The findings indicate that students are aware of the importance of biodiversity conservation as a prerequisite for ecosystem resilience and sustainable development. The usefulness of digitalisation in global biodiversity assessment (Figure 7) was positively evaluated, with 75% of respondents assigning high scores. This result demonstrates strong confidence in the contribution of digital technologies to biodiversity monitoring and management. The finding is supported by recent literature highlighting the transformative role of artificial intelligence, remote sensing, geographic information systems (GIS), and big data analytics in biodiversity assessment and conservation planning (Jetz et al., 2019; Hughes & Grumbine, 2023).

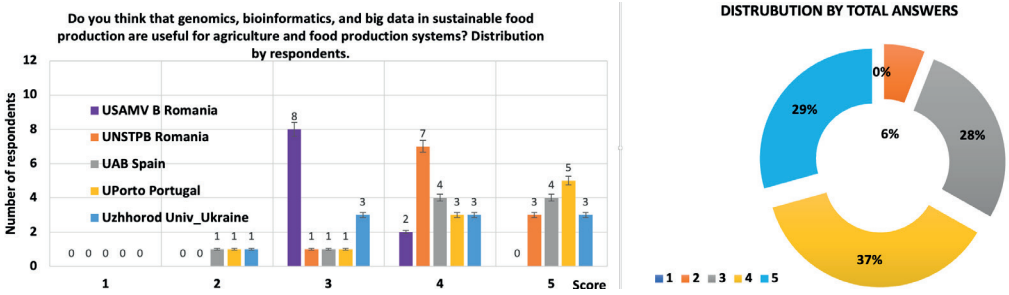

Figure 5. Assessment of the students' perceptions regarding the contribution of genomics, bioinformatics, and big data to sustainable food systems

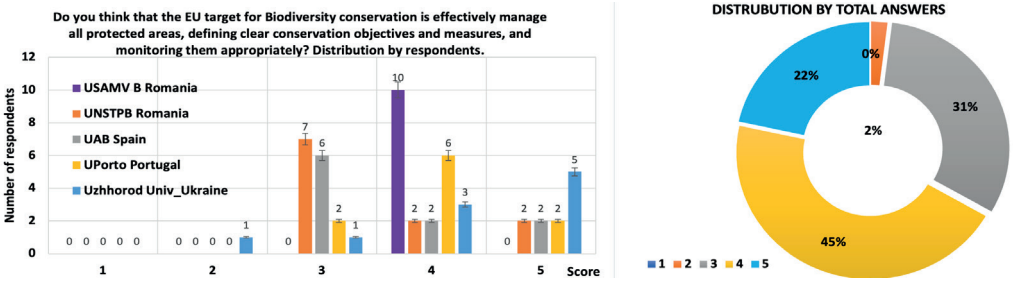

Figure 6. Assessment of the students' perceptions regarding EU Biodiversity conservation policies

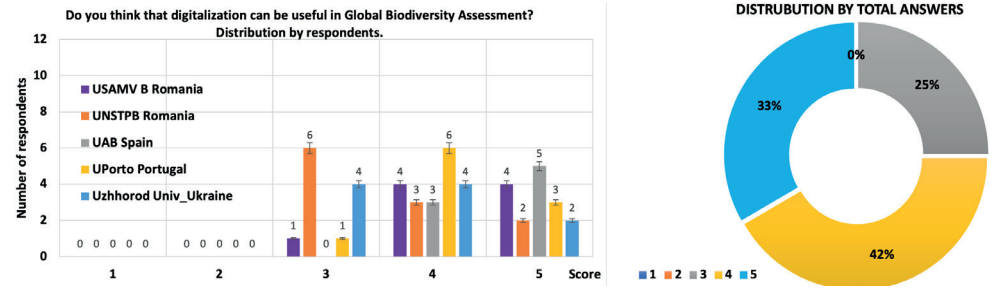

Figure 7. Assessment of the students' perceptions regarding the usefulness of digitalisation in global biodiversity assessment

Digital technologies enable large-scale ecological monitoring, improve data integration, and support evidence-based decision-making processes. Furthermore, advances in digital monitoring systems are considered essential for achieving the targets

established by the Kunming-Montreal Global Biodiversity Framework and for strengthening biodiversity governance at regional and global levels (Hughes & Grumbine, 2023).

Overall, the results indicate high levels of sustainability awareness and understanding among students from Romania, Spain, Portugal, and Ukraine, with limited inter-university variation and broadly consistent response patterns across cohorts.

A high level of environmental literacy among university students across Romania, Spain, Portugal, and Ukraine was obtained, particularly in relation to biodiversity conservation and the perceived role of digital technologies in ecological monitoring. This aligns with a broader shift in environmental education, which increasingly emphasizes systems thinking and the integration of technological competencies into sustainability-related curricula (Pauw et al., 2015; Reid, 2019).

A key finding is the strong endorsement (75%) of digitalisation in global biodiversity assessment. This reflects growing recognition of the role of emerging technologies such as artificial intelligence, remote sensing, geographic information systems (GIS), and big data analytics in transforming conservation science. These technologies enable continuous collection and integration of ecological data across spatial and temporal scales, improving biodiversity modelling, forecasting, and risk assessment (Radu et al., 2006; Dima et al., 2007; Pettorelli et al., 2014; Kissling et al., 2018; Jetz et al., 2019). Recent developments in digital Earth observation systems and AI-driven ecological monitoring further reinforce this transition toward data-intensive conservation paradigms (van der Plas et al., 2025; Miao et al., 2026). The expansion of global biodiversity platforms and digital infrastructure has also been identified as central to strengthening biodiversity governance and decision-making under rapid environmental change (Güntsch et al., 2025). The results are consistent with global scientific consensus that digital innovation is becoming indispensable for biodiversity governance. Similarly, the Kunming–Montreal Global Biodiversity Framework explicitly calls for strengthened monitoring systems, improved data accessibility, and the use of digital tools to support the implementation and evaluation of biodiversity targets. In this context, the positive student evaluations suggest an awareness of not only ecological challenges but also of the governance mechanisms required to address them. Furthermore, the limited variation across universities indicates a relatively homogeneous perception of sustainability and digitalisation in biodiversity contexts. This may reflect the increasing harmonisation of environmental science curricula across Europe, driven by the Bologna Process and the integration of sustainability competencies into higher education frameworks (Malmio & Liwång, 2023). Such consistency is important, as it suggests that future professionals across these countries may share a common conceptual foundation for addressing transboundary environmental challenges.

Overall, the data indicate a strong alignment between student perceptions and current scientific and policy directions in biodiversity conservation.

However, while optimism toward digital tools is justified, the literature also highlights persistent challenges, including unequal access to technology, data governance issues, and the need for interdisciplinary capacity building to ensure effective implementation (Pettorelli et al., 2014; Hughes & Grumbine, 2023).

## CONCLUSIONS

The survey revealed a generally high level of awareness among students regarding digitalization, biodiversity conservation, sustainable agriculture, and circular economy principles.

Digital technologies were widely recognized as valuable tools for biodiversity assessment and environmental monitoring, reflecting current trends in digital transformation and ecological management. Students demonstrated a good understanding of the relationship between the Common Agricultural Policy, the European Green Deal, and the Farm to Fork and Biodiversity strategies, although some neutral responses suggest opportunities for further educational interventions.

Genomics, bioinformatics, and big data were perceived as important contributors to future

sustainable food production systems, indicating growing acceptance of advanced agricultural technologies.

Biodiversity conservation and protected area management received strong support, highlighting the perceived importance of effective environmental governance.

The circular economy obtained the highest level of agreement among respondents, emphasizing the increasing relevance of resource efficiency and waste valorization concepts within sustainability education.

Collectively, these findings indicate that students from the participating European universities possess substantial sustainability literacy and recognize the importance of technological innovation and policy integration in addressing global environmental challenges.

## ACKNOWLEDGEMENTS

This research work was carried out with the support of the University of Agronomic Science and Veterinary Medicine of Bucharest, Romania, and was financed by the Project number: 2023-1-RO01-KA220-HED-000154433 entitled: Gender, Digitalization, Green: Ensuring a Sustainable Future for all in Europe.

***Abstract***

*This study evaluates the students' satisfaction with gamification tools in learning sessions on green digitization across Spain, Romania, and Portugal. Graduate participants were surveyed to assess how the gaming-based system influenced engagement, learning, and motivation. Questions focused on the effectiveness of gamification in encouraging participation, the perceived value of participation awards, the correlation between game points and progress, and the impact on learning outcomes. Results indicate that students responded positively, reporting increased participation due to gamified elements, satisfaction with awards, and a clear alignment between points and game levels. Moreover, participants highlighted improved learning outcomes and a deeper understanding of course content as a direct result of the gaming system. These findings suggest that gamification can be a powerful tool in higher education for Master`s and Doctoral programs, particularly for courses addressing digital and green transformation, fostering both motivation and effective learning among graduate students from three European universities.*

***Key words****: gamification, green, learning tools.*

## INTRODUCTION

The integration of gamification into digital education has become a prominent strategy for enhancing student engagement, motivation, and learning effectiveness in higher education environments. Gamification, defined as the use of game design elements in non-game contexts, has been increasingly applied to support active learning and improve learner participation in digitally mediated instructional settings (Christopoulos & Mystakidis, 2023). Recent studies emphasize that gamified learning environments can enhance intrinsic motivation through mechanisms such as feedback loops, points systems, and progress visualization, which align with self-determination theory and flow-based learning models (Ratinho & Martins, 2023; Oliveira & Hamari, 2024). In parallel, the concept of green digitisation education has emerged as a critical interdisciplinary domain, combining sustainability literacy with the development of digital competence. This educational paradigm aims to equip learners with the skills necessary to navigate and contribute to environmentally sustainable digital transformation processes (Spilotro et al., 2026). Within this context, gamification has been proposed as a pedagogical tool capable of bridging abstract sustainability concepts with interactive and experiential learning models (Seaborn & Fels, 2015; Oliveira et al., 2023). Despite growing theoretical support, empirical evidence regarding the effectiveness of gamification in enhancing participation and learning outcomes in green digitisation education remains limited, particularly across multi-institutional European cohorts. This study aimed to evaluate the students' perceptions regarding the use of gamified educational tools, implemented across five European universities, focusing on

engagement, perceived learning, motivation, and overall satisfaction. The digital tool with gamification elements was developed to improve students' knowledge and understanding of the European Green Deal principles across European universities in the Cycle I and II programs.

## MATERIALS AND METHODS

### Study design and participants

The studies performed were based on cross-sectional survey questionnaires involving 51 doctoral and master's students from five universities:

- University of Agronomic Sciences and Veterinary Medicine of Bucharest (USAMV), Romania (PhD Biotechnologies program);
- National University of Sciences and Technology Politehnica of Bucharest (UNSTPB), Romania (Master Computer Science program);
- University Autonoma de Barcelona (UAB), Spain (PhD Biochemistry and Environment program);
- University of Porto (UPorto), Portugal (PhD Chemical Engineering and Environment program);
- Uzhhorod National University (Uzhhorod), Ukraine (Master of Computer Science program).

Each group consisted of at least 10 participants. The Survey Questionnaires were completed anonymously

### Instrument and measurement scale

Data were structured in a survey questionnaire based on a 5-point Likert scale, as follows:

1 = No, not at all;
2 = Only to a certain extent;
3 = More or less;
4 = Mostly yes;
5 = Yes, always.

The questionnaire assessed five dimensions:

A. Gamification-induced participation;
B. Perceived correlation between points and games;
C. Perceived learning improvement;
D. Course satisfaction;
E. Motivation toward digital and green competences.

### Statistical analysis

Responses were analyzed using the mean Likert scores. Statistical analysis was made applying one-way ANOVA (to assess differences across universities), with Tukey post hoc analysis to identify the differences between pairs. The value $p < 0.05$ was considered significant.

Notation:

* $p < 0.05$;
** $p < 0.01$;
*** $p < 0.001$.

## RESULTS AND DISCUSSIONS

### Gamification-driven participation across disciplinary profiles

The results from Question A indicate a pronounced heterogeneity in perceived participation enhancement induced by gamification (Figure 1). The PhD students from the biotechnology program (USAMV of Bucharest, Romania) and biochemistry/environmental sciences (UAB Spain) reported uniformly negative perceptions of participation increase, whereas computer science students (Uzhhorod University and UNSTPB Romania) demonstrated substantially higher engagement levels, feedback loops, which may enhance perceived coherence of gamified systems.

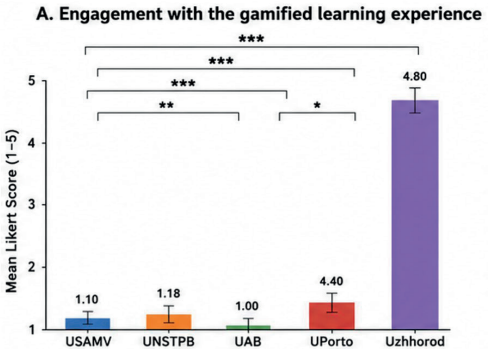

Figure 1. Engagement with the gamified learning experience of the students from USAMV, UNSTPB, UAB, UPorto and Uzhhorod

This disciplinary divergence aligns with recent findings suggesting that learners with stronger computational or systems-oriented backgrounds exhibit higher receptivity to

structured gamified environments, particularly those involving point systems and progression logic (Oliveira et al., 2025; Klock et al., 2026). Computer science students are typically more familiar with algorithmic reward structures and iterative. Conversely, students in biotechnology and biochemical engineering domains often engage in problem-based and experimental learning environments where intrinsic cognitive engagement is less dependent on external reward mechanisms. This may explain their lower responsiveness to gamified participation triggers, consistent with evidence that gamification effects are mediated by prior exposure to digital learning ecosystems (Dicheva et al., 2015). These results indicate statistically significant inter-university differences in perceived engagement (ANOVA $p < 0.05$), suggesting that gamification effectiveness is context-dependent and may be influenced by disciplinary or pedagogical culture.

**Perceived coherence of gamification mechanics (points–game alignment)**

Across all institutions, Question B (Figure 2) revealed generally positive evaluations regarding the alignment between points and game mechanics.

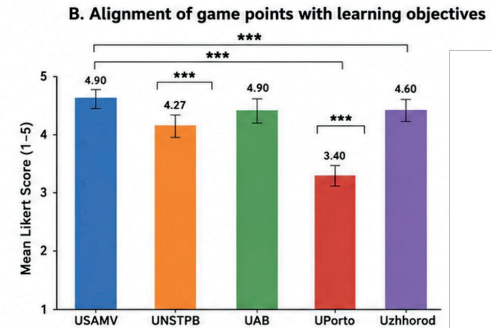

Figure 2. Alignment of the gamification tools with the learning objectives. Answers of the students from USAMV, UNSTPB, UAB, UPorto, and Uzhhorod

However, variation was observed in environmental and chemical engineering students (University of Porto), who reported lower coherence perception compared to computer science cohorts. This finding supports the argument that perceived transparency and structural clarity of gamified reward systems are critical determinants of engagement (Seaborn & Fels, 2015). In particular, students trained in computational disciplines may more easily interpret rule-based scoring systems as logically consistent, while students from life sciences or environmental engineering backgrounds may require more explicit contextual framing of gamification logic. The strong positive responses from USAMV, Uzhhorod University and UAB Spain suggest that when gamification is clearly mapped onto learning tasks, even interdisciplinary cohorts can achieve high perceived system coherence, reinforcing the importance of instructional design consistency (Seaborn & Fels, 2015; Toda et al., 2019; Rodriguez-Calzada et al., 2024).

**Perceived learning outcomes and cognitive integration**

The results for Question C (Figure 3) indicate moderate but consistent perceived learning improvements across all disciplines, with the highest scores observed in computer science students and the lowest in environmental chemical engineering students (University of Porto). This pattern may reflect differences in how gamified systems interact with domain-specific cognitive processing. In computer science education, learning tasks are often procedural and modular, which aligns naturally with gamified structures such as levels, scoring, and incremental progression. This structural compatibility enhances perceived learning gains, as supported by prior studies on gamification in STEM education (Rodrigues et al., 2022; Buenadicha-Mateos et al., 2025). In contrast, biotechnology and biochemical engineering education relies heavily on conceptual integration and experimental reasoning, which may not be directly enhanced by point-based gamification alone. As Ryan and Deci (2020) emphasize, perceived competence and autonomy are key mediators of learning motivation, suggesting that gamification must be carefully calibrated to avoid reducing complex scientific reasoning to superficial reward accumulation (Sailer & Homner, 2020; Ryan & Deci, 2020). Overall, ANOVA results indicate moderate but significant differences between institutions ($p < 0.05$), suggesting that gamification contributes to perceived learning

improvement, but with varying effectiveness across educational contexts.

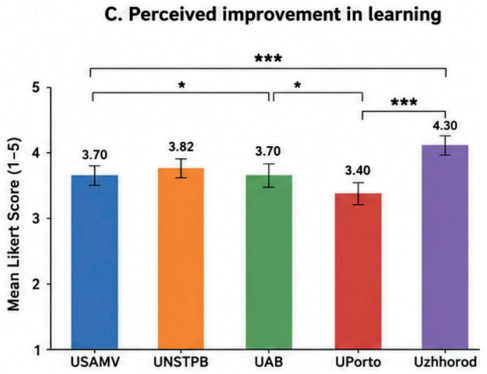

Figure 3. Perceived improvement in the learning process. Opinion of students from USAMV, UNSTPB, UAB, UPorto and Uzhhorod

## Course satisfaction as a function of disciplinary alignment

Overall satisfaction (Question D, Figure 4) was highest among computer science students and lowest among environmental chemical engineering students. This suggests that satisfaction is not only influenced by gamification design but also by disciplinary alignment between pedagogy and cognitive expectations.

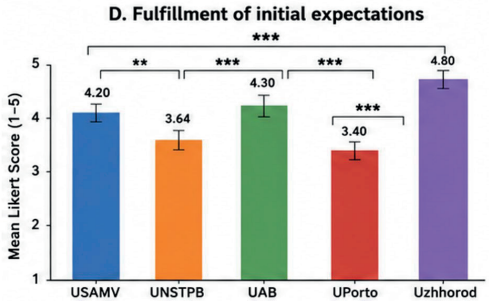

Figure 4. Students' initial expectations fulfilment at USAMV, UNSTPB, UAB, UPorto, and Uzhhorod

Gamified systems appear particularly effective when they reinforce structured problem-solving workflows, as is typical in computer science curricula. This is consistent with findings that gamification increases satisfaction when it supports goal clarity and immediate feedback mechanisms (Ratinho & Martins, 2023; David & Weinstein, 2024). However, in disciplines such as biotechnology and biochemical engineering, where learning is often exploratory and experimental, overly structured gamification may reduce perceived authenticity of learning experiences, leading to lower satisfaction despite similar instructional quality.

## Synthesis: disciplinary mediation of gamification effectiveness

Overall, the data suggest that gamification effectiveness in green digitization education is strongly mediated by disciplinary background. Computer science students consistently exhibit higher engagement, satisfaction, and perceived learning gains, likely due to cognitive alignment with structured digital systems (Question E, Figure 5).

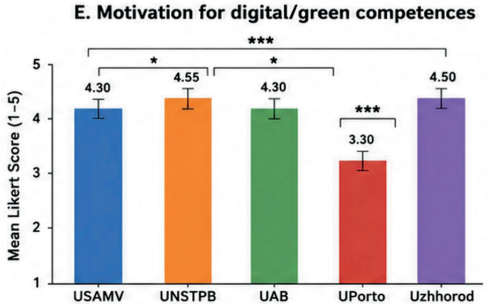

Figure 5. Motivation for digital/green competencies of students from USAMV, UNSTPB, UAB, UPorto and Uzhhorod

In contrast, biotechnology and biochemical engineering students demonstrate more selective responsiveness, indicating that gamification alone may not be sufficient to enhance engagement in domains requiring deeper conceptual reasoning or experimental interpretation. Environmental chemical engineering students occupy an intermediate position, benefiting from gamification when sustainability contexts are explicitly emphasized (Question E, Figure 5). This supports the notion that gamification is not universally effective but rather context-sensitive, requiring alignment with disciplinary epistemologies (van Roy & Zaman, 2018; Santiago et al., 2025; Klock et al., 2026). These findings reinforce the importance of adaptive

gamification design in higher education, particularly in interdisciplinary sustainability-oriented curricula. Across all five questions, a consistent pattern emerges: gamification tends to be more effective in institutions where participants report higher alignment between game mechanics and learning structure. The strongest overall effects were observed in Uzhhorod University, while the University of Porto consistently reported lower engagement and motivation scores. This heterogeneity highlights the importance of contextual factors such as disciplinary background, prior exposure to digital learning tools, and instructional design quality.

The integration of European Green Deal principles into educational processes through gamification-based tools facilitates the understanding of systemic relationships among the environment, production systems, and human well-being. In agriculture, such tools contribute to strengthening the transition toward sustainable and circular production models by simulating the impacts of resource-use decisions on soil degradation, greenhouse gas emissions, and biodiversity loss, as well as by promoting regenerative practices and the valorisation of biological residues in alignment with circular bioeconomy principles.

In the field of healthcare, gamification supports the development of an integrated One Health perspective, highlighting the interdependencies between environmental quality, food safety, and the incidence of diseases associated with ecological factors (Dima et al., 2007; Ciric et al., 2023). By incorporating game mechanics such as simulation, feedback loops, and structured progression, gamified learning environments enhance systems thinking across human, animal, and environmental health domains (Deterding et al., 2011; Ying & Wan Yahaya, 2026). Scenario-based serious games and outbreak simulations, in particular, improve engagement and facilitate applied learning in interdisciplinary contexts. Furthermore, gamified approaches contribute to the development of collaborative competencies essential for One Health practice, including cross-sector communication, coordinated decision-making, and data-driven reasoning. Such methods have been associated with improved knowledge retention and behavioral alignment in areas such as antimicrobial resistance stewardship and outbreak preparedness (Gan & Duan, 2026; van den Broek et al., 2026). However, limitations remain, including the risk of oversimplifying complex ecological systems and the potential disconnect between simulated environments and real-world operational performance. Therefore, gamification should be considered a complementary educational tool rather than a standalone methodology.

## CONCLUSIONS

This multi-university European study demonstrates that gamification can significantly enhance participation, motivation, and perceived learning outcomes in green digitization education. However, its effectiveness is not uniform across institutions and is strongly influenced by contextual and pedagogical factors. The results suggest that successful implementation of gamified learning systems requires careful alignment between game mechanics and educational objectives, as well as adaptation to disciplinary and cultural differences.

## ACKNOWLEDGEMENTS

This research work was carried out with the support of the University of Agronomic Science and Veterinary Medicine of Bucharest, Romania, and was financed by the Project number: 2023-1-RO01-KA220-HED-000154433 entitled: Gender, Digitalization, Green: Ensuring a Sustainable Future for all in Europe.

***Abstract***

*Parsley (Petroselinum crispum* Mill*.) is a plant valued for its high nutritional content and functional properties, being an important source of vitamins and essential minerals for human health. This study aims to evaluate the mineral composition of parsley root and assess its potential health benefits. The concentrations of macroelements (calcium, magnesium, potassium, and phosphorus) and microelements (iron, zinc, manganese, and copper) were determined using X-ray fluorescence spectrometry (XRF). Parsley root samples were collected from various supermarkets in Romania and the results were compared with data reported in the literature. The mineral analysis revealed a high and relatively consistent content of essential macro- and microelements across all samples. The measured levels of potassium, calcium, iron, manganese, and zinc were comparable to or slightly higher than those previously reported, highlighting the nutritional potential of parsley root as a natural mineral source. Variations among samples can be attributed to differences in soil composition and cultivation conditions, without significantly impacting the overall nutritional quality. These findings support the inclusion of parsley root as a valuable ingredient in balanced diets and functional food formulations.*

***Key words:*** *health benefits, mathematical model, Petroselinum crispum, X-ray fluorescence spectrometry.*

## INTRODUCTION

The vegetables with leaf and roots are valued due to their rich content in essential nutrients. They are also recognized for their significant contribution to human health. Among these, parsley (*Petroselinum crispum* Mill.), both the leaf and the root, represent a promising plant with relevant minerals content and considerable potential to facilitate various favorable health effects (Ahmed et al., 2025).

This work investigates the mineral composition of parsley roots using the X-ray fluorescence (XRF) technique.

Parsley *(Petroselinum crispum* Mill.*)* is an herbaceous leguminous plant that belongs to the Apiaceae family. According to the classification of A. L. de Jussieu, parsley (*Petroselinum crispum* Mill.) belongs to the Rosidae class and is known under the name of Umbelliferae. For this reason, it is often called the umbrella plant (Chauhan & Aishwarya, 2018). Native to Europe and western Asia it is currently widespread in many regions of the world (Mahmood et al., 2014). Parsley (*Petroselinum crispum* Mill.) is cultivated for its white taproot and intensely aromatic leaves. It is used for food, cosmetic, and pharmaceutical industries for their aromatic and culinary properties as well as for their medicinal benefits (Zaaboul & Liu, 2022). Also, it is wealthy in nutrients, vitamins, minerals (Zaaboul & Liu, 2022) and apiol, which is an organic compound found in parsley

seeds with therapeutic properties (Gogoaşă et al., 2014; Ajmera et al., 2019).

Parsley (*Petroselinum crispum* Mill.) is well known as an aromatic plant and it is widely used in both traditional and international cuisine. Generally, parsley is considered an auxiliary and decorative ingredient rather than a valuable source of nutrients (Ajmera et al., 2019; Bahramsoltani et al., 2024). The chemical composition of parsley root includes: 85% water, 3% protein, 6% carbohydrates, volatile oils and a significant amounts of minerals (especially potassium), phosphorus, magnesium, calcium, iron, as well as a number of vitamins (A, B, C). It is low in calories, one hundred grams of parsley root contains 36 kcal (Cozma et al., 2022; Wszelaczyńska et al., 2024). Among all root vegetables, parsley is characterized by a significant content of K (399 mg/100 g) and calcium (Ca) (43 mg/100 g). Moreover, parsley is also rich in folate (180 µg/100 g). Consumption of 100 g of parsley covers the daily requirement of folic acid by 30-40% (Knez et al., 2022).

Due to the diversity of bioactive compounds, parsley stands out as a vegetable with therapeutic potential and has been described in the scientific literature as exhibiting tonic, antianemia, antirachitic, antiasthmatic, anti-xerophthalmic, antiscorbutic, antifebrile, anti-inflammatory, mineralizing, depurative, diuretic, secretolytic, vasodilatory, expectorant, vermifuge, and uterotonic effects (Gogoaşă et al., 2014; Ajmera et al., 2019; Bahramsoltani et al., 2024).

Researcher's analyses have demonstrated the significance of dietary minerals, vital for disease prevention and maintaining overall good health. Although they constitute a relatively small proportion of approximately 4-6% of body weight, minerals are key components of the human diet (Özcan, 2004; Knez et al., 2022).

The minerals present in parsley have major importance, as each of them contributes significantly to the proper functioning of the body. Iron is a mineral vital for haemoglobin formation and oxygen transport in the blood. Magnesium plays an important role in the proper functioning of the nervous system, in regulating blood pressure, and has a relaxing effect on muscles. Calcium contributes to bone and dental health. Potassium has a key role in well function of hearth and blood pressure regulation, while zinc has beneficial effects to the immune system and protein synthesis, and phosphorus is essential for cellular energy production (Alobaidi, 2024).

The minerals present in parsley play an important role in maintaining optimal physiological functions, and their consumption contributes to overall health and helps prevent mineral deficiencies (Ajmera et al., 2019). Therefore, a healthy diet is based on a balanced and varied eating plan, which includes appropriate portions of vegetables, fruits and cereals rich in fiber and protein, along with a moderate consumption of fats, sugar and salt (Rădulescu et al., 2025).

To assess the mineral content of parsley roots and to identify variations determined by cultivation conditions and also by soil composition, it is necessary to apply an efficient and non-invasive analytical technique. Thus, X-ray fluorescence (XRF) is a rapid and precise method, which allows the simultaneous quantification of major minerals as well as trace elements without complex chemical preparation of the samples (Jenkins et al., 1995; Wszelaczyńska et al., 2024). The application of XRF in this study of parsley roots allows the determination of the complete mineral profile, thus providing valuable data for both nutrition and health as well as agricultural research.

## MATERIALS AND METHODS

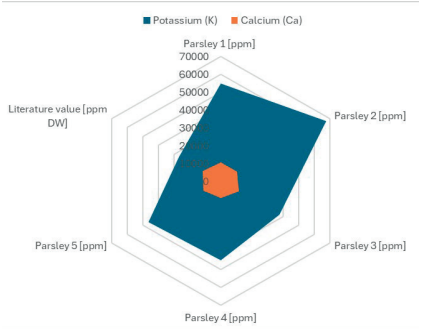
Parsley roots were purchased from five different supermarkets in Romania, then cleaned to remove impurities, scraped, and initially air-dried at room temperature. Subsequently, the roots were dried in an oven until the moisture content decreased below 5%, a level recommended for accurate mineral determination. The dried samples were then finely ground, packed in sterile airtight bags, properly labelled, and stored for further analyses and determinations.

For X-ray fluorescence (XRF) analyses, the powdered samples were examined using a Hitachi X-MET8000 portable spectrometer, which can measure a wide range of atomic elements, from sodium (Z11) to uranium (Z92), providing detection limits from a few parts per

million (ppm) up to high percentages (% by weight). This method was selected because XRF is an essential technique for the evaluation of soil and plant samples at medium air pressure, and it is frequently used for both qualitative and quantitative analyses. The method is based on the fact that each mineral present in the analysed material (parsley root) emits a characteristic set of fluorescent X-rays, a "fingerprint" specific to each element (Rădulescu et al., 2024). XRF spectrometry is advantageous because it provides rapid determination of elemental concentrations and presence, with high accuracy (Panebianco et al., 2023). Measurements were performed in triplicate to ensure precision and consistency, and the results were expressed in parts per million (ppm).

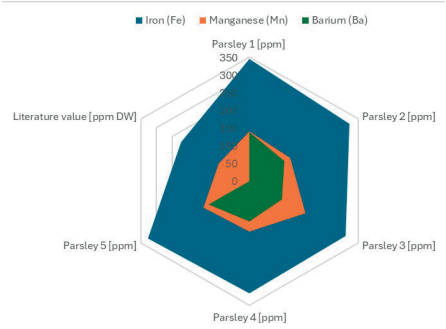
Statistical evaluation of the data was performed using PAST software, version 2.17c (Hammer et al., 2001). Data obtained from the mineral determinations were processed using descriptive statistics and expressed as mean values ± standard deviation.

## RESULTS AND DISCUSSIONS



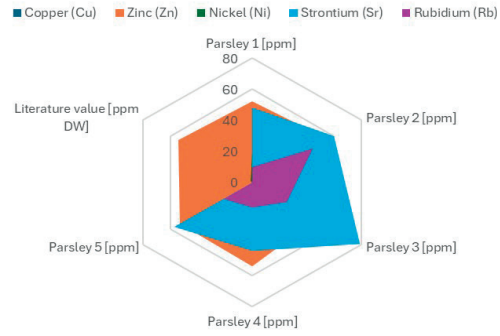
The analyzed parsley roots revealed high concentrations of several essential minerals, predominantly K and Fe, above literature reference values, demonstrating high nutritional potential. However, the increased levels of Cu, Ni, and Pb suggest possible environmental or soil-related contamination impacts. The variability between samples shows distinct geochemical or anthropogenic signatures connected with their provenience. Further soil–plant transfer factor assessment and comparison with regulatory maximum allowable limits are recommended to evaluate food safety implications (Table 1).

Table 1. Mineral composition of parsley root samples

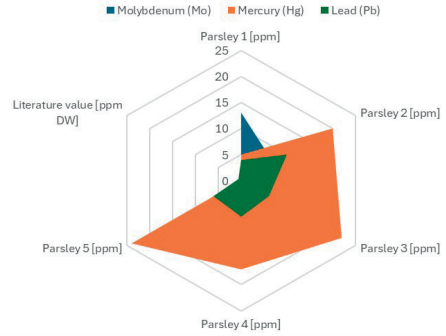


| Mineral | Parsley 1 [mg/kg] | Parsley 2 [mg/kg] | Parsley 3 [mg/kg] | Parsley 4 [mg/kg] | Parsley 5 [mg/kg] | Literature value (mg/kg DW) |
|---|---|---|---|---|---|---|
| Potassium (K) | 54707.00 ± 700.00 | 67462.00 ± 3,142.00 | 37,793.00 ± 930.00 | 44758.00 ± 315.00 | 46185.00 ± 1,690.00 | 63000.00 (Nutrition Data Hub, 2026) |
| Calcium (Ca) | 10525.00 ± 19.00 | 10585.00 ± 779.00 | 11732.00 ± 396.00 | 9811.00 ± 285.00 | 10906.00 ± 197.00 | 1760.00 (Nutrition Data Hub, 2026) |
| Iron (Fe) | 345.00 ± 8.00 | 323.00 ± 9.00 | 309.00 ± 7.00 | 317.00 ± 14.00 | 326.00 ± 18.00 | 539 (Nutrition Data Hub, 2026) |
| Copper (Cu) | 34.00 ± 1.00 | 47.00 ± 0.00 | 39.00 ± 0.00 | 40.00 ± 0.01 | 31.00 ± 3.00 | 4.6 (Nutrition Data Hub, 2026) |
| Manganese (Mn) | 140.00 ± 18.00 | 130.00 ± 23.00 | 181.00 ± 7.00 | 142.00 ± 21.00 | 149.00 ± 11.00 | 134 (Nutrition Data Hub, 2026) |
| Molybdenum (Mo) | 13.00 ± 3.00 | 7.00 ± 2.00 | 7.00 ± 0.00 | 10.00 ± 3.00 | 7.00 ± 3.00 | - |
| Zinc (Zn) | 52.00 ± 4.00 | 56.00 ± 1.00 | 47.00 ± 0.00 | 54.00 ± 1.00 | 53.00 ± 0.00 | 61.1 (Nutrition Data Hub, 2026) |
| Nickel (Ni) | 19.00 ± 1.00 | ND | 20.00 ± 4.00 | 22.00±0.00 | ND | 1.30 (Arsenov et al., 2021) |
| Barium (Ba) | 138.00 ± 16.00 | 113.00 ± 0.00 | 104.00 ± 0.02 | 114.00 ± 0.03 | 131.00 ± 0.00 | - |
| Strontium (Sr) | 48.00 ± 0.00 | 60.00 ± 2.00 | 79.00 ± 5.00 | 44.00 ± 2.00 | 57.00 ± 2.00 | - |
| Rubidium (Rb) | 10.00 ± 0.00 | 44.00 ± 3.00 | 25.00 ± 0.00 | 16.00 ± 0.00 | 21.00 ± 0.00 | - |
| Mercury (Hg) | 5.00 ± 0.00 | 20.00 ± 0.00 | 22.00 ± 2.00 | 17.00 ± 0.00 | 24.00 ± 5.00 | - |
| Lead (Pb) | 4.00 ± 0.00 | 10.00 ± 0.00 | 6.00 ± 0.00 | 7.00 ± 2.00 | 6.00 ± 0.00 | 0.55 (Winiarska-Mieczan et al., 2023) |

Data are presented as mean ± standard deviation
Legend: ND = Not Detected (below the detection limit of the XRF spectrometer).



The five parsley root samples displayed diverse mineral fingerprints reflecting variances in their provenience (Figure 1). Parsley 2 was characterized by high K, Cu, Pb, and Rb, whereas Parsley 3 showed enrichment in Mn and Sr. The occurrence of Ni in only three samples supplementary supports site-specific soil influence. These results indicate that mineral composition in parsley roots is strongly designed by environmental and geochemical factors rather than solely by plant physiological control.



Comparative Mineral Profile of K and Ca in the investigated Parsley Root Samples

Comparative Mineral Profile of Fe, Mn and Ba in the investigated Parsley Root Samples

Comparative Mineral Profile of Cu, Zn, Ni, Sr and Rb in in the investigated Parsley Root Samples

Comparative Mineral Profile of Mo, Hg and Pb in in the investigated Parsley Root Samples

Figure 1. Mineral Fingerprint of Parsley Roots Based on Mineral Content

Each sample presents a distinct mineral fingerprint**,** indicating different soil characteristics and possibly different anthropogenic pressures. As we can observe, the mineral composition of the parsley roots is shaped by different particularities like: Physiological regulation (Ca, Zn stability); Soil fertility differences (K variability), Geochemical background (Ba, Sr, Rb) and local environmental influence (Ni, Pb, Hg).

Radar plot analysis revealed distinct mineral fingerprints among the five parsley root samples. While calcium and zinc displayed limited variability, indicating physiological regulation, potassium showed pronounced variation, with Parsley 2 exhibiting the highest concentration. Trace elements such as Ni, Pb, Hg, Rb, and Sr demonstrated strong inter-sample differences, suggesting provenance-dependent geochemical and environmental influences. Parsley 3 was characterized by elevated Mn and Sr, whereas Parsley 2 exhibited increased Cu, Pb, and Rb levels. These findings confirm that mineral accumulation patterns in parsley roots are primarily shaped by soil composition and local environmental conditions rather than intrinsic plant physiology alone.

The PCA biplot illustrates the mineral composition of the investigated parsley root samples after standardization (Figure 2). PC1 (the first principal component) represents the major source of variance in the dataset and primarily reflects differences in mineral enrichment, predominantly determined by K, Zn, Fe, Ba, and Mo. Along PC1, Parsley 1 indicates a relatively enriched mineral profile, while Parsley 3 is positioned on the opposite side, showing lower concentrations of several macro- and microelements. This separation suggests that PC1 presents the differences primarily related to soil fertility and mineral availability.

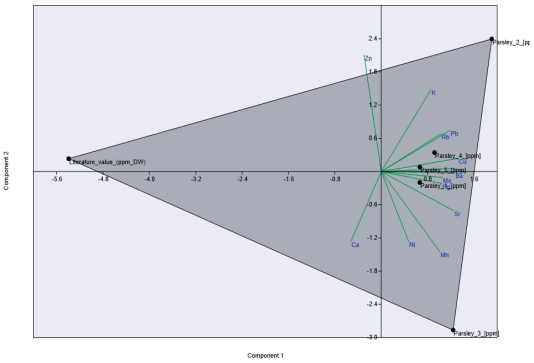


Figure 2. PCA Biplot of Mineral Composition in Parsley Roots Samples

PC2 (the second principal component) differentiates the samples based on the metals Pb, Rb, Cu, and Hg, which display stronger inter-sample variability and environmental sensitivity. Parsley 2 is clearly shifted upward along PC2, reflecting elevated Pb and Rb levels and thus a distinct geochemical signature. Parsley 3 appears in the lower quadrant, influenced more by Mn and Ca.

Parsley 2 is distinctly positioned in the positive PC2 quadrant, associated with high Pb and Rb levels, indicating a specific geochemical or environmental signature. In contrast, Parsley 3 appears in the lower quadrant, influenced more by Mn and Ca. The orientation and length of the vectors confirm that Rb, Pb, and Ni are among the strongest discriminant elements, contributing substantially to sample separation.

Overall, the PCA confirms that the mineral composition of parsley roots is governed by provenance-dependent factors. While some elements (e.g., Ca and Zn) appear relatively stable and physiologically regulated, others (notably Rb, Pb, Ni, and Mn) are responsible for the distinct mineral fingerprints observed among samples, highlighting the influence of soil geochemistry and localized environmental conditions.

## CONCLUSIONS

The analysis of parsley roots indicated high levels of essential minerals, potassium (K) and iron (Fe), exceeding the reference values reported in the scientific literature, thus reflecting a high nutritional potential. Trace elements such as copper (Cu), nickel (Ni), and lead (Pb) were present only in some of the samples, their occurrence highlighting possible influences of the environment or soil on contamination. The differences between the five studied samples reflect distinct geochemical or anthropogenic fingerprints, particularly related to their provenance and soil conditions. XRF analysis proved to be a very efficient, rapid, and non-destructive method, allowing both qualitative and quantitative assessment of the mineral composition of the parsley samples. The results obtained from principal component analysis (PCA) demonstrate that this composition is largely influenced by the provenance of the samples: elements such as Ca and Zn appear relatively stable and physiologically regulated, while other elements, such as Rb, Pb, Ni, and Mn, generate distinct mineral fingerprints, reflecting the influence of soil geochemistry and localized environmental conditions. Considering the above, further studies are recommended to evaluate the soil–plant transfer factor and to compare the values with the maximum allowable limits established by regulations, in order to assess implications for food safety. The high concentrations of potassium (K) and iron (Fe) emphasize the nutritional value of parsley root, while the analysis of trace elements and mineral fingerprints through XRF and PCA provides relevant data on provenance and environmental influences, thereby confirming the potential of parsley root as a source of essential minerals and the need for monitoring food safety.

## ACKNOWLEDGEMENTS

This work was carried out using the own research funds of the University of Life Sciences “King Mihai I” from Timișoara. The research was conducted with the support of the Interdisciplinary Research Platform of the University of Life Sciences “King Mihai I” from Timișoara. The acquisition of the XRF Hitachi X-MET8000 spectrometer was financed through the Interreg-IPA Cross-border Cooperation Romania-Serbia Programme, under the project “Modern technologies for monitoring land covered with waste in order to restore their initial use”, 2019-2021, e-MS code: RORS 365.

***Abstract***

*The increasing availability of satellite and airborne technologies has changed the way mining-affected areas are monitored and analyzed. Spatial geodetic methods such as GNSS, satellite radar interferometry (InSAR), multispectral remote sensing, and UAV-based photogrammetry and LiDAR now allow continuous and accurate observation of ground behavior over large areas. This paper presents an overview of the main spatial geodetic techniques used for monitoring mining geosystems, focusing on their practical application in detecting ground subsidence, slow surface deformations, structural instabilities, and volumetric changes of waste dumps and tailings dams. The strengths and limitations of each method are discussed from a practical perspective, taking into account accuracy, spatial coverage, operational constraints, and cost efficiency. Examples from Romania and other European mining regions highlight the benefits of combining GNSS, InSAR, UAV data, and GIS platforms into integrated monitoring systems. Such approaches support early detection of hazardous processes and contribute to safer and more sustainable management of mining and post-mining environments.*

***Key words:*** *geotechnical monitoring, GIS, GNSS, InSAR, LiDAR, mining waste dumps, remote sensing, spatial geodesy, tailings dams, UAV.*

## INTRODUCTION

Mining geosystems (open pits, underground operations, waste rock dumps, ash deposits, and tailings storage facilities) are dynamic engineered–natural systems that can evolve rapidly under changes in loading, groundwater, drainage, and material properties. Their deformation may remain subtle for long periods, then accelerate into hazardous states such as progressive slope failure, dam crest settlement, or wide-area subsidence. Internationally, the consequences of tailings failures have strengthened the demand for demonstrable monitoring capacity and transparent risk governance, including the Global Industry Standard on Tailings Management (UNEP, 2020). In the European Union, the management of waste from extractive industries is framed by Directive 2006/21/EC, which requires appropriate control and risk prevention measures throughout the lifecycle of tailings facilities and waste dumps (European Parliament & Council, 2006). These drivers, together with the availability of Copernicus Sentinel missions, have accelerated the uptake of spatial geodetic and Earth observation techniques for operational monitoring.

Spatial geodetic methods complement classical geotechnical instrumentation by providing geometrically consistent, often remotely acquired observations that link local deformation at critical structures to regional patterns. GNSS networks offer absolute 3D positioning with high temporal sampling, supporting early detection of deviations from expected behavior and serving as validation for remote sensing products (Scaioni et al., 2018). Multi-temporal InSAR provides dense, wide-area displacement measurements along the radar line of sight (LOS) and can reveal slow subsidence or creep processes that are difficult to capture with sparse ground points (Ferretti et al., 2001; Berardino et al., 2002; Crosetto et al., 2016; Aswathi et al., 2022). UAV-based photogrammetry (Structure-from-Motion, SfM) and UAV LiDAR deliver centimeter- to decimeter-scale 3D surface models and enable volumetric change analysis over waste dumps, tailings beaches, and open-pit benches (Westoby et al., 2012; Nex et al., 2022; Liu et al., 2023). Multispectral and hyperspectral

remote sensing add information on surface cover and mineralogical indicators that relate to erosion, dust emission, or acid mine drainage (Seifi et al., 2019; Dkhala et al., 2020).

The aim of this paper is to synthesize, from a practical perspective, the main spatial geodetic techniques used for monitoring mining-affected areas and to compare their accuracy, spatial and temporal coverage, operational constraints, and cost efficiency. We also emphasize integrated monitoring architectures that combine GNSS, InSAR, UAV-derived 3D products and GIS-based decision layers to support early warning and sustainable mine closure and post-mining management (Del Soldato et al., 2019; Poncoș et al., 2022).

## MATERIALS AND METHODS

This study is a structured review and comparative analysis of spatial geodetic approaches for deformation and change monitoring in mining geosystems. The comparison follows four practical criteria: (i) geometric performance (precision, accuracy, and sensitivity to deformation components), (ii) scale (point, object, and regional coverage), (iii) temporal sampling and operational availability, and (iv) implementation effort and costs (hardware, field time, data processing, and expertise). As the literature spans multiple domains (geodesy, remote sensing, mining engineering and risk management), we focus on methods with established workflows and demonstrated applications to subsidence, slope instability, and volumetric change.

For satellite radar interferometry, we adopt the standard distinction between single-pair DInSAR and multi-temporal techniques. PSI relies on stable radar targets to estimate long time-series displacement with reduced atmospheric noise (Ferretti et al., 2001; Hanssen, 2001). SBAS and related small-baseline methods exploit short temporal and spatial baselines to increase coherence over distributed targets (Berardino et al., 2002). In operational contexts, Sentinel-1 provides systematic C-band acquisitions with a 12-day repeat cycle for a single satellite and 6 days for a two-satellite constellation, with robust day-and-night and all-weather capability (Copernicus Data Space, 2025; SentiWiki, 2025). For optical remote sensing, Sentinel-2 MSI provides 13 spectral bands supporting land cover, moisture and mineral mapping at 10-60 m resolution (Copernicus Data Space, 2025; ESA, 2025).

For UAV surveys, we consider two principal data products: (a) dense point clouds and digital surface models (DSMs) from SfM photogrammetry, and (b) LiDAR point clouds acquired from airborne laser scanners mounted on UAVs. Change detection between epochs can be performed using DEM-of-difference or point-cloud-to-point-cloud approaches such as M3C2, which is well suited to rough, three-dimensional surfaces common in dumps and benches (Williams et al., 2021; Liu et al., 2023).

For GNSS monitoring, we consider both permanent stations (continuous) and campaign networks, with processing options ranging from relative positioning to PPP solutions depending on infrastructure and required accuracy (Scaioni et al., 2018).

The integrated monitoring concept is represented as a data pipeline where each observation type is quality controlled and co-registered into a consistent reference frame, then fused within a GIS platform for interpretation, thresholding, and alerting. This aligns with modern risk-based monitoring guidance for tailings facilities emphasizing defensible data, traceability, and timely escalation (UNEP, 2020).

An integrated workflow for multi-sensor spatial monitoring is summarized in Figure 1.

An effective monitoring system for mining geosystems requires the integration of several complementary data sources, because each observation technique provides different information about surface deformation and environmental change. Satellite SAR data processed through PSI/SBAS techniques allow regional detection of slow ground movements, while GNSS networks provide precise reference measurements and local validation of displacement trends. UAV photogrammetry and UAV LiDAR add high-resolution three-dimensional information, useful for analysing local changes in waste dumps, tailings dams, open-pit slopes and other unstable mining structures. The combined interpretation of these datasets within a GIS/database environment makes it possible to perform quality control, compare independent measurements, detect

abnormal deformation patterns and transform geodetic observations into practical risk indicators. Figure 1 presents the proposed integrated workflow, from data acquisition and processing to GIS-based quality assessment and early warning support.

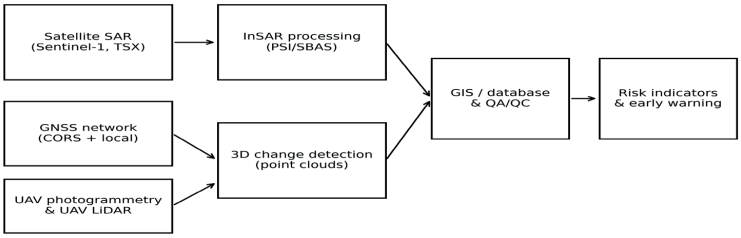

Figure 1. Integrated workflow combining satellite SAR, GNSS, UAV products and GIS decision layers

## RESULTS AND DISCUSSIONS

Table 1 highlights that no single method optimally satisfies precision, coverage and update frequency simultaneously. For operational risk management, method selection should be hazard-driven and multi-scale. Regional screening (e.g., subsidence bowls and creep zones) is effectively addressed by multi-temporal InSAR (Ferretti et al., 2001; Berardino et al., 2002; Crosetto et al., 2016), while structural performance at crest monuments or critical facilities requires high-fidelity ground measurements such as GNSS or classical geodetic control (Scaioni et al., 2018). For rapidly evolving geometry (bench retreat, dump reshaping, tailings beach migration), UAV point clouds enable frequent volumetric updates and local instability mapping (Westoby et al., 2012; Liu et al., 2023).

Table 1. Comparative overview of spatial geodetic methods for mining geosystem monitoring

| **Method** | **Main outputs** | **Typical deformation sensitivity** | **Spatial/temporal coverage** | **Strengths** | **Key limitations** |
|---|---|---|---|---|---|
| GNSS (campaign/continuous) | 3D point displacement; velocity; reference frame control | mm–cm at monitored points (daily–subdaily for permanent stations) | Points to networks; high rate possible | Absolute 3D; real-time options; strong for validation and critical structures | Sparse spatial sampling; requires installation and maintenance |
| InSAR (PSI/SBAS, Sentinel-1 or high-res SAR) | LOS displacement maps and time series; regional deformation patterns | mm–cm along LOS for coherent targets | $10^2$-$10^5$ km²; revisit 6-12 days (Sentinel-1) | Wide-area, dense measurements; retrospective analysis; cost-efficient at scale | LOS-only; decorrelation on vegetation/water; atmospheric artefacts; phase unwrapping issues |
| UAV photogrammetry (SfM) | Dense point clouds, orthomosaics, DSM/DTM; volumetric change | cm-dm (site dependent) | 0.1-10 km² per flight; on-demand | Very high spatial resolution; flexible survey geometry; low equipment cost | Requires safe access/flight permissions; lighting/wind constraints; GCP/direct georeferencing needed |
| UAV LiDAR | LiDAR point clouds; vegetation-penetrating surface; change vectors | dm to few cm (platform dependent) | 0.1-10 km²; on-demand (lower speed than photogrammetry) | Performs in low texture; less sensitive to illumination; better in vegetation | Higher sensor cost; calibration/boresight; point density depends on flight plan |
| Multispectral / hyperspectral EO (Sentinel-2, airborne) | Land cover, moisture proxies, mineral/contamination indicators | Indirect (not deformation); complements geometric monitoring | 10-60 m (Sentinel-2); revisit days | Supports environmental context: erosion, seepage, AMD indicators | Cloud sensitivity; mixed pixels; requires field validation for mineralogical interpretation |

The relationship between spatial coverage and vertical precision is an important criterion when selecting monitoring techniques for mining geosystems. Methods such as levelling, GNSS and terrestrial laser scanning provide high vertical accuracy, but their spatial coverage is

usually limited to points, profiles or local areas (Calina et al., 2021). In contrast, satellite-based InSAR offers regional coverage over very large surfaces, although the vertical precision is influenced by radar geometry, coherence, atmospheric effects and the need to convert line-of-sight displacement into vertical deformation. UAV photogrammetry and UAV LiDAR occupy an intermediate position, providing high-resolution spatial products over site-scale areas, which makes them particularly useful for monitoring waste dumps, tailings dams and open-pit slopes. Therefore, the choice of method should not be based only on precision, but also on the required monitoring scale, update frequency, accessibility of the site and the type of deformation process being investigated. Figure 2 illustrates this practical trade-off between typical spatial coverage and vertical precision for the main geodetic and remote-sensing techniques used in mining-area monitoring.

The practical value of spatial methods depends on uncertainty communication. InSAR products, for instance, are susceptible to atmospheric artefacts and may exhibit spatially correlated errors (Table 2); multi-temporal processing and the use of stable reference areas are therefore essential (Hanssen, 2001; Crosetto et al., 2016).

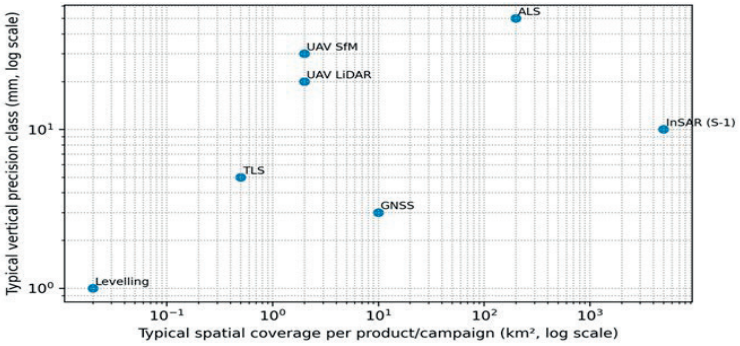

Figure 2. Trade-off between typical spatial coverage and precision class for common monitoring approaches (illustrative)

Table 2. Major error sources and mitigation strategies for spatial geodetic monitoring in mining areas

| Technique | Dominant error sources | Mitigation / QA-QC | Practical notes |
|---|---|---|---|
| InSAR (PSI/SBAS) | Atmospheric delay; temporal/spatial decorrelation; unwrapping errors; geometry (LOS) | Use multi-temporal methods; atmospheric filtering; ascending/descending decomposition; GNSS tie points | Best for slow deformation; interpret LOS; validate locally where possible |
| GNSS | Multipath; antenna stability; reference frame drift; troposphere modelling | Stable monuments; choke-ring antennas; network adjustment; PPP/relative processing; redundancy | High temporal sampling; critical points on crests and abutments |
| UAV SfM | Camera calibration; GCP quality; poor texture; wind; rolling shutter; time-varying shadows | Robust GCP network or RTK/PPK; calibration checks; overlap planning; independent checkpoints | Excellent for geometry and volumes; repeatable flight plans improve consistency |
| UAV LiDAR | Boresight misalignment; IMU drift; scan geometry; strip adjustment | Calibration flights; strip adjustment; ground truth targets; stable control points | Better than SfM on low-texture surfaces and in vegetation; higher sensor cost. |

Where deformation vectors are needed, combining ascending and descending tracks allows decomposition into vertical and east–west components, although the north–south component typically remains weakly observed (Crosetto et al., 2016). For UAV change detection, point-cloud-to-point-cloud techniques (e.g., M3C2) reduce bias introduced by gridding and are well suited for rough quarry and dump surfaces (Williams et al., 2021; Liu et al., 2023).

A typical integration pattern is to use GNSS time series to validate InSAR trends and to strengthen interpretation of low-rate deformation (Figure 3).

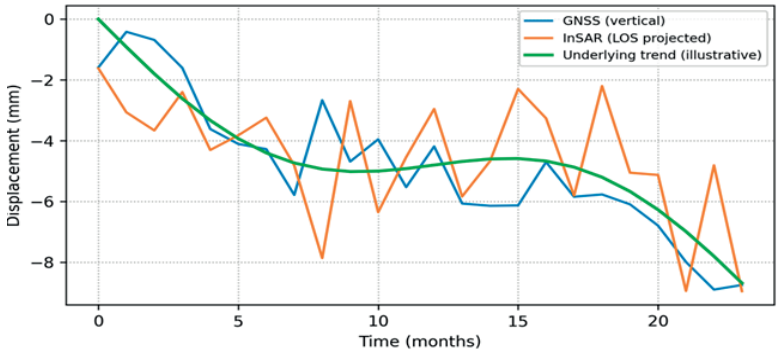

Figure 3. Example of GNSS-InSAR time series consistency for slow deformation

Integration is most effective when each method is assigned a clear role. In mining subsidence, for example, InSAR can provide long-term regional context and reveal residual subsidence beyond the footprint of active panels, while GNSS and classical control networks constrain absolute displacement at infrastructure points. This complementarity has been demonstrated in multiple European mining regions. In Poland's Upper Silesian Coal Basin, multi-decadal InSAR analysis revealed both active subsidence troughs and residual deformation zones over thousands of square kilometers (Przyłucka et al., 2022). In southeast Spain (La Unión), advanced DInSAR was used to map small-scale subsidence affecting built-up areas within historic mining districts (Herrera et al., 2007).

Romania provides diverse mining settings where integrated approaches are increasingly relevant (Stefan et al., 2009). A Sentinel-1 based study in the Călimani area demonstrated the use of interferometric processing for terrain reconstruction and monitoring in a former sulphur quarry, motivated by high costs and accessibility constraints of terrestrial surveys (Gheorghe & Vodă Marc, 2020). National-scale services have also been developed: a ground motion monitoring product for Romania highlighted the potential of InSAR to detect subtle deformation patterns and to support infrastructure and environmental assessment (Terrasigna, 2020). More recently, integrated EO monitoring of the Roșia Poieni copper mine has been discussed as a pathway to link geomorphic evolution and environmental indicators to operational decision-making (Herban et al., 2024; Kirsch et al., 2025).

From an operational point of view, decision makers often need a simplified comparison of method attributes; a qualitative scoring example is shown in Figure 4.

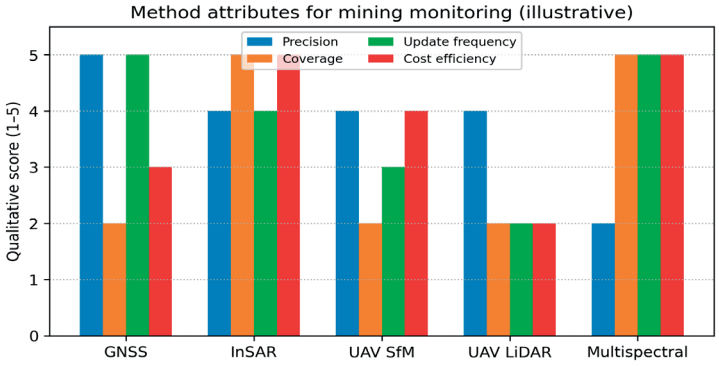

Figure 4. Qualitative comparison of method attributes relevant for mining monitoring

Table 3 summarizes practical configurations that align method capability with hazards. For tailings facilities, integrated schemes are increasingly coupled with numerical modelling and risk assessment. For instance, combining InSAR with modelling has been shown to improve interpretation and to support early detection of slope instability patterns in tailings ponds (Lu et al., 2025). InSAR-based ground motion services can also support prioritization, directing limited field resources to zones showing acceleration or anomalous trends (Del Soldato et al., 2019; Poncoș et al., 2022).

Table 3. Recommended integrated monitoring configurations by mining object and dominant hazard

| Object / hazard | Regional screening | Local high-resolution monitoring | Decision layer |
|---|---|---|---|
| Tailings dam: crest settlement, slope instability | InSAR (PSI/SBAS) + optical change detection for seepage indicators | GNSS on crest/abutments + UAV LiDAR/SfM for beach and slope geometry | Thresholds on velocities/accelerations; integration with geotechnical readings and GISTM controls |
| Waste rock dump: creep, erosion, runout susceptibility | InSAR + multispectral (moisture/vegetation) for surface condition | UAV SfM for frequent 3D updates; TLS for critical scarps; GNSS targets where needed | Change maps and volume budgets; trigger surveys after intense rainfall or operational regrading |
| Open pit slopes: bench instability, rockfall precursors | InSAR where coherent; regional context for surrounding infrastructure | UAV SfM/LiDAR + TLS for detailed discontinuity mapping and change detection | Spatial zoning of deformation; hazard maps; coupling with operational plans |
| Underground mining: subsidence bowls and infrastructure impact | InSAR time series (long-term) | GNSS/levelling lines along critical assets; UAV mapping for local cracks | Subsidence prediction vs observations; maintenance prioritization; public safety communication |

Beyond deformation, multispectral and hyperspectral remote sensing provides environmental context relevant for post-mining management, such as the spatial pattern of mineralogical anomalies in tailings and surrounding soils (Dkhala et al., 2020; Milut et al., 2020), or the mapping of acid mine drainage potential using spectral information (Seifi et al., 2019). Early Romanian work using Landsat data demonstrated the feasibility of mapping mining waste deposits across large areas in Romania and Slovakia (Vîjdea et al., 2004), while more recent local studies have applied Landsat and Sentinel imagery to monitor land-cover change around Roșia Poieni (Herban et al., 2024).

The main limitation of integrated monitoring is not data availability but operationalization: stable reference frames, repeatable acquisition plans, and transparent uncertainty reporting are required to avoid false alarms or missed detections. The monitoring chain should therefore include (i) a well-defined geodetic reference network anchored in stable ground, (ii) standardized processing and metadata, (iii) cross-validation between independent methods, and (iv) governance rules for escalation and documentation consistent with risk-based standards (Scaioni et al., 2018; UNEP, 2020).

## CONCLUSIONS

Spatial geodetic monitoring has become central to mining geosystem risk management because it links point-scale structural observations to regional deformation patterns.

Multi-temporal InSAR is the most cost-efficient option for wide-area screening of slow deformation, but it requires careful treatment of LOS geometry, coherence and atmospheric artefacts, and benefits from local GNSS validation.

GNSS remains indispensable for absolute 3D control at critical structures (e.g., dam crests) and for near-real-time trend detection at selected points.

UAV SfM photogrammetry and UAV LiDAR provide high-resolution 3D geometry and volumetric change estimates, enabling detailed assessment of dumps, benches and tailings beaches when flights can be conducted safely and repeatably.

Integrated monitoring architectures combining InSAR, GNSS, UAV products and GIS decision layers support early warning, efficient field prioritization and defensible reporting aligned with modern tailings governance standards.

## ACKNOWLEDGEMENTS

The authors acknowledge the open-access Copernicus Sentinel data and the scientific community that provides processing tools and methodological developments supporting operational deformation monitoring in mining and post-mining environments.

***Abstract***

*The present study investigates methods for detecting human presence in remote natural environments, including nature reserves and protected areas. Such regions play a critical role in environmental sustainability, and excessive human activity may adversely affect these sensitive ecosystems. Conversely, accurate estimation of visitor numbers is essential for effective management and long-term preservation of these areas. Several approaches exist for human detection, including optical systems based on visible-spectrum or infrared imaging. However, these techniques may raise concerns regarding privacy and personal data protection. To address these limitations, this research explores the application of Wi-Fi-based detection methods. Given that a significant proportion of mobile device users keep Wi-Fi functionality enabled, passive monitoring systems can identify and record Wi-Fi signal activity without direct personal identification. A dedicated hardware and software framework was developed to quantify mobile Wi-Fi activity within a designated remote study area. Validation was conducted by simultaneous visual counting, and the results indicate that Wi-Fi-based detection provides a reliable method for estimating the absolute number of visitors, as well as their temporal distribution.*

***Key words****: environment monitoring, data collection, sensor network, Wi-Fi.*

## INTRODUCTION

Detecting human presence in nature has become increasingly vital for balancing conservation, education, and sustainable recreation. As more people seek connection with the outdoors, understanding where and when humans interact with wild spaces allows us to protect fragile ecosystems while highlighting nature's educational value. Nature trails, scenic overlooks, and biodiversity hotspots serve as living classrooms, demonstrating the importance of preserving habitats, biodiversity, and ecological processes. By monitoring visitation patterns - such as peak days of the week, time-of-day surges, seasonal trends, and rough visitor counts - land managers and educators can optimize trail maintenance, crowd-flow strategies, and interpretive programs that foster deeper public appreciation for the natural world (Leverington et al., 2010; Wu et al., 2015).

At the same time, certain sensitive areas must remain largely undisturbed to safeguard endangered species, prevent soil erosion, or maintain pristine habitats. Over-visitation in these zones can cause irreversible damage, from compacted trails and habitat fragmentation to the spread of invasive species carried on hikers' boots. Real-time or near-real-time detection of human presence enables authorities to identify emerging pressure points, issue timely alerts, or temporarily close sections before degradation accelerates. This dual approach - encouraging responsible access to "welcome" areas while quietly guarding "avoid" zones - helps ensure that nature's educational and recreational benefits endure for future generations (Lindgren et al., 2016).

The ubiquity of smartphones makes passive, cost-effective monitoring possible without invasive cameras or expensive sensor networks. Even when a phone's Wi-Fi is turned off, modern devices periodically broadcast 802.11 probe request frames in search of known networks. These tiny, anonymous radio signals can be captured by simple, low-power receivers placed discreetly along trails or at trailheads. By analysing the volume, timing, and movement patterns of these packets, researchers and park managers can estimate human presence and movement with surprising accuracy. This technique offers a privacy-

friendly, scalable solution that requires minimal infrastructure and can be deployed in remote locations where traditional counting methods (cameras, trail counters, or manual surveys) are impractical or cost-prohibitive (Wang et al., 2013; Farshad et al., 2014).

Ultimately, the goal is to present a practical, affordable methodology that transforms everyday smartphone emissions into actionable ecological intelligence. By turning the invisible digital chatter of visitors into meaningful insights about human-nature interactions, we can better protect wild places, enhance educational experiences, and promote truly sustainable outdoor recreation - all while keeping deployment costs low enough for widespread adoption by conservation organizations, national parks, and local communities.

## MATERIALS AND METHODS

### The test area

The Sóstó Natural Reserve is situated on the periphery of the city, in close proximity to the urban center. The area has a long-standing history of land use, having functioned as a recreational zone for approximately two centuries. Following the World War II, the site was repurposed as a municipal waste disposal area for nearly 40 years, during which both solid waste and sewage sludge were deposited.

Subsequent to the political transitions of the 1990s, extensive remediation and ecological restoration efforts were undertaken. As a result, the area was rehabilitated and officially designated as a protected natural reserve, ultimately becoming a prominent recreational destination for local residents. The hydrological conditions of the reserve are artificially supported: the wetland ecosystem is maintained through the daily input of approximately 550 $m^3$ of treated water supplied from a wastewater treatment facility (Udvardy et al., 2023).

The core of the reserve is located adjacent to the main sports arena of Székesfehérvár, reflecting a notable integration of urban infrastructure and environmental sustainability. The site attracts several hundred thousand visitors annually, and it also serves an important educational function, hosting structured environmental and sustainability programs in collaboration with local schools and the reserve's managing authority. Figure 1 shows the Sóstó natural reserve area with the city's contours as it locates very close to the city centre.

Figure 1. The Sóstó natural reserve test area

### Human presence detection

Cameras, paired with computer vision algorithms (using edge AI or cloud-based processing), can identify humans based on shape, motion, or facial features. This approach provides the most accurate approximation of the number of people and can support additional attributes, such as age estimation. Cameras perform best in daylight conditions, although infrared (IR) cameras are available for low-light environments. However, machine-vision–based systems typically have high power consumption and significant cost. Their operation requires a clear line of sight, making them sensitive to occlusions and adverse weather conditions. Privacy concerns represent an additional and often critical limitation (Berger & Lu, 2022).

PIR (Passive Infrared) detectors sense differential infrared radiation emitted by warm, moving bodies as they pass through segmented Fresnel lenses. These sensors are highly attractive due to their ultra-low power consumption, cost-effectiveness, simple installation, and completely passive operation with no active emissions. However, PIR detectors have several inherent limitations (Andrews et al., 2020).

Their effective detection range is relatively short, typically between 5 and 12 meters, and they exhibit a high false-trigger rate caused by animals, direct sunlight, wind-blown vegetation, or environmental thermal gradients. In addition, PIR sensors are unable to count people, determine movement direction, or detect stationary humans. It is important to

emphasize that PIR sensors respond only to motion and provide a strictly binary output, offering no estimate of the number of people present (Gami, 2018).

Microwave Doppler sensors are compact radar modules, operating mostly at 5.8 GHz or 10.525 GHz, emit continuous-wave microwave signals and measure Doppler frequency shifts produced by moving objects. Their advantages include the ability to penetrate light foliage, clothing, or thin barriers, reliable operation in total darkness and adverse weather conditions such as fog, rain, or snow, a moderate detection range, and relatively low power consumption (Arab et al., 2022).

The main disadvantages are the inability to reliably distinguish humans from animals, swaying vegetation, or even moving water surfaces. These sensors are also sensitive to environmental vibrations and can detect only motion rather than static presence. In addition, regulatory restrictions on transmitted power apply in some countries, and the limited spatial resolution makes precise trail-segment counting or accurate crowd-size estimation challenging (Tada et al., 2022).

Ultrasonic transducers emit short acoustic pulses at approximately 40 kHz and measure the time of flight of echoes reflected from nearby objects. Their advantages include excellent short-range accuracy, very low cost, immunity to lighting conditions, and the ability to perform precise distance-based presence detection without relying on visual or thermal signatures. However, ultrasonic sensing has significant limitations in outdoor environments. The effective range is extremely limited in open natural settings, as sound waves attenuate rapidly and scatter due to wind and vegetation such as leaves. Performance is also highly sensitive to temperature, humidity, wind, rain, and ambient acoustic noise. Ultrasonic waves cannot penetrate vegetation or physical obstacles, and frequently produce false readings due to insects or small animals (Biryukova & Koretskaya, 2020).

**Architecture**

Wi-Fi communication is defined by the IEEE 802.11 standard. It is built entirely around the exchange of structured packets called frames.

Every transmission – whether announcing a network, requesting information, establishing a connection, or carrying actual data – takes one of three broad categories:

- Management frames are responsible for discovering access points, joining them, roaming between them, and maintaining the connection.
- Control frames manage medium access and acknowledge successful receptions.
- Data frames carry the actual user payload, mostly IP traffic.

The management frames are identified by the Type field in the Frame Control field being set to 00 (binary). The 4-bit Subtype field then specifies the exact kind of management frame. These frames handle network discovery, joining/leaving a Basic Service Set (BSS), authentication, association, and other administrative functions. Figure 2 shows the 802.11 packet structure which is the base for the system architecture (Du et al., 2025).

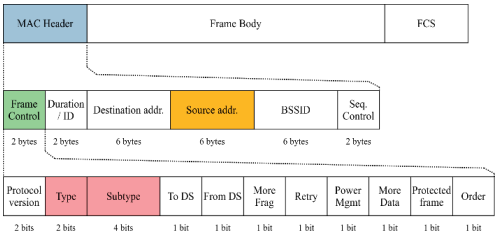

Figure 2. The 802.11 packet structure with the MAC header detailed

The defined management frame subtypes (as per the core 802.11 standard and its amendments up through recent revisions) are as follows, listed with their binary subtype values and common names:

- 0000 - Association Request;
- 0001 - Association Response;
- 0010 - Reassociation Request;
- 0011 - Reassociation Response;
- 0100 - Probe Request;
- 0101 - Probe Response;
- 0110 - Timing Advertisement (introduced in later amendments for synchronization);
- 1000 - Beacon;
- 1001 - Announcement Traffic Indication Message (ATIM) - used in Independent BSS (ad-hoc) networks for power-save coordination

- 1010 - Disassociation
- 1011 - Authentication
- 1100 - Deauthentication
- 1101 - Action (used for various management actions, spectrum management, radio measurement, etc.)
- 1110 - Action No ACK (a variant of Action frames that does not require acknowledgment, added in later amendments for efficiency in certain scenarios)

Subtypes 0111 and 1111 are typically reserved (unused or for future extensions), depending on the specific 802.11 amendment.

To connect to a Wi-Fi network, client devices such as smartphones and laptops must first discover which networks are available in their vicinity. One key method for this discovery is passive scanning, in which the device quietly listens across available channels without transmitting any frames. Access points (APs) in IEEE 802.11 wireless networks actively broadcast their Service Set Identifier (SSID) – the human-readable name of the Wi-Fi network – primarily through periodic beacon frames, which serve as the network's ongoing advertisement and synchronization signal.

These beacon frames are management frames transmitted at regular intervals, typically every 100-time units (approximately 102.4 milliseconds), on the AP's operating channel and at the lowest supported basic data rate to ensure maximum reachability by all potential clients in range. The SSID is included as a mandatory information element within the beacon frame body, allowing nearby devices performing passive scanning to discover available networks. This broadcast enables client devices to collect and list visible Wi-Fi networks (Gollier & Vanhoef, 2024).

Passive scanning requires a client device to listen on each Wi-Fi channel long enough to reliably capture at least one beacon frame from any nearby access point, since beacons are transmitted periodically – typically every 100-time units (approximately 102.4 ms), though the exact timing is asynchronous and unknown in advance. In the 2.4 GHz band, where most consumer devices operate in regions supporting channels 1 through 11 (or up to 13/14 depending on regulatory domain), this means the radio must remain powered on in receive mode for roughly 110-120 ms per channel to account for the beacon interval plus a small safety margin for channel switching overhead and potential beacon jitter. With 11 channels, a full passive scan can thus consume around 1.2-1.7 seconds of continuous operation of the radio, drawing significant power, often hundreds of milliwatts, during active listening. This energy cost is particularly burdensome for battery-powered smartphones. Figure 3 shows the in situ prototype of the detecting equipment.

Figure 3. Prototype of the Wi-Fi detection system deployed in situ

Another approach for network discovery is active scanning, in which client devices (such as smartphones and laptops) actively transmit probe request frames - management frames broadcast to the destination address ff:ff:ff:ff:ff:ff - targeting either specific known SSIDs (directed probes) or any available network (wildcard or null probes). This method is significantly faster than passive scanning because the device does not need to wait for the asynchronous arrival of beacon frames; instead, nearby access points that receive the probe request promptly reply with probe response frames containing the same essential BSS information (SSID, capabilities, security parameters, etc.) as beacons (Choi et al., 2017).

**Hardware architecture**

The hardware architecture of the human presence detection system is depicted in Figure 4. It is based on the ESP32-CAM module, originally designed to extend the ESP32 microcontroller with camera capabilities.

The board integrates a camera interface, an SD card slot, a Wi-Fi antenna, multiple IO ports, and a programming interface. In this implementation, the camera interface was not utilized. The ESP32-CAM was selected primarily because it offered the simplest design among available options that included a built-in SD card slot, while also being one of the most cost-effective solutions.

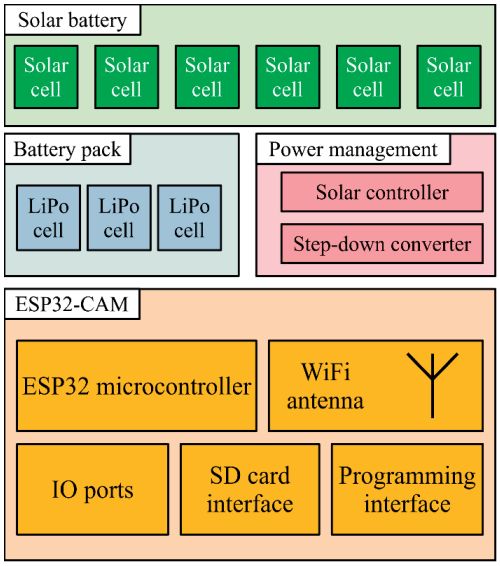

Figure 4. The hardware architecture of the system

The main component of the ESP32-CAM board is the ESP32 microcontroller. This device has two 32-bit xTensa CPU cores running at 240 MHz. The cores have IO port connections, high-speed serial buses (I2C and SPI) with DMA capability, timers and other common peripherals. The ESP32 stands out from the 32-bit ARM or RiscV families with its versatile Wi-Fi capabilities. It can act as a Wi-Fi client (station), access point (AP), or can even capture raw Wi-Fi packets.

The microcontroller is equipped with a 4 MB flash memory and 320 kB RAM to store the firmware and store the runtime data.

The ESP32 has several compatible sensor and other peripheral options from temperature, light, acceleration sensors to servos, SD card interfaces or even cameras.

The power source of the system is a 3-cell 2500 mAh lithium-polymer battery pack that provides a nominal voltage of 11.1 V. Power regulation and distribution are handled by a dedicated power management module, which incorporates both a solar charge controller and a step-down voltage regulator. Optionally, the battery pack can be recharged using a solar panel consisting of 6 photovoltaic cells connected in series.

**Software architecture**

The software of the human presence detection system is built on the FreeRTOS real-time operating system. FreeRTOS provides essential multitasking capabilities, including task management, scheduling, synchronization primitives, and message queues, along with direct access to the Wi-Fi subsystem and other hardware peripherals. Additional drivers handle SD card access and file system operations.

Upon boot, the Wi-Fi interface is configured in client (station) mode and attempts to connect to a predefined access point. Once connected, the system synchronizes its clock using the Network Time Protocol (NTP). Both the Wi-Fi connection and NTP synchronization are retried until successful. After time synchronization is completed, the Wi-Fi module is switched to a passive packet capture mode in which it listens continuously for all decodable packets, with probe request frames specifically filtered for processing.

Each captured probe request is placed into a message queue. Data from this queue is periodically flushed to the SD card as a CSV file at regular intervals (default: 30 minutes) or when the queue is nearing capacity. The CSV file is opened only during actual write operations and closed immediately afterward.

This approach, as opposed to writing after every packet or keeping the file continuously open, significantly extends the lifespan of the SD card and reduces the risk of file system corruption.

Each record in the CSV file contains the capture timestamp (year, month, day, hour, minute, and second), the source MAC address, the received signal strength (RSSI), and the

probed SSID. It should be noted that modern Android and iOS devices employ MAC address randomization and frequently transmit broadcast probe requests with an empty SSID field.
Consequently, a unique captured MAC address does not necessarily correspond to a unique physical device, and unique devices cannot be reliably distinguished based on the SSID field alone. Nevertheless, this method provides a practical and reasonably accurate approximation of the number of nearby Wi-Fi-enabled devices.

## RESULTS AND DISCUSSIONS

To evaluate the performance and usefulness of the human presence detection system, the device was deployed at the Sóstó Natural Reserve in a remote area far from residential buildings and other human infrastructure. This placement ensured that the system would detect primarily visitors genuinely present in the protected natural area rather than nearby residents or passers-by.
Figure 5 presents the recorded data for a single day. The logged probe requests were aggregated into one-hour intervals, and for each hour the number of unique MAC addresses from which at least one probe request was received was counted.

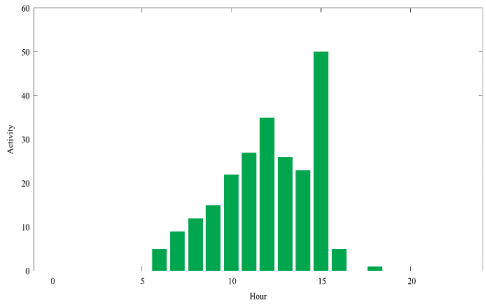

Figure 5. The collected and visualized activity data during a spring workday

As it was early spring, no visitors were detected before 6:00 a.m. or after 7:00 p.m. During the day, visitor activity showed a clear increase, reaching a first peak around noon. After a temporary decline, a second and larger peak occurred at 3:00 p.m., which corresponds to the most pleasant time of day for outdoor walks in early spring. A small additional peak was observed at 5:00 p.m., shortly after the typical end of a workday.
The absence of any detections during night time hours confirms that the system produced no false positives. The remote placement of the device, far from any residential areas, significantly contributed to this result by minimizing external interference.
This represents a notable advantage over many conventional human-presence monitoring systems, which often struggle with false triggers in populated environments. It is important to note that these detection-free periods were not caused by power loss, as any interruption in power supply is clearly visible in the system's log files.
The system's power consumption was also evaluated. After the initial setup phase, the average current draw stabilized at 39 mA. This low power requirement can be easily met by a moderately sized solar panel, even under modest lighting conditions. Furthermore, the system can operate autonomously for several days without solar input, with runtime depending primarily on battery capacity. For example, a compact 6 Ah battery can reliably power the system for approximately four days.
The robustness of the system was also evaluated through multiple power cycle tests. The log files remained fully consistent after each cycle, with no data loss or corruption observed.

## CONCLUSIONS

The Wi-Fi-based sensing systems represent a robust, scalable, and privacy-aware solution for monitoring human presence in remote natural environments, such as protected areas and nature reserves. Unlike conventional optical or infrared-based detection systems, which may raise significant concerns regarding personal data protection and require favourable environmental conditions, the proposed approach leverages passive monitoring of Wi-Fi probe signals. This enables an indirect yet effective detection of human presence without capturing personally identifiable information, thus aligning well with increasing legal expectations related to privacy.
The newly constructed hardware and software framework demonstrated reliable performance

in a real-world scenario. The system was capable of continuously capturing Wi-Fi signal activity and transforming it into meaningful indicators of visitor presence and movement patterns.

Comparative validation using simultaneous visual counting showed a strong correspondence between measured Wi-Fi activity and the actual number of individuals present in the monitored area. In addition to estimating absolute visitor counts, the system also provided valuable insights into temporal dynamics, such as peak visitation periods and fluctuations in human activity over time.

These capabilities are particularly relevant for environmental management and conservation practices. Accurate, continuous, and non-intrusive monitoring can support decision-makers in assessing anthropogenic pressure on sensitive ecosystems, optimizing the number of visitors and implementing adaptive management strategies. Furthermore, the relatively low cost, ease of deployment, and minimal maintenance requirements of Wi-Fi-based systems make the system especially suitable for large-scale or hard-to-access regions where traditional monitoring infrastructure may be impractical. Solar powered solutions contribute to solve sustainability challenges.

Despite the many advantages there are certain limitations that must be considered. The method inherently depends on the proportion of visitors carrying Wi-Fi-enabled devices with active signal broadcasting, which may introduce bias in absolute estimations under specific demographic or behavioural conditions. Additionally, environmental factors such as terrain, vegetation density, and signal interference can influence detection range and accuracy. Addressing these challenges may require calibration procedures, site-specific parameter tuning, or the integration of complementary sensing modalities.

Future research directions include the fusion of Wi-Fi sensing with other non-invasive technologies such as another environmental sensor, the application of advanced data analytics and machine learning techniques for improved signal interpretation, and the development of adaptive algorithms capable of compensating for environmental variability. Expanding long-term deployments across diverse ecological contexts would further validate the generalizability and reliability of the approach.

In summary, the presented Wi-Fi-based detection methodology offers a promising pathway toward sustainable, privacy-conscious and data-driven monitoring of human activity in ecologically sensitive areas, contributing to more effective conservation and management practices.
